Cardiogenic shock is most commonly due to ischemic myocardial injury with a total of 40% of the myocardium nonfunctional.[50,52–54] Such damage may involve a single large myocardial infarction (MI) or may involve accumulation of damage from multiple infarctions. In addition, viable but dysfunctional "stunned" myocardium may temporarily contribute to cardiogenic shock after infarction. Cardiogenic shock usually involves an anterior MI with left main or proximal left anterior descending artery occlusion. Historically, the incidence of cardiogenic shock caused by Q-wave infarction has ranged from 8% to 20%.[49,55–57] Although several large studies demonstrate lower incidence rates (4%–7%) when patients receive thrombolytic interventions,[56,58–61] retrospective community studies suggest no overall decrease in incidence of postinfarction cardiogenic shock or cardiogenic shock mortality (70%–90%) in the first decades after the introduction of this therapy.[49] Further, no trials have demonstrated that thrombolytic therapy reduces mortality rates in patients with established cardiogenic shock.[58,62] In contrast, several major studies suggest that mortality of infarction-related cardiogenic shock may be improved by emergent angioplasty.[63–65] Accordingly, recent data suggest a reduction in incidence of acute infarction-related cardiogenic shock to less than 2% in 2003 in association with widespread use of emergent percutaneous coronary intervention.[63] This intervention has also been associated with a reduction of cardiogenic shock mortality risk from 60% to 84% to 43% to 47% in two large analyses.[63,66,67]

Mortality is better for cardiogenic shock resulting from surgically remediable cardiac lesions. Mitral valve failure may be associated with rupture or dysfunction of chordae or papillary muscles owing to myocardial ischemia or infarction, endocarditis, blunt chest trauma, or prosthetic valve deterioration and is characterized by "v" waves of greater than 10 mm Hg on a PAOP tracing. Ischemic papillary muscle rupture frequently occurs 3 to 7 days after an infarct in left anterior descending coronary artery territory and may be preceded by the onset of a mitral regurgitant murmur.[68] Mortality is high in the absence of surgical therapy.[68] Acute aortic valve failure is most commonly the result of endocarditis but may involve mechanical failure of prosthetic valves, or aortic dissection.

TABLE 22.1 Hemodynamic Profiles of Shock[a]

Diagnosis	CO	SVR	PWP	CVP	$S\bar{V}O_2$	Comments
Cardiogenic Shock						
Caused by myocardial dysfunction	↓↓	↑	↑↑	↑↑	↓	Usually occurs with evidence of extensive myocardial infarction (>40% of left ventricular myocardium nonfunctional), severe cardiomyopathy, or myocarditis
Caused by a mechanical defect						
Acute ventricular septal defect	LVCO ↓↓ RVCO > LVCO	↑	nl or ↑	↑↑	↑ or ↑↑	If shunt is left to right, pulmonary blood flow is greater than systemic blood flow; oxygen saturation "step-up" (≥5%) occurs at right ventricular level; ↑ $S\bar{V}O_2$ is caused by left to right shunt
Acute mitral regurgitation	Forward CO ↓↓	↑	↑↑	↑ or ↑↑	↓	Large V waves (≥10 mm Hg) in pulmonary wedge pressure tracing
Right ventricular infarction	↓↓	↑	nl or ↑	↑↑	↓	Elevated right atrial and right ventricular filling pressures with low or normal pulmonary wedge pressures
Extracardiac Obstructive Shock						
Pericardial tamponade	↓ or ↓↓	↑	↑↑	↑↑	↓	Dip and plateau in right and left ventricular pressure tracings. The right atrial mean, right ventricular end-diastolic, pulmonary artery end-diastolic, and pulmonary wedge pressures are within 5 mm Hg of each other.
Massive pulmonary emboli	↓↓	↑	nl or ↓	↑↑	↓	Usual finding is elevated right-sided heart pressures with low or normal pulmonary wedge pressure
Hypovolemic Shock						
	↓↓	↑	↓↓	↓↓	↓	Filling pressures may appear normal if hypovolemia occurs in the setting of baseline myocardial compromise
Distributive Shock						
Septic shock	↑↑ or nl, rarely ↓	↓ or ↓↓	↓ or nl	↓ or nl	↑ or ↑↑	The hyperdynamic circulatory state (↑CO, ↓SVR) associated with distributive forms of shock usually depends on resuscitation with fluids; before such resuscitation, a hypodynamic circulation is typical
Anaphylaxis	↑↑ or nl, rarely ↓	↓ or ↓↓	↓ or nl	↓ or nl	↑ or ↑↑	

[a]The hemodynamic profiles summarized in this table refer to patients with the diagnosis listed in the left column who are also in shock (mean arterial blood pressure <60–65 mm Hg).
CO, Cardiac output; *CVP,* central venous pressure; *LV,* left ventricular; *nl,* normal; *PWP,* pulmonary wedge pressure; *SVR,* systemic vascular resistance; $S\bar{V}O_2$, mixed venous oxygen saturation; ↑↑ or ↓, mild to moderate increase or decrease; ↑↑ or ↓, moderate to severe increase or decrease.
Modified from Parrillo JE. Septic shock: clinical manifestations, pathogenesis, hemodynamics, and management in a critical care unit. In: Parrillo JE, Ayers SM, eds. *Major Issues in Critical Care Medicine.* Baltimore: Williams & Wilkins; 1984.

Ventricular septal defects caused by MI may also result in the abrupt onset of cardiogenic shock and can be diagnosed by a 5% step-up in hemoglobin oxygen saturation between the right atrium and the pulmonary artery (owing to left to right shunting of blood through the septum).[69] As with ischemic papillary muscle rupture, rupture of the intraventricular septum is most frequently seen with occlusions of the left anterior descending artery a few days after infarction.[69]

The pathophysiology of cardiogenic shock caused by a right ventricular infarction and failure is different than other forms of cardiogenic shock. Although some degree of right ventricular involvement is seen in half of inferior MIs, only the largest 10% to 20% result in right ventricular failure and cardiogenic shock.[70] These infarctions usually involve part of the left ventricular wall as well. Isolated infractions of the right ventricle are rare.[70,71] Because therapy for this form of shock requires fluid resuscitation and inotropes (rather than vasopressors), differentiation from other causes of cardiogenic shock is crucial. Conditions compromising right ventricular function, such as cardiac tamponade, restrictive cardiomyopathy, constrictive pericarditis, and pulmonary embolus, are also included in the differential diagnosis. Each of these conditions may present with some of the typical clinical and hemodynamic findings of right ventricular infarction, including Kussmaul sign, pulsus paradoxus with elevation and equalization of CVP, right ventricular systolic pressure, pulmonary artery diastolic pressure, and PAOP. Prognosis in this form of cardiogenic shock is distinctly better than that of cardiogenic shock owing to left ventricular infarction[72,73]; however, an inferior infarction with right ventricular injury has a substantially worse prognosis than such an infarction without significant right-sided involvement.[74]

As with hypovolemic shock, a number of interactions may complicate the development of cardiogenic shock. Optimal cardiac

performance in patients with impaired myocardial contractility may occur at substantially higher than normal PAOP (i.e., 20–24 mm Hg). Yet patients in whom cardiogenic shock develops are frequently initially treated with diuretics and may have a degree of hypovolemia (relative to their optimal requirements). Thus patients should not be diagnosed with cardiogenic shock unless hypotension (MAP < 65 mm Hg) and reduced CO (CI < 2.2 L/min per m^2) coexist with an elevated ventricular filling pressure.[75] Cautious fluid challenge may be required (in the absence of overt pulmonary edema) to increase the filling pressures to an optimal range. Other interactions include increased right ventricular ischemia owing to decreased right coronary perfusion pressure (MAP decreased while right ventricular end-diastolic pressure is increased) and increased right ventricular afterload owing to pulmonary hypertension. Right ventricular ischemia may also lead to right ventricular dilatation, septal shift, and impairment of left ventricular function.

Other causes of cardiogenic shock include acute myocarditis, end-stage cardiomyopathy, bradyarrhythmias or tachyarrhythmias, hypertrophic cardiomyopathy with obstruction, and traumatic myocardial contusion (see Box 22.2).

Obstructive Shock

Extracardiac obstructive shock results from an obstruction to flow in the cardiovascular circuit (see Box 22.2 and Fig. 22.1). Pericardial tamponade and constrictive pericarditis directly impair diastolic filling of the right ventricle. Tension pneumothorax and intrathoracic tumors indirectly impair right ventricular filling by obstructing venous return. Massive pulmonary emboli (two or more lobar arteries with >50% of the vascular bed occluded), nonembolic acute pulmonary hypertension, large systemic emboli (e.g., saddle embolus), and aortic dissection may result in shock owing to increased ventricular afterload.

The characteristic hemodynamic/metabolic patterns are, in most ways, similar to other low-output shock states (see Table 22.1). CI, SVI, and stroke work indices are usually decreased. Because tissue perfusion is decreased, the MvO_2 is low, the arteriovenous oxygen content difference increased, and serum lactate frequently elevated. Other hemodynamic parameters are dependent on the site of the obstruction. Tension pneumothorax and mediastinal tumors may obstruct the great thoracic veins, resulting in a hemodynamic pattern (decreased CI and elevated SVR) similar to hypovolemia (although distended jugular and peripheral veins may be seen). Cardiac tamponade typically causes increased and equalized right and left heart ventricular diastolic pressures, pulmonary artery diastolic pressure, CVP, and PAOP. In constrictive pericarditis, right and left ventricular diastolic pressures are elevated and within 5 mm Hg of each other. Mean right and left atrial pressures may or may not be equal as well. Massive pulmonary embolus results in right ventricular failure with elevated pulmonary artery and right heart pressures, whereas PAOP remains normal. A systemic saddle embolus or aortic occlusion owing to dissection cause peripheral hypotension and signs of left ventricular failure including an elevated PAOP. Clinical signs are similarly dependent on the site of the obstruction.

As with other forms of shock, the time course of development of the insult has a substantial impact on the clinical response. Ischemic rupture of the left ventricular free wall (usually 3 to 7 days after MI) leads to immediate cardiac tamponade and shock with as little as 150 mL blood in the pericardium.[76–78] Survival requires emergency surgery.[77,78] Similar situations may develop with bleeding into the pericardium after blunt chest trauma or thrombolytic therapy. Pericardial tamponade owing to malignant or inflammatory pericardial effusions usually develops much more slowly. Although shock may still develop, it usually requires substantially more pericardial fluid (1–2 L) to cause critical failure of right ventricular diastolic filling.[76] No large reliable studies examining mortality rates with and without therapy in these conditions are available because of the small numbers of cases.

A similar time course–dependent risk is seen with major pulmonary emboli. In those without preexisting cardiopulmonary disease, a massive embolus involving two or more lobar arteries and 50% to 60% of the vascular bed[79,80] may result in obstructive shock. However, if recurrent smaller pulmonary emboli result in right ventricular hypertrophy, a substantially larger total occlusion of the pulmonary vascular bed may be required to cause right ventricular decompensation. Recent analyses have suggested that the presence of shock owing to pulmonary embolus (regardless of underlying chronic cardiopulmonary dysfunction) indicates a three- to sevenfold increase in mortality risk with the majority of deaths occurring within an hour of presentation.[81,82] An analysis of more than 70,000 unstable (hemodynamic instability or ventilator-requiring) patients with pulmonary embolus in the National Inpatient Sample shows that mortality in untreated patients is approximately 47%.[83] Systemic thrombolysis is associated with a substantial reduction in mortality to 15%. Where available, catheter-directed therapy may be even more efficacious with lower risk of serious hemorrhage.[84] Shock resulting from pulmonary embolism is an indication for urgent thrombolytic or catheter-directed intervention.

Distributive Shock

The defining feature of distributive shock is loss of peripheral resistance. Septic shock is the most common form and has the greatest impact on intensive care unit (ICU) morbidity and mortality.

Hemodynamically, distributive shock is characterized by an overall decrease in SVR (see Table 22.1). However, resistance in any specific organ bed or tissue may be decreased, increased, or unchanged. Initially, CI may be depressed and ventricular filling pressures decreased. After fluid resuscitation, when filling pressures are normalized or increased, CI is usually elevated. Owing to hypotension, left and right ventricular stroke work indices are normally decreased. MvO_2 is increased above normal. Concomitantly, the arteriovenous oxygen content difference is narrowed despite the fact that oxygen demand is usually increased (particularly in sepsis). The basis of this phenomenon may be that while total body perfusion (CI) is increased, perfusion is not effective in that either it does not reach the necessary tissues or the tissues cannot use the substrates presented. As a reflection of this inadequate "effective" tissue perfusion, lactic acidosis may ensue. Clinical characteristics of resuscitated distributive shock include, in contrast to the other forms of shock, warm, well-perfused extremities, a decreased diastolic blood pressure, and an increased pulse pressure. Nonspecific signs of shock include tachycardia, tachypnea, decreased urine output, and altered mentation. In addition, evidence of the primary insult may exist (urticaria for anaphylaxis, spinal injury for neurogenic shock, and evidence of infection in septic shock).

Septic shock (shock caused by infection) and sepsis-associated multiple organ failure are the most common cause of death in ICUs of the industrialized world. As many as 800,000 patients with sepsis are admitted every year to American hospitals

(comparable to the incidence of first MIs), half of whom develop septic shock and about half (200,000) who die.[85] The past four decades have seen a progressive increase in the incidence of and total deaths from sepsis and septic shock.[86] The total toll of septic deaths is comparable to deaths from MI and far exceeds the impact of illnesses such as AIDS or breast cancer together.[85,87]

Septic shock is caused by the systemic activation of the inflammatory cascade. Numerous mediators, including cytokines, kinins, complement, coagulation factors, and eicosanoids, are activated or systemically released, resulting in profound disturbances of cardiovascular and organ system function[88] (see Table 22.2). These mediators, particularly tumor necrosis factor α (TNF-α), interleukin

TABLE 22.2 Inflammatory Mediators in Sepsis and Septic Shock

Mediator	Major Reported Effects
Proinflammatory Cytokines	
TNF-α	Stimulates release of IL-1, IL-6, IL-8, platelet-activating factor, leukotrienes, thromboxane A_2, prostaglandins; may be able to stimulate macrophages directly to promote its own release
	Stimulates production of polymorphonuclear cells by bone marrow; enhances phagocytic activity of polymorphonuclear cells
	Promotes adhesion of endothelial cells, polymorphonuclear cells, eosinophils, basophils, monocytes, and, occasionally, lymphocytes by inducing increased expression of adhesion molecules
	Activates common pathway of coagulation and complement system
	Directly toxic to vascular endothelial cells; increases microvascular permeability
	Acts directly on hypothalamus to produce fever
	Reduces transmembrane potential of muscle cells and depresses myocardial contractility
	Decreases arterial pressure, systemic vascular resistance, and ventricular ejection fraction; increases cardiac output
IL-1β	Stimulates release of TNF, IL-6, IL-8, platelet-activating factor, leukotrienes, thromboxane A_2, prostaglandins; may also be capable of stimulating its own production
	Activates resting T cells to produce lymphocytes and other products; supports B-cell proliferation and antibody production; is cytotoxic for insulin-producing B cells
	Promotes adhesion of endothelial cells, polymorphonuclear cells, eosinophils, basophils, monocytes, and occasionally, lymphocytes by inducing increased expression of adhesion molecules
	Promotes polymorphonuclear cell activation and accumulation
	Increases endothelial procoagulant activity
	Acts synergistically with TNF; enhances tissue cell sensitivity to TNF
	Depresses myocardial contractility
	Acts directly on hypothalamus to produce fever
IL-2	May promote release of TNF and INF-γ
	Decreases arterial pressure, systemic vascular resistance, and ejection fraction; increases cardiac output
IL-4	Enhances lymphocyte adhesion to endothelial cells
	Induces antigen expression on macrophages
	Synergistically increases TNF- or IL-1–induced antigen expression on endothelial cells, but inhibits the increased expression of adhesion molecules by TNF, IL-1, or INF-γ
IL-6	Induction of hepatic acute-phase protein response
	Induces myelomonocytic and terminal B lymphocyte differentiation; activates T cells/thymocytes
	May contribute to septic myocardial depression
	Inhibits TNF production
IL-8	Chemotactic for both neutrophils and lymphocytes; induces tissue infiltration of both
	Inhibits endothelial-leukocyte adhesion; decreases the hyperadhesion induced by those molecules
IL-17	Induces synthesis of TNF-α, IL-1β, IL-6, G-CSF, GM-CSF, TGF-β, and other chemokines
IL-18	Initiates cell-mediated immune response
	Increases secretion of interferon-γ
INF-γ	Promotes release of TNF, IL-1, IL-6 (possibly because of its ability to augment effects of endotoxin on macrophages); augments production of adhesion molecules
	May act synergistically with TNF to produce cytotoxic and cytostatic activity; interacts with other cytokines in variable ways
	Encourages polymorphonuclear cell activation and accumulation; enhances the phagocytic activity of polymorphonuclear cells
	Promotes macrophage activation, macrophage microbicidal function, and expression of cellular receptors for TNF-α
Macrophage migration inhibitory factor	Increases TNF-α and Toll-like receptor 4 expression
	Activates T lymphocytes
	Increases mortality in experimental peritonitis
High-mobility group box protein 1	Possesses both cytokine and intracellular signaling activity
	May generate late organ failure of sepsis
	Impairs vascular endothelial integrity

Continued

TABLE 22.2 Inflammatory Mediators in Sepsis and Septic Shock—cont'd

Mediator	Major Reported Effects
Antiinflammatory Cytokines	
IL-4	Induction of differentiation of naïve helper T cells to T helper type 2 cells
IL-10	Downregulation of macrophage function, leading to decreased TNF-α release
IL-1 receptor antagonist	Antagonistic blockade of IL-1β
Transforming growth factor β1	Broad immunomodulatory activity (protective in endotoxic shock)
	Inhibition of effect of proinflammatory cytokines on a variety of tissues
	Suppression of macrophage proinflammatory responses
	Interference with phagocytic activation
Endothelial Factors	
Endothelin 1	Strongly promotes vasoconstriction
Nitric oxide	Mediates vascular smooth muscle relaxation and arteriovenular dilatation in septic shock
	May be responsible for septic myocardial depression
	Involved in leukocyte/macrophage antimicrobial activity
Arachidonic Acid Pathway Factors and Metabolites	
Phospholipase A_2	Releases arachidonic acid (the precursor of eicosanoids such as leukotrienes, prostaglandins, and thromboxanes)
	Decreases arterial pressure, systemic vascular resistance, and ventricular ejection fraction; increases cardiac output
Leukotrienes	Promote neutrophil chemotaxis and adhesion of neutrophils to endothelium (neutrophils have specific receptors for leukotriene B_4)
	Increase vascular permeability, either directly or through interaction of neutrophils and endothelial cells
	Decrease coronary blood flow and myocardial contractility
Thromboxane A_2	Produces vasoconstriction of vascular beds; secondarily promotes release of endothelium-derived relaxing factor and may stimulate prostacyclin production
	Causes platelet aggregation and neutrophil accumulation
	Increases vascular permeability; enhances permeability of both single- and double-unit membranes
	Produces pulmonary bronchoconstriction
Prostaglandin E_2	Inhibits IL-1 production
	Low concentrations stimulate TNF release; higher concentrations suppress TNF production at a dose-dependent level
	Causes vasodilation and increased blood flow
	Has a beneficial effect on tissue perfusion and may thereby decrease the severity of tissue damage
	Acts synergistically with prostacyclin to increase the effects of serotonin and bradykinin on vascular permeability
Prostacyclin (prostaglandin I_2)	Inhibits platelet aggregation and adhesion
	Causes vasodilation and increased blood flow; in early sepsis, exerts a beneficial effect on tissue perfusion
	Produces smooth muscle relaxation
Others	
Platelet-activating factor	Stimulates release of TNF, leukotrienes, thromboxane A_2
	Promotes leukocyte activation and subsequent free radical formation
	Encourages platelet aggregation, leading to thrombosis
	Markedly alters microvascular permeability, thereby promoting microvascular fluid loss
	Exerts a negative inotropic effect on the heart; lowers arterial blood pressure
Complement fragment C3a	Causes mast cell degranulation and vasodilatory mediator release
Fragment C5a	Causes smooth muscle contraction and mucous secretion
	Causes mast cells to degranulate and release vasodilatory mediators
	Promotes TNF release
	Enhances polymorphonuclear cell activation, migration, adherence, and aggregation
	Induces capillary leakage
	May decrease systemic vascular resistance and produce hypotension

(IL) 1β (IL-1β), platelet-activating factor (PAF), and prostaglandins are thought to mediate reduced peripheral vascular resistance seen in septic shock.

The triggers for systemic activation of the inflammatory cascade include a large number of constitutive and/or inducible elements of invasive microorganisms. Beyond endotoxin (lipopolysaccharide), which represents a major trigger in gram-negative bacilli (that cause as much as 50% of septic shock cases with an identified pathogen), other major initiators of the systemic inflammatory response characteristic of sepsis include various exotoxins (all bacteria), peptidoglycans (streptococci), and techioic acid (*Staphylococcus aureus*); lipoarabinomannan of mycobacteria; bacterial DNA and ribonucleic (RNA); and mannoproteins and β-glucan of fungi.[89–95] Recent investigations suggest a surprising commonality

of signaling mechanisms in septic shock via Toll-like receptors from a broad range of etiologic agents.[90,96–99]

More than any other form of shock, distributive and, particularly, septic shock involves substantial elements of the hemodynamic characteristics of other shock categories (see Fig. 22.1 and Table 22.1). As noted, all forms of distributive shock involve decreased mean peripheral vascular resistance. Before fluid resuscitation, distributive shock also involves a relative hypovolemic component. The first element of this relative hypovolemia is an increase of the vascular capacitance as the result of venodilatation. This phenomenon has been directly supported in animal models of sepsis[100–104] and is reinforced by the fact that clinical hypodynamic septic shock (low CO) can usually be converted to hyperdynamic shock (high CO) with adequate fluid resuscitation.[105–107] Relaxation of vascular smooth muscle is attributed to a number of the mediators known to circulate during sepsis. These same mediators also contribute to the second cause of hypovolemia in sepsis: third-spacing of fluid to the interstitium owing to loss of endothelial integrity. In addition, a number of studies have demonstrated that human septic shock is characterized by myocardial depression (biventricular dilatation and decreased ejection fraction).[33–35] Circulating substances such as TNF-α, IL-1β, PAF, leukotrienes, and most recently, IL-6 have been implicated in this process.[108–115]

Anaphylactic shock is a form of distributive shock caused by release of mediators from tissue mast cells and circulating basophils. Anaphylaxis, an immediate hypersensitivity reaction, is mediated by the interaction of immunoglobulin (Ig) E (IgE) antibodies on the surface of mast cells and basophils with the appropriate antigen. Antigen binding results in release of the primary mediators of anaphylaxis contained in the basophilic granules of mast cells and basophils. These include histamine, serotonin, eosinophil chemotactic factor, and various proteolytic enzymes.[116] Subsequently, a number of secondary lipid mediators are synthesized and released, including PAF, bradykinin prostaglandins, and leukotrienes (slow-reacting substance of anaphylaxis).[116] An anaphylactoid reaction (clinically indistinguishable from anaphylaxis) results from direct, nonimmunologic release of mediators from mast cells and basophils and can also result in shock.

Anaphylaxis is triggered by insect envenomations (*Hymenoptera* bees, hornets, and wasps), foods (including eggs and nuts, especially peanuts) and certain drugs, particularly antibiotics (β-lactams, cephalosporins, sulfonamides, and vancomycin).[116] In addition, less frequently, heterologous serum (e.g., tetanus antitoxin, snake antitoxin, antilymphocyte antisera), blood transfusion, immunoglobulin (particularly in IgA-deficient patients) and egg-based vaccine products have been implicated.[116] Anaphylactoid reactions can be caused by a wide range of medical agents, including ionic contrast media, protamine, opiates, polysaccharide volume expanders, such as dextran and hydroxyethyl starch, muscle relaxants, and anesthetics.[116]

The hemodynamic features of anaphylactic shock are very similar to septic shock and include elements of hypovolemia (owing to interstitial edema and venodilatation) and myocardial depression.[117–121] CO and ventricular filling pressures may be reduced until patients are fluid resuscitated.[117,122] In addition to typical findings of shock, patients may demonstrate urticaria, angioedema, laryngeal edema, and severe bronchospasm.

Neurogenic shock involves loss of peripheral vasomotor control as the result of dysfunction or injury of the nervous system. The classic example is shock associated with spinal injury. A similar phenomenon is active in vasovagal syncope and spinal anesthesia, but such conditions are self-limited and transient. The major cause of shock in spinal injury appears to be loss of venous tone resulting in increased venous capacitance. Arteriolar tone may also be affected, resulting in increased CO after fluid resuscitation.

Adrenal crisis is an uncommon cause of shock which can be difficult to diagnose since it occurs in patients with other active disease processes and the clinical features may mimic infection. It is a life-threatening emergency which requires prompt diagnosis and management.

Adrenal crisis is caused by a deficiency of adrenal production of mineralocorticoids and glucocorticoids. It may occur de novo in patients with critical illness or against a background of occult adrenal insufficiency. In the critical care setting, the most common cause of de novo acute adrenal insufficiency is bilateral adrenal hemorrhage in association with overwhelming infections (classically meningococcal, but frequently gram-negative bacteria), human immunodeficiency virus infection, or anticoagulation.[123,124] In addition, fungal infections such as histoplasmosis, blastomycosis, and coccidioidomycosis and malignant infiltration of the adrenal glands may cause acute adrenal insufficiency in ICU patients.[123] In some patients, steroid production remains adequate for the baseline state despite adrenal disease. Once stressed, however, adrenal response is inadequate, leading to decompensation and adrenal crisis. Stressors may be relatively innocuous or may be severe. A febrile illness, infection, trauma, surgery, dehydration, or any other intercurrent illness may trigger the crisis. Abrupt cessation of glucocorticoid therapy or replacement may also result in adrenal crisis.

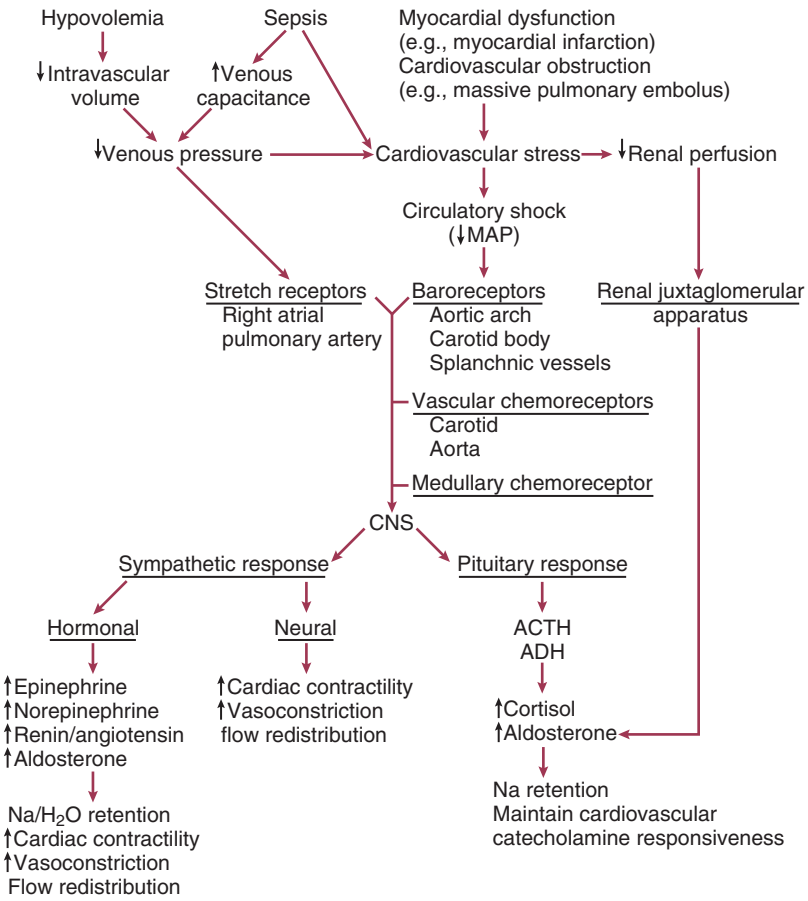
Symptoms are generally nonspecific and may include anorexia, nausea, vomiting, diarrhea, abdominal pain, myalgia, joint pains, headache, weakness, confusion, and agitation or delirium.[123,125] Fever (often out of proportion to any minor infection) is almost always present, and hypotension, initially caused by hypovolemia, is frequent.[123] The initial hemodynamic pattern may resemble hypovolemic shock (if shock is due only to adrenal crisis). With volume resuscitation, a high-output, vasopressor-refractory shock may become apparent.[126,127]

Shock owing to adrenal crisis may be masked by or contribute to shock owing to other concomitant critical illness, particularly septic shock. Thus if vasopressor-refractory shock occurs in patients potentially predisposed to adrenal insufficiency, a cortisol level and rapid adrenocorticotropic hormone stimulation test must be performed and the patient given glucocorticoids and other therapy.

An unrecognized "relative" adrenal insufficiency has been implicated in the pathogenesis of human septic shock.[128–135] In this circumstance, sepsis is associated with a suboptimal adrenal response with an improvement in cardiovascular parameters and/or outcome with "stress" dose corticosteroid administration.[128,129,132–137] One randomized controlled trial suggested that prospective "stress dose" therapy with a combination of hydrocortisone (50 mg intravenous [IV] every 6 hours) and fludrocortisone (50 μg oral/nasogastric daily) for 7 days improved outcome in nonresponders to corticotropin challenge.[138] Confirmatory randomized trials have failed to reproduce this finding.[139,140] However, given solid data suggesting a vasopressor-sparing effect,[136,137] the current recommendation is to consider administration of hydrocortisone only in refractory septic shock (when there is a suboptimal response to appropriate fluid resuscitation and vasopressors).[141–143]

Pathogenesis and Pathophysiology of Shock

The inability of cells to obtain and/or use oxygen in sufficient quantity to optimally meet their metabolic requirements has



• **Fig. 22.2** Neurohormonal response to shock. During early cardiovascular stress, the neurohormonal response may be limited to increased activity of the juxtaglomerular apparatus and stimulation of right atrial and pulmonary artery low-pressure mechanoreceptors. With further hypotension, high-pressure vascular baroreceptors, vascular chemoreceptors, and the medullary chemoreceptor are sequentially stimulated resulting in augmented neurohormonal activity with increased pituitary hormone (adrenocorticotropic hormone *[ACTH]* and antidiuretic hormone *[ADH]*) release and increased sympathetic outflow from the central nervous system *(CNS)*. Volume retention, increased venous tone, increased cardiac contractility, and blood flow redistribution to vital organs results. *MAP,* Mean arterial pressure; *Na,* sodium; H_2O, water.

classically been considered to be the pathophysiologic basis of all forms of shock. In the first half of the 20th century, the study of shock focused on the relatively distinct hemodynamic physiology that characterizes the different forms of shock. Since then evidence has accumulated that the various types of clinical shock have significant overlap in their hemodynamic characteristics. In parallel, shock of most causes has been shown to involve similar biochemical and metabolic pathways. In the following section, the pathophysiology and pathogenesis of shock are reviewed from the hemodynamic to the molecular level. (See the online supplement for discussion on the "Hemodynamic Basis of Shock," "Microvascular Function in Shock," and "Mechanisms of Cellular Injury in Shock.")

Compensatory Responses to Shock

Shock is usually not a discrete condition occurring abruptly after injury or infection. With the onset of hemodynamic stress, homeostatic compensatory mechanisms engage to maintain effective tissue perfusion. At this time, subtle clinical evidence of hemodynamic stress may be apparent (tachycardia, decreased urine output) but overt evidence of shock (hypotension, altered sensorium, metabolic acidosis) may not. Therapeutic interventions have a high probability of preventing ischemic tissue injury and initiation of progressive systemic inflammatory cascades during this early compensated stage. Adaptive compensatory mechanisms fail and organ damage/failure ensues if the injury that initiates shock is too extensive or progresses despite therapy.[284] As the duration of established shock increases, therapy is less likely to be effective in preventing organ failure and death.

Various sensing mechanisms involved in physiologic compensatory responses exist to recognize hemodynamic and metabolic dyshomeostasis (Fig. 22.2). Low-pressure right atrial and pulmonary artery stretch receptors sense volume changes. A decrease in circulating volume (or increase of venous capacitance) results in an increase in sympathetic discharge from the medullary vasomotor center.[144,285,286] Aortic arch, carotid, and splanchnic high-pressure baroreceptors sense early blood pressure changes close to the physiologic range.[144,285,286] An increase of sympathetic discharge from the medullary vasomotor center results from a small to moderate decrease in blood pressure associated with early shock.

Hemodynamic Basis of Shock

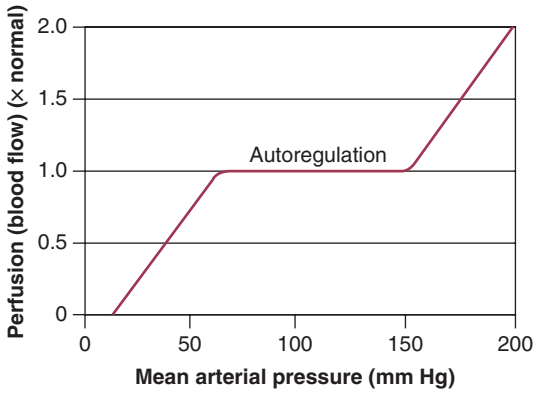
From a hemodynamic perspective, shock is the failure of cardiovascular adaptation to systemic dyshomeostasis induced by trauma, infection, or other insult such that CO and/or blood pressure are compromised. This failure is manifested by inadequate organ and tissue perfusion. Although effective perfusion is also dependent on microcirculatory and intracellular factors (see Box 22.1), the hemodynamic aspects of shock can be described, in part, by the contributions of cardiac and arterial vascular function to blood pressure and CO.

Arterial Pressure

Although CO may be expressed as a function of MAP and vascular resistance [CO = (MAP – CVP)/SVR], CO is not directly dependent on MAP in most physiologic states. Instead, blood pressure is typically dependent on CO and vascular resistance. Blood pressure, however, does provide a mechanism to indirectly sense CO and global perfusion perturbations for autoregulatory purposes.

The ability of all organ vascular beds to support normal blood flow is dependent on maintenance of blood pressure within the defined range for that organ (eFig. 22.1).[144] Vital organs, such as the brain and heart, in particular, are able to autoregulate blood flow over a wide range of blood pressure. Failure to maintain the minimal MAP and perfusion pressure required for autoregulation during hypodynamic circulatory shock indicates a severe reduction in CO. Pharmacologic support of blood pressure in such situations (with α-adrenergic agonists) usually results in decreased total systemic perfusion as sensitive vascular beds constrict and overall vascular resistance increases. However, because of their strong autoregulatory capacity, vital organs will maintain increased perfusion under these conditions.

In addition to sufficient CO, effective perfusion requires appropriate distribution of blood flow. Failure to maintain blood pressure within the autoregulatory range results in distribution of blood flow which is strictly dependent on the passive mechanical properties of the vasculature.[145] This may result in inappropriate distribution of perfusion between and within tissues and organs. Late hemorrhagic shock has been shown to be characterized by abnormal microvascular flow with dilatation of precapillary sphincters.[38]



• **eFig. 22.1** Idealized representation of blood flow autoregulation. Within the autoregulatory range of blood pressure for a tissue or organ, perfusion can be held relatively constant. Outside this range, autoregulation fails and perfusion becomes a function of mean arterial pressure.

Cardiac Output

The fact that total systemic perfusion is defined by CO underlies its importance in shock. The product of HR and stroke volume (SV) determines CO (CO = HR × SV). SV (a measure of myocardial performance) is dependent on preload, afterload, and contractility.

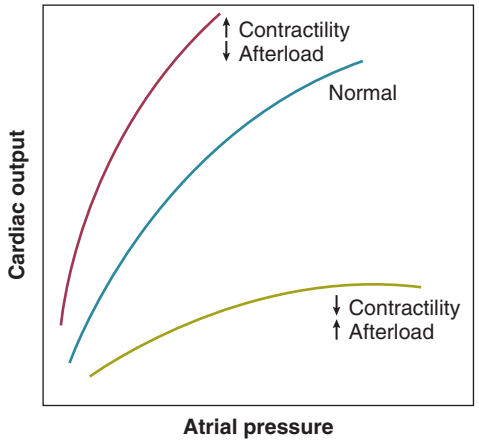
Preload represents the extent of precontraction myocardial fiber (or sarcomere) stretch. In vivo, preload is the end-diastolic ventricular volume. Because measurement of such volumes in the clinical context is difficult, intracardiac pressures, which can be determined more easily, are frequently substituted. There are difficulties with this approach. The relationship of ventricular end-diastolic volume (preload) to end-diastolic pressure is nonlinear. Further, alterations of myocardial compliance render CVP and PAOP unreliable as estimates of preload in critically ill patients.[146]

Preload is dependent on circulating volume, venous tone, atrial contraction, and intrathoracic pressure among other factors.[144,147] Atrial contraction is particularly important in those with impaired ventricular function. Although accounting for only 5% to 10% of CO in healthy humans, synchronized atrial contraction contributes as much as 40% to 50% of the CO in patients with severe left ventricular dysfunction.[147] Increased intrathoracic pressure or increased venous capacitance affect preload by reducing venous return.[144,148] Nitrovasodilators such as nitroglycerin may decrease CO despite arteriolar vasodilation owing to their venodilatory (decreased preload) effects. Conversely, the earliest increases in CO seen with sympathetic stimulation and exogenous catecholamine infusion are related to venoconstriction-induced increases of venous return and preload.[149] Cardiogenic and some forms of obstructive shock are typically characterized by increased preload. Preresuscitation distributive shock and hypovolemic shock are uniformly associated with decreased preload.[144]

Afterload refers to the total resistance to ejection of blood from the ventricle during contraction. Increasing afterload results in decreased extent and velocity of myocardial contraction.[144] Excessive afterload (aortic dissection, pulmonary embolus) causes some forms of obstructive shock. Ex vivo, afterload can be easily defined as a resistive force applied to an isolated papillary muscle. Because the heart does not displace a fixed mass but rather rhythmically moves a viscous, non-Newtonian fluid through branching viscoelastic conduits, the definition of afterload in vivo is difficult.

Afterload has been suggested to be equivalent to systolic myocardial wall stress. This definition suggests that afterload is substantially dependent on intrinsic cardiac mechanical and functional properties.[150] An alternative approach equates left ventricular afterload with the mechanical properties of the arterial side of the circulatory system. Aortic input impedance, which represents the total resistance to flow from outside the left ventricle, is determined by the inertial and viscous properties of blood, and the resistive and viscoelastic properties of the arterial system. The term is inclusive of SVR, HR effects, and pulse wave reflections in the arterial tree.[150] Although an accurate measure of afterload in pulsatile systems, assessment of impedance is technically difficult, requiring continuous harmonic analysis of rhythmic variations of aortic pressure and flow. SVR is a limited approximation of aortic input impedance based on a model that assumes nonpulsatile flow. At an HR of 0, SVR and aortic input impedance are equivalent. From a clinical point of view, SVR is the most practical way of assessing afterload.

Afterload is increased in pathologic conditions such as aortic stenosis, systemic embolism, and hypertension. Vasopressors including α-agonists (e.g., phenylephrine, norepinephrine) and



• **eFig. 22.2** Cardiac function curve demonstrating the effect of variations of preload (atrial pressure), contractility, and afterload on cardiac performance.

vasopressin also increase afterload, whereas nitrates and other vasodilator agents decrease it. Increased intrathoracic pressure owing to mechanical ventilation and positive end-expiratory pressure decrease left ventricular afterload while increasing right ventricular afterload. Hypodynamic and hyperdynamic shock are usually characterized by increased and decreased afterload, respectively.

Contractility refers to the intrinsic ability of myocardial fibers to shorten under given loading conditions. Under normal conditions determinants of contractility include myocardial mass and sympathoadrenal activation state. In pathologic states (e.g., shock), hypoperfusion/ischemia, myocardial cell injury (e.g., reperfusion injury, myocarditis), acidosis, and circulating myocardial depressant substances (such as seen in sepsis) depress cardiac contractility (eFig. 22.2).

As with preload and afterload, the ex vivo/in vitro assessment of contractility is straightforward. Assessment of in vivo contractility (even in experimental animals) is substantially more difficult owing to intrinsic lability of preload and afterload. Relatively load-independent variables, such as the peak systolic pressure/end-systolic volume ratio, may be the most clinically useful measures of contractility.[151] Many of these variables can be obtained echocardiographically.[152,153]

Venous Function in Shock

Given that the cardiovascular circuit is a closed system and CO cannot exceed the rate of return of blood to the right ventricle, venous return can be considered a fundamental determinant of cardiac performance. Although preload is a related variable, it primarily reflects ventricular properties related to compliance and HR, whereas venous return is substantially dependent on the extracardiac properties of the systemic venous circulation. Maximum venous return is described by the following equation:

$$(Pmc - Pa)/Rv, \quad (1)$$

where Pmc is the mean circulatory pressure (the upstream driving pressure of the systemic venous circulation—i.e., the intravascular pressure measured when the heart is stopped), Pa is the right atrial pressure (the downstream pressure that opposes flow to the right ventricle), and Rv is the venous resistance (resistance of the conduit to flow). Pmc equals the stressed volume or Vs (the portion of the vascular volume that contributes to venous pressure) divided by the mean vascular compliance (C):

$$Pmc = Vs/C \quad (2)$$

Vs is dependent on total vascular volume (Vt) and the state of venous tone (i.e., venoconstriction). It is defined as the difference between Vt and the unstressed vascular volume (V_0), the intravascular volume that remains when the vascular circuit is equalized to atmospheric pressure (i.e., the volume remaining after passive exsanguination). Vs volume is approximately 30% of total blood volume in both humans and in experimental animals.[154–156] Compliance refers to the total elastic properties of the entire cardiovascular circuit inclusive of the heart and vasculature.

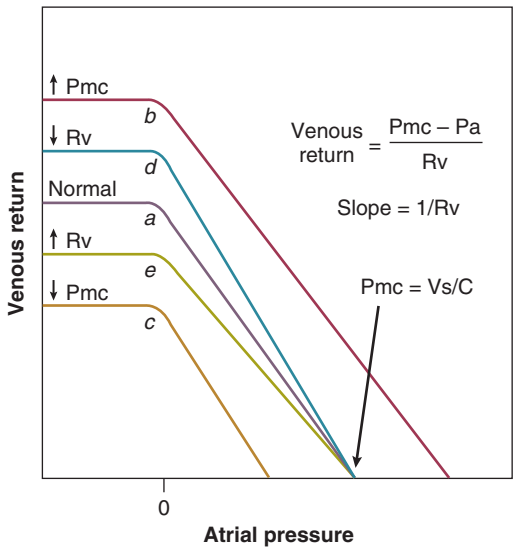
As Eq. (1) shows, the only direct role the heart plays on venous return is by altering right atrial pressure (Pa). MAP has no direct effect at all despite the fact that it is closely related to CO in the systemic circulation (MAP − CVP = CO × SVR).

Rapid alterations of venous return are typically mediated by changes of Pmc or Rv. Pmc is acutely influenced by changes of Vs, either directly through alterations of venous capacitance, which primarily involves changes of small vein and venular tone (exogenous vasopressors or vasodilators, sympathetic stimulation); or indirectly by changes of Vt (volume depletion or infusion). Compliance is substantially a passive mechanical property of the vasculature and does not cause acute alterations of Pmc or venous return. Rv to flow is acutely altered by changes of the caliber of large-diameter veins, particularly the vena cava and great veins of the thorax. However, although resistance resides primarily in large veins and the vena cava, and venous capacitance resides primarily in small veins and venules, all veins contribute to resistance and capacitance to some extent. Alterations of venous tone (either pharmacologic or physiologic) therefore tend to induce opposing changes in Pmc and Rv with respect to venous return. Vasodilatation decreases Pmc by decreasing Vs but it also decreases Rv. Vasoconstriction results in increases of both Pmc and Rv. Only alterations in Vt alter Pmc without affecting Rv.

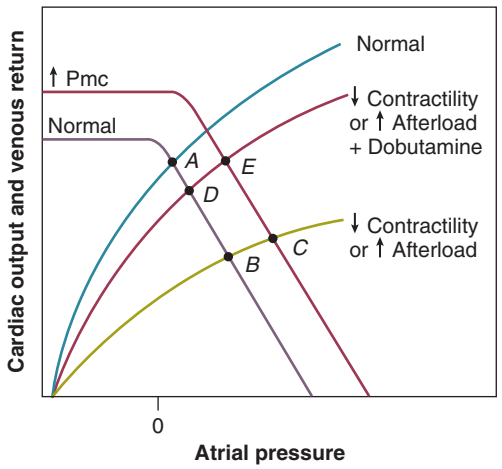
The venous return relationship is shown in eFig. 22.3.[144,157–159] Because the systemic venous bed constitutes the bulk of venous capacitance, the systemic venous vasculature dominates the physiology of venous return. Venous return is linearly related to Pa down to 0 cm H_2O (= atmospheric pressure), at which point intermittent collapse of the great veins results in limitation of return producing the plateau.[144,159,160] The slope of the line representing venous return is the inverse of the resistance (1/Rv). The ordinate intercept denotes the Pa at which venous return is zero. But according to Eq. (1), venous return is zero only when Pa equals the Pmc. Thus the intercept of the atrial pressure axis represents Pmc. Changes of Pmc shift the curve to the left or right without changing the slope of the line (Fig. 22.3, line a to lines b and c). Changes of Rv change the slope of the line without changing the Pmc (eFig. 22.3, line a to lines d and e).

Graphic Analysis of Venous-Cardiac Interactions During Shock

In a closed system, CO as determined by HR, preload, afterload, and contractility must equal venous return as determined by mean circulatory pressure, right atrial pressure, and Rv. CO therefore is not strictly a product of cardiac or vascular function but is dependent on their interaction. Because venous return and CO are equal and are dependent on atrial pressure, the right heart Starling function curves can be superimposed on the systemic venous return curves using the same graphic parameters. The intersection of the two



• **eFig. 22.3** Graphic representation of venous return with varying atrial pressures, mean circulatory pressures and venous resistance. Altering mean circulatory pressure displaces the line representing venous return (line *a* to line *b* or *c*) without changing the slope (which represents venous resistance to flow). Altering venous resistance changes the slope of the venous return curve (line *a* to line *d* or *e*) without changing the intercept point of the venous return line with the ordinate (which defines mean circulatory pressure). *C,* Mean vascular compliance; *Pa,* right atrial pressure; *Pmc,* mean circulatory pressure; *Rv,* venous resistance; *Vs,* stressed volume. See text for details.



• **eFig. 22.4** Graphic representation of systemic venous return–right heart performance interactions during cardiogenic shock (point *A* to *B*) and therapy (see text for details). *Pmc,* Mean circulatory pressure.

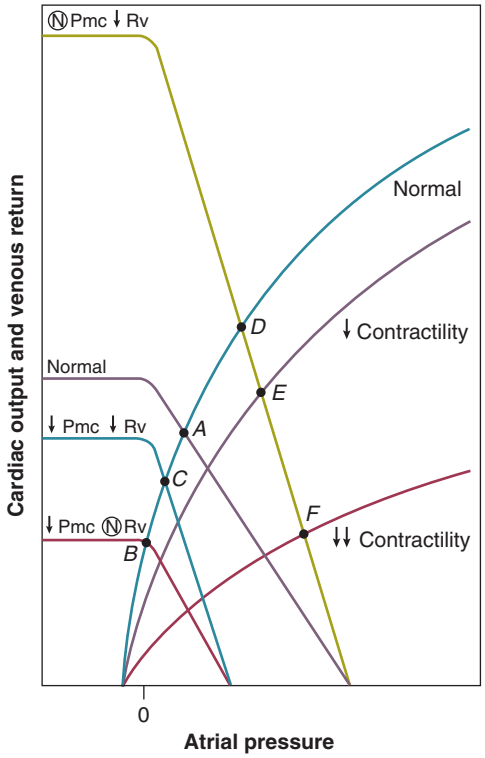
curves defines CO and venous return for any given set of conditions involving the right heart and the systemic venous circulation. The circulatory physiology of shock can be described by the interaction of cardiac function and venous return curves.

Cardiogenic shock and obstructive shock owing to increased afterload of the right or left ventricle (e.g., massive pulmonary embolus) result in a common change of the right ventricular Starling function curves. In the case of primary left ventricular loading or damage, this occurs because increased left ventricular filling pressures are passively transmitted to the right ventricle. The Starling curves are shifted downward and to the right (flatter) (eFig. 22.4, point A to B), resulting in decreased CO at increased atrial pressures. Therapy can consist of fluid resuscitation (increased Vt and Pmc), which may result in only modest augmentation of CO despite significant increases of atrial pressures and ventricular filling pressures (point C); dobutamine, a β_1- and β_2-agonist that increases CO by increasing contractility (point D); and both fluids and dobutamine (point E). Other catecholamines such as dopamine and norepinephrine, which both increase myocardial contractility and reduce venous capacitance, also increase afterload and have variable effects on CO and venous return depending on which effect is dominant. Resistance to therapy may be noted if myocardial damage is sufficiently severe to flatten the Starling function curve to the point that increasing Pmc has little effect on increasing venous return/CO and insufficient functional myocardium remains to respond to inotropes with increased contractility (a steeper Starling relationship).

Hypovolemic shock results from decreased Vt, Vs, and Pmc (eFig. 22.5, point A to B). The venous return curve is shifted downward and to the left, resulting in a reduced venous return and CO at lower Pas. Although late depression of myocardial contractility with shift of the Starling function curve downward and to the right (analogous to myocardial depression during cardiogenic shock) has been noted in experimental hemorrhagic shock,[36,37] this phenomenon is not considered here. Volume therapy, whether with crystalloid or colloid, tends to correct Pmc and venous return toward the original value (point C). Although optimal therapy of hypovolemic shock involves volume resuscitation, low-dose catecholamines exert similar hemodynamic effects; Pmc (and venous return) are augmented by an increase of the Vs while the total (reduced from baseline) circulating volume (Vt) is unchanged (also point C).[158,161,162] These changes outweigh any deleterious effect on increasing Rv. Cardiac contractility and vascular resistance are minimally affected at these doses. At moderate infusion rates (and with sympathetic stimulation), cardiac contractility is also augmented (point D). With higher catecholamine infusion rates, Vr and afterload may increase resulting to the point of decreasing CO and venous return (not shown). For that reason, vasopressors may be used only with great caution in hypovolemic shock.[163]



• **eFig. 22.6** Graphic representation of systemic venous return–right heart performance interactions during septic shock (point *A* to *B*) and therapy (see text for details). *Pmc,* Mean circulatory pressure; *Rv,* venous resistance.

Septic shock is especially complicated. Sepsis may involve elements of hypovolemia, myocardial depression, and altered distribution of CO. Vt and Vs are decreased owing to loss of fluids to the interstitium (third-spacing) and insensible losses. Vs is further decreased as the result of active dilation of small venules/veins, resulting in increased venous capacitance. This increase in Vt and decrease in Vs has been confirmed in experimental animal models of canine and porcine endotoxemia.[101,164] Thus in unresuscitated septic shock, Pmc is almost universally decreased, resulting in reduced venous return and CO (eFig. 22.6, point A to B). Sepsis is also associated with dilatation of large veins and shunting of arterial blood flow to low-resistance (fast time constant) vascular beds, both of which decrease Vr and tend to augment venous return. Decreased Vr, however, does not fully compensate for decreased Pmc in unresuscitated septic shock. CO remains depressed (point B to C). With fluid resuscitation Pmc may be corrected back toward normal, allowing the decreased Rv to be manifested by supernormal CO and venous return (point D).[101] Patients with septic shock also develop myocardial depression, which is typically masked by the overall increase in CO (point E). In about a fifth of patients, however, myocardial depression is sufficiently severe that venous return and, therefore, CO remains depressed even after resuscitation (point F).

Human data suggest that sepsis is associated with a decrease of total vascular compliance.[165,166] However, it is unclear whether this represents a primary septic phenomenon or a neurohumorally mediated compensatory response.[149,165,167] After fluid resuscitation, therapy of septic shock primarily involves catecholamines such as norepinephrine and dopamine. These affect the venous and cardiac function curves as specified earlier, although some data suggest that both vascular and myocardial responsiveness to sympathomimetics may be reduced. In addition, they may also affect vascular compliance, similar to the potential compensatory neurohumoral effects described earlier.

Obstructive forms of shock such as those caused by pericardial tamponade and tension pneumothorax can also be analyzed in the context of venous/cardiac interactions. For a detailed review of this subject matter, the reader is referred to several excellent reviews of this subject.[149,168,169]

Ventricular function of each distinct form of shock can also be examined by using end-systolic and end-diastolic pressure-volume analysis. Such analysis can be demonstrated graphically using ventricular pressure-volume loops. Changes in SV and ventricular contractility can be examined with respect to ventricular volume and pressure alterations in circulatory shock states. Although this represents a useful approach to the study of circulatory shock physiology, a review of the subject is beyond the scope of this chapter. The interested reader is referred to a number of cogent reviews.[170–172]

Microvascular Function in Shock

Preserved microvascular (vessels <100–150 μM in diameter) function is a critical determinant of appropriate tissue perfusion during shock. Although adequate CO at sufficient blood pressure is required for appropriate global perfusion and systemic hemodynamics, effective tissue perfusion also requires intact local and systemic microvascular function.

Distribution of CO is a complicated process involving local intrinsic autoregulation and extrinsic regulation mediated by autonomic tone and humoral factors. Blood flow to individual organs may be affected by system-wide changes in microarteriolar tone or by local alterations in metabolic activity. Blood flow within organs also requires microvascular regulation to match blood flow to areas of highest metabolic activity.

Intrinsic control (autoregulation) of blood flow is thought to occur through two mechanisms. Rapid alterations of microvascular tone are mediated through endothelial stretch receptors so that sudden changes in perfusion pressure can be compensated by opposing changes in vascular resistance to maintain perfusion.[173] In addition, increases in metabolic activity within tissues and organs are thought to cause local elevation of various metabolites (carbon dioxide [CO_2], hydrogen ion [H^+], and so on), resulting in vasodilation and increased perfusion to match substrate demand.[173]

Extrinsic control of vascular tone is primarily exerted through the autonomic nervous system. Parasympathetic release of acetylcholine to blood vessels results in nitric oxide (NO) and cyclic guanosine monophosphate (cGMP) generation in endothelial cells and vascular smooth muscle, leading to vascular relaxation. Increases of sympathetic tone cause local norepinephrine release, activation of vascular α-adrenoreceptors, and increased vascular tone (eFig. 22.7). Under stress, epinephrine and norepinephrine can be systemically released by sympathetic stimulation of the adrenal medulla. Basal control of blood pressure and flow resides in the activity of the renin-angiotensin system.

Alterations in microvascular function are effected through precapillary and postcapillary sphincters that are sensitive to both intrinsic and extrinsic control mechanisms. Because exchange of CO_2, oxygen, and other substrates/metabolites and compartmental regulation of fluids occur at the capillary level, alteration of tone of either sphincter may have varying effects. Opening of either

nonnutrient capillary sphincters (microanatomic shunts)[174] or increased flow to hypometabolic tissues (functional shunts)[175] results in suboptimal distribution of substrate supply with increased MvO_2. Failure to dilate sphincters supplying metabolically active tissues may result in ischemia and anaerobic metabolism with lactate production. Increased precapillary tone as seen with sympathetic stimulation results in increased blood pressure systemically and decreased hydrostatic pressure locally. This decreased hydrostatic pressure favors redistribution of volume from the interstitium to the circulation. Increased postcapillary tone (relative to precapillary) results in vascular pooling of blood and loss of fluid to interstitium (owing to increased hydrostatic pressure).

Organ blood flow changes are well characterized in shock states. Autoregulation of blood flow is dependent on maintenance of blood pressure within a defined range that varies among organs. The autoregulatory capacity of various organs can be determined by mechanically altering blood pressure in the organ vascular bed. With isolated local hypotension, the brain exhibits dominant autoregulatory capability with the ability to maintain blood flow over a wide range of pressures (30–200 mm Hg in dogs).[145] Coronary perfusion is also substantially autoregulated between 40 and 100 mm Hg. In contrast, mesenteric and renal blood flow becomes pressure dependent below about 60 mm Hg, whereas the vascular bed of skeletal muscle behaves in a passive manner at pressures outside 50 and 100 mm Hg. Human data suggest that, overall, good autoregulation of blood flow exists in humans between pressures of 60 and 100 mm Hg.[145] In the context of normal physiology, blood flow is not effectively autoregulated outside this range. Without local adaptation, this would result in mismatching of blood flow and metabolic demands, producing organ failure and the metabolic correlates of shock. However, extrinsic adaptive mechanisms to protect the most vital organs come into play.

During hypovolemia and other hypodynamic forms of shock, extrinsic blood flow regulatory mechanisms overwhelm the autoregulatory response of most vascular beds. Blood flow to the heart and brain are well preserved owing to dominant local autoregulation of flow. Blood flow to other organs is reduced relative to the decrease in total CO as organ vascular resistance increases to maintain blood pressure.[176] This effect is mediated in part by both sympathetic neural activity and adrenal release of catecholamines.[145,176] This adaptive mechanism maintains perfusion to vital organs at mild to moderate levels of reduced CO. If the insult is sufficiently severe or prolonged, organ ischemia and subsequent organ failure may develop. Even if resuscitation restores systemic circulatory hemodynamics, microvascular perfusion abnormalities persist for days.[177] Experimental data suggest that perfusion of brain, kidneys, liver, and other splanchnic organs remains impaired after resuscitation from hemorrhagic shock.[177] Persistence of inadequate matching of tissue substrate demand and delivery after resuscitation of shock can lead to continued ischemia/hypoxia of some tissues. This may explain why hemorrhagic shock-related tissue injury can be irreversible if the duration and severity of is excessive. Animal models suggest this irreversible phase of severe hemorrhagic shock is characterized by vasodilatation of precapillary sphincters.[178]

During sepsis and septic shock, organ blood flow is disturbed at higher MAP, suggesting a primary defect of microvascular function. Cerebral blood flow to the brain in humans has been shown to be depressed even before the onset of septic shock in patients with systemic inflammatory response syndrome.[179] This pathologic vasoconstriction (apparently a unique response of the cerebral circulation to sepsis) does not appear to be the cause of septic encephalopathy. Cerebral autoregulation remains intact during sepsis.[180] The greater decrease in coronary than SVR during human septic shock may suggest that myocardial autoregulation also remains intact despite the fact that, in contrast to the brain, myocardial perfusion is often increased during septic shock.[181,182]

Animal models demonstrate that all other vascular beds (splanchnic, renal, skeletal, cutaneous) exhibit decreased vascular resistance, with flow in these beds becoming increasingly dependent on CO. This suggests both an active vasodilatory process and failure of extrinsic control of blood flow.[145] Inappropriate levels

of splanchnic and skeletal muscle perfusion are also observed in humans during sepsis.[183] Other experimental data suggest that sepsis and septic shock are also associated with aberrant distribution of flow within organs.[175] In sepsis, vasodilatation and autoregulatory failure of the microvasculature may be responsible for mismatches of oxygen delivery and results in anaerobic glycolysis with lactate production despite increased mixed venous oxygen saturation.

During both irreversible hemorrhagic shock and septic shock, peripheral vascular failure results in worsened matching of tissue demand and substrate supply leading to failure of all organs and death. The following are among the potential responsible mechanisms:

1. Tissue acidosis[184]
2. Catecholamine depletion and mediator-related vascular resistance to catecholamines[185]
3. Release of vasodilating and vasoconstricting arachidonic acid metabolites[186]
4. Decreased sympathetic tone as the result of altered central nervous system (CNS) perfusion[187]
5. Pathologic generation of NO by vascular smooth muscle cells[39,188]

In addition to vasomotor dysfunction, shock is associated with other microvascular pathology recently referred to as shock-induced endotheliopathy.[189,190] Prime among these is disruption of endothelial cell barrier integrity. The endothelial layer is responsible for maintaining oncotic proteins (mostly albumin) within the circulatory space. During shock capillary permeability is increased, resulting in loss of plasma proteins into the interstitium. Endothelial injury, through the action of neutrophil-generated free radicals[191] and NO/peroxynitrite generation,[192,193] may account for this phenomenon. Release of vasoactive intermediaries such as histamine, bradykinin, PAF, leukotrienes, and TNF-α appear to drive this pathologic process. Injury is initiated by leukocyte-endothelial cell interactions via adhesion molecules (integrins, selectins) that allow emigration of neutrophils to the tissues. Blockade of such activity or depletion of neutrophils attenuates tissue injury in animal models of shock.[194] With the loss of plasma proteins, the plasma oncotic pressure drops, interstitial edema develops, and circulating volume falls.

There is also evidence of intravascular hemagglutination of red blood cells, white blood cells, and platelets in almost all shock syndromes.[175,189,195] This may be due to primary microvascular clotting leading to microthrombi. Alternately, clotting may occur as a consequence of primary endothelial damage owing to circulating cytokines, free radicals produced by reperfusion and neutrophils, or complement activation.[189] In any case, the result may be further endothelial cell injury, microvascular abnormalities, and inadequate distribution of perfusion within tissues. Decreased deformability of erythrocytes caused by membrane free radical injury may also play a role in microcirculatory alterations in hemorrhagic and septic shock.[196]

Mechanisms of Cellular Injury in Shock

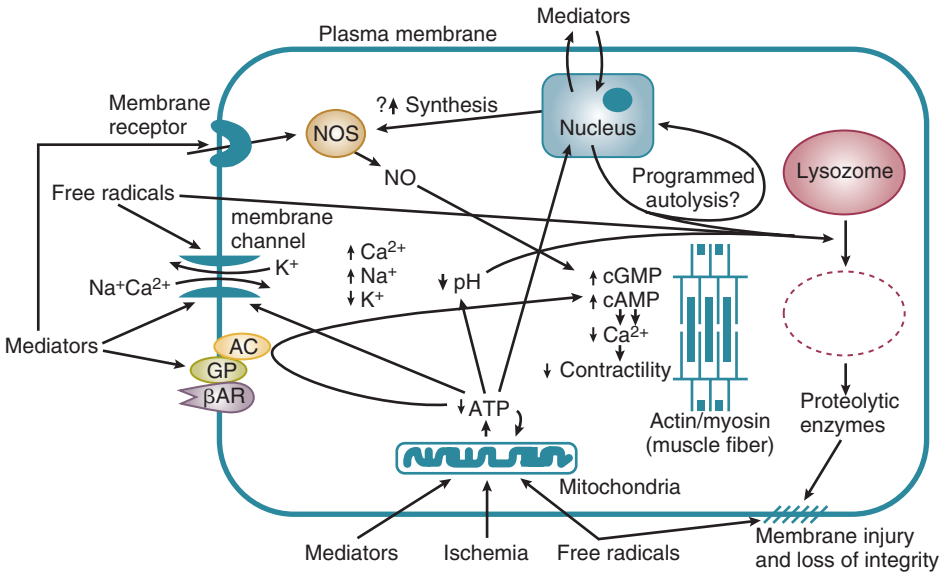
Although different forms of shock have their different precipitants, they do share common mechanisms of cellular dysfunction and injury. Eventually, events at the cellular level result in organ dysfunction and death. The pathogenesis of the cellular dysfunction is a combination of the interrelated precipitants and consequences of shock, including (1) ischemia, (2) inflammation, and (3) free radical injury (eFig. 22.8). Genetic factors are also felt to play a role in an individual's susceptibility and response to shock.

The metabolic pathways involved in shock, like all cellular pathways, involve multiple levels of feedback. Some pathways have positive feedback mechanisms, where an initial small signal results in accelerating downstream effects, and negative feedback mechanisms, where downstream effects results in downregulation of upstream processes. Because cellular mechanisms from different signal transduction pathways often share common elements, different pathways have positive and negative feedback effects on each other; this is termed *crosstalk*.

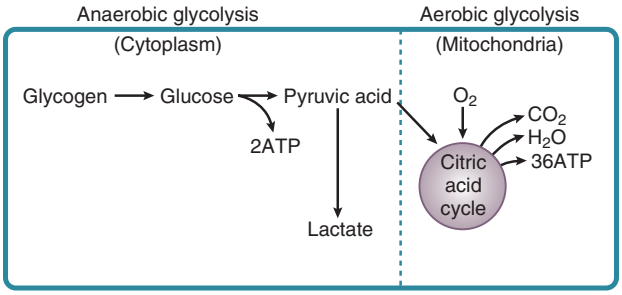
In all forms of shock, the hemodynamic changes involved eventually result in decreased oxygen delivery to target organs, with resultant cellular ischemia. The degree to which this is important in the development of organ damage and death in the different shock forms may vary, but it clearly is the major factor in hypodynamic forms of shock, and it also plays a large role in the ultimate mortality of hyperdynamic, hypermetabolic shock.

In the stressed preshock phase, physiologic adaptive mechanisms attempt to compensate and perfusion to vital organs is maintained. With the onset of shock, these mechanisms fail, and thus oxygen delivery to tissues is not maintained. At the cellular level, a lack of oxygen prevents the mitochondrial citric acid cycle from functioning and pyruvate accumulates (eFig. 22.9). The failure of aerobic respiration requires shunting of pyruvate into the lactic acid pathway to recycle nicotinamide adenine dinucleotide (NAD) and allow glycolysis to continue. However, the loss of the aerobic citric acid cycle results in a large decrease in adenosine triphosphate (ATP) production (net 2 molecules of ATP per molecule of glucose versus a theoretical net of 38 molecules of ATP per glucose molecule in the entire aerobic pathway). In addition, shunting to the lactic acid pathway results in the accumulation of hydrogen ions. Thus loss of perfusion results in a rapid decrease in cellular energy stores, with inadequate ATP regeneration rates. As ATP is the primary source of energy in the cell, energy-dependent cellular systems cease functioning. This includes energy-dependent enzymes, maintenance of transmembrane gradients including electrical potential,[197] mitochondrial function,[198] carbohydrate metabolism,[199] and even the glycolysis pathway itself, which requires two ATP molecules to prime each glucose molecule at the entry point into the pathway. Some cell types are more sensitive than others to depletion of energy stores, such as in the liver and kidney, but eventually all organs are affected.[197,200–203] With the loss of energy-dependent cell maintenance functions, ultrastructural breakdown, including mitochondria, occurs.[204] Systemically, the combination of worsening acidosis and loss of energy stores results in a positive feedback loop of worsening shock, organ failure, and eventual death.

Ischemia is felt to play a minor role in early sepsis, with high COs maintaining perfusion to more sensitive, higher energy-consuming tissues, and that ATP levels remain normal in these tissues, with mitochondrial function preserved. Instead, early septic organ dysfunction results from other causes.[205–207] However, localized areas of ischemia are not ruled out. Potentially, microthrombi may result in small areas of decreased microcirculatory flow, resulting in localized ischemia. Evidence to support a role for ischemia in cellular dysfunction in sepsis includes oxygen supply–dependent oxygen consumption, washout of organic acids from ischemic areas in patients in septic shock receiving vasodilators, and elevated ATP degradation products. In any case, the role of ischemia in septic shock remains a question. For example, alterations of liver and skeletal muscle transmembrane potential occur early in shock before the decrease in levels of high-energy phosphates and onset of hypotension. Further, this membrane defect is not prevented by



• **eFig. 22.8** Mechanisms of cellular dysfunction and injury in shock. Cell injury is mediated by multiple mechanisms during shock. Tissue ischemia may result in limitation of aerobic adenosine triphosphate (*ATP*) generation. This results in further mitochondrial impairment owing to deficits of mitochondrial membrane function, altered signal transduction including decreased muscle contractility (ATP is the precursor of cyclic adenosine monophosphate [AMP]), impaired energy-dependent maintenance of transmembrane potential and ion gradients, increased intracellular pH owing to anaerobic metabolism, and possible initiation of autolytic mechanisms. Free radicals may result in broad injury to cellular membranes, resulting in impaired maintenance of transmembrane potential and ion gradients, mitochondrial generation of ATP, and activation of autolytic pathways involving DNA degradation and lysosomal rupture (apoptosis). Various circulating mediators (including cytokines, kinins, eicosanoids, and complement components) may result in mitochondrial dysfunction, signal transduction abnormalities, membrane protein channel alterations, and possibly alterations of gene expression. Any of these may lead to cell death through metabolic failure and lysosomal enzyme release. *AC,* adenylate cyclase; *Ca^{2+},* calcium ion; *cAMP,* cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *GP,* G proteins; *K^+,* potassium; *Na^+,* sodium ion; *NO,* nitric oxide; *NOS*, nitric oxide synthetase; *βAR,* β-adrenergic receptor.



• **eFig. 22.9** Aerobic and anaerobic glucose metabolism. Under anaerobic conditions, pyruvic acid cannot enter the citric acid cycle in the mitochondria (to optimally produce adenosine triphosphate [*ATP*]) and is shunted to lactate in the cytoplasm. This produces less high-energy phosphates per mole of glucose metabolized. Hydrolysis of ATP molecules in an anaerobic environment results in production of hydrogen ions that cannot be metabolized or cleared resulting in intracellular acidosis. *ATP,* Adenosine triphosphate; *CO_2,* carbon dioxide; *H_2O,* water; *O_2*, oxygen. Adapted with permission.[401]

administration of membrane-permeable forms of high-energy phosphates such as ATP-magnesium chloride ($MgCl_2$).[208]

Inflammation, on the other hand, is a major contributor to the development of septic shock and its effects on cellular and organ dysfunction.[209,210] Other forms of shock also result in activation of the inflammatory cascade—for example, in hemorrhagic shock with tissue trauma.[211] Indeed, shock is associated with systemic activation of the inflammatory cascade. The resulting cellular and tissue dysfunction and hypermetabolic state contribute to organ dysfunction and failure. The inflammatory cascade in sepsis can be roughly broken down into initiation, transduction, and release of inflammatory mediators.

Initiation of the inflammatory cascade in sepsis is thought to rely largely on the innate immune response.[212–214] This ancient immune pathway evolved to recognize nonself molecular signatures, produced by pathogens including bacteria, yeast, and viruses, which have remained invariant over time. These signatures are called pathogen-associated molecular patterns (PAMPs), and they are recognized by a series of receptors known as pattern recognition receptors (PRRs). In addition, signature host proteins can also be released extracellularly in response to cellular damage, and these proteins, also called alarmins, are known as damage-associated molecular patterns (DAMPs), and these too may be recognized by PRRs. Thus both nonself PAMPs and self-expressed DAMPs may lead to initiation of the inflammatory cascade via the PRRs. Known PRRs include the following:

1. Toll-like receptors (TLRs)
2. C-type lectin receptors (CLRs)
3. Nucleotide oligomerization domain (NOD)-like receptors (NLRs)
4. Retinoic acid–inducible gene I–like receptors (RLRs)

The TLRs and CLRs, as transmembrane receptors, are presented on the cell surface or within the lumens of endosomes or lysosomes.[209,214,215] Currently 10 families of TLRs have been identified in humans. Different TLR families on the cell surface recognize various bacterial lipoproteins, lipopolysaccharides, or flagellins, with sources that may be bacterial, viral, or protozoan. In contrast, those TLR families located in endosomal lumens recognize single-stranded RNA, double-stranded RNA, and modified oligodeoxynucleotide-DNA, which may be of viral or bacterial origin. Interestingly, different individual families of TLRs can form both homodimers and heterodimers on the cell surface, increasing their range of ligand recognition. Meanwhile, the CLRs are presented on the cell surface, and as lectins, recognize polysaccharides present in yeast and fungi, mycobacteria, and viruses.

In contrast, the NLRs and RLRs are intracellular, and require that their ligands be present in the cytoplasm of the cell.[215] NLRs recognize bacterial peptidoglycans; the RLR ligands consist primarily of double-stranded RNA, cytoplasmically produced either by dsRNA viruses or as an intermediate step in the replication of single-stranded RNA viruses.

Once initiated by recognition of PAMPs or DAMPs, the inflammatory cascade involves a large number of protein, kinase, and second-messenger cascades. These cascades can lead to activation of transcription factors or to posttranscriptional or posttranslational activation of inflammatory mediators.

The TLRs have been shown to use two primary pathways.[215] All the TLRs, with the exception of TLR3, use a pathway dependent on the myeloid differentiation adaptor protein (MyD88), which binds to the intracellular sections of the TLRs; for some of the TLRs, another adaptor protein is required to bind MyD88. Upon activation of the TLR, MyD88 recruits a serine/threonine kinase, IRAK-4 (IL-1 receptor–associated kinase 4), in turn recruiting further kinases such as IRAK-1 and IRAK-2. Ultimately, the cytoplasmic cascade results in phosphorylation and degradation of IκB, an inhibitor of the transcription factor nuclear factor κ light-chain enhancer of activated B cells (NF-κB). This allows NF-κB to enter the nucleus, resulting in the activation of transcription of a suite of inflammatory mediators and modulators. In contrast, TLR3 uses a pathway dependent on the TRIF adaptor protein, which also ultimately results in NF-κB activation. In both pathways, other adaptor proteins may be required for individual TLRs to activate these cascades; for example, TLR4 can also use the TRIF-dependent pathway but is dependent on the TRAM adaptor protein to do this. Different cell types may express different adaptor proteins, resulting in intertissue variation in the cascades. In addition, protein inhibitors of the cascades can be expressed variably in different cell types.

In contrast, the NLRs act via formation of a multiprotein complex, termed the *inflammasome*.[209,215,216] The caspases,[217] a family of cysteine proteases, are central to this cascade. Upon activation, the NLR recruits a pro-caspase, along with an adaptor protein ASC, which recruits a second pro-caspase. This complex allows the pro-caspase pair to autoactivate, resulting in active caspase. The best studied of these is caspase-1, although other caspases may be involved. Once activated, caspase-1 in turn activates the inflammatory cytokine IL-1β, allowing its release from the cell. Similarly, caspase-1 is also responsible for the activation and release of other cytokines, including IL-18. In this way, the NLR's prime function is to regulate inflammatory mediator release through a posttranslation system. Crosstalk from the TLR cascades may also activate some NLRs and result in inflammasome formation.

At the center of these cascades is transcriptional regulation of inflammatory cytokines and mediators. The transcription factor NF-κB sits at the end of many of these cascades and plays a crucial role in the regulation of expression of many of these factors.[209,215,218] NF-κB is present in an inactive form in the cytoplasm, in complex with repressor proteins.[219] When the repressors, known as IκB proteins, are phosphorylated and subsequently degraded, NF-κB is released and transported into the nucleus, where it can act on its target sequences. By being stored in inactive form in the cytoplasm, no new NF-κB need be expressed, allowing for rapid response to the signals received by the PRRs. Inflammatory mediators under the control of NF-κB include cytokines such as TNF-α, IL-1β, and IL-6, enzymes involved in inflammation, such as inducible NO synthase and others.[209]

Inflammatory mediator effects on cellular metabolism are of prime importance in organ dysfunction owing to sepsis and septic shock. Circulating inflammatory mediators may also play a substantial role in other forms of shock, including hemorrhagic shock associated with extensive tissue trauma.[220,221] Both sepsis and trauma are associated with generalized, systemic activation of the inflammatory response. Resulting cell injury and hypermetabolism may culminate in organ failure. A number of triggers can result in activation of the inflammatory cascade. The best studied is endotoxin from gram-negative bacteria, but other bacterial antigens and cell injury itself can also initiate the cascade. Macrophage production of cytokines such as TNF-α, IL-1β, and IL-6 appears to be central.

TNF-α is a 51-kD trimeric peptide produced by macrophages in response to a variety of inflammatory stimuli, including bacterial antigens and other cytokines. Circulating levels of TNF-α are transiently elevated soon after the onset of shock (particularly septic shock).[222] Administration of TNF-α to animals or humans results in a hyperdynamic circulatory state (± dose-dependent hypotension) similar to untreated sepsis and septic shock.[111] Although clinical trials to date have yielded disappointing results, anti–TNF-α strategies protect animals from experimental endotoxic and septic shock.[223] Among the many effects of TNF-α are release of IL-1β, IL-6, IL-8, PAF, leukotrienes, thromboxanes, and prostaglandins; stimulation of production and activity of polymorphonuclear leukocytes; promotion of immune cell adhesion to endothelium; activation of coagulation and complement systems; direct endothelial cell cytotoxicity; depression of myocardial contractility; and fever production by the hypothalamus.[111,224] Notably, TNF-α causes alterations of skeletal transmembrane electrical potential similar to those described in hemorrhagic and septic shock.[225] These membrane effects precede hemodynamic alterations, suggesting that TNF-α exerts a primary effect on cell metabolism independent of perfusion alterations. Although TNF-α appears to be of central importance in the pathogenesis of septic shock, it is also known to be elevated in CHF[226] and hemorrhagic shock.[220]

Other substances involved in the inflammatory process include the following:

IL-1β, which can potentiate the in vivo effects of TNF-α

IL-2, which can cause hemodynamic abnormalities in humans

IL-6, which is involved in the acute-phase response and has recently been implicated in septic myocardial depression

Interferon (INF)-γ, which promotes the release of other cytokines, enhances adhesion of immune cells, and promotes macrophage activation

IL-10, which is an antiinflammatory cytokine that limits macrophage generation of proinflammatory cytokines;

TGF-β, which is another antiinflammatory cytokine that, in addition to limiting macrophage proinflammatory responses,

also blocks the effects of proinflammatory cytokines on target cells

Endothelin-1, a cytokine which strongly promotes vasoconstriction, particularly in the renal vascular bed, possibly resulting in renal hypoperfusion and decreased glomerular filtration rate

PAF, which stimulates TNF-α, thromboxane, and leukotriene release; stimulates free radical formation; and alters microvascular permeability

Leukotrienes, which release other arachidonic acid metabolites, alter vascular endothelial permeability, and may mediate vascular and myocardial depression in shock

Thromboxanes, which may contribute to altered microvascular vasomotor and permeability function

Prostaglandins, which produce fever, induce vasodilatation, and inhibit thrombus formation

Complement fragments C3a and C5a, which constrict vascular smooth muscle, release histamine, and promote chemotaxis.[115,227,228]

Several newly recognized mediators/mediator groups have been shown to have important roles in shock, particularly septic shock. These include high-mobility group 1 protein (HMG-1), myocardial depressant substances, and NO/peroxynitrites. HMG-1 appears to have a key role in the late pathogenesis of sepsis[229,230] and may also have a role in traumatic/hemorrhagic shock.[224,231,232] HMG-1 is a late mediator of inflammation. Mice show increased levels of HMG-1 in serum 8 to 32 hours after endotoxin administration. Patients succumbing to septic shock also demonstrate increased serum HMG-1 levels.[229] Administration of HMG-1 to normal and endotoxin-resistant mice induces dose-dependent mortality with signs consistent with endotoxic shock.[229,230] Several anti–HMG-1 therapies are in development.[232]

A circulating myocardial-depressant substance is present in the blood of patients with septic shock who exhibit myocardial depression with biventricular dilatation and reduced ventricular ejection fractions.[233] Similar substances have been shown to be present in animal models of hemorrhagic shock.[234] Other data suggest canine MI[235] and human cardiogenic shock[236] may also be associated with a circulating myocardial-depressant substances. Serum from appropriate septic patients or animal models depresses myocardial tissue in vitro.[144,233] Myocardial depressant substances from both septic and hemorrhagic shock appear to be dependent on calcium.[237] The substance implicated in human sepsis may represents a synergistic combination of TNF-α and IL-1β that produce depression by inducing myocardial NO production.[233,238,239] TNF-α and IL-1β are both elevated in shock and cause similar depression of myocardial tissue.[238,240] Other data suggest that IL-6 may have a central role.[115,227,241]

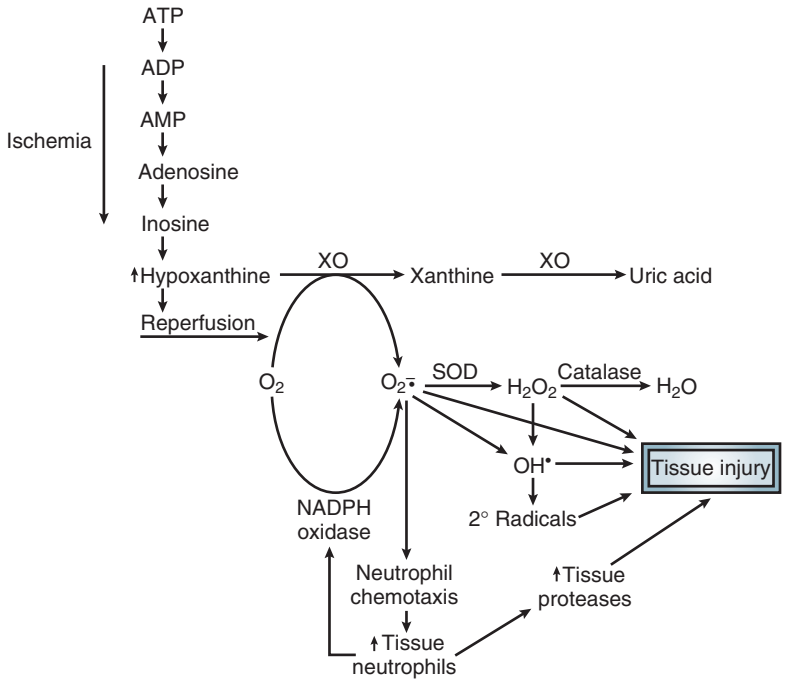
Another important mediator, NO, has a vital role in normal intracellular signal transduction.[242] Of particular importance to shock, NO is the mediator through which endothelial cells normally cause relaxation of adjacent smooth muscle.[242] Endothelial cells, through a constitutive NO synthetase, produce picomolar quantities of NO in response to a number of vasodilatory mediators such as acetylcholine and bradykinin. This NO diffuses to adjacent smooth muscle and activates guanylate cyclase to produce cGMP, which affects vascular relaxation. Nitrovasodilators bypass NO synthetase to relax smooth muscle directly though the guanylate cyclase pathway. During septic shock, an inducible NO synthetase capable of producing nanomolar quantities of NO is generated in vascular smooth muscle.[242,243] Studies have also implicated NO in late vascular dysfunction seen in hemorrhagic shock.[39] NO-mediated generation of cGMP may explain the profound loss of arterial vascular tone and venodilatation seen in septic shock[243,244] and may, in part, explain irreversible vascular collapse seen late in hemorrhagic shock.[39] A potential role for NO in inflammation-associated edema and third-spacing during shock has also been suggested.[192] The in vitro myocardial depressant effects of TNF-α, IL-1β, and serum from septic humans may be mediated by a similar NO- and cGMP-dependent pathway.[111,238]

An alternative pathway by which NO may play a role in the cardiovascular pathophysiology of shock and sepsis was described by Beckman and colleagues in 1990.[245] Peroxynitrite ($ONOO^-$), a highly reactive oxidant, is produced from the interaction of superoxide (OH^-) and NO (NO^-). It is known to react rapidly with proteins, lipids, and DNA during sepsis and shock states.[246–249] Lipids may be peroxidized and although proteins may be oxidized, nitrated, or nitrosated, the last resulting in nitrotyrosine residues.[245,250,251] Peroxynitrite inactivates mitochondrial aconitase disrupting the Kreb cycle and otherwise interferes with ATP production and utilization,[252–257] an activity similar to that described for NO.[258–260] It also generates DNA strand breaks, leading to poly-adenosine diphosphate (ADP) ribose synthetase activation that may itself have significant pathophysiologic effects.[261,262] Peroxynitrite, like NO, also activates guanylate cyclase in vascular tissues.[263,264] In the periphery, the result may be cellular energetic failure, vascular contractile dysfunction (vasodilation), and reperfusion injury.[261,265–267] Many other molecular targets of NO relevant to the cardiovascular system exist and are well reviewed elsewhere.[250,268]

It is of note that as part of the release of inflammatory mediators, immune cells, including macrophages, polymorphonuclear leukocytes, and lymphocytes, may also be activated in some forms of hypodynamic shock (e.g., hemorrhagic shock), resulting in a self-perpetuating, systemic inflammatory response (similar to that seen in sepsis). This response can contribute to vascular and parenchymal injury and culminate in MODS.

Free radical injury induced by reperfusion or neutrophil activity is another mechanism of organ injury during hemorrhagic and septic shock as well as burns and MI.[269] During tissue ischemia, oxygen deficiency leads to accumulation of ATP degradation products, including adenosine, inosine, and hypoxanthine (eFig. 22.10).[270] With resuscitation and reperfusion of ischemic areas, oxygen drives the generation of superoxide (O_2^-), the most common precursor of reactive oxidants, by xanthine oxidase in endothelial cells. Most of the superoxide is converted, either spontaneously or through superoxide dismutase to hydrogen peroxide ($H_2O_2^-$). This further reacts to produce tissue-damaging hydroxyl radicals (or other highly reactive free radicals).[269] These radicals interact with critical cell targets, such as the plasma membrane, lipid membranes of organelles, and various enzymes, resulting in cell lysis and tissue injury. Oxidant activity, directly and through endothelial damage, attracts and activates neutrophils, resulting in amplification of superoxide generation by a neutrophil dihydronicotinamide adenine dinucleotide phosphate (NADPH)-oxidase and in further tissue damage owing to neutrophil protease release.[269] Injured tissue may release xanthine oxidase into the circulation resulting in systemic microvascular injury.[271]

A parallel process is found during reperfusion of ischemic myocardium after MI.[272] Thrombolytic therapy or balloon angioplasty results in sudden delivery of oxygen to ischemic myocardium. Although substantial salvage of myocardial function results, free oxygen radical–mediated reperfusion injury can contribute to myocardial "stunning."[273] Cardiogenic shock during this phase may resolve as the reperfusion injury settles. Free radical damage likely also plays a role in tissue damage during sepsis and septic shock. After activation by inflammatory mediators and during phagocytosis,



• **eFig. 22.10** Free radical–mediated tissue injury. Superoxide *(O_2^-)* is primarily produced in shock from hypoxanthine (a metabolite of adenosine triphosphate [*ATP*] degradation) by xanthine oxidase *(XO)* during reperfusion after ischemia. Superoxide can be converted to hydrogen peroxide *(H_2O_2)* by superoxide dismutase *(SOD)* and then to water *(H_2O)* or may be converted to the highly reactive hydroxyl *(OH^-)* that mediates tissue injury. Free radical tissue injury may be amplified by superoxide recruitment of neutrophils that secondarily produce additional superoxide through NADPH oxidase. *2°,* Second degree; *NADPH,* reduced nicotinamide adenine dinucleotide phosphate. (Adapted with permission from Girardin E, Grau GE, Dayer JM, et al. Plasma tumor necrosis factor and interleukin-1 in the serum of children with severe infectious purpura. *N Engl J Med*. 1989;319:397–400.)

polymorphonuclear leukocytes undergo a respiratory burst during which they consume oxygen and generate both superoxide and hydrogen peroxide through a membrane-associated NADPH-oxidase.[269] Macrophages similarly produce oxygen radicals upon activation. Activation also enhances adhesion and tissue migration of leukocytes so that both vascular endothelial and parenchymal tissue damage may result. Free radical injury may play an important role in the development of organ failure after shock.[274]

Variations in stress response genes between individuals and alteration of gene expression in immune, endothelial, muscle, and organ parenchymal cells are other important aspects of cellular dysfunction/injury in circulatory shock. Although shock can be present immediately after injury (massive trauma, hemorrhage, or endotoxin infusion) before the onset of substantial alterations of gene expression, its evolution is dependent on a combination of the ongoing nature of the insult, the genetically passive compensatory physiologic/metabolic response, the underlying genotype with respect to stress response elements, and stress-related modulation of gene expression in a variety of cells.

The clinical presentation of shock, progression of the syndrome, and final outcome may be substantially controlled by genetic factors.[275] Genetic factors have been best studied in septic shock. Studies have demonstrated that the human TNF-α promoter polymorphism, TNF-2, imparts an increased susceptibility to and mortality from septic shock.[276] Other studies suggest increased TNF-α generation, severity of sepsis, and mortality with another human TNF-α gene polymorphism.[277] A specific locus on chromosome 12 in mice has been shown to be associated with resistance to mortality owing to TNF-α–induced shock.[278] A human IL-1β receptor antagonist gene polymorphism has been linked to increased susceptibility to sepsis.[279] Several additional linked polymorphisms have been described in recent years.[280] It appears likely that gene polymorphisms may also play similar roles in other forms of shock.

Beyond the role of gene alleles in the development and clinical response to shock, the progression of irreversible circulatory shock and MODS may have its basis in genetically driven vascular or parenchymal responses. Production of cytokines by macrophages during shock requires acute expression of the genes coding for TNF-α, IL-1β, and other proinflammatory cytokines. The production of adhesion molecules by endothelial cells and inducible NO synthetase by vascular smooth muscle during shock requires active upregulation of gene expression. Both events are thought to be key to the development of MODS after shock in humans. In addition, human and animal research indicate that apoptosis, a genetically programmed process of cell autolysis, occurs in a variety of organs during shock and subsequent organ failure.[281,282] Recent data suggest that a variety of transcription factors may be activated in models of sepsis in association with the process.[283] Further research should elucidate the important link between irreversible/refractory shock/shock-associated MODS and genetically programmed cell responses to inflammatory stimulation and/or injury.

Whatever the initiating event or events, progressive cell metabolic failure occurs. Mitochondrial activity continues to deteriorate, subcellular organelles are damaged, and intracellular (and possibly, systemic) release of lysosome hydrolytic enzymes occurs, accelerating cell death and organ failure.

However, once MAP falls below about 80 to 90 mm Hg, aortic baroreceptor activity is absent. Subsequently, carotid baroreceptor response is eliminated as mean pressure falls below 60 mm Hg. As blood pressure falls further, carotid and aortic chemoreceptors, sensitive to decreased partial pressure of oxygen (P_{O_2}), increased partial pressure of arterial carbon dioxide (P_{CO_2}), and increased H^+ concentrations (decreased pH), dominate the response. These receptor complexes, active only when mean blood pressure is less than approximately 80 mm Hg, are of minimal relevance during physiologic states.[144] During shock, they make a substantial contribution to increases of sympathetic tone.

During severe shock, the most powerful stimulus to sympathetic tone is the CNS ischemic response.[144] The lower medullary chemoreceptors for this response (thought to be sensitive to increased CO_2 associated with decreased cerebral perfusion) become active when mean blood pressure falls below 60 mm Hg. Sympathetic stimulation provided by these receptors peaks at mean pressures of 15 to 20 mm Hg and results in maximal stimulation of the cardiovascular system.[144] The Cushing response to increased intracranial pressure is an example of activation of this reflex under different circumstances.

Other mechanisms also play a role in the compensatory response to shock. Vasopressin release is regulated by alterations of serum osmolality. During effective hypovolemia owing to intravascular volume loss or increased vascular capacitance, low-pressure, right atrial stretch receptors can override osmolar control of vasopressin response to effect retention of body water.[144,287] Similarly, during hypovolemia and shock, the juxtaglomerular apparatus in the kidneys respond to decreased perfusion pressure by renin release.[144]

All compensatory responses to shock, whether hemodynamic, metabolic or biochemical, support oxygen delivery to vital organs. These responses are similar (to varying extents) for different classes of shock and can be broken down into four components: (1) maintenance of mean circulatory pressure (a measure of venous pressure) by either maintaining total intravascular volume, or increasing stressed volume (i.e., increasing venous tone); (2) optimizing cardiac performance; (3) redistributing perfusion to vital organs; and (4) optimizing unloading of oxygen at the tissues (Box 22.3, see eFig. 22.3).

Mean circulatory pressure (and venous return) are sustained in early shock by a number of mechanisms. Acutely, total intravascular volume is supported by alterations of capillary hydrostatic pressure as described by Starling.[288] Sympathetic activation results in precapillary vasoconstriction. In combination with initial hypotension, this results in decreased capillary hydrostatic pressure.[288] A decrease in capillary hydrostatic pressure enhances intravascular fluid shift owing to maintained plasma oncotic pressures. Transcapillary fluid influx after removal of 500 to 1000 mL blood volumes in humans can be as high as 2 mL/min with full correction of intravascular volume by 24 to 48 hours.[289] The intravascular volume may also be supported by the osmotic activity of glucose generated by glycogenolysis. Increased extracellular osmolarity results in fluid redistribution from the intracellular to the extracellular space.

Intravascular volume is also conserved by decreasing renal fluid losses. Renal compensatory mechanisms are of limited value in acute shock but can have more impact in the subacute phase. Decreased renal perfusion associated with reduced CO and afferent arteriolar constriction results in a fall in glomerular filtration rate and urine output. In addition, decreased renal perfusion pressure, sympathetic stimulation, and compositional changes in tubular fluid[144] result in renin release from the juxtaglomerular apparatus. Renin release leads to adrenal cortical release of aldosterone (via angiotensin II), which increases sodium reabsorption in the distal tubules of the kidney in exchange for potassium or hydrogen ion.[144] Angiotensin II also exerts a powerful direct vasoconstricting effect (particularly on mesenteric vessels) while increasing sympathetic outflow and adrenal epinephrine release.[290] As noted, vasopressin (antidiuretic hormone) release occurs through activation of right atrial low pressure. Angiotensin II augments this release by increasing sympathetic outflow. The release of vasopressin from the posterior pituitary results in water retention at the expense of osmolarity. Hyponatremia can result. Vasopressin, like angiotensin II, also results in vasoconstriction, particularly of the splanchnic circulation.[290]

Finally, increased sympathetic activity and release of adrenal epinephrine results in systemic venoconstriction, particularly of the venous capacitance vessels of the splanchnic circulation. This supports mean circulatory pressure and venous return by increasing stressed volume.

Increased sympathetic nervous system activity accounts for most of the enhancement of cardiac performance during shock. Local release of norepinephrine by sympathetic nerves and systemic release of epinephrine result in stimulation of cardiac α- and β-adrenergic receptors, resulting in increases of HR and contractility that optimize CO and support blood pressure. Angiotensin II may also exert direct as well as indirect (sympathetic stimulation) inotropic effects on myocardium. Improved cardiac function also results in decreased right atrial pressure, which tends to increase venous return.

Redistribution of blood flow during shock has already been discussed. Increased sympathetic vasoconstrictor tone, systemic release of epinephrine from the adrenals, vasopressin, endothelin, and angiotensin II cause vasoconstriction in all sensitive vascular

• BOX 22.3 Cardiovascular/Metabolic Compensatory Responses to Shock

1. Maintain mean circulatory pressure (venous pressure)
   - Volume
     - Fluid redistribution to vascular space (increased total vascular volume) from interstitium (Starling effect) from intracellular space (osmotic)
     - Decreased renal fluid losses
     - Decreased glomerular filtration rate
     - Increased aldosterone
     - Increased vasopressin
   - Pressure
     - Decreased venous capacitance (increased stressed volume) increased sympathetic activity
     - Increased circulating (adrenal) epinephrine
     - Increased angiotensin
     - Increased vasopressin
2. Maximize cardiac performance
   - Increase contractility
   - Sympathetic stimulation
   - Adrenal stimulation
3. Redistribute perfusion
   - Extrinsic regulation of systemic arterial tone
   - Dominant autoregulation of vital organs (heart, brain)
4. Optimize oxygen unloading
   - Increased RBC 2,3-DPG
   - Tissue acidosis
   - Pyrexia
   - Decreased tissue P_{O_2}

2,3-DPG, *2,3-Diphosphoglycerate;* P_{O_2}, *partial pressure of oxygen.*

beds, including skin, skeletal muscle, kidneys, and splanchnic organs.[145] Dominant autoregulatory control of blood flow spares brain and heart blood work from these effects. Redistribution of flow to these vital organs is the effective result.

The effects of decreased delivery of oxygen to the tissues during shock can be attenuated by local adaptive responses. Hypoperfusion and tissue ischemia result in local acidosis as the result of decreased clearance of CO_2 and anaerobic metabolism. Local acidosis results in decreased affinity between oxygen and hemoglobin at the capillary level.[144] The resultant rightward shift of the oxyhemoglobin dissociation curve allows greater unloading of oxygen from hemoglobin for a given P_{O_2}. Tissue ischemia is also accompanied by decreased tissue P_{O_2} (relative to normal), which further augments unloading of oxygen. Pyrexia associated with sepsis may also contribute to a rightward shift of the oxyhemoglobin dissociation curve, whereas hypothermia is associated with a leftward shift. For that reason, maintenance of normothermia during resuscitation from shock is helpful in optimizing oxygen unloading.

Organ System Dysfunction Owing to Shock (Table 22.3)

Central Nervous System

CNS neurons are extremely sensitive to ischemia. Fortunately, the CNS vascular supply is highly resistant to extrinsic regulatory mechanisms. Although cerebral perfusion is clearly impaired in shock, flow remains relatively well preserved until the later stages.[291,292] Absent primary cerebrovascular impairment, cerebral function is well supported until MAP fall below approximately 50 and 60 mm Hg.[293] Eventually, irreversible ischemic injury may occur to the most sensitive areas of the brain (cerebral cortex). Before this fixed injury, an altered level of consciousness, varying from confusion to unconsciousness, may be seen depending on the degree of perfusion deficit. Disturbances of acid/base/electrolytes may also contribute. Electroencephalographic recordings demonstrate nonspecific changes compatible with encephalopathy. Sepsis-related encephalopathy may occur at higher blood pressures (owing in part to the effects of circulating inflammatory mediators) and is associated with increased mortality.[294]

Heart

The major clinically apparent manifestations of shock on the heart are due to sympathoadrenal stimulation. Increased HR, in the absence of disturbances of cardiac conduction, is almost universally present. Vagally mediated paradoxical bradycardia may be seen on occasion in severe hemorrhage.[41] In patients predisposed to myocardial ischemia or irritability, catecholamine-driven supraventricular tachycardias and ventricular ectopy with ischemic electrocardiographic (ECG) changes are not common. Like the brain, the blood supply to the heart is autoregulated. This, in combination with the resilient nature of myocardial tissue, renders it resistant to sympathetically driven vasoconstriction and shock-related hypoperfusion injury. Overt necrosis does not typically occur, although evidence of cellular injury may be present.

Most forms of shock are associated with increased contractility of healthy myocardium. Despite this, shock can have substantial impact on myocardial contractility and compliance. Hypotension during cardiogenic (and other forms of shock) is associated with decreased coronary artery perfusion pressure. In patients with coronary artery disease (CAD) and/or increased filling pressures, decreased coronary artery perfusion pressure may lead to overt ischemia. Further, circulating myocardial-depressant substances contribute to myocardial depression in septic[233] and hemorrhagic[234] shock. This has been linked to decreased β-adrenoreceptor affinity and density as well as potential defects of intracellular signal transduction involving NO, G proteins, cyclic adenosine monophosphate (cAMP), and cGMP.[111] Circulating depressant substances may also be present during cardiogenic shock.[236]

TABLE 22.3 Organ System Dysfunction in Shock

Central nervous system	Encephalopathy (ischemic or septic) Cortical necrosis
Heart	Tachycardia, bradycardia Supraventricular tachycardia Ventricular ectopy Myocardial ischemia Myocardial depression
Pulmonary system	Acute respiratory failure Acute respiratory distress syndrome
Kidney	Prerenal failure Acute tubular necrosis
Gastrointestinal system	Ileus Erosive gastritis Pancreatitis Acalculous cholecystitis Colonic submucosal hemorrhage Transluminal translocation of bacteria/antigens
Liver	Ischemic hepatitis "Shock" liver Intrahepatic cholestasis
Hematologic system	Disseminated intravascular coagulation Dilutional thrombocytopenia
Metabolic	Hyperglycemia Glycogenolysis Gluconeogenesis Hypoglycemia (late) Hypertriglyceridemia
Immune system	Gut barrier function depression Cellular immune depression Humoral immune depression

Respiratory System

Early alterations of pulmonary function seen during acute circulatory shock are primary related to changes in central drive or muscle fatigue. Increased minute volume occurs as a result of augmented respiratory drive owing to peripheral stimulation of pulmonary J receptors and carotid body chemoreceptors as well as hypoperfusion of the medullary respiratory center. This results in hypocapnia and primary respiratory alkalosis.[144,295] With increased minute volume and decreased CO, the ventilation-perfusion ($\dot{V}/\dot{Q}$) ratio is increased. Unless arterial hypoxemia complicates shock, pulmonary resistance is initially unchanged or minimally increased. Coupled with an increased workload, respiratory and diaphragmatic muscle impairment related to hypoperfusion (manifested by decreased transmembrane electrical potential) may lead to early respiratory failure.[296] ARDS owing to inflammatory or free radical injury to the

alveocapillary cell layers after established shock may develop as a late cause of respiratory failure.

Kidney

ARF is a major complication of circulatory shock with associated mortality rates between 35% and 80%.[297] Although initial injury manifested by decreased urine output occurs, other clinical manifestations of renal dysfunction (increased creatinine, urea, and potassium) may not be noted for 1 to 3 days. Once hemodynamic stabilization has been achieved, it becomes apparent that urine output does not immediately improve and both serum creatinine and urea continue to rise. The single most common cause of ARF is renal hypoperfusion resulting in ATN. The most frequent cause of renal hypoperfusion is hemodynamic compromise from septic shock, hemorrhage, hypovolemia, trauma, and major operative procedures. ATN that occurs in the setting of circulatory shock is associated with a higher mortality than in other situations.

Part of the reason for the kidney's sensitivity to hypoperfusion relates to the nature of its vascular supply. The renal vascular bed is moderately autoregulated. Increases of efferent arteriolar tone can initially maintain glomerular perfusion despite compromise of renal flow.[298] Renal hypoperfusion does not become critical until relatively late in shock when maximal vasoconstriction of renal preglomerular arterioles[298] results in cortical, then medullary, ischemic injury.

Decreased urine output in shock can pose a diagnostic dilemma because it can be associated with both oliguric ATN and hypoperfusion-related prerenal failure without ATN. Indices suggestive of the latter include a benign urine sediment; urine sodium concentration less than 20 mEq/L; fractional urine sodium excretion less than 1%; urine osmolality greater than 450 mOsm/L; and urine/plasma creatinine ratio greater than 40. Useful markers of ARF owing to ATN include hematuria and heme granular casts; urine sodium concentration to more than 40 mEq/mL; fractional excretion of urine sodium to more than 2%; urine osmolarity less than 350 mOsm/L; and urine:plasma creatinine ratio less than 20.[299] Of note, ATN caused by circulatory shock may be associated with urine sodium less than 20 mEq/L and fractional excretion less than 1% if the acute renal injury is superimposed on chronic effective volume depletion as may be seen with cirrhosis and CHF.[300]

Gastrointestinal System

The gut is relatively sensitive to circulatory failure. The splanchnic vasculature is highly responsive to sympathetic vasoconstriction. Typical clinical gut manifestations of hypoperfusion, sympathetic stimulation, and inflammatory injury associated with shock include ileus, erosive gastritis, pancreatitis, acalculous cholecystitis, and colonic submucosal hemorrhage. Enteric ischemia produced by circulatory shock and free radical injury with resuscitation may breach gut barrier integrity with translocation of enteric bacteria and antigens (notably endotoxin) from the gut lumen to the systemic circulation, resulting in propogation and amplification of shock and MODS.[301,302]

Liver

Like the gut, the liver is highly sensitive to hypotension and hypoperfusion injury. "Shock liver," associated with massive ischemic necrosis and major elevations of transaminases, is atypical in the absence of extensive hepatocellular disease on very severe insult.[303] Centrilobular injury with mild increases of transaminases and lactate dehydrogenase is more typical. Transaminases usually peak within 1 to 3 days of the insult and resolve over 3 to 10 days. In either case, early increases in bilirubin and alkaline phosphatase are modest. Despite the production of acute-phase reactants in early circulatory shock, synthetic functions may be impaired with decreased generation of prealbumin, albumin, and hepatic coagulation factors. After hemodynamic resolution of shock, evidence of biliary stasis with increased bilirubin and alkaline phosphatase can develop even though the patient is otherwise improving. Postshock MODS involves similar hepatic pathology.

Hematologic System

Hemotologic manifestations of circulatory shock tend to be dependent on the nature of shock. Disseminated intravascular coagulation (DIC), characterized by microangiopathic hemolysis, consumptive thrombocytopenia, consumptive coagulopathy, and microthrombi with tissue injury, is most commonly seen in association with septic shock. Because it is due to simultaneous systemic activation of coagulation and fibrinolysis cascades, it can be differentiated from the coagulopathy of liver failure by determination of endothelial cell–produced factor 8 (normal or increased with hepatic dysfunction). In the absence of extensive tissue injury/trauma, hemorrhagic shock is rarely associated with DIC.[304] Dilutional thrombocytopenia is the most common cause of coagulation deficits after resuscitation for hemorrhage.[305]

Metabolic Alterations

Metabolic alterations associated with shock occur in a predictable pattern. Early in shock, when hemodynamic instability triggers compensatory responses, sympathoadrenal activity is enhanced. Increased release of adrenocorticotropic hormone, glucocorticoids, and glucagon and decreased release of insulin results in glycogenolysis, gluconeogenesis, and hyperglycemia.[287,306] Increased release of epinephrine results in skeletal muscle insulin resistance, sparing glucose for use by glucose dependent organs (heart and brain). Late in shock, hypoglycemia may develop, possibly owing to glycogen depletion or failure of hepatic glucose synthesis. Fatty acids are increased early in shock but fall later as hypoperfusion of adipose-containing peripheral tissue progresses. Hypertriglyceridemia is often seen during shock as a consequence of catecholamine stimulation and reduced lipoprotein lipase expression induced by circulating TNFα.[306] Increased catecholamines, glucocorticoids, and glucagon also increase protein catabolism resulting in a negative nitrogen balance.[306]

Immune System

Immune dysfunction, frequent during and after circulatory shock and trauma, rarely has immediate adverse effects but likely contributes to late mortality. Underlying mechanisms of immune dysfunction that induce dysfunction of the cellular and humoral immune system include ischemic injury to barrier mucosa (particularly of the gut), leading to anatomical breaches (colonic ulceration) and potential mucosal translocation of bacteria and bacterial products; parenchymal tissue injury owing to associated trauma, inflammation, ischemia or free radical injury; and direct ischemic or mediator (immunosuppressant cytokines, corticosteroids, prostaglandins, catecholamines, endorphins).[307,308] In particular, macrophage function is adversely affected during trauma and circulatory shock. A decrease in antigen presenting ability impairs the activation of T and B lymphocytes. Associated with this defect are a decrease in Ia antigen expression, decrease in membrane IL-1β receptors, and the presence of suppressor T lymphocytes. Phagocytic activity of the reticuloendothelial system is also compromised, partially because of an acute decrease in fibronectin levels.

Suppression of T-lymphocyte immune function is manifested by decreased responsiveness to antigenic stimulation and a decreased helper:suppressor ratio. Decreased production of IgG and IgM suggests B-cell suppression. Nonspecific immune suppression is expressed as decreased neutrophil bactericidal function, chemotaxis, opsonization, and phagocytosis.

Resuscitation agents used in shock may also substantially depress immune function. For example, red blood cell transfusion used in traumatic hemorrhagic shock and in support of oxygen transport in septic shock[309] has been shown to suppress immune function, leading to increased infections (and improved allograft survival).[310,311] Similarly, dopamine, used for hemodynamic support in shock, has been shown to suppress pituitary production of prolactin (required for optimal immune function), resulting in suppression of T-cell proliferative responses.[312] Thus dopamine may contribute, along with stress-induced increases in immunosuppressive glucocorticoids, to T-cell anergy seen in critically ill patients.

These factors may contribute to the propensity of critically ill patients to develop ongoing organ system dysfunction as well as a variety of infections during the postshock phase. It is notable that one-third to one-half of patients with shock die late in their course after resolution of the acute-shock phase.

Diagnostic Approach and Evaluation

Shock is always a life-threatening emergency. Diagnosis, evaluation, and management must often occur virtually simultaneously. The diagnosis must be made as early as possible while shock is well compensated. Once marked hypotension and hypoperfusion are present, mortality is increased. Because early recognition and treatment are key to survival, the diagnosis is primarily a clinical one. Laboratory and imaging studies are useful for confirmation of the diagnosis and determination of the specific shock etiology. Elevated lactate might help identify patients for whom the diagnosis of shock is not obvious clinically. However, therapy of shock should never be delayed to accommodate these studies. The initial diagnosis of shock can and should be made strictly on clinical signs and symptoms. Because shock is the common endpoint of a variety of insults, evaluation and management for all forms of shock involves a common approach (Box 22.4).

Clinical Evaluation

Impending shock is characterized by the typical compensatory response to cardiovascular stress. Tachycardia, tachypnea, and oliguria (<0.5 mL/kg per hour) are usually present. Cool extremities are seen in hypovolemic, cardiogenic, and obstructive shock. The blood pressure may be elevated or normal with maximal sympathetic stimulation. With progression, however, blood pressure falls while pulse pressure narrows (except in the case of distributive shock). Frank hypotension (MAP <60–65 mm Hg in adults) may ensue. The chronic level of blood pressure must be considered. Normotension in a normally hypertensive patient may denote a critical degree of hypoperfusion. With further progression anuria may develop, extremities may become mottled and dusky (except in distributive shock), and the sensorium may become clouded. It is important to note that clinical parameters can underestimate initial resuscitative requirements in critically ill subjects including those with septic shock.[313–316]

Other clinical manifestations of shock are useful in attempting to attempt to differentiate the etiology. Hypovolemic shock is characterized by decreased jugular venous pressure. Cardiogenic shock may evidence elevated jugular venous pressure with hepatojugular reflux, an S_3, an S_4, and regurgitant heart murmurs. Obstructive shock signs are usually dependent on the nature of the obstruction. Pulmonary embolus may be characterized by dyspnea and right-sided evidence of heart failure. Cardiac tamponade may demonstrate the Kussmaul sign, a pulsus paradoxus, and distant heart sounds. Septic shock in the absence of neutropenia usually exhibits a focus of infection along with fever, chills, and warm extremities. Patients with septic shock and neutropenia often have no clinically apparent focus. Elderly patients may present with little more than unexplained hyperventilation and hypotension.

• BOX 22.4 General Approach to Shock: Initial Diagnosis and Evaluation

- Clinical (primary diagnosis)
  - Tachycardia, hypotension (systolic blood pressure <90 mm Hg) tachypnea, oliguria, encephalopathy (confusion), peripheral hypoperfusion (mottled extremities), cyanosis
- Laboratory (confirmatory)
  - Hemoglobin, WBC, platelets
- Prothrombin time/partial thromboplastin time
  - Electrolytes, arterial blood gases, Ca, Mg, BUN, creatinine, serum lactate
  - ECG
- Monitoring (continuous ECG and respiratory monitors)
  - Pulse oximetry
  - Urinary catheter (urine output)
  - Point-of-care ultrasonography (heart, lung, abdominal, and major vessels)
  - Arterial pressure catheter
  - Central venous pressure monitor (uncomplicated shock)
  - Pulmonary artery flotation catheter
    - Cardiac output
    - Pulmonary artery occlusion pressure
    - Central and/or mixed venous oxygen saturation (intermittent or continuous)
  - Oximetry[a]
- Imaging (chest x-ray)
  - X-ray views of abdomen[a]
  - Computed tomographic scan: abdomen or chest[a]
  - Formal transthoracic and/or transesophageal echocardiogram[a]

Laboratory Studies

Laboratory data are used to confirm the diagnosis of shock and to help clarify the etiology. Leukocyte count is frequently elevated early in shock owing to demargination of neutrophils. Leukopenia may be found in sepsis and late shock. Hemoglobin concentration is variably affected depending on the etiology of shock. For example, nonhemorrhagic hypovolemic shock and septic shock with extravasation of intravascular water to the interstitium may result in an apparent erythrocytosis. Platelet count increases acutely with the stress of circulatory shock, but with progression of sepsis or resuscitation of massive hemorrhage, thrombocytopenia may occur. Arterial blood gases and electrolytes may demonstrate a nonanion gap acidosis if hypovolemic shock is associated with excessive diarrhea and metabolic alkalosis if associated with vomiting. An anion gap acidosis, often caused by elevated levels of lactic acid, usually reflects prolonged inadequate tissue perfusion. Serum

creatinine and blood urea nitrogen are rarely changed after the acute onset of shock even if renal injury is present. With slower onset of shock—for example, in sepsis—increased creatinine is common and early resolution is an excellent marker of effective resuscitation and survival. Markers of renal function can also be helpful diagnostically. An isolated increased blood urea nitrogen with anemia and normal creatinine may suggest gastrointestinal bleeding. An arterial blood gas analysis will help to determine adequacy of oxygenation and give evidence of acid-base disturbances. An ECG is critical for diagnosis of ischemic cardiac injury either as a primary cause of cardiogenic shock or secondary to hypotension associated with shock of another etiology.

Lactate levels (particularly serial determinations) are useful in assessment of prognosis. Substantial data suggest that lactate levels, as a marker of tissue oxygen debt, can predict outcome in shock.[46,47,317–321] The utility of lactate assessment is limited by the fact that it is a relatively late marker of tissue hypoperfusion.[322,323] Significant tissue ischemia and injury are present by the time it is elevated. In addition, lactate is cleared primarily by the liver. Liver failure may markedly increase elevated lactate levels during hypoperfusion. Conversely, normal hepatic clearance may obscure limited lactate production by ischemic tissues. Glycolysis and alkalosis will also nonspecifically increase lactate levels.[324,325] However, because in the appropriate setting, arterial lactate levels beyond 2 mEq/L are associated with increased mortality,[47,51,319,320,326] such levels should be considered to represent tissue ischemia in the absence of another clearly defined etiology. The adequacy of resuscitation of shock can also be assessed using serial changes of systemic lactate.[321,326,327] A protocol of resuscitation using a goal of lactate clearance greater than or equal to 10% versus a target of central venous oxygen saturation ($cSvO_2$) greater than or equal to 70% was found to be noninferior.[328] Therefore reduction in lactate concentration after initial management is a reassuring indicator of adequacy of resuscitation and serial lactate measurement can replace more invasive monitoring for certain cases.

$cSvO_2$ can also be used to assess prognosis and efficacy of resuscitation in shock states including septic shock.[309,316,329,330] However, central venous saturation, which has been suggested to represent a reliable marker of resuscitation efficacy in sepsis,[309] does not appear to correlate well with lactate clearance in some sepsis studies, perhaps reflecting elements other than oxygen debt in those conditions.[327] Poor correlation with mixed venous oxygen saturation has also been noted in septic shock.[331] Achievement of central venous saturation of 70% or higher was less predictive of good outcome in septic shock compared with lactate clearance of 10% or higher.

Imaging

A chest radiograph is useful in ruling out pneumonia as a source of septic shock, pulmonary edema as a manifestation of cardiogenic shock, tension pneumothorax, pericardial tamponade, and so on. Although abdominal views may be helpful on occasion, intra-abdominal processes resulting in shock are usually clinically apparent. Computed axial tomograms may be helpful in directing management in specific instances (occult internal hemorrhage, aortic dissection, pulmonary embolus). Similarly, transthoracic and transesophageal echocardiography can diagnose specific repairable cardiac or aortic lesions associated with shock with great accuracy and can be highly suggestive of other important diagnoses, including hemodynamically significant pulmonary embolus. Other imaging modalities have less of a role in the evaluation of acute shock.

Invasive Hemodynamic Monitoring

All patients suspected of having circulatory shock should have an indwelling arterial pressure catheter placed. Although there are no randomized controlled trials showing benefit of arterial pressure catheters, we believe there are reasonable grounds to use them in shock.[332] Blood pressure assessment by manual sphygmomanometry or automated noninvasive oscillometric techniques may be inaccurate during shock owing to marked peripheral vasoconstriction.[333] In addition, neither technique supplies continuous monitoring of the rapidly changing hemodynamic status of unstable patients. Further, an arterial catheter allows ready access for arterial blood gas samples and other laboratory tests. In most cases, a peripheral site, such as the radial artery, is used. However, given the potential for disparity of pressures between central and peripheral sites,[334] if marked peripheral vasoconstriction caused by either sympathetic stimulation or exogenous catecholamines obscures the peripheral pulses, a central site such as the femoral artery may be preferred.

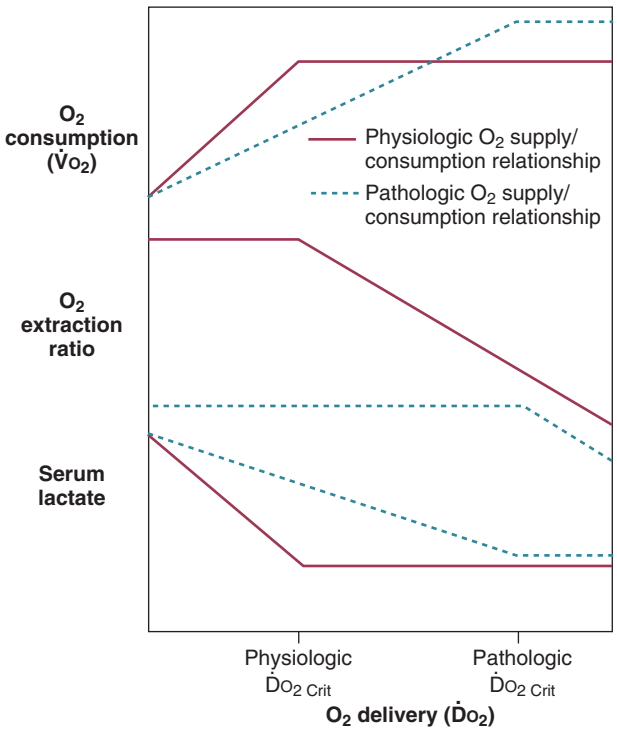
CVP monitoring is frequently used during the perioperative period for assessment of intravascular volume status in patients without critical illness. Because of the relatively stable hemodynamic status of these patients and the questionable benefit of pulmonary artery catheterization in such patients, such an approach is adequate. Similarly, CVP monitoring for otherwise healthy patients being resuscitated for hypovolemic shock may provide useful data. In the appropriate clinical context, CVP monitoring may also occasionally be useful in differentiating between different forms of shock (e.g., low CVP in hypovolemic shock, high CVP in cardiac tamponade). As a rule, though, CVP monitoring is inadequate for the hemodynamic assessment of critically ill patients, particularly those with shock. A number of studies have conclusively shown that CVP does not accurately estimate left ventricular preload in critically ill patients.[335,336] In fact, data suggest that static measures of CVP do not correlate with right or left ventricular volumes in normal volunteers.[337]

The use of the flow-directed balloon-tipped pulmonary artery catheters (PACs) with thermodilution CO determination capability has been the standard of practice for the hemodynamic assessment of circulatory shock. Their use is supported by a number of studies that demonstrate that experienced physicians cannot accurately determine cardiac filling pressures or CO based on clinical evaluation alone.[338,339] In addition to CO determination, PACs provide continuous monitoring of central venous and pulmonary artery waveforms and pressures. Pulmonary artery occlusion pressure (as an estimate of left ventricular end-diastolic pressure and volume) and waveform can be obtained intermittently. Although substantially supplanted by the increased availability of bedside echocardiography in developed nations, waveform analysis may be useful in cardiovascular diagnoses of cardiac tamponade, restrictive cardiomyopathy, CHF, ventricular hypertrophy, and mitral or tricuspid regurgitation if echocardiography access is limited. In addition, PACs can demonstrate evidence of right heart and pulmonary artery oxygen saturation step-ups for the diagnosis of left-to-right shunts associated with cardiac anatomic abnormalities such as ventricular septal defect. These devices also allow withdrawal of blood from the pulmonary artery enabling determination of MvO_2 to verify sufficient oxygen delivery during hypodynamic shock. In shock, the flow-directed balloon-tipped PAC is useful for etiologic classification, determination of optimal management, and to follow the response to therapy. Typical hemodynamic profiles of different forms of shock have been described in Table 22.1.

The utility of pulmonary artery catheterization has been questioned over the past decade. A case-matched study suggested increased resource utilization and mortality associated with the use of PACs in the ICU.[340] A series of randomized studies performed since then have reported on the role of the PAC in the setting of major non-cardiac surgery,[341] CHF,[342] sepsis and ARDS,[343] acute lung injury,[344] and in the general ICU setting.[345,346] In the perioperative management of patients undergoing major noncardiac surgery, the use of a PAC did not impact mortality and was associated with a greater incidence of pulmonary embolism.[341] In critically ill patients diagnosed with CHF, management directed with the use of a PAC did not influence mortality but resulted in more in-hospital adverse events.[342] Another study comparing the use of PAC versus central venous monitoring in acute lung injury found no difference in organ failure or mortality.[344] A large trial evaluating the role of the PAC in the management of patients with ARDS secondary to sepsis also found no significant differences in mortality if a PAC was used or not.[343] Two randomized studies of general ICU patients similarly concluded that the use of PACs among critically ill patients neither increased nor decreased mortality.[345,346] Most, although not all, meta-analyses have shown no consistent benefit with PACs.[347–350] These studies failing to show a lack of clinical benefit have been paralleled by other studies questioning some of the basic premises of PAC utility. Several studies have shown a lack of correlation between PAOP/CVP and ventricular volumes in the critically ill.[351,352] One study has even demonstrated that PAOP and CVP fail to predict ventricular filling volume, cardiac performance, or the response to volume infusion in normal volunteer subjects.[337] Despite these data, no studies have examined the use of PACs in cases of shock specifically. Nonetheless, the use of PACs in the United States has decreased dramatically over the past 20 years.[353]

Given the lack of evidence of benefit of PACs and alternative diagnostic and monitoring tools such as bedside ultrasonography, we believe that PACs should not be routinely inserted in shock. However, there is still room for PACs in cases of mixed shock, right ventricular failure, or in instances when the diagnostic evaluation including bedside ultrasonography cannot reveal the cause of the shock.

Another parameter provided by a PAC is mixed venous oxygen saturation. Compared with $cSvO_2$, which reflects mixed oxygen saturation from the superior vena cava, MvO_2 reflects a global picture of oxygen extraction. This measure may provide an assessment of adequacy of resuscitation of low output states before the presence of anaerobic metabolism (as signified by increased lactate). MvO_2 rises with increases of perfusion above requirements and falls, with increasing oxygen extraction ratio, as perfusion becomes inadequate (see Fig. 22.3). Normal MvO_2 falls within the 65% to 75% range. During MI saturations of less than 60% are found with CHF and less than 40% with cardiogenic shock.[330] Lactate accumulation and supply-dependent oxygen consumption begin to appear as saturation levels fall below 30% to 40%.[354,355] MvO_2 is especially useful in determining whether low COs indicate supply-dependent oxygen consumption (MvO_2 low) or normally depressed metabolic demands (normal MvO_2). Owing to the maldistribution of perfusion in distributive shock (or substrate utilization defect in septic shock) and left-to-right shunting in cardiogenic shock associated with ventricular septal defects, MvO_2 is not useful in assessment in those conditions. Recently $cSvO_2$ has been proposed as an alternate method to examine adequacy of resuscitation, although correlation with MvO_2 is imperfect in septic shock.[309,316,331]



• **Fig. 22.3** Oxygen supply–dependent oxygen *(O_2)* consumption in shock. Physiologic supply-dependent oxygen consumption is characterized by a biphasic relationship between oxygen delivery *($\dot{D}O_2$)* and oxygen consumption *($\dot{V}O_2$)*. The inflection point defines the physiologic critical oxygen *delivery ($\dot{D}O_{2crit}$)*. Below this $\dot{D}O_{2crit}$, $\dot{V}O_2$ is linearly dependent on $\dot{D}O_2$, the oxygen extraction ratio is maximal, and lactate (indicating anaerobic metabolism) is produced. Above the physiologic $\dot{D}O_{2crit}$, $\dot{V}O_2$ is independent of $\dot{D}O_2$, the oxygen extraction ratio varies to maintain a constant $\dot{V}O_2$, and lactate is not produced.

Oxygen delivery and oxygen consumption variables can also be determined using PAC-derived data. Although such global perfusion data appear to have prognostic significance for large groups of the critically ill, their utility is limited when applied to individual patients.

Recent modifications to the standard pulmonary artery flotation catheter allow continuous monitoring of MvO_2 or determination of right ventricular ejection fractions and volumes. Although both innovations have been used for clinical research purposes and each theoretically offers unique insights into shock, they have no defined role at this time in clinical shock management.

Ancillary Monitoring Techniques

Oximetry

Because oxygen delivery is dependent on arterial oxygen saturation, pulse oximetry should, in theory, provide useful data during circulatory shock. However, limitations of the technique include the fact that ambient light sources, dyhemoglobinemias (methemoglobin, carboxyhemoglobin), lipemia, and hypothermia can affect results.[356] Motion artifact may generate a false signal.[357] Shock-associated vasoconstriction also impairs signal acquisition. One study has shown that a CI less than 2.4 L/min per m^2 is associated with signal loss.[358] Although these problems limit the utility of pulse oximetry in the acute management of circulatory shock, the technique may be more helpful during postresuscitation monitoring.

At this time, sequential arterial blood gases provide more reliable data during acute shock.

Ultrasound/Echocardiography

The application of point-of-care (POC) ultrasound in the ICU environment as diagnostic and intermittent monitoring tools may represent one of the most exciting developments in critical care management. A number of factors have hastened this development. These include questions regarding the safety and efficacy of routine PAC utilization; the availability of relatively inexpensive, portable echocardiography systems; the application of advanced software algorithms to analysis of data; and the development of new, high-resolution echocardiographic techniques, including transesophageal and contrast echocardiography. The confluence of these factors has resulted in a substantial increase in use of echocardiography in the ICU for assessment of hemodynamic instability and shock. In addition to its long-recognized ability to detect anatomic lesions (pericardial tamponade, pericardial effusion, septal defects, valvular disease, aortic dissection), new techniques allow assessment of CO, SV, preload (ventricular volumes), intravascular volume status (inspiratory inferior caval collapse), pulmonary artery pressures, systolic contractility (ejection fraction), diastolic function, and regional motion abnormalities at baseline and under stressed conditions.[359] Utility for diagnosis of hemodynamically significant pulmonary embolism has also been established.[360] The widespread dissemination of echocardiographic skills among the next generation of intensivists has allowed for a substantial reduction in use of invasive monitoring techniques including pulmonary artery catheterization. Multiple different algorithms have been developed for the use of POC ultrasound in shock, including Rapid Ultrasound for Shock and Hypotension (RUSH) and Abdominal and Cardiac Evaluation with Sonography in Shock (ACES).[361,362]

As part of these algorithms, heart, lungs, abdomen, and large vessels are usually examined. Views of the heart are examined to look for signs of pericardial effusion and tamponade. The overall size and contractility of the right and left ventricles are appreciated. Left ventricle hypokinesis is suggestive of cardiogenic shock, and the presence of regional wall motion abnormalities should raise the suspicion of a coronary artery lesion. Right ventricular dilatation and hypokinesis may suggest pulmonary embolism or right ventricular infarction. The size of the inferior vena cava as well as respiratory variation can give an estimation of CVP as well as fluid responsiveness. Lung ultrasound can be used to identify pneumothorax with the absence of lung sliding and lung pulse and presence of a lung point. It is also useful to identify B-lines that represent interstitial fluid, which could represent pulmonary edema or pneumonia. Evaluation of the pleural space is more accurate with ultrasound than with standard chest radiography. Abdominal ultrasound is useful to identify free fluid in the peritoneum that might be the source of hypovolemic shock, for example, in trauma. Evaluation of the abdominal aorta is very accurate to identify abdominal aortic aneurysm. Finally, compression ultrasonography of the femoral veins can quickly identify proximal deep venous thrombus.

A POC ultrasonography examination of heart, lung, abdomen and great vessels should take only a few minutes and can often quickly diagnose the cause of shock. It can be repeated after therapeutic interventions (fluid bolus, inotropes). It should be remembered that ultrasonography is very operator dependent. Thus clinicians should ensure they are competent in POC ultrasound before basing their clinical decision on their ultrasound findings.[363] If there is a suspicion of a diagnosis not easily seen on POC ultrasound, such as valvular abnormalities or intracardiac shunt, formal transthoracic or transesophageal echocardiography should be obtained.

Management and Therapy

Patients in whom circulatory shock is suspected should be managed in an ICU with continuous ECG monitoring and close nursing support. Those whose etiologic diagnosis is in doubt, whose hemodynamic instability does not quickly resolve with IV fluids, or whose conditions are medically complicated should undergo invasive hemodynamic monitoring with arterial and central venous catheters or PACs. POC ultrasonography should generally be performed. Laboratory tests as mentioned earlier should be performed at or before admission.

Management of shock can be divided into specific therapy for the triggering injury and general therapy of the shock syndrome. Examples of specific therapy include antibiotics for infections causing septic shock, blood transfusion for hemorrhagic shock, thrombolysis for acute MI or massive pulmonary embolus, and pericardial aspiration for pericardial tamponade. Specific therapy for different etiologies of shock is discussed in Chapters 23 and 26.

Aims

Because the shock syndrome shares many characteristics across different etiologies, the general management of shock is similar in all cases. The basic goal of circulatory shock therapy is the rapid restoration of effective perfusion to vital organs and tissues before the onset of cellular injury. Effective tissue perfusion is dependent on both sufficient CO and adequate driving pressure. Consequently, ideal therapy of shock requires early reestablishment of both an appropriate CI and mean blood pressure (Box 22.5). However, because for brief periods marked hypoperfusion is better tolerated than severe hypotension, the first specific resuscitative aim—support of blood pressure (>60–65 mm Hg in a baseline normotensive

• BOX 22.5 General Approach to Shock: Immediate Goals

General
- Find cause of shock and apply specific treatment (examples: antibiotics for sepsis or pericardiocentesis for tamponade)

Hemodynamic
- MAP >65 mm Hg (higher in the presence of coronary artery disease or chronic hypertension)
- CVP = 8–12 mm Hg/PAOP = 12–15 mm Hg (may be higher for cardiogenic shock)[a]
- CI >2.1 L/min per m^2[a]

Optimization of oxygen delivery
- Hemoglobin >7–9 g/dL; >7 g/L after shock is sufficient
- Arterial saturation > 92%
- Mvo_2 > 60%, sCV02 > 70%*
- Normalization of serum lactate (to <2.2 mM/L)

Reverse organ system dysfunction
- Reverse encephalopathy
- Maintain urine output >0.5 mL/kg per hour

[a]*Optional.*

CI, *Cardiac index;* CVP, *central venous pressure;* MAP, *mean arterial pressure;* Mvo_2, *mixed venous oxygen saturation;* PAOP, *pulmonary artery occlusion pressure.*

patient)—may initially take priority over the second specific aim—maintenance of CI. The blood pressure goal target has traditionally been MAP greater than 65 mm Hg. A recent randomized controlled trial in septic shock failed to show benefit for a MAP goal of 80 to 85 mm Hg versus 65 to 70 mm Hg with more atrial fibrillation in the higher MAP goal. For patients with chronic hypertension, a higher MAP goal was associated with less renal replacement therapy but similar mortality.[364] Based on these data, a MAP greater than 65 mm Hg for most patients is reasonable. Finally, maintaining perfusion sufficiently high that arterial lactate concentration remains below 2.2 mmol/L is a generally accepted approach to avoiding anaerobic metabolism and ischemic tissue injury (Box 22.5).

The practice of targeting oxygen delivery to specified supranormal oxygen delivery goals or to evidence of supply-independent oxygen consumption in the ICU has been substantially discredited by clinical studies.[365–368] In an earlier study, early targeting (<6 hours after presentation) to a $cSvO_2$ of greater than 70% using a defined protocol with fluids, blood transfusion, and dobutamine support has been shown to improve outcome in severe sepsis and septic shock.[309] However, three more recent randomized controlled trials have shown that this protocol is not superior to standard treatment.[369–371]

The reasons for the discrepancy between the initial study by Rivers and the latest three randomized controlled trials are not totally clear.[309] However, it appears that the standard of care for septic shock has shifted in recent years to earlier recognition and aggressive early management, which might have decreased the relative benefit of the early goal-directed therapy protocol.

One of the major achievements in shock therapy in the past decade has been the recognition that speed of implementation of supportive and specific therapies may be critical to improvement in outcomes. This concept of a "golden hour" has long been recognized in the context of specific and resuscitative therapy of trauma-induced hypovolemic shock with blood products and surgical management[372,373] and then cardiogenic shock owing to MI with emergent primary angioplasty or thrombolysis.[374] In recent years, a similar rapid treatment paradigm has been established for thrombolytic therapy for obstructive shock caused by a massive pulmonary embolus.[81,82,375] Similarly, rapid fluid resuscitation (<6 hours)[309] and antimicrobial therapy (<1 hours)[376–378] have been shown to be key to maximizing survival in severe sepsis and septic shock. Accelerated provision of effective therapy probably accounts for reports of improved clinical outcomes with medical emergency response teams.[379–381] The variation in baseline provision of effective therapy likely accounts for the inconsistent results seen with such teams.[382] The importance of early aggressive resuscitative and specific therapy of all shock states cannot be sufficiently emphasized.

Resuscitation

The universal basics of resuscitation underlie the initial management of circulatory shock. Because many patients with circulatory shock may have accompanying trauma and/or decreased level of consciousness, the ventilatory status of the patient must be secured. This may involve tracheal intubation and/or mechanical ventilation, if necessary. Oxygen should be provided at a sufficiently high concentration to provide an arterial oxygen saturation of greater than 90% to 92%. Unintubated patients may require high-flow (30–45 L/min) or rebreathing oxygen delivery systems because many patients have unusually high minute ventilation volumes. Intubated patients should initially receive full ventilatory support to decrease systemic oxygen demand. Given that pulmonary infiltrates (aspiration, pneumonia, or ARDS) are common, positive end-expiratory pressure may be necessary to ensure adequate oxygenation. Potential adverse hemodynamic effects from positive-pressure ventilation (related primarily to decreased venous return) may be seen but can be minimized by fluid loading so that the patient is euvolemic or modestly hypervolemic.

Depending on the clinical situation, pain management may be necessary. Again, potential adverse hemodynamic effects may be seen if intravascular volume is inadequate because all measures result in some degree of venodilation either directly or by decreasing sympathetic tone. Two- to 4-mg boluses of IV morphine are recommended. During circulatory shock clearance of morphine by the liver may be impaired owing to hepatic hypoperfusion. In addition to relieving pain, analgesia should also decrease systemic oxygen consumption.

Management of lactic acidosis that develops during circulatory shock is problematic. Bicarbonate therapy may have adverse effects on intracellular pH even while improving the pH of the extracellular fluid. Further, even when pH is extremely low, bicarbonate therapy does not improve systemic hemodynamics in shock associated with acidosis.[383] In addition, increasing serum pH may adversely affect the oxyhemoglobin dissociation relationship. The optimal approach to the management of lactic acidosis is to improve organ and systemic perfusion so that anaerobic metabolism is limited and the liver and, to a lesser extent, kidneys can clear the accumulated lactate. If this is not effective, restricting the use of sodium bicarbonate to situations in which pH is less than 7.1 to 7.15 may be appropriate.

Initial management of circulatory shock should almost always include a crystalloid fluid challenge. In the absence of invasive monitoring with a PAC, the only practical exception is if clinical evidence strongly suggests ventricular filling pressures are already elevated. This is usually limited to clinical situations involving cardiogenic shock and marked pulmonary edema. Even then, if pulmonary edema is manageable, crystalloid challenge may be appropriate. The volume of the challenge is variable. Large volumes, on the order of 1 to 2 L given rapidly (0.5–1.0 L every 10–15 minutes) are frequently used in hemorrhagic and septic shock. Boluses of 100 to 200 mL may be used during cardiogenic shock. If shock does not resolve promptly after the initial fluid challenge, patients should undergo more detailed invasive (central venous catheter) and/or noninvasive (echocardiographic) assessment. As previously discussed, a central role for pulmonary artery catheterization in shock is now highly questionable.

Although aggressive fluid resuscitation is well accepted in the therapy of shock, emerging data support more limited resuscitation in some contexts. Resuscitation to the lower limit of normal targets (target systolic blood pressure 90–100 mm Hg) has been recommended in hemorrhagic shock resulting from penetrating trauma based on data showing improved survival using this approach.[378,384] In addition, a limited fluid resuscitation protocol for 7 days has been shown to improve the number of ventilator- and ICU-free days in acute lung injury without increasing the prevalence of shock or the mortality rate.[385] A more limited early fluid resuscitation has also been shown to be associated with improved survival in children with shock associated with infection in underresourced settings.[386]

Although fluid is generally given as the first treatment, reassessment of fluid is needed throughout the resuscitation. Multiple static and dynamic predictors of fluid responsiveness have been used. CVP of 8 to 12 mm Hg has traditionally been a target in

shock management, but CVP is not a great predictor of fluid responsiveness and many factors influence the CVP value. Response to rapid infusion of fluid or passive leg raise seems to predict fluid responsiveness better than CVP, but the sensitivity of the test is better if CO is monitored rather than simply blood pressure or pulse pressure. In passive mechanically ventilated patients, pulse pressure variation and systolic pressure variation can be used. POC measurement of inferior vena cava (IVC) can be helpful with IVC variation of 50% or greater in unintubated patients and 12% to 18% and more in intubated patients associated with fluid responsiveness.[387,388]

In addition, substantial controversy exists regarding the appropriate use of crystalloid and colloid fluids after initial resuscitation attempts. The basis of this controversy lies with the differing oncotic properties of the fluids. Crystalloid fluids (such as normal saline solution and lactated Ringer solution) contain sodium chloride in a quantity that closely matches extracellular fluid. No large molecules are present. Thus such fluids distribute into the extracellular space. Colloids, in addition, contain albumin or large osmotically active carbohydrates (hydroxyethylstarch, dextran) that may be held within the intravascular space, resulting in an increase of the plasma oncotic pressure. It has been suggested that in shock associated with microvascular changes of permeability (such as sepsis), colloid fluids remain in the intravascular space, leading to decreased tissue edema and noncardiogenic pulmonary edema.[389] However, the limited human studies available suggest that although radiographic infiltrates may appear more severe with crystalloid resuscitation of sepsis, gas exchange is comparable to colloid resuscitation.[42]

More importantly, it has been proposed that colloids may provide better outcomes in the resuscitation of shock because of the rapidity and persistence of volume expansion compared with crystalloid infusion.[42,390] However, clinical studies for the most part have not supported this contention. For the most part, meta-analyses have failed to demonstrate clinical outcome superiority of crystalloids compared to either albumin or synthetic colloids.[391] In fact, one meta-analysis of randomized controlled studies examining the effect of fluid administration in critically ill patients with burn injury, hypovolemia, or hypoalbuminemia suggested increased mortality in patients treated with colloids.[392] In one large randomized study of albumin versus normal saline solution, there was no benefit to albumin. A trend toward improved outcomes with albumin in severe sepsis and saline solution in trauma failed to reach significance in that study.[393] A more recent study of albumin versus crystalloid in severe sepsis also failed to show any benefits to albumin. More recently, a substantial body of literature has shown that synthetic colloids increase the risk of renal injury and death, particularly in sepsis and septic shock.[394–396] An increased risk of renal injury/dialysis requirement and risk of death was shown for hydroxyethylstarch versus Ringer solution therapy in two large randomized trials of sepsis.[394,395] Some data, however, suggest colloid resuscitation may clear lactate more quickly and result in less renal injury than crystalloid in penetrating trauma.[397] Given the much higher costs of colloids and higher risk of renal injury and death with synthetic colloids, resuscitation of shock should generally focus on crystalloid solutions. Albumin can be considered in septic shock for volume replacement in patients who need substantial amount of crystalloid.[398]

During hemorrhagic shock, fluid resuscitation should consist mostly of blood products. Crystalloids are only acceptable if blood products are unavailable. Controversy exists on the exact ratio of packed red blood cells, fresh frozen plasma, and platelets. Observational studies suggested that a ratio of 1:1:1 was superior.[399] A recent randomized controlled trial of a 1:1:1 versus 1:1:2 transfusion ratio of platelets:plasma:packed red blood cells showed no significant differences in mortality at 30 days. However, more patients achieved hemostasis and fewer died of exsanguination in the 1:1:1 group.[400]

With respect to hemoglobin, one randomized trial has suggested that a hemoglobin level of 70 g/L is sufficient for most patients in the ICU (other than those with high severity of illness or acute coronary syndrome[401,402]). Although several other studies have noted the potential risks associated with blood transfusion in the ICU setting,[311,403–405] no study has directly examined hemoglobin requirements during shock. The only study to (indirectly) examine blood transfusion in shock suggested that early augmentation of hematocrit to more than 30% during septic shock as part of a protocol to drive $cSvO_2$ to more than 70% was associated with improved survival.[309] For that reason, it is reasonable to recommend that a hemoglobin level of 90 to 100 g/L be maintained during acute shock.

Once intravascular volume is optimized, the next line of therapy of circulatory shock usually involves inotropes and vasopressors. Alternately, vasopressors may be occasionally required for brief periods of blood pressure support in extremely hypotensive patients before initiation of fluid infusion.

Three major classes of agents are used clinically for inotropic or vasopressor support in critically ill patients: sympathomimetics, phosphodiesterase inhibitors, and vasopressin (antidiuretic hormone) (Table 22.4). Sympathomimetics (catecholamines) may activate cardiac β_1- and α-adrenoreceptors, peripheral vascular α- or β_2-receptors, and vascular dopaminergic receptors. Cardiac β_1-adrenoreceptors augment HR and myocardial contractility by increasing activity of adenylate cyclase, resulting in increased generation of c AMP.[406] α-Receptors act through phospholipase C production of inositol triphosphate and diacylglycerol.[407–409] Peripheral vascular α-receptors cause vasoconstriction, whereas peripheral β_2-adrenoreceptors induce a mild vasodilatation. Cardiac α-adrenoreceptors contribute to increased contractility (but not HR) when stimulated.[407,409] Dopaminergic adrenoreceptors, mediating dilatation, are found in the arterial vessels supplying vital organs (including the heart, brain, kidneys, and splanchnic organs).[410] Phosphodiesterase inhibitors such as amrinone and milrinone augment cardiac contractility by inhibition of cAMP degradation. They also relax vascular smooth muscle.[411] Despite a long history of digitalis use in the management of CHF and older data suggesting potential hemodynamic benefit in sepsis,[412] cardiac glycosides are rarely used for the acute management of circulatory shock because of their narrow therapeutic index and long half-life. Recent uncontrolled studies have shown that endogenous vasopressin concentrations may be relatively deficient in shock states and that infusion of vasopressin (which has little effect in healthy, normotensive subjects), can have a profound pressor effect during vasodilatory shock.[413–416]

Norepinephrine, an endogenous catecholamine, exerts both powerful inotropic (cardiac alpha and β_1-adrenoreceptors) and peripheral vasoconstriction effects (α-adrenoreceptors). It is currently the favored catecholamine for initial management of shock. It can be used for persistent hypotension despite high-dose dopamine during septic and obstructive shock. It should generally be used only transiently in cardiogenic shock because it may drastically reduce forward flow. Similarly, it should not be required during hemorrhagic shock except for extremely brief periods of blood pressure support pending volume infusion. Infusion rates of 2 to 20 μg/min are commonly used, but if necessary higher rates may be tried. Suggestions that there is clinical utility in the concomitant use of "low"-dose dopamine with norepinephrine to generate

TABLE 22.4 Relative Potency of Intravenously Administered Vasopressors/Inotropes Used in Shock[a]

		CARDIAC		PERIPHERAL VASCULATURE			
Drug	Dose	Heart Rate	Contractility	Vasoconstriction	Vasodilation	Dopaminergic	Typical Clinical Use
Dopamine	1–4 μg/kg/min 5–10 μg/kg/min 11–20 μg/kg/min	1+ 2+ 2+	1–2+ 2+ 2+	0 1–2+ 2–3+	1+ 1+ 1+	4+ 4+ 4+	All shock
Norepinephrine	0.01–0.3 μg/kg/min	2+	2+	4+	0	0	Refractory shock
Dobutamine	1–20 μg/kg/min	1–2+	3+	1+	2+	0	CHF; cardiogenic, obstructive and septic shock
Dopexamine[b]	0.5–6 μg/kg/min	2+	1+	0	3–4+	4+	CHF; cardiogenic shock
Epinephrine	0.05–0.2 μg/kg/min	4+	4+	4+	3+	0	Refractory shock or anaphylactic shock
Phenylephrine	0.1–1 μg/kg/min	0	1+	4+	0	0	Neurogenic or septic shock
Isoproterenol	1–8 μg/min	4+	4+	0	4+	0	Cardiogenic shock (bradyarrhythmia), torsades de pointes, ventricular tachycardia
Vasopressin	0.02–0.04 U/min	0	0	4+	0	0	Vasodilatory (e.g., septic) shock
Milrinone	37.5–75 μg/kg bolus over 10 min; 0.375–0.75 μg/kg/min infusion	1+	3+	0	2+	0	CHF; cardiogenic shock

CHF, Congestive heart failure.

sparing of pressor and shock-associated renal injury has been refuted.[417–419]

Dopamine has fallen out of favor as the initial vasopressor used for circulatory shock. A central and peripheral nervous system neurotransmitter and the biologic precursor of norepinephrine, dopamine stimulates three different receptors; vascular dopaminergic, cardiac β_1, and vascular α. In addition, part of dopamine's myocardial effects are mediated by release of endogenous norepinephrine. Dose-dependent maximal stimulation of each of each of dopamine's target receptors has been suggested to result in different typical hemodynamic responses at different infusion rates. At infusion rates of less than 4 to 5 μg/kg per minute, dopaminergic effects have been said to dominate, but studies suggest this has little clinical relevance (although in the past it was the theoretical basis for use of low-dose dopamine for renal protection).[417,418] Vascular dopamine 2 receptors vasodilate the renal, mesenteric, myocardial, and cerebral vascular beds. In addition, renal dopamine 1 receptors mediate a mild natriuresis.[420] β-Adrenoreceptor–mediated cardiac inotropic effects have been suggested to dominate at doses below approximately 10 μg/kg per minute with α-adrenoreceptor vasopressor effects more prominent at doses above 10 μg/kg per minute.[410] It is important to note, however, that dopaminergic and cardiac adrenergic effects are not suppressed at higher doses but rather that additional effects are seen. In addition, there is substantial interindividual variation in response, with some showing substantial vasopressor or inotropic responses at low infusion rates. For management of circulatory shock, dopamine is often started at 5 μg/kg per minute and increased rapidly (5 μg/kg per minute every 2 or 3 minutes) to a maximum of 20 μg/kg per minute until the target blood pressure is reached. If vasopressor effects are inadequate at these infusion rates, norepinephrine infusion is begun. In a randomized controlled trial in patients with shock, norepinephrine and dopamine were similar in regard to mortality. Dopamine was associated with more adverse effects including tachyarrhythmias and subgroup analysis suggested higher mortality for dopamine in the cardiogenic shock subgroup.[421]

Dobutamine, which is structurally derived from isoproterenol, is a racemic mixture of two synthetic stereoisomers. In combination, the stereoisomers result in increased myocardial contractility through α and β_1 cardiac adrenoreceptors.[422,423] Weak arteriolar vasodilatory effects are mediated through dominance of β_1-adrenoreceptor–mediated vascular relaxation over α-adrenoreceptor–mediated vasoconstriction in the arterial circulation. Evidence suggesting that dobutamine induces vasoconstriction in the systemic venous bed (resulting in increased mean circulatory pressure and augmentation of venous return/CO) implies that α-adrenoreceptor–mediated effects may be dominant in small capacitance vessels.[162,422,423]

Although its hemodynamic effects are otherwise similar to isoproterenol, dobutamine has been reputed to exert minimal chronotropic effects.[422,424] This attribute has been questioned in recent studies[425] and may have been based on the selection of CHF patients with β-adrenoreceptor downregulation and other potential alterations of adrenoreceptor signal transduction.[424,426] Dobutamine's powerful inotropic effect is due to a combination of its direct effect on myocardial contractility, its afterload reducing effect, and α-adrenoreceptor–mediated venoconstriction.[422,424] In contrast to dopamine, it causes a reduction in filling pressures and a greater increase in CO at equivalent doses.[427,428] In addition, although it increases myocardial oxygen demand (like dopamine), myocardial perfusion is also augmented (in contrast to dopamine).[429] The most well-accepted use of dobutamine in circulatory shock relates to cardiac etiologies.[422,424] Once blood pressure is corrected, dobutamine may be used to increase cardiac performance and decrease elevated ventricular filling pressures associated with cardiogenic pulmonary edema. In this setting dobutamine may in fact increase blood pressure. Alternatively, if myocardial damage is extensive, vasodilatory properties may dominate, resulting in hypotension. Dobutamine may also be of use in obstructive shock pending definitive intervention and can be used for augmentation of low CI occasionally seen in fluid-resuscitated septic shock. Our own experience suggests that a somewhat hypervolemic state (a PAOP of at least 15 mm Hg if a PAC is used) is required during dobutamine infusion to avoid hypotension in patients with septic shock. The use of dobutamine for routine augmentation of oxygen delivery in septic shock has been substantially rejected.[430,431]

Epinephrine is occasionally used when other inotrope/vasopressors have failed to support blood pressure and/or CO in circulatory shock. It is the first-line agent for management of anaphylactic shock. In addition, it is used to support myocardial contractility after cardiopulmonary bypass.[432] Epinephrine stimulation of α, β_1-, and β_2-receptors results in increases of myocardial contractility that are more pronounced than with any other inotrope. Infusion rates in nanograms per kilogram per minute result in significant increases in CO.[432] Epinephrine is also frequently used in septic shock refractory to other inotropes/vasopressors. Effects attributable to impaired myocardial perfusion (chest pain, arrhythmias, ST depression) in patients with known CAD are usually limited to patients receiving more than 0.1 μg/kg/min.[433] Although the usual infusion rate is 0.05–0.2 μg/kg/min higher rates can be used with the potential for increasing toxicity.

Milrinone, a bipyridine phosphodiesterase inhibitor, increases intracellular concentrations of cAMP by blocking cAMP breakdown.[411] Although some controversy has existed regarding the relative contributions of increased myocardial contractility and decreased vascular tone with respect to the apparent inotropic properties of phosphodiesterase inhibitors, recent data confirm the presence of substantial increases of myocardial contractility[434]; these agents also produce substantial vasodilatation. The most accepted use for milrinone in the ICU is in the management of CHF, cardiogenic shock, and postcardiopulmonary bypass myocardial dysfunction.[411] Experimental animal studies suggest phosphodiesterase inhibitors may exert beneficial hemodynamic effects in sepsis by augmenting CO and increasing oxygen delivery without increasing consumption.[435] Occasional clinical reports suggest a potential management role in catecholamine-refractory septic shock.[436]

Phenylephrine is a synthetic catecholamine that is unique in its almost pure α-adrenergic agonist effects. Its most common uses are intraoperatively to counteract the vasodilatory effects of anesthetics and in septic shock, in which its lack of β-adrenergic activity may help limit deleterious increases in HR seen with other agents. Isoproterenol is another synthetic catecholamine with dominant β_1 and β_2 activity. Its previous indications for use have largely been supplanted by dobutamine. Because of its powerful chronotropic effects, it can be useful in the management of bradyarrhythmias and torsades de pointes ventricular tachycardia (for overdrive pacing), but otherwise it has no specific role in the management of circulatory shock.

In recent years, vasopressin levels in septic shock have been shown to be significantly suppressed.[416] Studies have shown that IV infusion of vasopressin into patients with septic shock results in a profound pressor response.[415] This profound pressor response occurs despite the absence of such an effect with even larger amounts of vasopressin in normotensive patients. Investigators have also documented efficacy in other vasodilatory shock states with refractory hypotension, including milrinone-induced shock in severe heart failure,[437] postcardiotomy vasodilatory shock,[438] unstable brain-dead organ donors,[439] and late-phase hemorrhagic shock.[413] Vasopressin (0.1–1.0 U/mL in normal saline solution or 5% dextrose in water) may be initiated at 0.02 to 0.04 U/min. Few patients respond with higher doses and the dose should rarely, if ever, be higher than 0.04 U/min for an extended period of time. In large doses, vasopressin may produce bradycardia, minor arrhythmias, premature atrial contraction, heart block, peripheral vascular constriction or collapse, coronary insufficiency, decreased CO, myocardial ischemia, and MI. In patients with CAD, even small doses of the drug can precipitate angina. At the upper end of dosing, a significant subset of patients may develop digital, mesenteric, or myocardial ischemia; thus it is imperative to use the minimal amount of vasopressin possible to achieve desired blood pressure goals. Published data suggest vasopressin can be used for up to 4 to 6 days if necessary. A randomized, blinded study of vasopressin treatment of septic shock has shown that the addition of low-dose vasopressin (vs. norepinephrine) to open-label vasopressors offered no overall advantage.[440] A recent randomized controlled trial showed that vasopressin as a first-line vasopressor was safe but did not provide any advantages over norepinephrine.[441] Because of the limited experience with this compound and the relatively longer half-life of the drug, vasopressin should be used only after hemodynamic stabilization with standard agents (catecholamines) has been attempted.

Another agent in a totally different class that could be used as vasopressor is angiotensin II. In a recent randomized controlled trial, angiotensin II as an add-on to norepinephrine showed that it could increase MAP compared with placebo without significant adverse effects. The role of this agent in management of shock is still to be defined.[290]

Conclusion

Although the syndrome of shock ultimately involves common late pathologic elements, the early pathophysiologic processes underlying different conditions resulting in circulatory shock are both diverse and complex. Our concepts of shock, which once focused on broad cardiovascular physiologic mechanisms, have more recently centered on issues of microvascular function and cellular metabolism. In the future, this focus may evolve toward questions of altered cellular gene expression and metabolomics in a variety of tissues. Advances in therapy have developed in parallel to these changes in our

understanding of shock pathophysiology. Early work on therapy of shock concentrated on correction of hemodynamic derangements through the use of vasopressors and inotropes. Clinical trials over decades have centered on anticytokines such as anti–TNF-α and various novel resuscitative compounds. The most advanced experimental therapies being examined today involve direct manipulation of gene expression via antisense oligonucleotides and transcription factor inhibitors. Despite these advances, many questions remain. Only ongoing basic research and clinical trials will answer them.

Key Points

- Shock is the final pathway through which a variety of pathologic processes lead to cardiovascular failure and death.
- Shock is the state in which profound and widespread reduction of effective tissue perfusion leads to cellular injury. The inability of cells to obtain and/or use oxygen in sufficient quantity to optimally meet their metabolic requirements is common to all forms of shock. Hypotension alone does not define shock.
- Based on hemodynamic characteristics, shock is categorized as hypovolemic, cardiogenic, extracardiac obstructive, or distributive.
- Although one hemodynamic categorization dominates, most forms of clinical shock involve some cardiovascular characteristics of several categories.
- The clinical picture of shock is dependent on the etiology, the magnitude of the injury or insult, and the degree of physiologic compensation. Physiologic compensation is determined by the time course of development of shock and the preexisting cardiovascular reserve.
- The systemic hemodynamic aspects of shock can be described by the interactive contributions of cardiac and vascular function to blood pressure and CO.
- Physiologically, blood pressure is dependent on CO and vascular resistance; CO is not dependent on blood pressure.
- Failure to maintain the blood pressure required for autoregulation during hypodynamic circulatory shock indicates a severe reduction in CO.
- In a closed cardiovascular circuit, CO (as determined by HR, preload, afterload, and contractility) equals venous return (as determined by venous pressure [mean circulatory pressure]), right atrial pressure, and venous resistance. Total systemic perfusion is therefore dependent on cardiac and vascular interactions.
- In addition to sufficient CO at sufficient pressure, effective perfusion requires normal local and systemic microvascular function, resulting in appropriate distribution of CO.
- During hypovolemic and other forms of hypodynamic shock, extrinsic blood flow regulatory mechanisms overwhelm the autoregulatory response of most vascular beds. Blood flow to vital organs such as the heart and brain is relatively well preserved owing to dominant autoregulatory control.
- During distributive shock, particularly septic shock, organ blood flow is disturbed at higher MAPs, suggesting a primary defect of microvascular function.
- Cellular dysfunction and organ failure in shock involves the interactions of cellular ischemia, circulating or local inflammatory mediators, and free radical injury.
- All compensatory responses to shock support oxygen delivery to vital tissues. The mechanisms include support of venous pressure, maximization of cardiac function, redistribution of perfusion to vital organs, and optimization of oxygen unloading.
- Circulatory shock may be associated with encephalopathy, ARDS, ATN, ischemic hepatitis or intrahepatic cholestasis, thrombocytopenia, immunosuppression, and MODS.
- Because early recognition and treatment is key to improved survival, the diagnosis of shock is primarily based on clinical criteria. Laboratory and radiologic data are used to confirm the diagnosis and to help clarify etiology.
- Clinically, shock is characterized by physiologic compensatory responses, including tachycardia, tachypnea, oliguria, and by signs of physiologic decompensation, particularly hypotension.
- Shock should be managed in an ICU with continuous monitoring and close nursing support. Those patients whose etiologic diagnosis is in doubt, whose hemodynamic instability does not quickly resolve with IV fluids, or whose conditions are medically complicated should undergo noninvasive (echocardiographic) and/or invasive hemodynamic monitoring with arterial and centrally placed catheters. PACs remain a reasonable option in some cases.
- The basic goal of therapy of circulatory shock is the restoration of effective perfusion to vital organs and tissues before the onset of cellular injury.
- The speed with which effective perfusion is established and the underlying cause of hemodynamic instability is definitively addressed are critical determinants of survival in shock.
- The specific aims of resuscitation of shock include support of mean blood pressure above 60 to 65 mm Hg, maintenance of CI greater than 2.1 L/min per m^2, and restriction of arterial lactate concentrations to less than 2.2 mmol/L.

Review Questions

1. A 33-year-old woman is brought to the intensive care unit (ICU) for dyspnea and acute hepatic dysfunction. Her symptoms began 2 weeks ago with an apparent upper respiratory tract infection, cough, and fever. She subsequently developed complaints of progressive fatigue, weakness, and dyspnea. Overnight decompensation continues with increasing dyspnea and hypoxemia, requiring endotracheal intubation. She becomes hypotensive and oliguric despite repeated intravenous fluid boluses. The electrocardiogram (ECG) shows sinus tachycardia, with nonspecific ST-segment changes. Transaminase levels are elevated: aspartate aminotransferase, 689 U/L; alanine aminotransferase, 580 U/L. Pulmonary artery (PA) catheterization is performed; right atrial (RA) pressure is 14 mm Hg; PA pressure is 43/26 mm Hg; pulmonary capillary wedge pressure is 22 mm Hg; cardiac index 1.3 L/min/m^2; and systemic vascular resistance is 1250 dyne/sec/cm^{-5}. What is her likely diagnosis?

a. Pulmonary embolism
b. Septic shock
c. Acute myocardial infarction
d. Acute myocarditis
e. Anaphylactic shock

Answer: d. This patient experienced a viral infection that progressed to acute viral myocarditis with cardiogenic shock. Her mild transaminase elevation was secondary to a low cardiac output state. PA catheter findings in pulmonary embolism (PE) include a depressed cardiac output/index, with elevated RA pressures, and an elevated PA diastolic to pulmonary capillary wedge pressure (PCWP) gradient (classically >10 mm Hg). In PE-induced shock, the PCWP would be decreased because it only produces hypotension by decreasing left ventricular (LV) filling. Anaphylaxis and sepsis are both forms of distributive shock. These "hyperdynamic" forms of shock typically present with an elevated cardiac output/index. Central venous pressure (CVPs) and PCWPs are often low because of the intravascular volume depletion resulting from profound capillary leak, and systemic vascular resistance (SVR) is markedly reduced from arteriolar vasodilatation. Hypovolemic shock usually presents with reduced cardiac index (CI), reduced CVP and PCWP, and very high SVR. Cardiogenic shock presents with reduced cardiac indices, elevated CVP and PCWP, and elevated SVR as seen in this patient. However, there is no ST-segment elevation or Q-wave suggesting an acute infarct in this case.

2. Which of the following correctly defines oxygen consumption (Q = cardiac output; CaO_2 = arterial oxygen content; CvO_2 = mixed venous oxygen content; Hb = hemoglobin concentration; PaO_2 = arterial partial pressure of oxygen; SaO_2 = arterial oxygen consumption; SvO_2 = venous oxygen saturation)?

a. $Q \times CaO_2$
b. $SaO_2 - SvO_2/SvO_2$
c. $Q \times (CaO_2 - CvO_2)$
d. $(1.34 \times Hb \times SaO_2) + (0.0031 \times PaO_2)$

Answer: c. Systemic oxygen delivery is defined as the product of cardiac output and the total oxygen content of arterial blood ($Q \times CaO_2$). Oxygen content can be defined as the oxygen bound to arterial or venous hemoglobin ($1.34 \times Hb \times S[a \text{ or } v]O_2$ plus the amount of oxygen dissolved in blood ($0.0031 \times P[a \text{ or } v]O_2$). Oxygen consumption therefore can be defined as a difference between oxygen delivery and oxygen demand ($Q \times [CaO_2 - CvO_2]$). Calculating the oxygen extraction ratio represents another way to define oxygen consumption. Simply put, this is the ratio of oxygen consumption to oxygen delivery, or $SaO_2 - SvO_2/SvO_2$. The normal extraction ratio is approximately 0.25:0.33, which reflects a mixed venous saturation of 65% to 70%.

3. Match each of the following clinical scenarios with the best choice of vasoactive medication (a–d) listed below.

Scenario 1: A 58-year-old man with a history of hypertension and diabetes is brought to the ICU after successful angioplasty in the setting of acute myocardial infarction. The cardiac index is markedly low (1.5 L/min/m^2). His blood pressure is 120/70 mm Hg and his heart rate is 115 beats/min.

Scenario 2: A 24-year-old woman without medical history presents with septic shock and is still hypotensive despite adequate cardiac filling pressures and a high rate of dopamine infusion.

Scenario 3: A 67-year-old man presents in shock after a motor vehicle collision in which he has spinal cord impingement at the C4-C5 vertebrae.

a. Dopamine
b. Norepinephrine
c. Milrinone
d. Phenylephrine

Answers: Scenario 1: c; Scenario 2: b; Scenario 3: d. Dopamine stimulates dopaminergic, β-adrenergic, and α-adrenergic receptors. At low doses, dopamine receptor stimulation leads to improved renal perfusion. At moderate doses (5–10 μg/kg/min), β_1-adrenergic stimulation augments cardiac function. At high doses (10–20 μg/kg/min) α-adrenergic receptor stimulation causes peripheral vascular constriction. The β_1 effects of dopamine can cause significant tachycardia. Therefore norepinephrine, which strongly stimulates α-adrenergic receptors (with lesser β-adrenergic receptor stimulation), may increase blood pressure without the chronotropic effects of dopamine. Phenylephrine, which exclusively stimulates α-adrenergic receptors, can be used as a venous and arterial vasoconstrictor for pure vasodilatory shock states such as neurogenic or anaphylactic shock. Milrinone inhibits cyclic adenosine monophosphate (cAMP) degradation. The overall effects of milrinone include increased cardiac contractility and peripheral and pulmonary vasodilation. Similar to dobutamine, the vasodilation associated with milrinone may precipitate arterial hypotension; thus this agent must be used with caution in patients with marginal blood pressure.

The first scenario is low cardiac output state with normal blood pressure and thus milrinone is the correct choice as the use of dopamine may exacerbate tachycardia. In the second scenario, norepinephrine would be the best choice to achieve an acceptable mean arterial pressure. The third scenario is "spinal shock"; a pure vasoconstrictor (phenylephrine) is the best choice.

4. Which of the following is most correct regarding issues of invasive hemodynamic monitoring?

a. Many studies have proven that PA catheters improve mortality.
b. Manual sphygmomanometry or automated blood pressure cuffs are relatively accurate in shock states.
c. Monitoring CVP can be helpful to accurately estimate left ventricle preload in the critically ill.
d. Serum lactate will be elevated at mixed oxygen saturation levels below 30% to 40%.

Answer: d. Invasive hemodynamic monitoring may provide the clinician with a great deal of important physiologic information. Arterial catheters should be used for blood pressure measurement in shock states. Manual and automated blood pressure measurement techniques have been found to be inaccurate in hypotensive patients. CVP can be used to monitor volume status. A markedly low CVP correctly identifies a hypovolemic state. However, a normal or high CVP value does not necessarily ensure adequate cardiac filling, because the value for CVP can be influenced by valvular heart disease or intrathoracic pressure. PA catheters can provide data reflecting left venctricular preload (PCWP) and can measure cardiac output via thermodilution techniques. Data from the PA catheter can be diagnostic (differentiating shock states) or used to guide therapy. However, no study has linked PA catheter utilization with improved outcomes. PA blood can be obtained to measure SvO_2. In assessing oxygen supply dependency in shock, an SvO_2 of 65% to 70% suggests that global tissue oxygen supply is meeting tissue oxygen demands. Tissue oxygen extraction would be increased in this condition. Lactate accumulation and supply-dependent oxygen consumption reliably occur at SvO_2 levels below 30% to 40%. However, lactate levels may be elevated at higher levels of SvO_2 if regional (rather than global) hypoperfusion is occurring.

Mechanical Support

Conclusion

Cardiogenic shock is the syndrome that ensues when the heart is unable to deliver enough blood to maintain adequate tissue perfusion. Acute myocardial infarction (MI) is the leading cause, but other potential etiologies need to be considered.[1,2] Without prompt diagnosis and appropriate management, morbidity and mortality remain substantial.[2–4] Rapid evaluation and prompt initiation of supportive measures and definitive therapy in patients with cardiogenic shock may improve both early and long-term outcomes.

Definition

Cardiogenic shock is defined clinically by decreased cardiac output with evidence of tissue hypoxia in the presence of adequate intravascular volume. The diagnosis of circulatory shock (Box 23.1) is made at the bedside by the presence of hypotension along with a combination of clinical signs indicative of poor tissue perfusion, including oliguria, clouded sensorium, and cool, mottled extremities. Hemodynamic criteria include sustained hypotension (systolic blood pressure [SBP] <90 mm Hg for at least 30 minutes, or requiring vasopressor support to maintain SBP >90 mm Hg) and a reduced cardiac index (<2.2 L/min per m^2) in the presence of elevated filling pressures (pulmonary capillary occlusion pressure >15 mm Hg).[5] Cardiogenic shock is diagnosed after documentation of myocardial dysfunction and exclusion or correction of extrinsic factors such as hypovolemia, hypoxia, and acidosis.

History

Pump failure caused by cardiogenic shock has long been known to carry a high mortality rate. The seminal article outlining prognosis after MI was a single-center series of 250 patients reported by Killip in 1967.[6] Killip divided patients into four classes as follows:

Killip class I: no evidence of congestive heart failure
Killip class II: presence of an S_3 gallop and/or bibasilar rales
Killip class III: pulmonary edema (rales greater than halfway up the lung fields)
Killip class IV: cardiogenic shock.

Nineteen percent of the 250 patients were in class IV at presentation and their mortality rate was 81%.[6]

With the advent of right heart catheterization, Forrester and Swan defined hemodynamic subsets after MI analogous to the clinical subsets outlined by Killip.[5]

Subset I: Normal pulmonary capillary wedge pressure (PCWP) and cardiac output
Subset II: Elevated PCWP and normal cardiac output
Subset III: Normal PCWP and decreased cardiac output
Subset IV: Elevated PCWP and decreased cardiac output.

These subsets correspond with the Killip classes, and mortality was markedly increased in the subset with hemodynamics indicative of cardiogenic shock.[7]

Despite advances in management of heart failure and acute MI, the mortality rate of patients with cardiogenic shock has remained high.[2,8–10] Data suggest an increase in survival in the 1990s coincident with the use of reperfusion strategies.[9–11] More recent registry data, however, suggest that in-hospital mortality in

patients treated with percutaneous coronary intervention (PCI) for cardiogenic shock may be rising a bit, from 27.6% in 2006 to 30.6% in 2013, perhaps owing to exclusion of fewer extremely ill patients in the cohort of patients receiving PCI.[12] Cardiogenic shock still remains the most common cause of death in hospitalized patients with acute MI.

Incidence

Accurate determination of the precise incidence of cardiogenic shock is difficult because patients who die of MI before reaching the hospital generally do not receive this diagnosis.[8,13–16] Nonetheless, estimates from a variety of sources have been fairly consistent. The Worcester Heart Attack Study,[8] a community-wide analysis, found an incidence of cardiogenic shock of 7.5%, an incidence that remained fairly stable from 1975 to 1997.[8,11] The incidence was similar in the randomized Guangzhou Uptake of Surgery Trial (GUSTO) trial (7.2%),[17] in other multicenter thrombolytic trials,[13–15] and in patients with ST-elevation MI in the National Registry of Myocardial Infarction (NRMI) database from 1995 to 2004 (8.6%).[9] Although the Worcester Heart Attack Study reported a decrease from 8% to 6% from 1975 to 2005,[3] a more contemporary report from the National Inpatient Sample actually showed an increase in cardiogenic shock incidence from 6.5% in 2003 to 10.1% in 2010, with an increasingly complex profile of patients owing to higher rates of comorbidities.[4]

Etiology and Epidemiology

The most common cause of cardiogenic shock is left ventricular (LV) failure in the setting of an extensive acute MI, although a smaller infarction in a patient with previously compromised LV function may also precipitate shock. Cardiogenic shock can also be caused by mechanical complications—such as acute mitral regurgitation, rupture of the interventricular septum, or rupture of the free wall—or by large right ventricular (RV) infarctions. In a report of the SHOCK (*Sh*ould we emergently revascularize *O*ccluded *C*oronaries for shoc*K*) trial registry of 1160 patients with cardiogenic shock,[2] 78.5% of patients had predominant LV failure, 6.9% had acute mitral regurgitation, 3.9% had ventricular septal rupture, 2.8% had isolated RV shock, 1.4% had tamponade or cardiac rupture, and 6.5% had shock resulting from other causes.

Other causes of cardiogenic shock include myocarditis, end-stage cardiomyopathy, myocardial contusion, septic shock with severe myocardial depression, myocardial dysfunction after prolonged cardiopulmonary bypass (CPB), valvular heart disease, and hypertrophic obstructive cardiomyopathy (Box 23.2). An important consideration is that some cardiogenic shock may have an iatrogenic component. Early diagnosis of impending shock or of patients at high risk for development of shock is essential, both to speed intervention and to avoid therapies that may worsen hemodynamics. In many cases of cardiogenic shock in the setting of MI, the diagnosis is not made until the patient has undergone triage and has been admitted to an inpatient setting. Patients may have received early β-blockade and/or angiotensin-converting enzyme inhibition, therapies that may affect hemodynamic substantially.

Only one-fourth of patients with cardiogenic shock have shock at initial presentation; the median delay in the SHOCK trial registry was 7 hours.[2] This suggests that early treatment may potentially prevent shock, and some data indicate that early thrombolytic therapy may decrease the incidence of cardiogenic shock.[18] Comparison of the clinical characteristics of patients with early and late shock shows a similar demographic, historical, clinical, and hemodynamic characteristics, but shock tends to develop earlier in patients with single-vessel coronary artery disease (CAD) than in those with triple-vessel disease.[19] This finding suggests that early shock in the setting of acute MI may be more likely to resolve after revascularization of the culprit vessel, whereas shock developing later may require more complete revascularization.

Risk factors for the development of cardiogenic shock in MI generally parallel those for LV dysfunction and the severity of CAD. Epidemiologic and historical factors that predict the development of shock include advanced age, diabetes, previous MI or decreased ejection fraction, peripheral vascular disease, and cerebrovascular disease.[20,21] Analysis from the GUSTO-3 trial has identified age, lower systolic blood pressure, heart rate, and Killip

class as significant predictors of the risk for development of cardiogenic shock after presentation with acute MI.[22] Use of predictive scoring systems may be useful in identifying patients at high risk for the development of cardiogenic shock and targeting such patients for closer monitoring.[22]

Cardiogenic shock is most often associated with anterior MI.[2,23] Angiography most often demonstrates multivessel CAD (left main occlusion in 20% of patients, three-vessel disease in 64%, two-vessel disease in 23%, and one-vessel disease in 13% of patients).[24] The high prevalence of multivessel CAD is important because compensatory hyperkinesis normally develops in myocardial segments that are not involved in an acute MI, and this response helps maintain cardiac output. Failure to develop such a response, because of previous infarction or high-grade coronary stenoses, is an important risk factor for cardiogenic shock and death.[25]

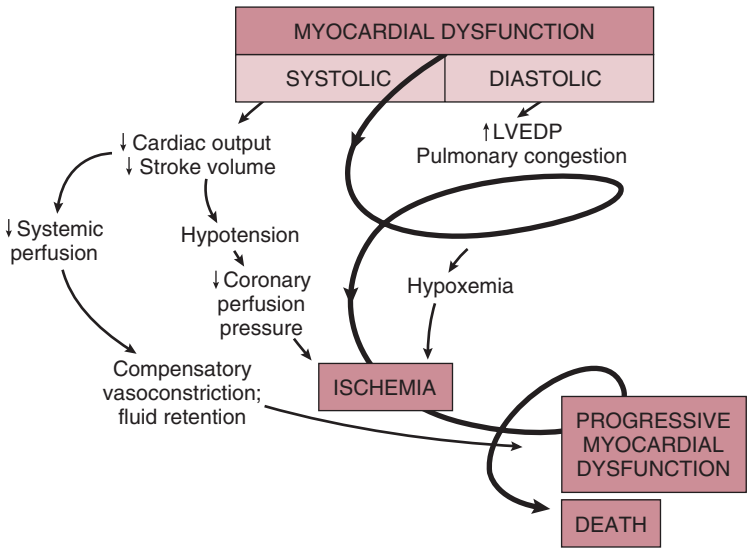
Clinical and hemodynamic data can be used to predict in-hospital mortality in patients with cardiogenic shock. Multivariate models derived from the SHOCK trial have shown that eight clinical risk factors—advanced age, previous coronary artery bypass grafting (CABG), noninferior MI, creatinine elevated above 1.9 mg/dL, decreased systolic blood pressure, shock on admission, anoxic brain injury, and clinical evidence of end-organ hypoperfusion—can divide patients into strata with mortality ranging from 12% to 88%.[26] This model can be refined by adding hemodynamic variables: stroke work and ejection fraction less than 28%.[26] Interestingly, the effect of early revascularization did not differ by risk group in the SHOCK trial, suggesting that all patients have the potential to benefit.[26]

Pathogenesis

Systemic Effects

Cardiac dysfunction in patients with cardiogenic shock is usually initiated by MI or ischemia. The myocardial dysfunction resulting from ischemia worsens that ischemia, creating a downward cascade[27] (Fig. 23.1). Myocardial dysfunction reduces stroke volume, cardiac output, and blood pressure, compromising myocardial perfusion, which depends on the gradient between systemic and LV diastolic pressure. Pump failure, which increases LV diastolic pressures and further reduces coronary perfusion pressure and also increases LV wall stress and myocardial oxygen requirements, further worsens ischemia. Elevation of left atrial pressure owing to pump failure can lead to pulmonary congestion and hypoxemia, with exacerbation of myocardial ischemia and impaired ventricular performance. Decreased cardiac output can also compromise systemic perfusion.

When myocardial function is depressed, several compensatory mechanisms are activated, including sympathetic stimulation to increase heart rate and contractility and renal fluid retention to increase preload. These compensatory mechanisms may become maladaptive and can actually worsen the situation when cardiogenic shock develops. Increased heart rate and contractility increase myocardial oxygen demand and exacerbate ischemia. Vasoconstriction to maintain blood pressure increases myocardial afterload, further impairing cardiac performance and increasing myocardial oxygen demand. This increased demand, in the face of inadequate



• **Fig. 23.1** The downward spiral in cardiogenic shock. Cardiac dysfunction is usually initiated by myocardial infarction or ischemia. The myocardial dysfunction resulting from ischemia worsens that ischemia, creating a downward cascade. Myocardial dysfunction reduces stroke volume, cardiac output, and blood pressure, compromising myocardial perfusion, which depends on the gradient between systemic and left ventricular (LV) diastolic pressure. Pump failure, which increases LV diastolic pressures and further reduces coronary perfusion pressure and also increases LV wall stress and myocardial oxygen requirements, further worsens ischemia. Elevation of left atrial pressure owing to pump failure can lead to pulmonary congestion and hypoxemia, with exacerbation of myocardial ischemia and impaired ventricular performance. Decreased cardiac output can also compromise systemic perfusion. The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock. *LVEDP,* Left ventricular end-diastolic pressure. perfusion, can worsen ischemia and begin a vicious cycle that will end in death if not interrupted (Fig. 23.1). The interruption of this cycle of myocardial dysfunction and ischemia forms the basis for the therapeutic regimens for cardiogenic shock.

Not all patients fit into this classic paradigm. In the SHOCK trial, the average systemic vascular resistance (SVR) was not elevated, and the range of values was wide, suggesting that compensatory vasoconstriction is not universal. Some patients had fever and elevated white blood cell counts along with decreased SVR, suggesting a systemic inflammatory response syndrome.[28] This has led to an expansion of the paradigm to include the possibility of the contribution of inflammatory responses to vasodilation and myocardial stunning, leading clinically to persistence of shock (Fig. 23.2).[28] Supporting this notion is the fact that the mean ejection fraction in the SHOCK trial was only moderately decreased (30%), suggesting that mechanisms other than pump failure were operative.[28] Immune activation appears to be common to a number of different forms of shock. Activation of inducible nitric oxide synthase with production of nitric oxide and peroxynitrate has been proposed as one potential mechanism.

Myocardial Pathology

Cardiogenic shock is characterized by both systolic and diastolic myocardial dysfunction.[29,30] Progressive myocardial necrosis has been observed consistently in clinical and pathologic studies of patients with cardiogenic shock.[29,31] Patients who develop shock after admission often have evidence of infarct extension, which can result from reocclusion of a transiently patent infarct artery, propagation of intracoronary thrombus, or a combination of decreased coronary perfusion pressure and increased myocardial oxygen demand.[20,21] Myocytes at the border zone of an infarction are more susceptible to additional ischemic episodes; therefore these adjacent segments are at particular risk.[32] Mechanical infarct expansion, which is seen most dramatically after extensive anterior MI, can also contribute to late development of cardiogenic shock.[20,33]

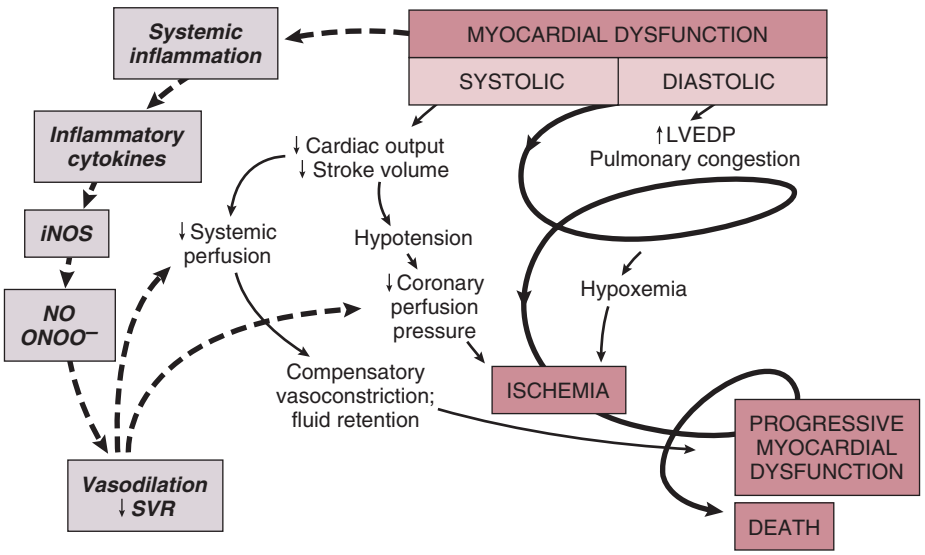
Ischemia remote from the infarct zone may be particularly important in producing systolic dysfunction in patients with cardiogenic shock.[25,34] Patients with cardiogenic shock usually have multivessel CAD,[2,29] with limited vasodilator reserve, impaired autoregulation, and consequent pressure-dependent coronary flow in several perfusion territories.[35] Hypotension and metabolic derangements thus have the potential to impair the contractility of noninfarcted myocardium in patients with shock.[36] This can limit hyperkinesis of uninvolved segments, a compensatory mechanism typically seen early after MI.[25,34]

In addition to abnormalities in myocardial performance, valvular abnormalities can contribute to increased pulmonary congestion. Papillary muscle dysfunction caused by ischemia is common and can lead to substantial increases in left atrial pressure; the degree of mitral regurgitation may be lessened by afterload reduction. This mechanism is distinct from complete rupture of the papillary muscle, a mechanical complication that presents dramatically, with pulmonary edema and cardiogenic shock.

Reversible Myocardial Dysfunction

A key to understanding the pathophysiology and treatment of cardiogenic shock is to realize that large areas of nonfunctional but viable myocardium can cause or contribute to the development of cardiogenic shock in patients after MI (Fig. 23.3). This reversible dysfunction can be described in two main categories: stunning and hibernation.

Myocardial stunning represents postischemic dysfunction that persists despite restoration of normal blood flow; myocardial performance eventually recovers.[37] Originally defined in animal models of ischemia and reperfusion,[38] stunning has been recognized



• **Fig. 23.2** Expansion of the pathophysiologic paradigm of cardiogenic shock to include the potential contribution of inflammatory mediators. Inhibition of nitric oxide, however, has not been shown to be beneficial in patients with cardiogenic shock.[114] *iNOS,* Inducible nitric oxide synthase; *LVEDP,* left ventricular end–diastolic pressure; *NO,* nitric oxide; $ONOO^-$, peroxynitrite; *SVR,* systemic vascular resistance. • **Fig. 23.3** Possible outcomes after myocardial ischemia. After myocardial ischemia, either necrosis or reversible dysfunction may occur. Myocardial stunning represents postischemic dysfunction that persists despite restoration of normal flow. These segments respond to inotropes and will recover function if supported. Hibernating myocardium is a state of persistently impaired myocardial function at rest owing to residual stenosis; function can be restored to normal by relieving ischemia. Repetitive episodes of stunning can coexist with and/or mimic myocardial hibernation. The concept that stunned or hibernating segments can recover contractile function emphasizes the importance of measures to support hemodynamics in patients with cardiogenic shock. (Modified from Hollenberg SM, Kavinsky CJ, Parrillo JE. Cardiogenic shock. *Ann Intern Med.* 1999;131:47–50, with permission.)

in patients on the basis of postreperfusion myocardial dysfunction with subsequent improvement.[37] Direct evidence for myocardial stunning in humans has been found using positron emission tomography scanning in patients, with demonstration of persistent wall motion abnormalities after angioplasty for acute coronary syndromes with normal perfusion measured simultaneously by ^{13}N-ammonia.[39] The pathogenesis of stunning has not been conclusively established but appears to involve a combination of oxidative stress,[40] perturbation of calcium homeostasis, and decreased myofilament responsiveness to calcium.[41–43] The intensity of stunning is determined primarily by the severity of the antecedent ischemic insult.[43]

Myocardial hibernation represents segments with persistently impaired function at rest as the result of severely reduced coronary blood flow, with improved function after restoration of blood flow.[44] Hibernation can be seen as an adaptive response to reduce contractile function of hypoperfused myocardium and restore equilibrium between flow and function, thereby minimizing the potential for ischemia or necrosis.[45] Revascularization of hibernating myocardium can lead to improved myocardial function,[46] and improved function appears to translate into improved prognosis.[47,48]

Although hibernation is conceptually and pathophysiologically different from myocardial stunning, the two conditions are difficult to distinguish in the clinical setting and may coexist.[43,48] Repetitive episodes of myocardial stunning can occur in areas of viable myocardium subtended by a critical coronary stenosis, mimicking myocardial hibernation.[37,43,49,50] Consideration of myocardial stunning and hibernation is vital in patients with cardiogenic shock because of their therapeutic implications. Hibernating myocardium improves with revascularization, and stunned myocardium retains inotropic reserve and can respond to inotropic stimulation.[43] The potential for myocardial recovery provides a rationale for coronary revascularization and also emphasizes the importance of measures to support hemodynamics and thus minimize myocardial necrosis in patients with cardiogenic shock.

Clinical Assessment and Initial Management

Evaluation

Cardiogenic shock is an emergency. The clinician must initiate therapy before shock irreversibly damages vital organs; at the same time, he or she must perform the clinical assessment required to understand the cause of shock and to target therapy to that cause. A practical approach is to make a rapid initial evaluation on the basis of a limited history, physical examination, and specific diagnostic procedures (Fig. 23.4).[27] Exclusion of alternative causes of hypotension and documentation of myocardial dysfunction is essential for the diagnosis of cardiogenic shock.

The majority of patients with cardiogenic shock present "wet" and "cold." Patients with shock are usually ashen or cyanotic, and they have cool skin and mottled extremities. Cerebral hypoperfusion may cloud the sensorium. Pulses are rapid and faint, and may be irregular in the presence of arrhythmias. Jugular venous distention and pulmonary rales are usually present, although their absence does not exclude the diagnosis. A precordial heave resulting from LV dyskinesis may be palpable. The heart sounds may be distant, and third and/or fourth heart sounds are usually present. A systolic murmur of mitral regurgitation or ventricular septal defect may be heard, but either complication may occur without an audible murmur.

An electrocardiogram (ECG) should be performed immediately. In cardiogenic shock caused by acute MI, the ECG most commonly shows ST elevation, but ST depression or nonspecific changes are found in 25% of cases. If RV infarction is suspected, ST elevation in modified right-sided leads may be diagnostic. The ECG may also provide information on previous MIs and rhythm abnormalities. A relatively normal ECG or one showing only diffuse, nonspecific changes in a patient with clinical cardiogenic shock should suggest myocarditis, especially if the patient has arrhythmias. In end-stage heart failure, the ECG may show Q waves and/or bundle branch block, indicative of extensive disease.

Other initial diagnostic tests include a chest radiograph, complete blood cell count, and measurement of arterial blood gases, electrolytes, and cardiac biomarkers. A high-quality chest film can assess signs of pulmonary edema and is helpful when signs suggest an alternative diagnosis, such as a widened mediastinum indicative of aortic dissection.

Echocardiography is an indispensable tool for confirming the diagnosis of cardiogenic shock and ruling out other causes of shock (Box 23.3) and should be performed as early as possible, preferably with color flow Doppler. Echocardiography provides information on overall and regional systolic function, and can rapidly diagnose mechanical causes of shock such as papillary muscle rupture and acute mitral regurgitation, acute ventricular septal defect, and free wall rupture and tamponade.[51,52] Unsuspected severe mitral regurgitation is not uncommon. In some cases, echocardiography may reveal findings compatible with RV infarction.

Diagnose right ventricular infarction

Invasive Hemodynamic Monitoring

If the history, physical examination, chest radiograph, and echocardiogram demonstrate systemic hypoperfusion, low cardiac output, and elevation of venous pressures, right heart catheterization may not be necessary for diagnosis. If there is any uncertainty, however, invasive hemodynamic monitoring can be quite useful to characterize the hemodynamics and to exclude volume depletion, RV infarction, and mechanical complications.[29,53] The hemodynamic profile of cardiogenic shock includes a PCWP greater than 15 mm Hg and a cardiac index less than 2.2 L/min per m^2.[2] It should be recognized that PCWP optimal filling pressures may be greater than 15 mm Hg in individual patients owing to LV diastolic dysfunction. Right heart catheterization may reveal an oxygen step-up diagnostic of ventricular septal rupture or a large V wave that suggests severe mitral regurgitation. RV infarction should be suspected when the PCWP is normal but right-sided filling pressures are notably elevated.[54,55]

Right heart catheterization is most useful, however, to optimize therapy in patients with cardiogenic shock. Clinical estimates of filling pressures can be unreliable, and changes in myocardial performance or therapeutic interventions can change cardiac output and filling pressures precipitously. These changes may occur after revascularization in the cardiac catheterization laboratory. Concomitant RV dysfunction is often underrecognized in patients with cardiogenic shock, and its importance underappreciated; right heart catheterization is the best and most expeditious way to assess right-sided hemodynamics in these patients. In the opinion of the authors, even if the diagnosis is not in question, in most patients undergoing left heart catheterization for cardiogenic shock, right heart catheterization should be performed and the catheter left in place, because of its utility in guiding subsequent therapy. Bedside right heart catheterization is another option.

Initial Management

Initial stabilization of the patient with suspected cardiogenic shock consists of venous access, supplemental oxygen, and continuous ECG monitoring. Many patients require intubation and mechanical ventilation, if only to reduce the work of breathing and facilitate

sedation and stabilization before cardiac catheterization. Central venous and arterial access, bladder catheterization, and pulse oximetry are routine. Electrolyte abnormalities should be corrected. Hypokalemia and hypomagnesemia are predisposing factors to ventricular arrhythmias, and acidosis can decrease contractile function. Relief of pain and anxiety with opiates can reduce excessive sympathetic activity and decrease oxygen demand, preload, and afterload. Atrial bradyarrhythmias and tachyarrhythmias and ventricular tachyarrhythmias may have major effects on cardiac output and should be corrected promptly with antiarrhythmic drugs, cardioversion, or pacing. Cardiology consultation has been shown to be associated with improved outcomes in patients with MI and is strongly indicated in the setting of cardiogenic shock.[56]

If the cause is likely an acute MI, aspirin and heparin should be given immediately. Some therapies routinely used in acute MI, such as nitrates, β-blockers, and angiotensin-converting enzyme inhibitors,[57] have the potential to exacerbate hypotension in cardiogenic shock and should be withheld until the patient's condition stabilizes.

An initial assessment of fluid status and systemic perfusion should be performed. Patients are commonly diaphoretic and relative hypovolemia may be present. In the original description of hemodynamic subsets in MI, approximately 20% of patients had low cardiac index and low PCWP; most had reduced stroke volume and compensatory tachycardia.[7] Some of these patients would be expected to respond to fluid infusion with an increase in stroke volume, although the magnitude of such a response depends on the degree of ischemia and cardiac reserve. Some patients may benefit from judicious fluid replacement with 100- to 200-mL fluid boluses titrated to clinical endpoints of heart rate, urine output, and blood pressure.[58] Ischemia produces diastolic as well as systolic dysfunction, and thus elevated filling pressures may be necessary to maintain stroke volume in patients with cardiogenic shock. Patients who do not respond rapidly to initial fluid boluses or those with poor physiologic reserve should be considered for invasive hemodynamic monitoring. Optimal filling pressures vary from patient to patient; hemodynamic monitoring can be used to construct a Starling curve at the bedside, identifying the filling pressure at which cardiac output is maximized. Maintenance of adequate preload is particularly important in patients with RV infarction.

Maintenance of adequate blood pressure is essential to break the vicious cycle of progressive hypotension and further myocardial ischemia. When arterial pressure remains inadequate, therapy with vasopressor agents, titrated not only to blood pressure but also to clinical indices of perfusion and mixed venous oxygen saturation, may be required to maintain coronary perfusion pressure. Norepinephrine is preferable to dopamine for hypotension in this situation. Dopamine acts as both an inotrope (particularly between 3 and 10 μg/kg per minute) and a vasopressor (10–20 μg/kg per minute). Norepinephrine (0.02–1.0 μg/kg per minute) acts primarily as a vasoconstrictor, has a mild inotropic effect, and increases coronary flow. A randomized trial comparing norepinephrine and dopamine in 1678 patients with shock found no significant difference in 28-day mortality in the overall trial, but a prespecified subgroup analysis did find increased mortality with dopamine in the 280 patients with cardiogenic shock.[59] More tachyarrhythmias were seen in the dopamine group in both the cardiogenic shock subset and the overall trial.[59] Phenylephrine, a selective α_1-adrenergic agonist, may support blood pressure when tachyarrhythmias limit therapy with other vasopressors, although it does not improve cardiac output and it is not especially potent. Vasopressin, which causes vasoconstriction, has a neutral or slightly depressant effect on cardiac output and increases vascular sensitivity to norepinephrine, may be added to catecholamines if needed.

Following initial stabilization and restoration of adequate blood pressure, tissue perfusion should be assessed (Fig. 23.4). If tissue perfusion remains inadequate, inotropic and/or mechanical support should be initiated. Dobutamine, a selective β_1-adrenergic receptor agonist, can improve myocardial contractility and increase cardiac output without markedly changing heart rate or SVR; it is the initial agent of choice in patients with systolic pressures greater than 90 mm Hg.[60–62] Dobutamine may exacerbate hypotension in some patients and can precipitate tachyarrhythmias. Phosphodiesterase inhibitors such as milrinone increase intracellular cyclic adenosine monophosphate by mechanisms not involving adrenergic receptors, producing both positive inotropic and vasodilatory actions. Milrinone has fewer chronotropic and arrhythmogenic effects than catecholamines.[63] In addition, because milrinone does not stimulate adrenergic receptors directly, its effects may be additive to those of the catecholamines.[64] Milrinone, however, has the potential to cause hypotension and has a long half-life; in patients with tenuous clinical status, its use is often reserved for situations in which other agents have proven ineffective.[29] The standard loading dose of milrinone should not be given in patients with marginal blood pressure, which usually describes patients with cardiogenic shock. Milrinone should be given by an infusion at a low dose and titrated according to the hemodynamic response.

Mechanical circulatory support should be considered in patients in whom pharmacotherapy has failed and is be discussed in a subsequent section.

Infusions of vasoactive agents need to be titrated carefully in patients with cardiogenic shock to maximize coronary perfusion pressure with the least possible increase in myocardial oxygen demand. Invasive hemodynamic monitoring can be extremely useful in allowing optimization of therapy in these unstable patients, because clinical estimates of filling pressure can be unreliable.[65] In addition, changes in myocardial performance and compliance and therapeutic interventions can change cardiac output and filling pressures precipitously. Optimization of filling pressures and serial measurements of cardiac output (and other parameters, such as mixed venous oxygen saturation) allow for titration of the dosage of inotropic agents and vasopressors to the minimum dosage required to achieve the chosen therapeutic goals. This can minimize the increases in myocardial oxygen demand and arrhythmogenic potential.[58,66] A hemodynamic assessment is mandatory in patients being considered for mechanical support.

Therapy

Fibrinolytic Therapy

Although fibrinolytic therapy reduces overall mortality rates in patients with acute MI,[13,67–69] the benefits of this therapy in patients with cardiogenic shock are less certain. Fibrinolytic therapy can reduce the likelihood of subsequent development of shock after initial presentation, but no trials have demonstrated that thrombolytic therapy reduces mortality in patients with established cardiogenic shock.[15,17,69] Rates of reperfusion are lower, suggesting reduced efficacy of lytics in this situation.[24,70] The reasons for decreased fibrinolytic efficacy in patients with cardiogenic shock include hemodynamic, mechanical, and metabolic factors. Decreased arterial pressure limits the penetration of fibrinolytic agents into a thrombus.[71] Passive collapse of the infarct artery in the setting

of hypotension can also contribute to decreased fibrinolytic efficacy, as can acidosis, which inhibits the conversion of plasminogen to plasmin.[71]

Intraaortic Balloon Pumping

An intraaortic balloon pump (IABP) reduces systolic afterload and augments diastolic perfusion pressure without increasing oxygen demand.[72,73] IABPs do not, however, produce a significant improvement in blood flow distal to a critical coronary stenosis.[74] IABPs are thus probably not sufficiently effective to be used as an independent modality to treat cardiogenic shock but may support patients through a critical period of shock, while definitive therapy is undertaken.

Despite a convincing hemodynamic rationale for their use, randomized trials have failed to show improvement in 30-day mortality with IABP insertion in patients with cardiogenic shock undergoing early revascularization. The IABP-SHOCK trial randomly assigned 45 patients with an acute MI and cardiogenic shock to IABP + PCI versus PCI alone; it was not powered for mortality benefit, but did not show either a decrease in mortality or a significant improvement in multiorgan dysfunction score with the addition of IABP counterpulsation to standard therapy.[75] The IABP-SHOCK II study, a much larger prospective, randomized, open-label, multicenter trial enrolling 600 patients with cardiogenic shock complicating acute MI, randomly assigned patients to an IABP group or a non-IABP group. There was no significant difference in the primary endpoint of 30-day all-cause mortality (39.7% vs. 41.3%, $P = 0.69$), nor was there a significant difference in any of the subgroups in exploratory analyses. Secondary safety endpoints such as major bleeding, peripheral ischemic complications, sepsis, and stroke, did not differ between the two groups.[76] Some randomly assigned patients received an IABP when they were hemodynamically stable and might not have been expected to derive great benefit, and 10% of patients in the control group crossed over to IABP therapy.[76]

Although the IABP-SHOCK II has dampened enthusiasm for the routine use of IABP, these trial results may not be applicable to all patients. Because of its widespread availability, safety, lower cost compared with other support devices, and ease of placement in many health care facilities, the opinion of the authors is that it is reasonable to use IABP counterpulsation as adjunctive therapy in cardiogenic shock, an opinion consistent with the class IIa recommendation for insertion of an IABP for patients with hemodynamic instability in the American College of Cardiologists/American Heart Association guidelines.[77] Whether its use for this indication will be superseded by other mechanical circulatory support devices remains to be seen.

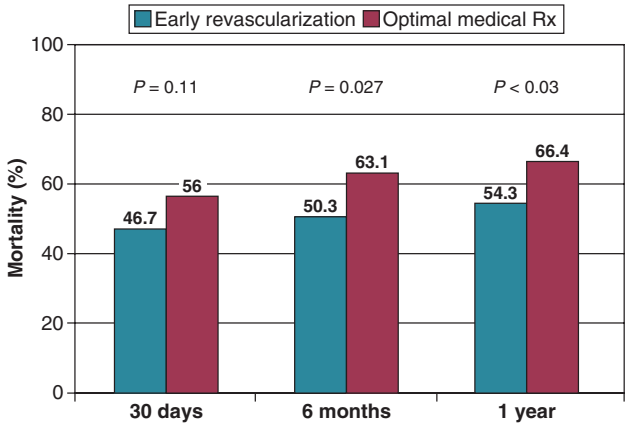
Revascularization

Supportive therapy may improve blood pressure and cardiac output in cardiogenic shock, but it does not interrupt the vicious circle of myocardial dysfunction and ischemia. Emergency percutaneous revascularization is the only intervention to date that has been shown to consistently reduce mortality rates in patients with cardiogenic shock.

Reestablishment of brisk (Thrombolysis in Myocardial Infarction [TIMI] grade 3) flow in the infarct-related artery is an important determinant of LV function and survival after MI.[70] In addition to improving wall motion in the infarct territory, increased perfusion of the infarct zone has been associated with augmented contraction of remote myocardium, possibly owing to recruitment of collateral blood flow.[25] After observational reported improved outcomes in patients with cardiogenic shock selected for revascularization,[17,78–80] a randomized trial was conducted, funded by the National Institutes of Health.

The landmark SHOCK study[81,82] was a randomized, multicenter international trial that assigned patients with cardiogenic shock to receive optimal medical management—including IABP and thrombolytic therapy—or to cardiac catheterization with revascularization using cutaneous transluminal coronary angioplasty or CABG.[81] The trial enrolled 302 patients and was powered to detect a 20% absolute decrease in 30-day all-cause mortality rates. Mortality at 30 days was 46.7% in patients treated with early intervention and 56% in patients treated with initial medical stabilization, but this difference did not quite reach statistical significance ($P = 0.11$).[81] It is important to note that the control group (patients who received medical management) had a lower mortality rate than that reported in previous studies; this may reflect the aggressive use of thrombolytic therapy (64%) and IABP (86%) in these controls. At 6 months, mortality with early intervention in the SHOCK trial was reduced significantly (50.3% compared with 63.1%, $P = 0.027$),[81] and this risk reduction was maintained at 12 months (mortality 53.3% vs. 66.4%, $P < 0.03$) (Fig. 23.5).[82] Encouragingly, this 13% absolute improvement in survival remained stable at both 3 and 6 years of follow-up.[83] In addition, most survivors had good functional status.[84]

Subgroup analysis showed a substantial improvement in mortality rates in patients younger than 75 years of age at both 30 days (41.4% vs. 56.8%, $P = 0.01$) and 6 months (44.9% vs. 65.0%, $P = 0.003$).[81] For patients older than 75 years, no benefit of revascularization was demonstrated in the SHOCK trial, although this was a small subgroup, and further analysis suggested baseline differences so that the elderly patients randomly assigned to medical therapy appeared to have been a lower-risk group.[85] In the SHOCK trial registry, elderly patients treated with early revascularization had better outcomes than those treated medically, suggesting that



• **Fig. 23.5** Mortality in the randomized SHOCK trial at 30 days, 6 months, and 1 year in the early revascularization and optimal medical management groups. (Data from Hochman JS, Sleeper LA, Webb JG, et al. Early revascularization in acute myocardial infarction complicated by cardiogenic shock. SHOCK Investigators. Should we emergently revascularize occluded coronaries for cardiogenic shock. *N Engl J Med* 1999;341:625–634; and Hochman JS, Sleeper LA, White HD, et al. One-year survival following early revascularization for cardiogenic shock. *JAMA* 2001;285:190–192.)

it is possible to select elderly patients who will benefit from aggressive treatment.[86]

When the results of the SHOCK trial are put into perspective with results from other randomized, controlled trials of patients with acute MI, an important point emerges: despite the moderate *relative* risk reduction (for the SHOCK trial 0.72, confidence interval 0.54–0.95) the *absolute* benefit is substantial, with 9 lives saved for 100 patients treated at 30 days, and 13.2 lives saved for 100 patients treated at 1 year. This latter figure corresponds to a number needed to treat of 7.6, one of the lowest figures ever observed in a randomized, controlled trial of cardiovascular disease (see Fig. 23.4). In the latest American College of Cardiology/American Heart Association guidelines for the management of acute MI, primary coronary intervention was given a class I indication for patients younger than 75 years and a class IIa indication for patients older than 75 years.[77]

Coronary Artery Bypass Surgery

Analysis of the SHOCK trial helps to define the indications for CABG in the setting of cardiogenic shock. CABG should be the first line of therapy offered in cases of left main disease or triple-vessel disease as well as when the patient has sustained mechanical complications necessitating surgical repair. In patients with multivessel disease in the SHOCK trial, complete revascularization was achieved more frequently (87% vs. 23%). Long-term mortality rates were similar in the CABG and PCI groups despite worse coronary anatomy and more diabetes in the surgical group.[87]

Other Causes of Cardiogenic Shock

Right Ventricular Infarction

RV infarction occurs in up to 30% of patients with inferior infarction and is clinically significant in 10%.[88] Patients present with hypotension, elevated neck veins, and clear lung fields. The diagnosis is made by identifying ST-segment elevation in right precordial leads or by characteristic hemodynamic findings on right heart catheterization (elevated right atrial and RV end-diastolic pressures with normal to low pulmonary artery occlusion pressure and low cardiac output). Echocardiography can demonstrate depressed RV contractility.[55] Patients with cardiogenic shock on the basis of RV infarction have a better prognosis than those with left-sided pump failure.[88] This may be due in part to the fact that RV function tends to return to normal over time with supportive therapy,[89] although such therapy may need to be prolonged.

Supportive therapy for patients with RV infarction begins with maintenance of RV preload with fluid administration. In some cases, however, fluid resuscitation may increase pulmonary capillary occlusion pressure but may not increase cardiac output, and overdilation of the right ventricle can compromise LV filling and cardiac output.[89] Inotropic therapy with dobutamine may be more effective in increasing cardiac output in some patients, and monitoring with serial echocardiograms may also be useful to detect RV overdistention.[89] Maintenance of atrioventricular synchrony is also important in these patients to optimize RV filling.[55] For patients with continued hemodynamic instability, an IABP may be considered, because elevated RV pressures and volumes increase wall stress and oxygen consumption and decrease right coronary perfusion pressure, exacerbating RV ischemia. Percutaneous axial flow pumps are now available that can provide temporary RV support, an attractive option given the potential for recovery of RV function. The small prospective RECOVER RIGHT trial has shown improved hemodynamics, with increased cardiac output and decreased central venous pressure with use of the Impella RP device (Abiomed, Danvers, MA).[90] There was no comparison group, and only 5 of 30 patients had acute MI, but outcomes with support were good and could be argued to have been better than expected.[90]

Acute Mitral Regurgitation

Ischemic mitral regurgitation is usually associated with inferior MI and ischemia or infarction of the posterior papillary muscle, which has a single blood supply, usually from the posterior descending branch of a dominant right coronary artery.[91] Papillary muscle rupture typically occurs 2 to 7 days after acute MI and presents dramatically with pulmonary edema, hypotension, and cardiogenic shock. When a papillary muscle ruptures, the murmur of acute mitral regurgitation may be limited to early systole because of rapid equalization of pressures in the left atrium and left ventricle. More importantly, the murmur may be soft or inaudible, especially when cardiac output is low.[92]

Echocardiography is extremely useful in the differential diagnosis, which includes free wall rupture, ventricular septal rupture, and infarct extension with pump failure. Hemodynamic monitoring with pulmonary artery catheterization may also be helpful. Management includes afterload reduction with nitroprusside and an IABP as temporizing measures. Inotropic or vasopressor therapy may also be needed to support cardiac output and blood pressure. Definitive therapy, however, is surgical valve repair or replacement, which should be undertaken as soon as possible since clinical deterioration can be sudden.[92,93] Although mortality is substantial, ranging from 20% to 40%, surgical results are improving,[94] and survival and ventricular function are improved compared with medical therapy.[94,95]

Ventricular Septal Rupture

Patients with ventricular septal rupture have severe heart failure or cardiogenic shock, with a pansystolic murmur and a parasternal thrill. The hallmark finding is a left-to-right intracardiac shunt (a step-up in oxygen saturation from right atrium to right ventricle). On pulmonary artery catheter tracing, it can be difficult to distinguish ventricular septal rupture from mitral regurgitation, because both can produce dramatic V waves. The diagnosis is most easily made with echocardiography.

Rapid stabilization—using intraaortic balloon pumping and pharmacologic measures followed by operative repair—is the only viable option for long-term survival. Because perforations are exposed to shear forces, the rupture site can expand abruptly. Repair can be technically difficult owing to the need to suture in areas of necrosis. Surgical mortality is 20% to 50%, especially for serpiginous inferoposterior ruptures, which typically are less well circumscribed than anteroapical ruptures.[96] RV function is an important determinant of outcome in this setting. Timing of surgery has been controversial, but guidelines now recommend that operative repair should be undertaken early: within 48 hours of the rupture.[97] Placement of a septal occluding device may be helpful in selected patients.

Free Wall Rupture

Ventricular free wall rupture usually occurs during the first week after MI; the classic patient is elderly, female, and hypertensive. The early use of thrombolytic therapy reduces the incidence of cardiac

rupture, but late use may increase the risk, particularly in older patients.[98] Free wall rupture presents as a catastrophic event with a pulseless rhythm. Salvage is possible with prompt recognition, pericardiocentesis to relieve acute tamponade, and thoracotomy with repair.[99]

Myocardial Dysfunction After Cardiopulmonary Bypass

Transient depression of ventricular contractility is common after CPB and can represent a significant clinical problem. The differential diagnosis includes inadequate operation, cardiac tamponade (which may be localized and difficult to detect), and increased RV afterload, but most cases likely result from myocardial stunning. The heart is rendered globally ischemic during aortic cross-clamping and then reperfused, and because demonstrable myocardial necrosis is rare, stunning can be implicated. Stunning after bypass has been documented in a study in which an ultrasonic probe was left on the epicardial surface for 2 to 3 days in 31 patients after bypass surgery; LV wall thickening fell after surgery, reached a nadir at 2 to 6 hours, and subsequently improved, usually returning to baseline by 24 to 48 hours.[100]

The degree of myocardial dysfunction after cardiac surgery is variable and may depend on the cardioplegia solution, the method of administration (antegrade or retrograde), the mode of administration (continuous or intermittent), and the temperature of the solution and of the patient during surgery.[43] In the clinical setting, transient depression of ventricular contractility is common and usually reversible within 24 to 48 hours. The depression of contractility can be severe enough to cause cardiogenic shock. In this event, therapy with inotropic agents, vasodilators, and intra-aortic balloon pumping is necessary. Occasionally, even a LV assist device may be used.[101] Better understanding of the mechanisms of post-CPB myocardial dysfunction may lead to better preventive and therapeutic approaches.

Myocarditis

Acute myocarditis can be benign and self-limited, or fulminant, with severe congestive heart failure and/or atrial and ventricular arrhythmias. Fulminant myocarditis presents with sudden onset of heart failure and can be severe enough to cause life-threatening shock. LV dysfunction is diffuse and severe, but unlike other causes of cardiomyopathy, the ventricle may not be dilated and thinned but rather thick and not dilated. Failure to dilate in the face of a low ejection fraction leads to low stroke volume. Fulminant myocarditis is a clinical rather than a histologic or etiologic diagnosis, but has classically been considered as an idiopathic lymphocytic myocarditis. In addition to clinical presentation and diffuse myocardial hypokinesis, typical patterns of late gadolinium enhancement on magnetic resonance imaging may be deemed sufficient to make the diagnosis of myocarditis.

Recent European guidelines have proposed a more granular classification of myocarditis into three broad categories: infectious, immune-mediated, and toxic/idiopathic.[102] The distinction would be made by biopsy, with viral antibodies defining infectious myocarditis, cardiac autoantibodies, or definition of an inflammatory process such as sarcoidosis in the absence of viral antibodies (thus indicating immune-mediated myocarditis), and absence of both denoting toxic/idiopathic myocarditis.[102] The question is whether the therapeutic implications of such a distinction would be sufficient to warrant myocardial biopsy. These guidelines propose consideration of antiviral and/or immunoglobulin therapy for viral myocarditis, and immunoabsorption, immunosuppressive and/or immunoglobulin therapy for immune-mediated myocarditis, but clinical trial data are limited.

Evidence exists that some patients with myocarditis benefit from immunosuppressive therapy, but the identification of which patients should be treated remains controversial. A trial initiated at the National Institutes of Health randomly assigned 102 patients with chronic dilated cardiomyopathy and ejection fraction less than 35% to receive oral prednisone or placebo.[103] The prospectively defined endpoint, an increase in radionuclide-measured ejection fraction of more than 5 percentage points, was observed in 53% of patients treated with prednisone compared with only 27% of controls at 3 months ($P < 0.05$), but the improvement did not persist at 9 months when patients were switched to alternate-day prednisone therapy.[103] Another single-center study of 85 patients with virus-negative inflammatory cardiomyopathy showed significant improvement of ejection fraction at 6 months in patients randomly assigned to immunosuppression and no improvement in those randomly assigned to placebo.[104] A randomized trial comparing intravenous immunoglobulin with placebo in patients with new-onset myocarditis, however, showed improvement of LV function in both groups to the same extent.[105]

Although it might seem that patients with fulminant myocarditis might be the best candidates for immunosuppressive therapy, the largest series confounds this notion by reporting excellent long-term survival in patients with myocarditis and a fulminant course.[106] An exception is patients with giant cell myocarditis, a rare inflammatory cardiomyopathy that usually presents in young adults, often with conduction abnormalities or arrhythmias in addition to heart failure, and for which immunosuppression is indicated, despite which outcomes are much worse than for other forms of myocarditis.[107]

Patients with fulminant myocarditis might be considered to have a more compelling rationale for myocardial biopsy than patients with more subacute presentations, particularly if information about potential infection or immune-mediated causes can be obtained from the biopsy. Further investigation is needed to identify subgroups of patients with myocarditis who might benefit from adjunctive therapies.

Mechanical Support

Mechanical circulatory support devices have the potential to interrupt the downward spiral of myocardial dysfunction, hypoperfusion, and ischemia in cardiogenic shock, allowing time for recovery of stunned or hibernating myocardium. These devices, to different extents, provide circulatory support, increasing mean arterial pressure, ventricular support, reducing LV filling pressures and afterload, and support coronary perfusion, increasing coronary perfusion pressure.

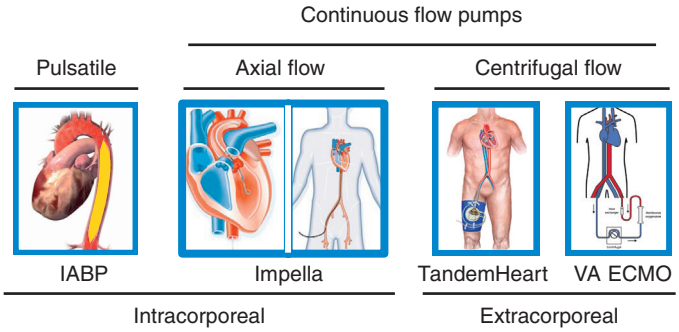
Four acute mechanical circulatory support platforms are currently available: IABP, centrifugally driven left atrial-to-femoral artery bypass (TandemHeart, Cardiac Assist, Pittsburgh, PA), centrifugally driven venoarterial extracorporeal membrane oxygenation (ECMO), and microaxial flow catheters (Impella) (Fig. 23.6). Percutaneously implanted mechanical support can be used in situations of cardiogenic shock, during high-risk percutaneous interventions, in postcardiotomy shock, and in fulminant myocarditis.

The IABP provides counterpulsation, increasing diastolic coronary perfusion pressure and decreasing afterload in systole. Counterpulsation requires pulsation, and so augmentation of cardiac

output in situations such as cardiogenic shock may be minimal, on the order of 0.5 L/min.[108]

The TandemHeart device is a bypass system with inflow of oxygenated blood from the left atrium via a transseptal catheter and outflow to the femoral artery using a centrifugal flow pump; it can increase cardiac output up to 5 L/min, depending on the size of the tubing and on left atrial volume. The TandemHeart reduces LV preload by removing blood from the left atrium but increases LV afterload because blood is returned to the aorta.[109] Since oxygenated blood is removed from the left atrium, no oxygenator is required.

ECMO provides cardiopulmonary support for both the heart and lungs and can either be venovenous or venoarterial (VA), but for patients with cardiogenic shock VA ECMO is used. ECMO involves a venous inflow catheter, a centrifugal pump, a membrane oxygenator, and an arterial return catheter. VA ECMO reduces RV and LV preload, increases blood pressure, and can provide a cardiac output up to 6 L/min.[109] VA ECMO increases LV afterload, and depending on native LV function and aortic valve disease, the LV may not eject through the AV during systole; in this case VA ECMO may increase LV diastolic pressure. Venting of the LV, using either a left atrial catheter or another assist device, may sometimes be used in this circumstance.[109]

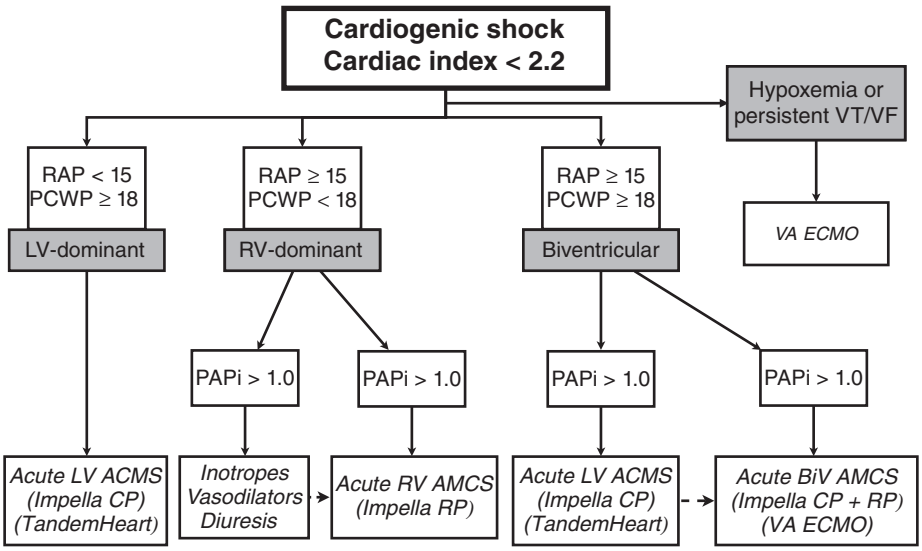


• **Fig. 23.6** Acute mechanical circulatory support devices for cardiogenic shock, classified by the type of pump and whether they are intracorporeal or extracorporeal. *ECMO,* Extracorporeal membrane oxygenation; *IABP,* intraaortic balloon pump. (Modified from Kapur NK, Esposito ML. Door to unload: a new paradigm for the management of cardiogenic shock. *Curr Cardiovasc Risk Rep.* 2016;10:41, with permission.)

The Impella device is a nonpulsatile axial flow catheter inserted retrograde across the aortic valve that pumps blood from a distal port from within the ventricle out to the ascending aorta through a proximal port of the device; there are several versions, one 12F device capable of pumping 2.5 L/min (Impella 2.5), a 21F device that can provide up to 5 L/min (Impella 5.0), and now a 14F device that can provide 3 to 4 L/min (Impella CP), although the actual flow is dependent on afterload. Impella activation increases mean arterial pressure, reduces LV diastolic pressure, increases myocardial perfusion pressure, and increases cardiac output, while decreasing myocardial oxygen demand.[109] These devices do require adequate RV function. A new device, the Impella RP, is an axial flow pump specifically designed to provide RV support by pumping blood from the right atrium into the pulmonary artery.

Two trials have compared the use of IABP to the TandemHeart for patients with cardiogenic shock,[108,110] and another compared use of the Impella to IABP therapy[111]; the results of these trials were combined in a meta-analysis that included 100 patients.[112] Hemodynamic benefits for the percutaneous LVADs compared with IABP were shown, with higher cardiac indices and mean arterial pressures as well as lower PCWPs. However, LVAD use showed no mortality benefit over IABP at 30 days.[112]

One of the key issues in choosing among mechanical support options is the function of the right ventricle. A recently proposed algorithm for acute mechanical support bases the choice on hemodynamic parameters (Fig. 23.7). Patients are divided into LV-dominant, RV-dominant, and biventricular cardiogenic shock. Among the patients with biventricular cardiogenic shock, further stratification is done using the pulmonary artery pulsatility index (PAPi), which is the pulmonary artery pulse pressure (a reflection of right-sided stroke volume) divided by RA pressure. Those with low PAPi might be considered for initial biventricular support.[113]



• **Fig. 23.7** Proposed algorithm for selection of acute mechanical support devices in patients with cardiogenic shock and low cardiac output. *ACMS,* Acute mechanical circulatory support; *LV,* left ventricle; *PAPi,* pulmonary artery pulsatility index; *PCWP,* pulmonary capillary wedge pressure; *RA,* right atrium; *RV,* right ventricle; *VA ECMO,* ventriculoarterial extracorporeal membrane oxygenation. (Modified from Kapur NK, Esposito ML. Door to unload: a new paradigm for the management of cardiogenic shock. *Curr Cardiovasc Risk Rep* 2016;10:41.)

The LV rarely fails alone for long, and assessment of RV hemodynamics with invasive hemodynamic monitoring is important to optimize mechanical support strategies.

For patients with end-stage heart failure and refractory shock, a variety of surgically placed assist devices can be used for circulatory support. These devices retrieve blood from the LV apex and use a pumping device, either continuous or pulsatile, to return the blood into the ascending aorta. Full consideration of these devices is beyond the scope of this chapter; in cardiogenic shock, they are usually used as a bridge to recovery or transplantation, although in other contexts they may be used as destination therapy.

Conclusion

Cardiogenic shock remains a prevalent and dangerous syndrome that requires accurate and efficient diagnosis. Mortality rates in patients with cardiogenic shock have improved but remain frustratingly high. Its pathophysiology involves a downward spiral in which ischemia causes myocardial dysfunction, which in turn worsens ischemia. Areas of nonfunctional but viable myocardium can also cause or contribute to the development of cardiogenic shock. Expeditious coronary revascularization is crucial, and the randomized multicenter SHOCK trial[81] has provided important data that help clarify the appropriate role and timing of revascularization in patients with cardiogenic shock. The potential for reversal of myocardial dysfunction with revascularization provides the rationale for supportive therapy to maintain coronary and tissue perfusion until more definitive revascularization measures can be undertaken. Application of a thorough understanding of the essentials of pathophysiology, diagnosis, and treatment of cardiogenic shock can allow for expeditious management and improved outcomes.

Key Points

- Cardiogenic shock is a state of inadequate tissue perfusion caused by cardiac dysfunction. Acute MI is the leading cause.
- The pathogenesis of cardiogenic shock is a downward spiral in which MI or ischemia causes myocardial dysfunction and compromised myocardial perfusion, exacerbating ischemia.
- Large areas of nonfunctional but viable myocardium (either stunned, hibernating, or both) can also cause or contribute to the development of cardiogenic shock in patients after MI.
- The challenge in initial management of cardiogenic shock is that evaluation and therapy must begin simultaneously. The clinician must perform the clinical assessment required to understand the cause of shock while initiating supportive therapy before shock causes irreversible damages.
- Pathophysiologic considerations and extensive retrospective data favor aggressive mechanical revascularization for patients with cardiogenic shock caused by MI. Clinical trials support a strategy of early revascularization in most patients with cardiogenic shock.
- Other acute mechanical causes of low cardiac output must be excluded. If present, urgent surgery may be required.
- In patients with potentially reversible causes of myocardial dysfunction (including severe myocarditis), optimization of hemodynamics with a combination of inotropic agents and mechanical circulatory support may be required for hours or days to allow sufficient time for recovery.

Review Questions

1. Which of the following describes Killip Class IV after myocardial infarction?
- **a.** Presence of an S_3 gallop and/or bibasilar rales
- **b.** Pulmonary edema (rales greater than halfway up the lung fields)
- **c.** Clear lungs with hypotension
- **d.** Pulmonary edema with hypotension

Answer: d. The Killip classification outlines prognosis after myocardial infarction by clinical presentation. The degree of heart failure was used to distinguish class II (S_3 gallop and/or bibasilar rales) from class III (pulmonary edema with rales more than half way up). Cardiogenic shock, defined as pulmonary edema with hypotension and decreased perfusion, was class IV, and had the highest mortality.

2. When should beta-blockers not be used initially in patients with acute myocardial infarction?
- **a.** Ejection fraction 40%
- **b.** Heart rate 65
- **c.** Blood pressure 105/60 mm Hg
- **d.** Pulmonary edema and heart rate 110 beats/min
- **e.** β-Blockers can be given in all of these situations

Answer: d. In patients with myocardial infarction and pulmonary edema, β-blockers can worsen heart failure and may precipitate hypotension, potentially inducing cardiogenic shock. Their use should be withheld until clinical stabilization is achieved. Left ventricular dysfunction alone is not a reason to withhold β-blockers, nor is a heart rate greater than 60 beats/min or systolic blood pressure greater than 100 mm Hg. After acute heart failure has resolved, initiation of β-blockade should be attempted.

3. Which of the findings on right heart catheterization is most consistent with acute ventricular septal rupture?
- **a.** Prominent V waves in the right atrial tracing
- **b.** Elevation and equalization of cardiac diastolic pressures
- **c.** Increased right heart pressure and decreased left heart pressure with respiration
- **d.** Oxygen step-up from right atrium to pulmonary artery

Answer: d. The hallmark finding on right heart catheterization in patients with ventricular septal rupture is a left-to-right intracardiac shunt, which is identified as an oxygen step-up in the right-sided circulation (i.e., oxygen saturation increases before the blood gets to the lungs). Prominent V waves in the right atrial tracing are suggestive of tricuspid regurgitation. Elevation and equalization of cardiac diastolic pressures suggest cardiac tamponade, which might occur in ventricular free wall rupture. Increased right heart pressure and decreased left heart pressure with respiration (Kussmaul sign) can occur during cardiac tamponade or constrictive pericarditis.

Severe Sepsis and Septic Shock

R. PHILLIP DELLINGER, AVIRAL ROY, AND JOSEPH E. PARRILLO

CHAPTER OUTLINE

Historical Perspective and Introduction

Definitions

Epidemiology

Pathogenesis and Pathophysiology of Severe Sepsis and Septic Shock
- Role of the Immune System
- Role of Inflammation
- Alterations in Hemostasis
- Microcirculatory and Mitochondrial Dysfunction
- Multiple Organ Dysfunction

Clinical Presentation

Cardiovascular Profile of Septic Shock
- Hypovolemia and Decreased Cardiac Filling
- Myocardial Dysfunction
- Vasodilation

Management of Severe Sepsis and Septic Shock
- Overview and Management Guidelines
- General Principles
- Antibiotic Therapy and Source Control
- Supportive Therapies
- Glucose Control
- Prophylaxis for Deep Vein Thrombosis and Stress Ulcers
- Nutrition
- Early Resuscitation and Hemodynamic Optimization
- Fluid Resuscitation
- Vasopressor Therapy
- Individual Vasoactive Agents
- Inotropic Support
- Corticosteroids
- Modulation of the Host Response

Summary

Historical Perspective and Introduction

Sepsis is a derivation of the Greek word "sepsin," which means to putrefy or "to make putrid." Sepsis was synonymous with putrefaction and pertained to the bacteria-mediated decomposition of organic matter.[1] The word was used almost unchanged for about 2700 years.[2]

The term *shock* comes from the French word "choquer," meaning "to collide with." This is particularly appropriate terminology for shock caused by sepsis, given our modern understanding of the sepsis pathophysiology, whereby the body's host defenses essentially collide with the invading microorganism, triggering a profound proinflammatory host response.

The relationship between an infection and sepsis has been well studied and recognized for many years; however, the precise mechanisms by which an infection results in organ dysfunction distant to the site of the infection continue to be unraveled. Infection-induced organ dysfunction and tissue hypoperfusion are among the deadliest of conditions known with a mortality rate of 25% to 30%.[3] The discussion in this chapter encompasses pathophysiology, assessment, hemodynamics, and management of infection-induced organ dysfunction and tissue hypoperfusion (hypotension, lactic acidosis, and oliguria). The focus is on adult patients.

Definitions

To standardize the definitions for both diagnosis and help guide future research, the Society of Critical Care Medicine (SCCM) and the American College of Chest Physicians (ACCP) published definitions for systemic inflammatory response syndrome, sepsis, severe sepsis, and septic shock in 1992.[4] These definitions were revisited in 2001 and no evidence was found to update these definitions with the exception of expanding the criteria for systemic manifestations of infection.[5] The Third International Consensus conference on sepsis definitions met in 2015 and published the proposed new definitions in 2016.[6] These proposed new definitions remain controversial and have not found widespread acceptance in the critical care community. In the 1992 consensus definitions, sepsis was defined as infection with two or more systemic inflammatory response syndrome (SIRS) criteria (abnormalities in temperature, respiratory rate, heart rate and white blood cell count). Severe sepsis was defined as infection-induced organ dysfunction or tissue hypoperfusion and septic shock as hypotension persisting despite reestablishing adequate intravascular volume. The second consensus conference in 2001 expanded the systemic manifestations of sepsis beyond the SIRS criteria and also included other laboratory perturbations and biomarkers as well as organ dysfunctions themselves as potential systemic manifestations of sepsis (Box 24.1). No single parameter or set of clinical or laboratory parameters has yet been shown to have high sensitivity or specificity to diagnose sepsis. The definitions of sepsis and severe sepsis remained unchanged with the 2001 document. A more refined definition for septic shock was also proposed: hypotension with a systolic blood pressure less than 90 mm Hg or a mean arterial blood pressure (MAP) less than 70 mm Hg, despite adequate fluid resuscitation.

• BOX 24.1 Diagnostic Criteria for Sepsis

Infection, documented or suspected, plus some of the following findings:
- Temperature >38.3°C or >36°C
- Heart rate >90 beats/min or >2 SD above normal value for age
- Arterial hypotension (SBP <90 mm Hg, MAP <70, or an SBP decrease >40 in adults or <SD below normal for age)
- Mixed venous oxygen saturation (Sv_{O_2}) >70%
- Cardiac index >3.5 L/min per m^2
- Tachypnea
- Decreased capillary refill or mottling
- Altered mental status
- Significant edema or positive fluid balances
- Hyperglycemia in the absence of diabetes
- WBC count >12,000 μL or <4000 μL
- Normal WBC with >10% immature forms
- Plasma C-reactive protein >2 SD above the normal value
- Plasma procalcitonin >SD above the normal value
- Hyperlactatemia (>1 mmol/L)
- Evidence of organ dysfunction:
- Arterial hypoxemia ($Pa_{O_2}/F_{I_{O_2}}$ <300)
- Acute oliguria
- Creatinine increase >0.5 mg/dL
- Coagulation abnormalities (INR >1.5 or a PTT >60 s)
- Ileus
- Thrombocytopenia
- Hyperbilirubinemia

$F_{I_{O_2}}$, *Fraction of inspired oxygen;* INR, *international normalized ratio;* MAP, *mean arterial pressure;* Pa_{O_2}, *partial pressure of arterial oxygen;* PTT, *partial thromboplastin time;* SBP, *systolic blood pressure;* SD, *standard deviation;* Sv_{O_2}, *mixed venous oxygen saturation;* WBC, *white blood cell.*

TABLE 24.1 Current Definitions of Sepsis

Condition	Criteria
Systemic inflammatory response	Systemic manifestations of infection to include two or more of the traditional SIRS criteria below in addition to any systemic perturbation that might be caused by sepsis and has no other explainable cause such as hypoglycemia, elevation in CRP or PCT, or organ dysfunction SIRS criteria • White blood cell count >12,000/mm^3 or <4000/mm^3 or >10% immature bands. • Respiratory rate >20 or $PaCO_2$ <32 mm Hg • Core body temperature >38°C (100.4°F) or <36°C (96.8°F) • Heart rate >90 beats/min
Sepsis	Systemic inflammatory response + suspected or known source of infection
Severe sepsis	Sepsis and any of the following: organ dysfunction, hypotension, tissue hypoperfusion (lactic acidosis, oliguria, altered mental status)
Septic shock	Sepsis + systolic blood pressure <90 mm Hg despite adequate volume resuscitation (i.e., requiring vasopressors) along with signs of tissue hypoperfusion

SIRS, Systemic inflammatory response syndrome.

The third consensus conference in 2015 proposed redefining of sepsis terminology and for the first time used several large databases to assist in that redefining. The committee recommended abandoning the term *severe sepsis* and using *sepsis* to describe infection-induced organ dysfunction or tissue hypoperfusion. Since the 1991 consensus document, sepsis had been used to define infection with systemic manifestations of infection. Some called this "simple sepsis" as contrasted to severe sepsis. The document also recommended de-emphasizing the SIRS criteria. What was previously called *sepsis* (infection plus systemic manifestations of infection) would now simply be called *infection* with no differentiation between infection with or without systemic manifestation of infection. A SOFA score of 2 points or more was identified as being associated with increased mortality at the time of diagnosis of infection and initiation of antibiotics. Septic shock was proposed to be defined as vasopressor requirement to maintain a MAP of 65 mm Hg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia after intravascular volume repletion. These proposed new definitions have received mixed reviews, endorsed by some scientific groups and not by others and currently have no impact on International Classification of Diseases codes or Centers for Medicare and Medicaid Services quality metrics, both of which continue to use the 1991 definitions. The eventual outcome regarding the use of these proposed new definitions is unclear. The most widely accepted definitions are as shown in Table 24.1 and represent the 2001 definitions. The proposed new definitions are as shown in Table 24.2. This chapter uses the 1992/2001 definitions.

Epidemiology

Severe sepsis and septic shock continue to be a source of major morbidity and mortality worldwide. With treatment costs of about $50,000 (U.S. dollars) per patient 650,000 to 750,000 cases a year, and a mortality rate of 20% to 40%, severe sepsis and septic shock rank among the most common causes of mortality and greatest cost of illness in adults in the world. Although mortality from sepsis-related diseases has been decreasing worldwide, there has been an increase in overall rates of sepsis-related entities.[7–11] Multiple large observational studies have demonstrated an increasing overall incidence of severe sepsis with a related decrease in mortality. There has also been an overall increase in the mean age of patients admitted with severe sepsis/septic shock. The patients being admitted to the hospital also are sicker with an increased incidence of multiorgan failure and mortality among the more severe groups.[10] The increase may be attributed to increased life span, increasing use of immunosuppressive medications, use of intravascular devices and implants, and the increasing incidence and burden of chronic disease. There is a slightly higher rate for men than for women who contract sepsis-related conditions, and African American and Hispanic populations have roughly double the rate of severe sepsis as compared with the Caucasian population in the United States. The causative organisms have also gradually shifted from primarily gram-negative to primarily gram-positive organisms with an increase in rates of fungal infections. This is due in part to the increasing

TABLE 24.2 Proposed New Definitions of Sepsis

Term	Definition	Criteria	Notes
Sepsis[a] (previously severe sepsis)	Life-threatening organ dysfunction caused by a dysregulated host response to infection	Organ dysfunction is identified as an acute change in the SOFA score ≥2 points from the baseline consequent to the infection	qSOFA (quick Sequential Organ Failure Assessment) Prolonged ICU stay or in-hospital mortality can be identified at the bedside with the qSOFA 1. Respiratory rate ≥22 breaths/min 2. Acute mental status change 3. Systolic blood pressure ≤100 mm Hg An increase in SOFA of ≥2 predicts a 10% mortality in the general hospital population Presume a baseline SOFA of 0 unless the patient has known (acute or chronic) organ dysfunction before the onset of infection
Septic shock	It is a subset of sepsis in which the underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality	A clinical construct of sepsis with persisting hypotension requiring vasopressors to maintain an MAP ≥65 mm Hg and having a serum lactate level ≥2 mmol/L despite adequate volume resuscitation	Septic shock portends a hospital mortality in excess of 40%

[a]Note that the proposed new definitions abandon the previous term "severe sepsis" to describe infection-induced organ dysfunction and now use "sepsis" to describe infection-induced organ dysfunction. The previous condition called "sepsis" is now just called "infection," and when infection is not associated with organ dysfunction, there is no differentiation between infection with or without systemic manifestations.
MAP, Mean arterial pressure.

use of long-term intravascular access catheters and increasing use of prosthetic hardware and devices, such as pacemakers and internal defibrillators. The more common sites of infection include the respiratory tree and intraabdominal and genitourinary tracts.

Pathogenesis and Pathophysiology of Severe Sepsis and Septic Shock

Infection-induced organ dysfunction and tissue hypoperfusion are the result of complex interactions between infecting organisms and the host response. Important components of this host response in the early phases of sepsis include the immune system, activation of the inflammatory cascade, and alterations in hemostasis. In later stages of sepsis, organ failure, immunosuppression, and apoptosis play an important pathophysiologic role. Characteristics of both the infecting organism and the host response influence the outcome of sepsis. Virulence factors, high burden of infection, and resistance to antibiotics are all organism characteristics associated with increased risk of severe sepsis. A growing body of literature suggests that host responses might be influenced by genetic polymorphisms.[12–19] This might explain why some patients develop severe sepsis to a particular pathogen and others do not. We further discuss some of the relevant components of the host response in severe sepsis.

Role of the Immune System

The immune response to infection takes place through the actions of two pathways: the innate immune system and the adaptive immune system. The goal of the innate immune system is to provide protection in the first minutes to hours after an infectious challenge. Although initially thought to be a nonspecific response, research has demonstrated that the innate immune system recognizes pathogens by means of pattern-recognition receptors (Toll-like receptors [TLRs], Table 24.3). TLRs bind to highly conserved structures on microorganisms, which are not easily altered by microbes to evade detection and are present on broad groups of organisms.[20] Our current understanding of TLRs suggests that the immune cells use different TLRs to detect several features of an organism and, based on the composite information gained,

TABLE 24.3 Toll-Like Receptors

Toll-Like Receptor	Pathogen or Disease State
TLR1	Lyme disease *Neisseria meningitidis*

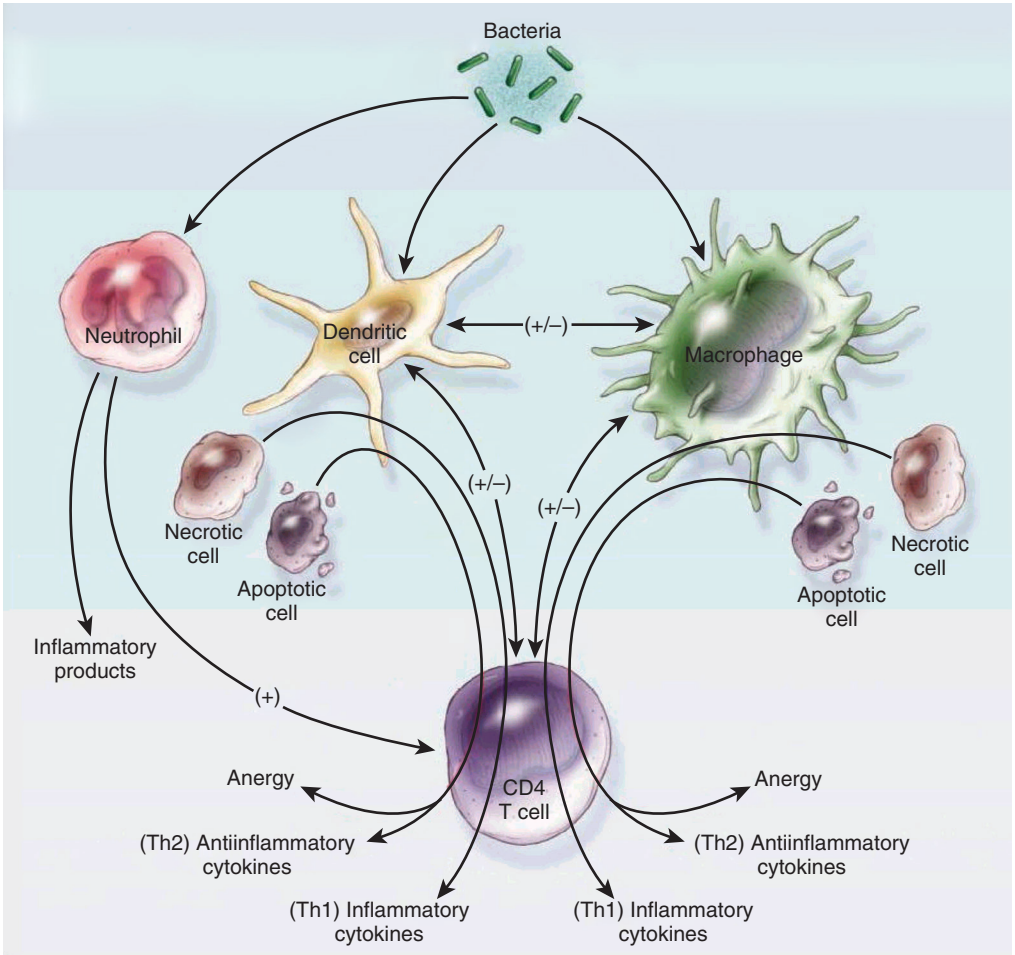
CMV, Cytomegalovirus; *TLR,* Toll-like receptor.

generate a tailored response to the invading pathogen.[20] Activation of TLRs by microorganisms stimulates signaling pathways that increase production of proinflammatory cytokines such as tumor necrosis factor α (TNF-α), interleukin IL 1β (IL-1β), and nuclear factor-kappa B (NF-κB), as well as antiinflammatory cytokines such as IL-10.[20,21] TLR activation also results in upregulation of microbial killing mechanisms, such as the production of reactive nitrogen species.[22] TLRs play a pivotal role in initiating the innate immune response and are important regulators of the adaptive immune response to infection. Recognition of these proteins and their functions expanded our understanding of the pathophysiology of sepsis and has provided a new target for therapeutic interventions.[22]

The adaptive immune system amplifies the response initiated by the innate immune system with a higher degree of specificity. In addition to their interactions with the innate immune system, microorganisms stimulate specific cell-mediated and humoral adaptive immune responses. Two types of lymphocytes, B cells and T cells, play an important role in the adaptive immune response. Adaptive immune responses (humoral and cellular) require days to develop. However, they are amnestic through the generation of memory T and B lymphocytes and, in the case of reexposure to the same pathogen, can elicit a faster and more robust response. CD4 T cells are divided into two types: type 1 helper T-cell (Th1) and type 2 helper T-cell (Th2). Factors such as the type of organism, site of infection, and burden of infection influence the response elicited by T cells. In general, Th1 cells secrete proinflammatory cytokines (TNF-α and IL-1β) and Th2 cells secrete antiinflammatory cytokines (IL-4 and IL-10).[23] B lymphocyte cells are responsible for releasing immunoglobulins in response to microorganisms. These immunoglobulins bind to organism-specific antigens and enhance recognition and destruction by other immune cells (natural killer cells and neutrophils). Several other cell types are involved in the adaptive immune response to infection (Fig. 24.1).

Role of Inflammation

For many years the prevailing theory has been that infection-induced organ dysfunction is the result of an uncontrolled inflammatory response.[24] This paradigm was based on extensive animal



• **Fig. 24.1** Response of immune cells to infection. The immune response to pathogens involves various types of cells. Crosstalk exists among the different cell lines of the immune system (dendritic cells, macrophages, lymphocytes, and neutrophils). The plus signs represent upregulation, and the minus signs represent downregulation. Many interactions on the figure have both plus and minus signs, representing the possibility of either upregulation or downregulation, depending on a variety of factors. *Th1,* Type 1 helper T cell; *Th2,* type 2 helper T cell. experimentation with models of inflammation that may not necessarily reflect human disease. Animal models of sepsis that used large doses of endotoxin or bacteria created a "cytokine storm" that when blocked resulted in improvements in mortality. However, in human sepsis most patients have a complex host response that includes activation of both proinflammatory and antiinflammatory cascades. Early death from overwhelming inflammation is not the norm, and most patients who die develop complications related to immunosuppression, apoptosis, and multiorgan failure later in the course of the disease. These differences may partially explain why so many antiinflammatory compounds worked in animal models yet failed to improve mortality in human clinical trials. The interplay among proinflammatory cytokines, antiinflammatory cytokines, and cytokine inhibitors is a dynamic process that influences the host response to sepsis. Proinflammatory cytokines such as TNF-α and IL-1β increase early in sepsis and have overlapping and synergistic effects in further stimulating the inflammatory cascade.[24] Proinflammatory cytokines activate monocytes, macrophages, and neutrophils; stimulate neutrophil margination; and increase gluconeogenesis. In addition, proinflammatory cytokines have an important role in the development of clinical abnormalities, such as fever, hypotension, capillary leakage with decreased intravascular volume, and myocardial depression.[24] More recently, proinflammatory cytokines such as macrophage migration inhibitory factor and high-mobility group 1 protein have received attention as downstream mediators of inflammation and potential therapeutic targets.[25] The role of antiinflammatory cytokines in sepsis is still not fully understood. Current understanding suggests that sepsis-induced multiorgan failure and death may be caused in part by a shift to an antiinflammatory phenotype and by apoptosis of key immune cells.[26,27] This shift is driven in part by increased levels of antiinflammatory cytokines and results from a shift in helper T-cell populations (from Th1 to Th2).[28] Inflammation plays an important role in the host response to sepsis. It is now apparent that simple therapeutic strategies that block specific proinflammatory cytokines are insufficient to modulate this response.[29,30] Given that more patients survive the initial stage of sepsis and have progressive long-term organ dysfunction, a "proimmune" strategy using immunostimulators to boost immune function in the later stage of the disease may have some benefit. As our understanding of the intricate relationship between proinflammatory and antiinflammatory responses increases, we might become more successful in modulating these to improve patients' outcomes with demonstrable immune dysfunction.

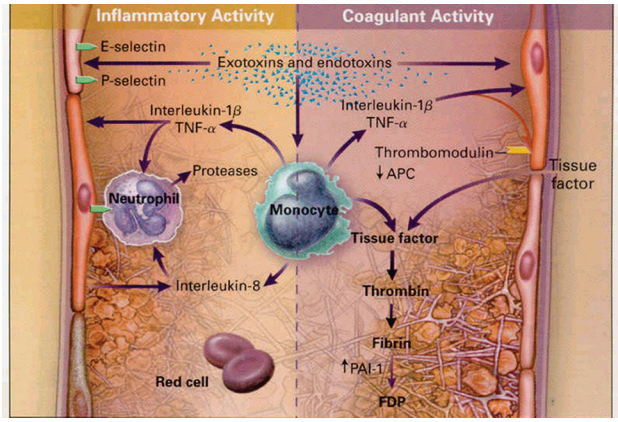
Alterations in Hemostasis

Another important factor in the pathophysiology of sepsis is the alteration of the hemostatic balance. In sepsis this balance is altered by an increase in procoagulant factors paired with a decrease in anticoagulant factors (Fig. 24.2). Under normal conditions the intraluminal vascular surface has anticoagulant properties. During sepsis, stimulation from cytokines promotes expression of tissue factor on endothelial cells, monocytes, and neutrophils.[31,32] Tissue factor triggers the extrinsic coagulation pathway by activating factor VII. Activation of the extrinsic pathway leads to the formation of thrombin. The intrinsic pathway is triggered by activation of factor XI and leads to amplification of the coagulation cascade with further formation of thrombin. Excessive coagulation is normally counterbalanced by several anticoagulant factors. Anticoagulant factors such as antithrombin III, activated protein C, protein S, and tissue factor pathway inhibitor are decreased in sepsis, along



• **Fig. 24.2** Relationship among inflammatory and coagulation systems in sepsis. Monocytes are activated by endotoxins and exotoxins from bacteria and release tumor necrosis factor α *(TNF-α)* and interleukin-1β (IL-1β). TNF-α and IL-1β activate the inflammatory cascade via neutrophils and the production of other proinflammatory cytokines, and in combination with tissue factor, they also activate the coagulation cascade, with production of fibrin and fibrin degradation products *(FDP). APC,* Activated protein C; *PAI-1,* plasminogen activator inhibitor-1. (Adapted from Matthay MA. Severe sepsis: a new treatment with both anticoagulant and anti-inflammatory properties. *N Engl J Med.* 2001;344:759-762, Figure 1A, p. 761.)

with a decreased expression of fibrinolytic pathway by plasminogen activation factor inhibitor-1 and thrombin-activated fibrinolysis inhibitor.[33] These circumstances push the hemostatic balance toward the procoagulant state. Activation of the coagulation cascade leads to a consumption of coagulation factors. The clinical expression of this phenomenon is disseminated intravascular coagulation (DIC). DIC is characterized by a consumptive coagulopathy, which can result in an increased risk of bleeding but can also be problematic by increasing the risk of thrombosis. In sepsis the excessive formation of fibrin from thrombin compounded by the suppression of fibrinolysis and the impairment of anticoagulant pathways may be associated with microthrombi. These microthrombi may lead to microcirculatory alterations and play a role in the pathogenesis of organ failure.[34] The cutaneous and acral manifestations of DIC are systemic peripheral gangrene and purpura fulminans which may lead to limb loss in the most extreme form. Bleeding may be seen at the sites of intravenous (IV) cannula and natural orifices.[35]

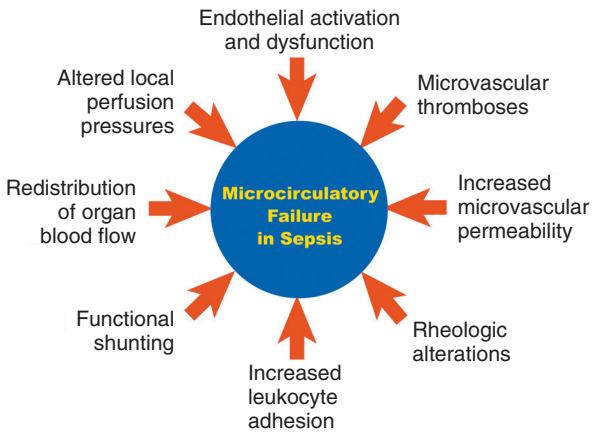
Microcirculatory and Mitochondrial Dysfunction

Microcirculatory dysfunction is a pivotal element of the pathogenesis of septic shock.[36–39] Although the macrocirculation (heart and large arteries) regulates the global distribution of blood flow throughout the body, it is the microcirculation that controls the final delivery of blood to tissues. Using intravital videomicroscopy, experimental models of sepsis have demonstrated impaired microcirculatory flow velocity, "stopped-flow" microvessels, increased heterogeneity of regional perfusion, and low density of perfused capillaries.[40–43] These derangements can cause marked alterations of oxygen transport including impaired tissue oxygen extraction.[42] With the advent of new investigational videomicroscopy techniques, it is now possible to study the microcirculatory network in human subjects with septic shock. Microcirculatory failure appears to be one of the critical pathogenic events in sepsis that is associated

with acute multiorgan dysfunction and death. As these alterations of microcirculatory flow in sepsis can occur in the *absence* of global hemodynamic perturbations (i.e., absence of low arterial pressure or low cardiac output [CO]),[36,43,44] derangements of small vessel perfusion are largely a function of intrinsic events in the microcirculation.

The causes of microcirculatory flow alterations in sepsis (Fig. 24.3) are multifactorial and include endothelial cell dysfunction, increased leukocyte adhesion, microthrombi formation, rheologic abnormalities, altered local perfusion pressures owing to regional redistribution of blood flow, and functional shunting.[40,45] The proinflammatory cytokines released in sepsis cause diffuse endothelial cell activation, which is associated with neutrophil activation, expression of endothelial adhesion molecules (i.e., integrins and selectins), and localization of white blood cells to areas of microvascular injury. Pan-endothelial cell injury increases microvascular permeability with the influx of proinflammatory cells into the tissues; this is hypothesized to be an important pathogenic step in the development of acute system organ dysfunction in sepsis. Leukocyte adhesion of white blood cells to the microvessel endothelial surface (primarily in the postcapillary venule) further impedes microcirculatory blood flow. The endothelial injury also triggers the activation of the coagulation cascade via expression of tissue factor on the microvascular endothelium, resulting in fibrin deposition and microvascular thrombosis that may further impair microcirculatory flow. All of these mechanisms collectively contribute to microcirculatory failure in septic shock.[38,40]

Although septic shock research has classically been focused on macrocirculatory hemodynamic parameters that reflect the distribution of blood flow globally throughout the body, a functional microcirculation is another critical component of the cardiovascular system that is necessary for *effective* blood flow to tissues. This conceptual framework is depicted in Fig. 24.4. Although a shift of research focus from global hemodynamic parameters to indices of microvascular perfusion could potentially be viewed as a major change of direction for septic shock research, the microcirculation likely represents a logical next frontier in the evolution of our understanding of circulatory failure in shock states.[40,45] Although there are currently no therapies to specifically target microcirculatory dysfunction in sepsis, going beyond optimization of macrocirculatory hemodynamics and developing new innovative strategies to reverse microcirculatory failure could (in the future) potentially represent a cutting edge method to augment tissue perfusion in sepsis.



• **Fig. 24.3** Causes of microcirculatory failure in sepsis. (Adapted from Spronk PE, Zandstra DF, Ince C. Bench-to-bedside review: sepsis is a disease of the microcirculation. *Crit Care.* 2004;8:462–468.)

There is strong evidence that cellular utilization of oxygen can be markedly impaired in septic shock.[46] Bioenergetic failure can occur even after effective restoration of blood flow to tissues has been achieved, and this has been termed "cytopathic hypoxia." Despite the current absence of therapies to reverse cytopathic hypoxia, this phenomenon does have some relevance for clinical practice, as impaired cellular oxygen extraction and utilization can manifest clinically with acute organ system failure in the setting of markedly elevated values for mixed (or central) venous oxygen saturation. Cytopathic hypoxia has been associated with acute organ dysfunction, but the extent to which this does or does not represent a cause-and-effect relationship has not yet been fully elucidated.

Microcirculatory and mitochondrial dysfunction likely coexist in septic shock. Both of these pathogenic mechanisms can impair tissue oxygen delivery and utilization, but the relative contribution of either mechanism is difficult to discern and may vary considerably. Fig. 24.5 demonstrates the pathogenetic sequence of events in septic shock.

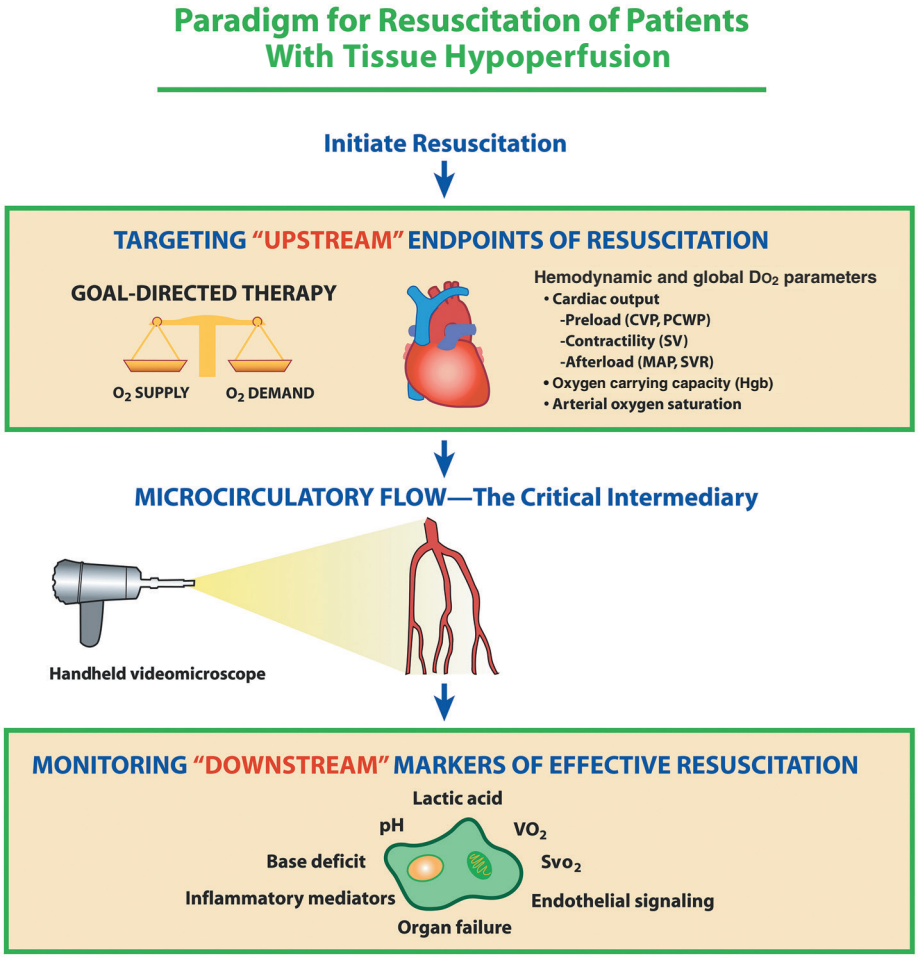
Multiple Organ Dysfunction

Multiple organ dysfunction is a common complication of sepsis. Multiple organ dysfunction syndrome (MODS) occurs when two or more organ systems fail sequentially or at the same time in a patient with sepsis. Various organs, such as the brain, heart, lung, kidney, and liver, can be affected in patients with severe sepsis. Often these organs are distant from the site of primary insult, and development of organ failure occurs as a response to complicated interactions and pathophysiologic events. These include the microcirculatory and bioenergetics failure as described previously. Metabolic and hematologic dysfunctions are also common with severe sepsis and MODS. MODS significantly contributes to higher mortality. Studies have shown that mortality in patients with severe sepsis increases in parallel with increases in number and severity of organ failures.[47,48] Russell and associates evaluated the pattern of organ dysfunction in early sepsis and its relationship with mortality.[48] In this study, clinically significant pulmonary dysfunction, although common early in sepsis, was not associated with 30-day mortality. Early dysfunction of other organs and, particularly, worsening neurologic, coagulation, and renal dysfunction over the first 3 days were associated with significantly higher 30-day mortality.

Recognition of early organ dysfunction is important because it is likely that early intervention can affect outcomes. The clinical manifestations of MODS for individual organs are summarized in Fig. 24.6. The cornerstones of treatment for MODS are based on appropriate treatment for the underlying cause (sepsis) and on early organ-specific support interventions. Early implementation of therapies directed at control of infection, hemodynamic support, and modulation of the host response are key to improving organ dysfunction and patient outcomes. Perhaps the single most important aspect relates to early and aggressive hemodynamic support. As demonstrated in the study by Rivers and colleagues, goal-directed interventions instituted in the first 6 hours of presentation to the hospital have a tremendous impact on long-term organ function and survival.[49]

Organ Dysfunction Scoring Systems

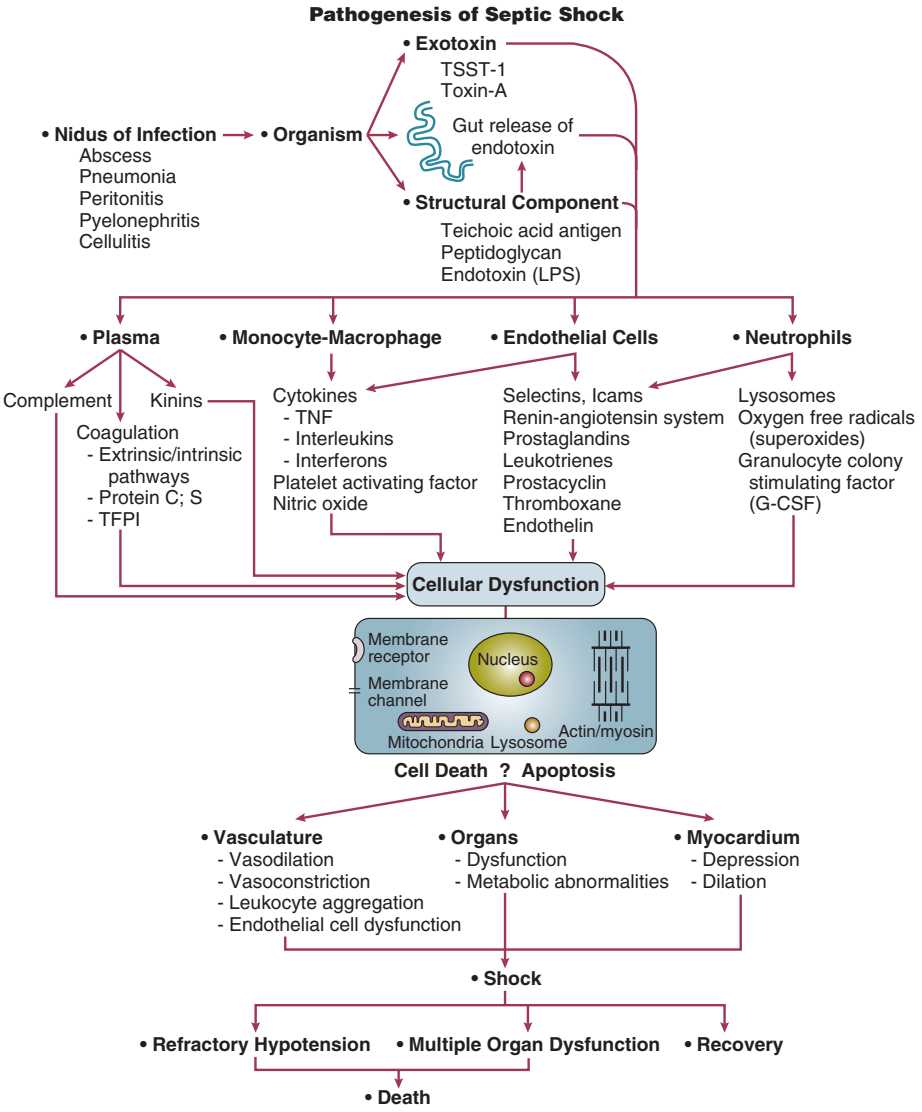
Severity of illness scoring systems have been developed and applied in the intensive care unit (ICU) to describe patient populations. These scoring systems have been useful in predicting expected



• **Fig. 24.4** New paradigm of the cardiovascular profile of septic shock featuring the importance of the microcirculation. Conventional resuscitation targets the optimization of macrocirculatory (i.e., "upstream") hemodynamic parameters, with the monitoring of "downstream" surrogates of tissue perfusion to determine the effectiveness of resuscitation. The microcirculation is the critical intermediary. Although the macrocirculation (heart and large arteries) regulates the global distribution of blood flow throughout the body, an intact and functional microcirculation is necessary for the effective delivery of blood flow to tissues. Intrinsic microcirculatory dysfunction can be a pivotal pathogenic event in the development of sepsis-associated tissue hypoperfusion. Using new videomicroscopy techniques, microcirculatory flow can now be studied in human subjects with septic shock. *CVP,* Central venous pressure; *DO_2,* oxygen delivery; *Hgb,* hemoglobin; *MAP,* mean arterial pressure; *PCWP,* pulmonary capillary wedge pressure; *SV,* stroke volume; *SvO_2,* mixed venous oxygen saturation; *SVR,* systemic vascular resistance; *VO_2,* oxygen consumption.

mortality and comparing different patient populations. The use of general outcome prediction models, such as the Acute Physiology and Chronic Health Evaluation (APACHE), the Mortality Probability Model (MPM), and the second Simplified Acute Physiology Score (SAPS), is discussed in greater detail in Chapter 67.

It is recognized that the risk of death for patients with severe sepsis is directly related to the number of dysfunctional organs. Organ dysfunction scoring systems have been developed as a tool for the clinician to characterize the severity of illness and follow the clinical evolution of patients with sepsis. The more commonly used systems are the SOFA, the Logistic Organ Dysfunction System, and the MODS. Perhaps the most commonly used is the SOFA score (Table 24.4). It was initially described by Vincent and colleagues to assess the incidence of organ dysfunction in critically ill patients.[47] Using the SOFA scores in patients with severe sepsis, these researchers found that mortality rates were lowest in patients without organ dysfunction (9%) and rose progressively with the number of organ dysfunctions (one organ, 22%; two organs, 38%; three organs, 69%; ≥four organs, 83%). The type of organ dysfunction also affects mortality. Hebert and coworkers[50] used logistic aggression analysis of the results of a simple multiple system organ failure score to determine the odds ratio for death for specific organ system dysfunctions. This study showed that the adjusted odds ratios (ORs) for covariates most predictive of mortality were hematologic (OR = 6.2), neurologic (OR = 4.4), hepatic (OR = 3.4), cardiovascular (OR = 2.6), and age (OR = 1.05). It is important to remember that there are caveats when using organ dysfunction scores for the management of individual patients with severe sepsis. Most important, organ dysfunction is not a static process and it changes over time. Levy and colleagues reported that changes in SOFA score over the first 24 hours were associated with outcomes in patients with severe sepsis.[51] Improvement in cardiovascular,



• **Fig. 24.5** Pathogenetic sequence of the events in septic shock. *G-CSF,* Granulocyte colony-forming factor; *LPS,* lipopolysaccharide; *TFPI,* tissue factor pathway inhibitor; *TNF,* tumor necrosis factor; *Toxin A, Pseudomonas aeruginosa* toxin A; *TSST-1,* toxic shock syndrome toxin 1. renal, or respiratory failure over the first 24 hours was associated with lower mortality. On the other hand, worsening SOFA scores for these organ systems were associated with higher mortality (an approximately 60% mortality rate). Finally, how these scores change over time in response to therapeutic interventions is probably of greater value than an initial organ dysfunction score.

Clinical Presentation

Patients with severe sepsis and septic shock typically manifest signs of systemic inflammation, including fever or hypothermia, tachycardia, tachypnea, and elevation or reduction of the white blood cell count. Infection-induced organ dysfunction may occur in the absence of hypotension; however, the hallmark of severe sepsis is hypotension. Other signs of potential tissue hypoperfusion may include lactic acidosis, oliguria, encephalopathy, or diminished capillary refill in the extremities. Hypotension that persists after intravascular volume repletion defines septic shock. Patients with septic shock typically have other organ system dysfunctions; clinical evidence of other organ system dysfunction may range from subtle abnormalities to overt organ failure. Multiorgan system involvement in sepsis may include cardiovascular, respiratory, renal, central nervous system, hepatic, metabolic, or hematologic dysfunction. Respiratory system dysfunction manifests as acute lung injury or, in the most extreme cases, the acute respiratory distress syndrome (ARDS). Sepsis-induced renal dysfunction typically manifests with oliguria and may progress to acute renal failure requiring dialysis. Central nervous system dysfunction manifests as encephalopathy, which may range from mild cognitive impairment to overt coma. Cholestasis is a common manifestation of hepatic dysfunction in sepsis, but in the presence of severe shock, ischemic hepatitis ("shock liver") may occur. Metabolic derangements of septic shock include a loss of glycemic control (hyperglycemia or hypoglycemia) as well as metabolic acidosis. Septic shock is commonly associated with a consumptive coagulopathy, which is likely present in almost all patients at least subclinically,[34,37] but may also manifest clinically

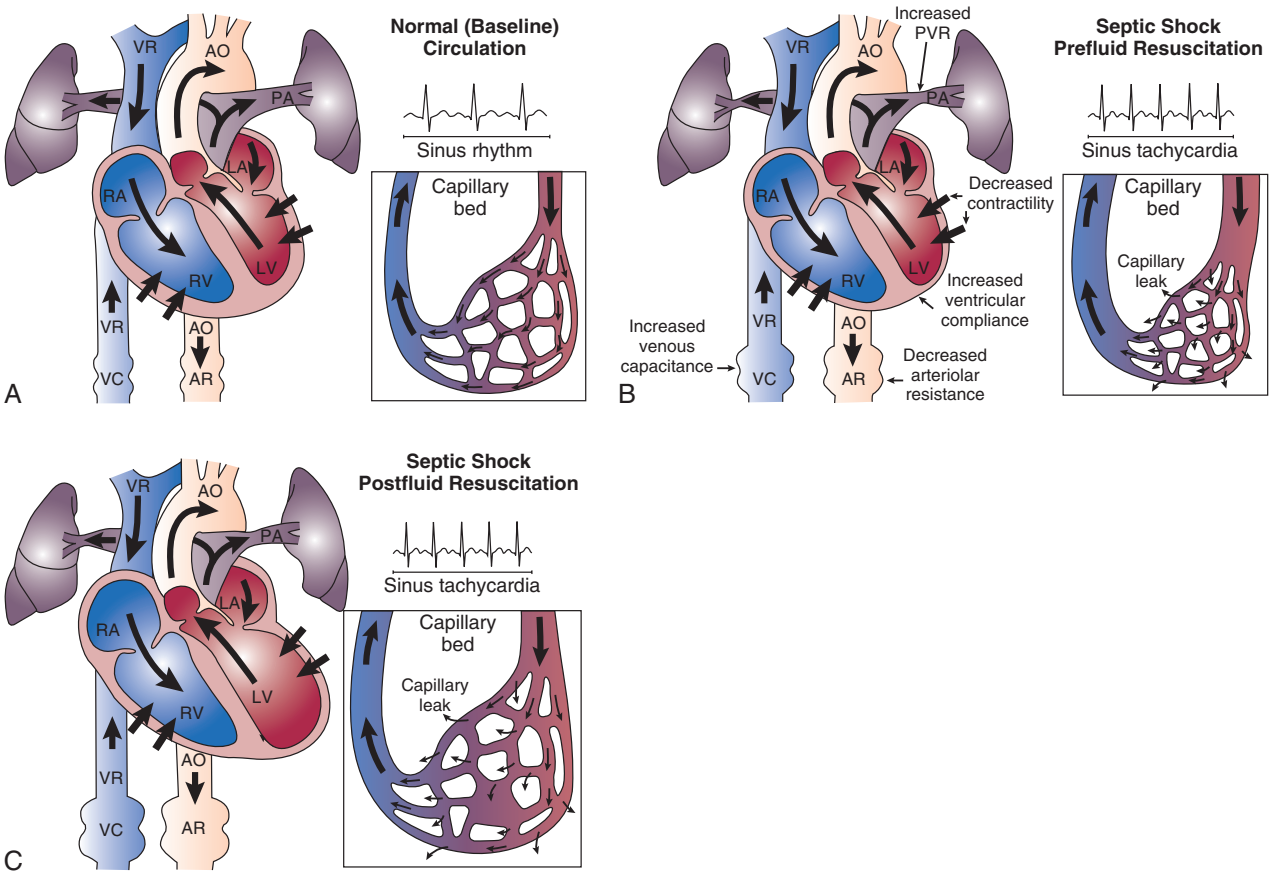
with thrombocytopenia, prolongation of the prothrombin time, or in the most severe cases, overt DIC.

Cardiovascular Profile of Septic Shock

The hemodynamic profile of septic shock is the most complex hemodynamic profile of all shock etiologies (Fig. 24.7).[52] What sets septic shock apart from other causes of circulatory shock is the fact that there may be multiple different mechanisms of circulatory shock occurring simultaneously. Septic shock may have features of (1) hypovolemic shock (poor cardiac filling secondary to systemic capillary leak and increased venous capacitance), (2) cardiogenic shock (infection-induced myocardial depression), and (3) distributive shock (arteriolar vasodilation with tissue hypoperfusion in the face of an adequate CO).

Hypovolemia and Decreased Cardiac Filling

The release of proinflammatory mediators into the circulation causes injury to the integrity of the endothelial cell surface throughout

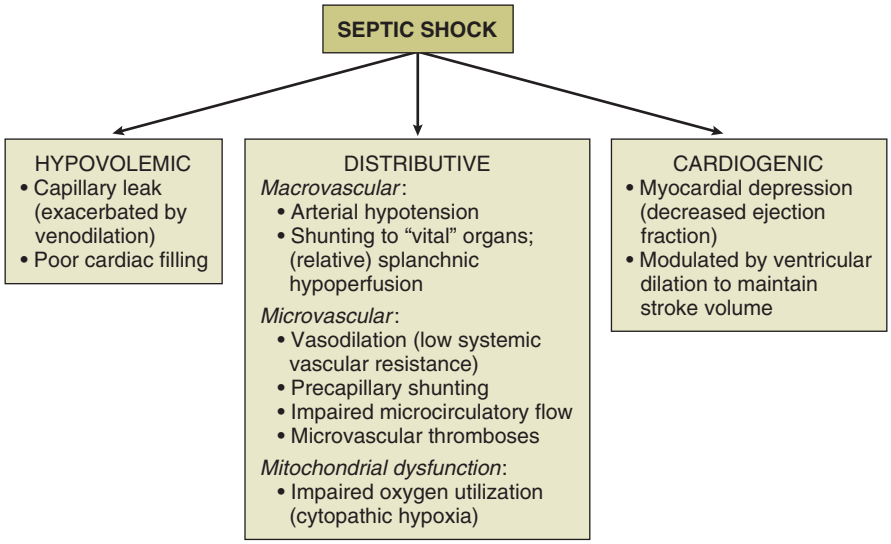


• **Fig. 24.7** Cardiovascular changes associated with septic shock and the effects of fluid resuscitation. A, Normal (baseline) state. B, In septic shock, left ventricular blood return is reduced owing to a combination of capillary leak *(inset),* increased venous capacitance *(VC),* and increased pulmonary vascular resistance. The stroke volume is further compromised by a sepsis-induced decrease in left and right ventricular *(RV)* contractility. Tachycardia and increased left ventricular compliance serve as countermeasures to combat low cardiac output, the latter by increasing left ventricular preload. However, cardiac output remains low to normal. Finally, a decrease in arteriolar (systemic vascular) resistance not only allows a higher stroke volume at any given contractility and left ventricular filling state, but also the potential for severe hypotension, despite restoration of adequate left ventricular filling. C, Aggressive fluid resuscitation compensates for capillary leak, increased venous capacitance, and increased pulmonary vascular resistance by reestablishing adequate left ventricular blood return. Decreased arteriolar resistance *(AR),* tachycardia and increased left ventricular compliance compensate for decreased ejection fraction. Ejection fraction increases as left ventricular filling increases. The net result is that after adequate volume resuscitation, most patients with severe sepsis have a high cardiac output and low systemic vascular resistance state. *AO,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *PVR,* peripheral vascular resistance; *RA,* right atrium; *VR,* venous return; ➞, blood flow (cardiac output); ⇄, contractility. (From Dellinger RP. Cardiovascular management of septic shock. *Crit Care Med.* 2003;31:946–955.)

the systemic microvasculature, resulting in severe capillary leak and extravasation of fluid into tissues. Venodilation also compromises venous return. These are major factors in producing hypovolemia and decreased cardiac filling in the patient with septic shock. Septic shock typically has a decreased cardiac preload in the initial phase of resuscitation. Fluid resuscitation with IV volume expansion then frequently produces the hallmark increased CO–low systemic vascular resistance (SVR) hemodynamic profile of septic shock (see the later "Vasodilation" section).[41] The combination of a decreased preload and myocardial depression means that in the early phase of sepsis resuscitation—before receiving adequate volume resuscitation—patients may initially have low CO. Capillary leak is an ongoing process in the course of septic shock therapy, and therefore hypovolemia may continue to be problematic, even after adequate cardiac filling has been initially achieved. Fluid balance (input of IV fluids and output of urine) is an unreliable parameter for assessing adequacy of fluid resuscitation in septic shock.

Myocardial Dysfunction

Septic shock is associated with depression of biventricular function with a decrease in the ejection fraction. Ventricular dilation occurs as a compensatory mechanism and raises end-diastolic volume so that stroke volume (SV) can be preserved, taking advantage of the Starling principle. When myocardial dysfunction occurs, a high CO can still be achieved in many circumstances because of biventricular dilation, tachycardia, and arteriolar dilatation, as long as the patient is adequately volume resuscitated and does not have a



• **Fig. 24.8** Major components of the hemodynamic profile in septic shock. (From Trzeciak S, Parrillo JE. Septic shock. In: *Society of Critical Care Medicine 8th Adult Critical Care Refresher Course*. Chicago: Society of Critical Care Medicine; 2004.)

severe cardiac suppression (related either to previously existing cardiac dysfunction or overwhelming sepsis-induced suppression of cardiac systolic function).[53] The most important inflammatory mediators that induce myocardial depression are TNF-α, IL-1, and perhaps nitric oxide.[54,55] Coronary blood flow is typically normal or increased in septic shock.[56] Although coronary blood flow can be diminished by severe arterial hypotension that compromises coronary perfusion pressure (especially if there is preexisting coronary artery disease), myocardial ischemia does not appear to be the causative factor of the depression in myocardial performance. It has been reported that nearly half of patients with septic shock have echocardiographic evidence of some degree of depression of systolic function, even in the absence of preexisting cardiac disease.[57] However, myocardial depression is typically not the predominant feature of the septic shock hemodynamic profile.[53] For the majority of patients, aggressive intravascular volume expansion to restore adequate cardiac filling pressures is enough to achieve a reasonable CO.

Vasodilation

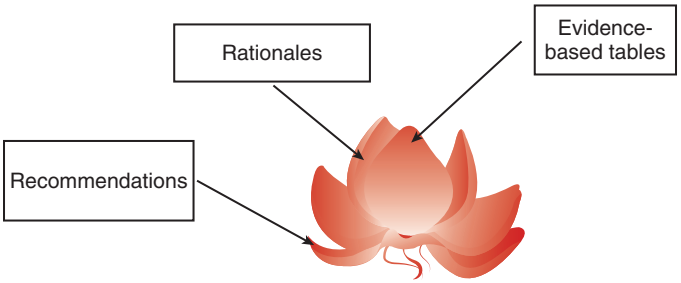
Septic shock is characterized by peripheral maldistribution of blood flow to tissues such that tissue hypoperfusion abnormalities can persist despite a normal or high CO. This is called "distributive shock."[53] This maldistribution of blood flow may occur at both microcirculatory and macrocirculatory levels. The role of microcirculatory dysfunction is discussed in detail in a separate section of this chapter. At the level of the macrocirculation, the autoregulation of blood flow within any single organ system in a normal host can typically maintain effective tissue perfusion over a wide range of systemic pressures (usually ranging from a MAP of 50 mm Hg to 150 mm Hg). However, there is heterogeneity of blood flow distribution throughout the body in septic shock owing to preferential shunting of blood flow to vital organs (e.g., the brain and myocardium). The gastrointestinal tract may be the earliest organ system to experience tissue hypoperfusion in septic shock, as blood is shunted away from the splanchnic circulation to preserve blood flow to the brain, myocardium, and skeletal muscles. Ischemic injury to the gastrointestinal tract and leakage of endotoxin into the systemic circulation may be a source of ongoing systemic inflammation in septic shock. The three components of the hemodynamic profile are displayed in Fig. 24.8.

Management of Severe Sepsis and Septic Shock

Overview and Management Guidelines

The Surviving Sepsis Campaign (SSC) first published comprehensive international consensus guidelines for sepsis management in 2004.[58] The SSC guidelines were updated in 2008 and then again in 2012 and then most recently in 2016 as the best evidence for sepsis management continues to evolve.[59,60] The critical care practitioner should be familiar with the concepts in the SSC guidelines and is referred to the most recent update for a comprehensive review, including evaluation of the strength of evidence for each recommendation. The SSC guidelines writing committee consisted of representatives from numerous medical professional societies that relate to the care of the septic patient, and these medical professional societies have endorsed the guidelines. The 2016 guidelines are 73 pages long and include 90 recommendations. A users' guide has been published that recommends differing approaches to the guidelines based on interests of the reader[61] (Fig. 24.9). A concise synthesis of the 2016 recommendations is included in the appendix presented later in this chapter.

The treatment recommendations in the SSC guidelines are intended to provide guidance for clinicians. However, treatment decisions must be individualized to the patient, and the recommendations cannot replace a clinician's decision-making capability when he or she is presented with a patient's unique set of clinical data. In addition, resource limitations in some institutions may prevent physicians from accomplishing some treatment recommendations. Thus the SSC guidelines are intended to represent "best practice" recommendations for the management of sepsis rather than standard of care. These guidelines have now been adopted by certain governments as quality indicators for the treatment of septic patients with mandatory reporting of performance.



• **Fig. 24.9** Layers of the Surviving Sepsis Campaign. The layers of an onion are paralleled to the components of the guidelines document, reflecting the depth of exploration by the user. (From Dellinger RP, Schorr CA, Levy MM. A users' guide to the 2016 Surviving Sepsis Guidelines. *Intensive Care Med.* 2017;43(3):299–303.)

General Principles

The patient should be brought to a critical care area in the emergency department (ED) or ICU as quickly as possible to facilitate appropriate monitoring, rapid resuscitation, and optimal hemodynamic support. Continuous electrocardiographic monitoring and pulse oximetry are useful tools in the management of critically ill patients with severe sepsis. In addition, a variety of more invasive devices may be of use. The arterial catheter has two functions. It allows frequent blood sampling and continuous assessment of arterial pressure. Metabolic parameters to monitor the effectiveness of resuscitation and cardiovascular support are limited; however, measurement of blood lactate can provide important information. In 1964, Broder and Weil first proposed the utilization of blood lactate levels as a surrogate of adequacy of tissue perfusion and presence of anaerobic glycolysis.[62] It is important to realize, however, that elevation of blood lactate does not always indicate ineffective tissue perfusion, as hyperlactatemia can be due to metabolic derangements or drug therapy (e.g., β-agonists such as epinephrine) and can be responsible for the elevation of blood lactate observed in sepsis. However, in the great majority of cases an elevated lactate represents ongoing tissue hypoperfusion. Blood lactate levels have prognostic value in septic patients. Regardless of the cause of lactate elevation in sepsis, markedly elevated blood lactate (e.g., lactate ≥4 mmol/L) signals an increased risk of death.[63–66]

Antibiotic Therapy and Source Control

Early administration of empiric antibiotic therapy and expeditious source control to eliminate any nidus of infection are imperative in the management of septic shock. Appropriate antibiotics given early may substantially improve the likelihood of survival.[67] A choice of antibiotics is usually empiric because the organism is not yet identified when antibiotics must be delivered. Failure to include antibiotic coverage for what is later identified to be the offending organism has been associated with increased risk of death[68]; therefore broad-spectrum antibiotics are necessary as soon as septic shock is identified. Kumar and associates performed a large-scale multicenter retrospective study of patients with septic shock and found a linear association between the duration of hypotension before the first dose of antibiotic administration and risk of death.[68] One prospective ED-based study from Puskarich and colleagues found higher survival rates if antibiotics were administered before the onset of shock compared to after shock onset, but in contrast to the Kumar data the authors did not find a measurable effect of incremental time to administration of antibiotics on survival.[69] One potential reason to explain these results is that the Kumar study was a heterogeneous population and the therapeutic interventions (e.g., early resuscitation and hemodynamic support) that the patients received were not standardized, whereas all the patients in the Puskarich study were ED patients treated according to a standardized early resuscitation protocol.

The SSC currently recommends that IV antimicrobial therapy be started as soon as possible, preferably within an hour of recognition of severe sepsis and septic shock. Even though a 1-hour time window is deemed desirable, longer time frames are common in real-world clinical practice. One reason for this could be the fact that sepsis often mimics other disorders, and the diagnosis of sepsis as the cause of the illness is often not obvious at the time of initial presentation. As such, the need for antimicrobial agents in the treatment of the patient may also not be immediately obvious. Once the diagnosis is made (or strongly suspected), antimicrobial therapy should be started promptly. When multiple antibiotics are to be given, it is important to think about what the more likely organism(s) is and how long each antibiotic takes to infuse when one antibiotic is to be administered followed by another. Initial empiric antimicrobial selection should be broad enough to cover all likely pathogens based on clinical circumstances. In patients with septic shock, de-escalation or restriction of antibiotic therapy as a strategy to reduce the development of antimicrobial resistance is not recommended until after a causative organism has been identified or after the patient's condition has markedly improved.

Pertaining to source control, the SSC recommends that a specific anatomic diagnosis of infection requiring consideration for emergent source control (e.g., laparotomy for intraabdominal source) be sought and diagnosed or excluded as rapidly as possible. Thus imaging studies, if needed, should be performed as soon as possible to make the diagnosis. One important caveat to this is the inherent hemodynamic instability and overall severity of illness in septic shock that may make invasive procedures or transport of patients outside the ICU for imaging studies potentially unsafe. Balancing potential risks and benefits in that scenario is very important. When a procedure for source control is found to be necessary, the surgical drainage should be undertaken for source control as soon as feasible after successful initial resuscitation and stabilization of the patient.[70,71]

Supportive Therapies

The 2016 SSC guidelines offer a comprehensive document on recommendations as it pertains to supportive therapies for the critically ill patient that are relevant for severe sepsis/septic shock.[60] In addition, the reader is referred to other chapters in this textbook dealing with organ-specific support therapies.

Glucose Control

Hyperglycemia and insulin resistance are common in sepsis and in the critically ill patient in general. In 2001, Van den Berghe and colleagues demonstrated that intensive insulin infusions titrated to strict glycemic control (80–110 mg/dL) in critically ill surgical patients could produce a mortality reduction (2016 guidelines).[72] A second study by Van den Berghe targeted medical ICU patients and used the same strict upper threshold target of 80 to 110 mg/dL.[73] In the intention-to-treat analysis, no significant difference

was found in mortality but the incidence of acute kidney injury was decreased and earlier weaning from mechanical ventilation was shown. Hypoglycemia occurred in one of 20 patients in the strict control arm compared with one in 100 in the control group.

A multicenter randomized trial in Germany, examining the role of intensive insulin therapy in critically ill patients using a similar insulin protocol, was stopped early because of a high incidence of hypoglycemia (17.0% vs. 4.1%, $P < 0.001$) with no difference in 28-day mortality.[74]

The Normoglycaemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) was a multicenter, multinational randomized clinical trial involving 6100 subjects from 42 hospitals in Australia, New Zealand, Canada, and the United States.[75] The NICE-SUGAR study compared maintaining the glucose concentration at 180 mg/dL or lower with strict glucose control with a target glucose of 81 to 108 mg/dL. Ninety-day mortality (the primary outcome variable) was higher in the intensive glucose control group (27.5% vs. 24.9%, $P = 0.02$). The treatment effect did not differ significantly between operative (surgical) patients and nonoperative (medical) patients as well as patients with sepsis versus those without sepsis. The higher mortality in the strict glucose control group occurred despite a much lower rate of hypoglycemia than previously reported in strict glycemic control protocols. The take-home message from the NICE-SUGAR trial would be that a glucose level higher than 180 mg/dL should be treated to achieve a target blood glucose concentration between 120 and 180 mg/dL.

Prophylaxis for Deep Vein Thrombosis and Stress Ulcers

Patients with severe sepsis and septic shock are at risk for thromboembolism and, in the absence of contraindications, are deserved of deep vein thrombosis prophylaxis. Low-molecular-weight heparin is preferred.[76]

Patients with severe sepsis and septic shock are at risk for gastric stress ulcers and should receive prophylaxis. The potential causes of stress ulcers include loss of mucosal protection from gastric acid, increased acid production, gastric mucosal hypoperfusion, and oxidative injury to the gastric mucosa.[77]

Risk factors for stress ulcers are shown in Box 24.2.[78,79] Proton pump inhibitors or histamine-2 receptor antagonists may be used for stress ulcer prophylaxis.

Nutrition

Although parenteral nutrition can provide targets for calories, protein, and essential fats, it is associated with complications; the primary one of concern is infection and it is not associated with the physiologic advantages of enteral feeding as it relates to mucosal health.[80] Therefore enteral feeding is preferred in patients with severe sepsis. Early parenteral nutrition should be avoided and initial low-dose (trophic/hypocaloric) enteral nutrition begun early in the course of the patients with sepsis and advanced as tolerated.[60] We do not consider septic shock a contraindication for initiation of enteral feeding and the use of prokinetic agents may facilitate tolerance.

Coagulopathy receiving renal replacement therapy
Mechanical ventilation >48 h
More severe organ failure score
Liver disease

Early Resuscitation and Hemodynamic Optimization

One of the goals in the early management of patients with sepsis is effective resuscitation to restore adequate tissue perfusion and decrease the risk of organ system injury. A number of hypotheses have been developed to explain the relationship between shock and the development of organ failure in critical illness. One hypothesis suggests that organ failure during critical care occurs as a consequence of inadequate oxygen delivery to the organs and tissues. Based on this hypothesis, several investigators have suggested that patients should be resuscitated to supranormal goals of systemic oxygen delivery in an attempt to prevent organ failure and improve outcome. The concept of supranormal oxygen delivery refers to the use of fluid resuscitation and inotropic drugs to drive up the oxygen delivery to achieve a predefined target. Several studies have examined this concept, although it is important to recognize that some studies have been performed in heterogeneous populations of critically ill patients rather than populations of patients with sepsis. The earliest clinical trials in perioperative high-risk surgery patients demonstrated an outcome benefit.[81,82] Subsequently, however, numerous trials of supranormal oxygen delivery in critically ill patients failed to demonstrate any benefit.[83,84] A meta-analysis concluded that supranormal oxygen delivery in critically ill patients was not beneficial[85] and this concept largely fell out of favor in the 1990s.

For goal-oriented hemodynamic optimization to be beneficial, it has become clear that *timing* is critical. In contrast to the trials in perioperative high-risk surgery patients, subjects in the earlier studies were randomly assigned to treatment much later, up to 72 hours after initial presentation.[83] In a meta-analysis of critically ill patients that stratified studies by severity and the timing of interventions (early vs. late), an outcome benefit was identified in the subset of patients with a high severity of illness and early initiation of interventions.[85] A meta-analysis, this time specifically focused on patients with sepsis, found that quantitative resuscitation (i.e., early hemodynamic optimization targeting predefined quantitative endpoints of resuscitation) was associated with lower mortality rate in patient with sepsis, but only if applied early, defined as less than 24 hours after presentation.[86] These data suggest that quantitative resuscitation in the treatment of severe sepsis and septic shock can in fact be beneficial—in the right patient.

This early intervention concept was the rationale behind the study of early goal-directed therapy (EGDT) for severe sepsis and septic shock by Rivers and colleagues.[49] EGDT is a type of quantitative resuscitation for patients with sepsis that involves targeting central venous oxygen saturation ($ScvO_2$) as a monitor of the adequacy of oxygen delivery. In a single-center randomized controlled trial of 263 ED patients with severe sepsis and septic shock, Rivers and colleagues targeted predefined endpoints of resuscitation, including central venous pressure (CVP) 8 to 12 mm Hg, MAP 65 mm Hg or greater, and $ScvO_2$ 70% or greater in the ED.[49] The authors reported that the EGDT protocol was associated with a 16% absolute risk reduction for mortality rate (30.5% vs. 46.5%). This study was a landmark contribution to the literature in showing that early interventions in the resuscitation phase of therapy can be associated with a significant improvement in long-term survival

for patients with sepsis. There have now been multiple large randomized controlled trials that now show that early aggressive resuscitation without CVP and $ScvO_2$ guidance is just as effective and noninferior to early goal-directed targets of the original Rivers trial.[87–90]

A multicenter-based randomized trial by Jones and associates compared lactate clearance (defined as a decrease by ≥10% in the serum lactate concentration) versus $ScvO_2$ as an endpoint of sepsis resuscitation.[90] Among 300 patients with sepsis-induced tissue hypoperfusion, the authors found that lactate clearance was noninferior to $ScvO_2$ for the primary outcome of all-cause in-hospital deaths. These data suggest that, in addition to ensuring adequate cardiac preload and arterial blood pressure, lactate clearance has potential as a resuscitation target in sepsis-induced tissue hypoperfusion.

The data are conflicting regarding which therapeutic interventions are typically needed beyond intravascular volume expansion and vasopressor agents in the early resuscitation of patients with sepsis. In the Jones trial, after aggressive administration of IV crystalloid to achieve a CVP of 8 to 12 mm Hg and vasopressor agents to achieve an arterial pressure of 65 mm Hg or greater in a stepwise resuscitation algorithm, very few patients required additional therapies for augmentation of oxygen delivery to achieve either lactate clearance or $ScvO_2$ goals (i.e., only 7% required packed red blood cell transfusion and 3% required inotropes).[90] In contrast, 64% of patients in the EGDT ($ScvO_2$-targeted) arm in the Rivers study were treated with blood transfusions and 14% were treated with inotropic support. The Rivers data would suggest that packed red blood cell transfusions and inotropes are commonly required therapies for optimization of oxygen delivery in sepsis resuscitation, whereas the Jones trial (and multiple other recent observational clinical studies) suggests that these additional therapies are rarely required to achieve resuscitation goals. Although the optimal endpoints of quantitative resuscitation for sepsis remain controversial, it is generally accepted that the earlier the therapeutic interventions are delivered, the greater the capacity for benefit. The ProMISe (Protocolized Management In Sepsis), ARISE (Australasian Resuscitation In Sepsis Evaluation), and ProCESS (Protocolized Care for Early Septic Shock) trials compared early resuscitation of septic shock with and without use of a central venous catheter (CVC) for measurement and protocolization use of CVP and $ScvO_2$ to guide therapy.[87–89] These trials compared the original EGDT protocol as devised by Rivers et al. to "usual care" in the ICU (no use of protocolized CVC variables) and found no difference in mortality. A meta-analyses of these three studies confirmed this outcome.[91] However, at time of randomization, patients in these large studies had already received significant crystalloid fluid resuscitation before randomization and antibiotics had already been administered in the great majority despite only a short stay in the ED.[87,89] Therefore the resuscitation phase of therapy incorporating early recognition and treatment of septic shock appears to be an important window of opportunity for impact on outcome.

Currently the SSC recommends at least 30 mL/kg of initial volume resuscitation with addition volume guided by frequent reassessment of hemodynamic status. For patients who present with an elevated lactate as a marker of tissue hypoperfusion, a normalization of lactate is a therapeutic target. A target MAP is at least 65 mm Hg using vasopressors as needed in septic shock. See Chapter 67 for a discussion of the sepsis quality metrics for the first 6 hours of treatment of severe sepsis and septic shock that are mandatory for reporting by U.S. hospitals.

The SSC acknowledges limitations with using static ventricular pressure estimates (e.g., CVP) for assessing intravascular volume status in patients with septic shock. Specifically, measuring CVP in a range that is typically thought to be normal (or even high) does not necessarily exclude the possibility of preload-dependent CO, especially in patients with preexisting chronically elevated cardiac filling pressures (e.g., cardiomyopathy or pulmonary artery hypertension). However, a markedly low value for CVP can be helpful in that it can reliably indicate the presence of hypovolemia in patients with circulatory shock. Targeting dynamic measures of fluid responsiveness (e.g., pressure variation) and volumetric indices (e.g., SV variation) may be useful. Bedside cardiovascular ultrasonography has gained wide application where it is used to assess intravascular volume and cardiac filling and contractility. Inferior vena cava size and respiratory cycle variation in size in a patient with a regular heart rhythm is thought to be helpful in decision making with regard to predicting a positive response to fluids. More recent data support that the superior vena cava may provide more precise data in this regard.[92] The ability to directly assess a global estimate of cardiac filling as well as assess cardiac contractility is also valuable. The latter would assist in decision making as to adding inotropic therapy for a patient believed to have adequate intravascular volume, depressed systolic function, and persisting evidence of tissue hypoperfusion.

It is appropriate to assume that SV is proportional to arterial pulse pressure.[93] Given that assumption, pulse contour devices use the same principle and relate the contour of the arterial pressure waveform to SV and SVR.[94] With constant SVR any pulse contour variation is produced solely by changes in SV. An algorithm is used to determine SV, and CO is then determined by factoring in heart rate. Devices that use pulse contour to estimate SV and CO may be calibrated or uncalibrated. Calibrated devices directly measure CO initially and then are able to assign the pulse contour at the time of that measurement to a precise SV. The pulse contour is then tracked with an increase or decrease in the pulse contour representing increase or decrease in SV, respectively. Uncalibrated devices use proprietary formulas to convert pulse waveform analysis to SV.

A number of devices are available that use pulse contour analysis for SV calculation. The PiCCO system (Pulsion Medical Systems SE, Munich, Germany) uses a thermistor-tipped arterial line in a proximal artery to measure the arterial waveform morphology while using transpulmonary thermodilution via a CVC for CO measurement and calibration.

The Vigileo/FloTrac system (Edwards Lifesciences, Irvine, CA) uses a standard arterial catheter. SV is calculated using a proprietary algorithm to calculate specific vascular compliance based on age, height, gender, weight, and waveform characteristics. It is does not calibrate by direct measurement of CO.

The LiDCO device (LiDCO, Cambridge, UK), also uses an arterial catheter but CO is measured with lithium dilution for calibration. Although conceptually similar, the analysis of the arterial waveform is a pulse power analysis instead of a pulse contour analysis.

Although potentially useful in the resuscitation of hypoperfused patients with sepsis, pulse contour analysis monitors do have potential limitations. First, these devices rely on an optimal arterial signal. Overdamped or underdamped traces may lead to inaccuracies of SV measurement. Arrhythmias, aortic regurgitation, and the use of an intraaortic balloon pump all affect the pulse contour and have been shown to affect accuracy.[95] Changes in SVR may also lead to inaccuracies in CO measurement. Recalibration or

recalculation of the referencing constant will assist with errors based on changes in SVR. Respiratory variation of SV as measured by pulse contour analysis can also assist in predicting which patients will respond to additional fluid administration with greater SV variation representing greater likelihood of response.[96]

The pulmonary artery catheter (PAC) can provide data such as cardiac filling pressures, cardiac index, and SVR. The data gathered from the PAC can be useful for titrating vasoactive medications in septic shock. Although indications for PAC use are controversial and are often debated, it is important to recognize that the PAC represents a tool for guiding therapy rather than being a therapeutic intervention in itself. Monitoring venous oxygen saturation (either mixed venous oxygen saturation [SvO_2] or $ScvO_2$) can yield information on the oxygen supply/demand relationship, especially in the early resuscitation phase of septic shock therapy. A markedly low value for either SvO_2 or $ScvO_2$ indicates a significant imbalance in the oxygen supply/demand relationship and likely indicates a need for augmenting global oxygen delivery in most patients. Paradoxically, in patients whose cells are unable to consume oxygen (precapillary shunting or mitochondrial dysfunction) an elevated SvO_2 or $ScvO_2$ with an elevated lactate level becomes a very poor prognostic indicator and identifies patients in whom increasing oxygen delivery will not correct tissue hypoxemia.

Fluid Resuscitation

Intravascular volume expansion is another important aspect of sepsis management and is the best initial therapy for the cardiovascular instability of septic shock. The initial hypotension observed in many patients with sepsis-induced cardiovascular instability may be reversed with volume infusion alone. A reasonable approach to initial volume resuscitation in the adult patient is the rapid administration of 30 mL/kg or 2 to 3 L of crystalloid solution (e.g., 0.9% sodium chloride [NaCl] or lactated Ringer solution). If (after initial volume infusion) the hemodynamic instability has resolved, further aggressive resuscitation may be unnecessary and the patient may be relegated to a somewhat higher maintenance fluid.

Crystalloid fluid can be administered as normal saline or balanced crystalloid (Ringer lactate, Ringer acetate, Plasma-Lyte [Baxter Healthcare, Deerfield, IL]). Normal saline solution has chloride concentrations that significantly exceed those of plasma while the sodium concentration is similar. Giving large amounts of normal saline solution to patients with septic shock would narrow the strong ion gap (difference between sodium and chloride) and produce a non–anion gap hyperchloremic acidosis. Database and prehistorical and posthistorical control studies have shown an association between normal saline solution–based fluid administration compared with balanced crystalloid, and worse outcomes including increased renal replacement therapy.[97–99] A small animal study suggested that balanced crystalloids might be better for renal stress in a hemorrhagic shock model.[100] The SPLIT (Saline vs. Plasma-Lyte Fluid Therapy) trial randomly assigned 2278 patients admitted to the ICU to receive normal saline solution versus balanced crystalloids and showed no difference in outcomes. However, these were predominantly postoperative patients and the median fluid amount during the ICU stay was only 2 L.[101] The SMART study (Isotonic Solutions and Major Adverse Renal Events Trial) randomly assigned 15,802 patients admitted to the ICU to receive either balanced crystalloids or normal saline solution for the duration of the hospital stay and found a significant difference between treatment groups as to an a priori combined renal morbidity/mortality score (MAKE30 [major adverse renal events by 30 days after acute kidney injury]) that favored balanced crystalloid (14.3% vs. 15.4%).[102] Of the patients in the study, 15% had severe sepsis or septic shock. Two additional megatrials comparing normal saline solution and balanced crystalloid are also under way (one in Australia/New Zealand and one in Brazil) with a companion design offering the ability for a combined analysis. The summation of literature to date as applied to the critically ill patient population in general would favor the use of balanced crystalloid such as Ringer lactate or Ringer acetate in patients with severe sepsis/septic shock without clinically significant hyponatremia, metabolic alkalosis, or the need for hypernatremia as a therapeutic target (such as in the presence of increased intracranial pressure).

Because there is no proven benefit of colloid therapy over crystalloids in resuscitation,[103] the SSC currently recommends initiating volume resuscitation with crystalloid for patients with septic shock and suspicion of hypovolemia. The SSC-recommended volume of crystalloid is a minimum of a 30-mL/kg fluid challenge. If there is hemodynamic improvement with this initial fluid challenge, clinicians may continue repeated fluid challenges to see if further hemodynamic improvement occurs. The SSC further suggests consideration of the addition of albumin infusion to initial crystalloid resuscitation if the initial crystalloids are judged to be ineffective. The SSC recommends against the use of synthetic hydroxyethyl starches in volume resuscitation because these agents have been associated with increased risk of acute kidney injury and increased mortality.[104]

One prudent strategy of volume resuscitation (rather than targeting a predefined cardiac filling pressure) would be to continue fluid bolus administration until the cardiac index or SV fails to rise with additional intravascular volume expansion, indicating optimization of cardiac preload. This would be accomplished by directly measuring or estimating flow. With the increasing use of point-of-care ultrasonography and bedside cardiac ultrasonography, the ability to predict volume responsiveness using IVC/SVC measurements, aortic flow, and intracardiac pressures is becoming increasingly more prevalent. A high left ventricular filling pressure should be avoided because it could contribute to pulmonary capillary leak and cause impairment of oxygenation if the patient has concomitant acute lung injury. The association of poor outcome with high input-output ratios has raised concern about the potential detriment of overly aggressive fluid administration in resuscitation of septic shock.[105] However, patients with more severe sepsis (and therefore more likely to die) would be expected to have more severe venodilation and more severe capillary leak and by definition require more fluids to maintain adequate intravascular volume. The challenge is knowing the optimal intravascular volume. For each patient there is likely an optimal mix of fluid and vasopressor to maintain MAP, and the challenge for the clinician is to determine this optimal mix. A guideline recommendation for an initial fluid bolus that fits most patients is needed, particularly when directed to the practitioner who is not skilled in caring for the critically ill, hypoperfused patient with sepsis. It is likely that both underresuscitation and overresuscitation occur and influence outcome. Individualization of fluid resuscitation by those more experienced in caring for such patients is important.[106] When life-threatening hypotension is present, norepinephrine should be started early even before hypovolemia has resolved regardless of the reason for poor outcomes after fluid resuscitation. In 2017 the New York State–mandated hospital quality improvement efforts were published showing that rapid completion of the entire 3-hour bundle and rapid administration of antibiotics—but not rapid completion of

initial fluid bolus—were associated with better outcome.[107] It is possible that a sense of urgency was a confounder that correlated with patients with more severe illness and could not be accounted for in the risk adjustment. Even if early aggressive fluid resuscitation saves lives, there is likely still a price to pay downstream with the fluid that is left in the extravascular tissues once the pathogens are eradicated and the inflammation response is quenched. This fluid is typically mobilized (so-called autodiuresis) in patients with adequate renal function as capillary membranes heal during the recovery phase. Whether this diuresis could be encouraged with an IV diuretic after a patient's infection is cleared and tissue hypoperfusion no longer exists is a matter that requires more research. A conceptual model proposing four phases of IV fluid therapy has been proposed.[108,109] The four phases are rescue, optimization, stabilization, and de-escalation (Fig. 24.10). Rescue should occur within minutes and may be lifesaving. Optimization occurs over hours and maintains tissue perfusion. Stabilization occurs over days and aims for zero fluid balance while maintaining organ support. Finally, de-escalation is characterized by mobilization of fluid and autodiuresis as a sign of recovery of capillary function and organs. Of note, it has also been shown that outcomes are better when diuresis is targeted to produce lower intravascular filling pressures in patients with ARDS who are not using vasopressors and do not have an elevated lactate level.[110]

Vasopressor Therapy

In addition to fluid administration, pharmacologic support of blood pressure is frequently necessary in both the initial resuscitation and subsequent support of patients with septic shock. After administration of fluids these agents are the next most important interventions for the initial management of the hemodynamically unstable patient. Restoration of adequate arterial pressure is the endpoint of vasopressor therapy. The SSC recommends targeting a MAP of 65 mm Hg or higher; however, blood pressure does not always equate to systemic blood flow and the precise MAP to target may not necessarily be the same for all patients. LeDoux and coworkers demonstrated that in patients with septic shock treated with norepinephrine to maintain target MAP, MAPs of 65, 75, and 85 mm Hg achieved equivalent indices of tissue perfusion.[111] In an observational study of patients with septic shock Varpula and associates found that an area under the curve of 65 mm Hg was the best predictor of positive outcome and showed that among multiple hemodynamic variables, a MAP above 65 mm Hg was the best predictor of a favorable outcome.[112] A large multicenter randomized controlled trial noted that a MAP goal of 80 to 85 mm Hg has similar outcomes compared to a MAP goal of 65 to 70 mm Hg. The higher dose range was associated with an increased rate of new-onset atrial fibrillation,[113] and in patients with chronic hypertension the higher MAP target was associated with a lower need for renal replacement therapy. A MAP of 65 mm Hg may be inadequate for a patient with preexisting poorly controlled essential hypertension and associated vascular disease. Similarly, it should be recognized that in some patients it is possible to have MAPs lower than 65 mm Hg with adequate tissue perfusion. A pooled analysis of higher versus lower MAP targets for vasopressor therapy in septic/vasodilatory shock revealed increased mortality with the higher target when started more than 6 hours after initiation of vasopressors.[114] The OVATION (Optimal Vasopressor Titration) study showed better outcomes in vasodilatory shock with an MAP target of 60 to 65 mm Hg versus 75 to 80 mm Hg.[115] Thus the most appropriate MAP target in an individual patient remains elusive and likely should be judged based on history of uncontrolled hypertension and tissue perfusion parameters at the blood pressure currently chosen. It is hypotension in the presence of tissue hypoperfusion that merits therapy with vasopressor agents. Endpoints of resuscitation such as arterial pressure should be combined with assessments of regional and global perfusion. Other bedside indicators of persistent tissue hypoperfusion (besides hypotension) include oliguria, encephalopathy, poor capillary refill, and metabolic acidosis, and should also be considered as targets for blood pressure and fluid management. Thus even though the SSC recommends targeting a MAP of 65 mm Hg for most patients, the optimal MAP should be individualized based on the clinical considerations noted here.

The appropriate use of vasopressors may require accurate assessment of a patient's cardiovascular status with invasive hemodynamic monitoring. However, in the earliest stage of therapy, it is common to institute vasopressor therapy when invasive monitoring data are not immediately available if a patient remains hypotensive despite adequate intravascular volume expansion. If the MAP remains low (e.g., <65 mm Hg) with evidence of ongoing tissue hypoperfusion despite adequate fluid resuscitation, vasopressor therapy is indicated. In some circumstances, patients with sepsis may require vasopressor support even if hypovolemia has not yet been resolved. Below a threshold blood pressure, autoregulation of blood flow in vascular beds may be lost and linearly dependent on blood pressure; thus the administration of vasopressor agents to achieve a minimal perfusion pressure and maintain adequate flow is reasonable as an emergency measure in some situations while fluid resuscitation is ongoing.

Individual Vasoactive Agents

Multiple different vasoactive agents, including norepinephrine, epinephrine, vasopressin, dopamine, and phenylephrine, can achieve arterial pressure goals in the management of patients with septic shock. The different catecholamine agents have different effects on α- and β-adrenergic receptors. The hemodynamic actions of these receptors is well described: α-adrenergic receptors promote vasoconstriction, but β_1-adrenergic receptors increase heart rate and myocardial contractility and β_2-adrenergic receptors cause

peripheral vasodilation. Given the differential effects of vasopressor drugs on adrenergic receptors, these different agents have different effects on arterial pressure and systemic blood flow. In this context, the quintessential question as to which catecholamine is the best initial choice for treating septic shock is best framed as a question of which agent is most appropriate for a given therapeutic strategy in an individual patient, and the choice is largely dependent on that individual patient's hemodynamic status. Rather than a "one-size-fits-all" strategy, vasoactive agents should be carefully selected based on the intended goals of therapy.

Vasoactive agents and their characteristics are summarized in Table 24.5. The selection of one of these drugs over the other as a first-line agent is a controversial and an often debated subject in the field of critical care medicine. Both norepinephrine and dopamine effectively raise the blood pressure and the cardiac index, but the rise in cardiac index is greater with dopamine. Dopamine, however, may cause or exacerbate tachycardia or dysrythmias.[116] Norepinephrine is a more potent drug than dopamine in achieving a target MAP. Information from five randomized trials ($n = 1993$ patients with septic shock) comparing norepinephrine and dopamine does not support the routine use of dopamine in the management of septic shock.[117]

Epinephrine is a potent α- and β-adrenergic agent that increases MAP by vasoconstriction and also increases the cardiac index. Although epinephrine is a potent agent in raising the arterial pressure, the chief concern with the use of epinephrine has been the potential for impaired splanchnic perfusion.[118] A large-scale randomized controlled trial comparing epinephrine to norepinephrine plus dobutamine reported no difference in vasopressor withdrawal, organ failure, and mortality rate.[119] There was also no difference in the rates of serious adverse events. The authors concluded that there is no difference in efficacy and safety for epinephrine versus norepinephrine plus dobutamine in the management of septic shock.

Vasopressin is an agent that has both vasoconstriction and antidiuretic properties. Vasopressin constricts vascular smooth muscle directly via V_1 receptors and may also increase the responsiveness of the vasculature to endogenous or exogenous catecholamines.[120,121] Normally, endogenous vasopressin levels are very low and there is essentially no vasoconstriction effect in a normal host. However, in septic shock vasopressin levels are initially extremely elevated. In prolonged septic shock, a relative vasopressin deficiency can develop.[122] It has been postulated that this relative vasopressin deficiency may be the result of the depletion of the pituitary stores or the downregulation of vasopressin production by the pituitary gland via the effects of nitric oxide. Exogenous administration of low-dose vasopressin can have a dramatic hemodynamic response in this scenario, rapidly restoring arterial pressure.[123] A large randomized clinical trial compared vasopressin to norepinephrine in 776 subjects with vasopressor-dependent septic shock. Patients receiving norepinephrine to maintain MAP target in septic shock were randomized to receive vasopressin 0.03 U/min or additional norepinephrine in a blinded fashion such that either vasopressor would likely result in a downtitration of the basal norepinephrine dose. The low dose vasopressin was then continued while the norepinephrine was weaned as allowed.[124] It appears that vasopressin (up to 0.03 U/min) may be as equally safe and effective as norepinephrine in patients with septic shock after fluid resuscitation. The VANISH (Vasopressin versus Norepinephrine as Initial Therapy in Septic Shock) trial used slightly higher doses of vasopressin, up to 0.06 U/min, before norepinephrine was initiated as initial vasopressor compared to norepinephrine alone in a randomized controlled trial.[125] This was a factorial design trial and each vasopressor arm also had either placebo or hydrocortisone. This trial was primarily targeted to detect any renal failure–sparing effect that vasopressin might offer. There was no difference in mortality or renal failure–free days between the two groups.

Phenylephrine is a pure vasoconstrictor with α-adrenergic effects alone. Although one potential advantage of using phenylephrine is that it will not cause or exacerbate tachycardia, the increase in peripheral resistance may produce a deleterious lowering of CO. It is not recommended for routine use in septic shock. Phenylephrine may be useful in select patients with severe dysrhythmias associated with catecholamine infusion because it has no β-adrenergic effects, as well as in patients with refractory hypotension in the presence of a known high cardiac index.

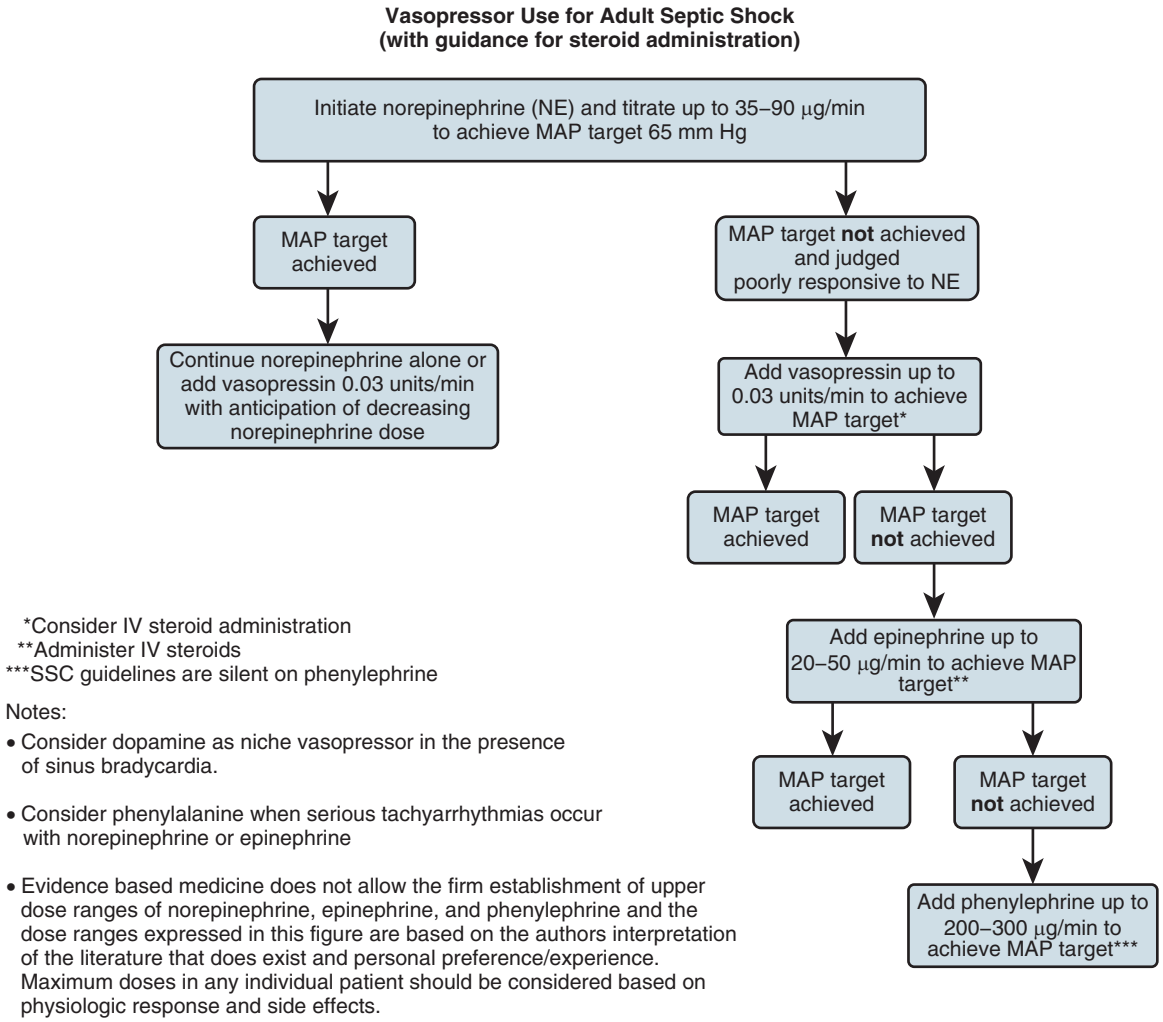
The SSC recommends norepinephrine as the first-line vasopressor agent in septic shock. The SSC further recommends the addition of either epinephrine or vasopressin (0.03 U/min) if a second vasopressor agent is needed to support the blood pressure. Fig. 24.11 offers a general guide to vasopressor selection and escalation in septic shock.

The Angiotensin II for the Treatment of High-Output Shock 3 (ATHOS-3) trial (randomized controlled) comparing angiotensin II with placebo in 344 patients with vasodilatory shock, 80% of whom had sepsis, was recently published. All the patients were receiving conventional vasopressor support (primarily norepinephrine) at the time of enrollment. Angiotensin II or placebo was

TABLE 24.5 Vasoactive Agents for Potential Use in the Hemodynamic Support of Septic Shock[a]

Agent	Typical Dose	Chronotropic Effects	Inotropic Effects	Vasoconstriction
Dopamine	6–20 μg/kg per minute	++	++	+/++ (dose-dependent)
Epinephrine	1–10 μg/min	++	++	++
Norepinephrine	2–50 μg/min	+	+	++
Phenylephrine	20–200 μg/min	–	–	++
Vasopressin	0.01–0.03 U/min	–	–	++
Dobutamine	2–15 μg/kg per minute	++	++	–

[a]Doses shown are common range of use. +, Low effect; ++, high effect; –, no effect.
Modified from Trzeciak S, Parrillo JE. Septic shock. In: *Society of Critical Care Medicine, 8th Adult Critical Care Refresher Course.* Chicago: Society of Critical Care Medicine; 2004.



• **Fig. 24.11** An example of how the guideline recommendations on vasopressor and steroid use can be molded into a flow diagram approach to the management of septic shock. (From Dellinger RP, Schorr CA, Levy MM. A users' guide to the 2016 Surviving Sepsis Guidelines. *Crit Care Med.* 2017;45:381–385.)

added to the background vasopressor regimen.[126] The primary endpoint was an increase in blood pressure at 3 hours without an increase in background vasopressor dose. The primary endpoint was reached by more patients in the angiotensin II group than in the placebo group (69.9% vs. 23.4%, $P < 0.001$). Rates of serious adverse events were not dissimilar between groups (60.7% with angiotensin II and 67.1% with placebo). This study showed that angiotensin II is an effective agent for raising blood pressure and works by a different mechanism than previously available vasopressors. It appeared safe in the patient population enrolled in this study that targeted patients without evidence of low CO. As a pure vasopressor there would be some concern if it was used in a low-CO septic shock scenario.[127]

Inotropic Support

Inotropic support may be required for patients with septic shock. In the context of severe sepsis-induced myocardial depression, or if the patient has severe preexisting myocardial dysfunction, an inotrope may be necessary to augment CO (in combination with a drug that is supporting the MAP). The SSC recommends that dobutamine be the inotrope selected. When used beyond early quantitative resuscitation (first 6 hours of therapy), inotropic therapy is ideally guided by measurements of cardiac index. A reasonable goal for inotropic therapy would be a cardiac index of 3.0 L/min per m^2 or greater.

Corticosteroids

Administering high doses of steroids (30 mg/kg of methylprednisolone) failed to show an outcome benefit in septic shock in large-scale randomized controlled trials in the 1980s.[128,129] These studies used large doses of steroids over a short time period in an attempt to blunt the proinflammatory response of sepsis. In contrast, an alternative strategy of administering low-dose (i.e., "stress" or "physiologic" dose) steroids appeared to be promising in multiple small studies in the 1990s.[130,131] Despite the fact that patients with septic shock typically have elevated serum cortisol levels, it was identified that some patients with septic shock may have "relative adrenal insufficiency," as evidenced by failure to mount a significant elevation of serum cortisol in response to IV adrenocorticotropic hormone (ACTH) stimulation. Relative adrenal insufficiency in the context of septic shock may predispose a patient to persistent cardiovascular failure that is refractory to conventional hemodynamic

support therapies, and administration of exogenous low-dose steroids could help achieve shock reversal. On the other hand, administration of exogenous steroids could be associated with deleterious effects such as immunosuppression or myopathy.

In 2000 Annane and colleagues performed an observational study focusing on the ability to respond to an ACTH stimulation test in septic shock.[132] The highest 28-day mortality rate (75%) was observed in patients who did not increase serum cortisol level greater than 9 μg/dL. Being a "nonresponder" was a better predictor of death than an initially low cortisol value. In a randomized controlled trial by the same investigators in 2002, 300 severely ill (persistent hypotension despite fluid resuscitation and vasopressor initiation) patients with septic shock were randomly assigned to 7 days of hydrocortisone plus fludrocortisone versus placebo.[133] The study found that in the 229 nonresponders administration of low-dose steroids was associated with an improvement in time to shock reversal and mortality rate. Patients who responded appropriately to ACTH stimulation test did not demonstrate a benefit with low-dose steroids.

The concept of low-dose steroid administration was further tested in a multicenter randomized controlled trial (Corticosteroid Therapy of Septic Shock [CORTICUS]).[134] This study found no difference in the primary outcome measure of mortality rate between those treated with steroids compared to placebo. However, it is notable that (1) in contrast to the Annane study in which all subjects had vasopressor-refractory septic shock, the CORTICUS study tested a more diverse patient population with overall lower severity sepsis, and (2) randomization in the Annane study occurred within 8 hours of patients developing shock as opposed to CORTICUS, which randomly assigned subjects up to 72 hours after shock onset.

The 2016 Surviving Sepsis Campaign guidelines suggest against the use of low-dose hydrocortisone (200 mg/day) if fluid resuscitation and vasopressors are able to restore hemodynamic stability. Since the publication of these guidelines a recent *New England Journal of Medicine* study randomly assigned 3800 mechanically ventilated patients with septic shock to a continuous daily infusion of 200 mg hydrocortisone versus placebo.[135] Steroids or placebo were continued until 7 days, death, or discharge from ICU. There was no difference in mortality at 90 days, primary endpoint (steroids 27.9% vs. placebo 28.8%, $P = 0.50$) or at 28 days (steroids 22.3% vs. placebo 24.3, $P = 0.13$). There was no difference in any of the secondary endpoints with the exception of faster resolution of shock and fewer transfusions in the steroid-treated patients. There was no evidence of increase in secondary infections (bacteremia or fungemia) in the steroid group. It is noteworthy that there was no steroid signal with more severe versus less severe illness or earlier versus later treatment. Patients taking higher doses of catecholamines did have better outcomes in the steroid-treated group compared to patients using lower doses of catecholamines. This large study was stellar in design, execution, and reporting but will unlikely end the debate about utility of steroids in select patients with septic shock.

Yet another recent trial testing the potential benefit of steroids in septic shock has been published, the APROCCHSS (Activated Protein C and Corticosteroids for Human Septic Shock) trial.[136] In this trial of 1241 patients with septic shock receiving 0.25 μg/kg or more of norepinephrine for at least 6 hours with severe dysfunction of at least 2 organ systems, the 90-day mortality was significantly less in patients treated with hydrocortisone 50 mg IV every 6 hours and oral fludrocortisone 50 μg each morning versus placebo. The 90-day survival was significantly increased in the steroid-treated group. There was an increase in vasopressor-free days in the steroid treatment group as well as increase in hyperglycemia, the latter common to all trials of steroids versus placebo in septic shock.

Despite the fact that low-dose steroids do not consistently improve clinical outcome in clinical trials, septic shock patients receiving sustained high doses of norepinephrine or multiple vasopressors may benefit. In this group steroids should be considered.

The recommended dose of IV hydrocortisone is 200 mg/day as either 50 mg IV every 6 hours or a 50-mg IV bolus followed by a 200-mg continuous infusion over 24 hours. The ACTH stimulation test is not recommended to identify candidates for steroid therapy, but rather the use of bedside clinical criteria of severity of shock. Hydrocortisone is administered for 7 days.

Modulation of the Host Response

The toxin, primary mediator, and secondary mediator cascade thought to drive infection-induced organ dysfunction is elaborate and often redundant. A multitude of studies since the late 1980s have targeted modulation of the host response due to the premise that organ dysfunction and mortality in severe sepsis and septic shock are based on a disorganized host response to microbial toxin. Large multicenter trials have targeted endotoxin (neutralization and removal), the proinflammatory response (such as anti-TNF, anti–IL-1, anti-bradykinin), and the procoagulant response (recombinant human–activated protein C, tissue factor pathway inhibitor). All efforts to date have been unsuccessful. More recently attention has turned toward immune enhancement in select patient populations in whom organ dysfunction and secondary infections may be driven by immune suppression with resultant morbidity and mortality. Efforts continue to unravel the molecular biology of severe sepsis and the potential to leverage that knowledge for patient benefit.

Summary

The systemic changes seen in sepsis are driven initially by the proinflammatory and procoagulant responses. Organ dysfunction may result and septic shock may be a result. Septic shock is a composite of hypovolemic, cardiogenic, and vasodilatory shock with the potential for intracellular mitochondrial dysfunction. Management includes restoring intravascular volume losses, both capillary leak (absolute loss) and venodilation (functional loss). Crystalloids are preferred as the initial fluid of choice. Vasopressors may be required if blood pressure is not restored with fluid administration. The balance of fluids and vasopressors to maintain mean arterial pressure is controversial and currently more of an art than a science. Corticosteroids, although controversial, do lead to earlier shock reversal but without proven mortality benefit and may be useful in select patients with more severe shock. Despite failure to date with clinical trials testing novel interventions targeting the sepsis cascade, study continues looking for success in this area.

Appendix: Recommendations and Best Practice Statements

A. Initial Resuscitation

1. Sepsis and septic shock are medical emergencies, and we recommend that treatment and resuscitation begin immediately (BPS [best practice statement]).
2. We recommend that, in the resuscitation from sepsis-induced hypoperfusion, at least 30 mL/kg of IV crystalloid fluid be given within the first 3 hours (strong recommendation, low quality of evidence).
3. We recommend that, following initial fluid resuscitation, additional fluids be guided by frequent reassessment of hemodynamic status (BPS).

   Remarks: Reassessment should include a thorough clinical examination and evaluation of available physiologic variables (heart rate, blood pressure, arterial oxygen saturation, respiratory rate, temperature, urine output, and others, as available) as well as other noninvasive or invasive monitoring, as available.
4. We recommend further hemodynamic assessment (such as assessing cardiac function) to determine the type of shock if the clinical examination does not lead to a clear diagnosis (BPS).
5. We suggest that dynamic over static variables be used to predict fluid responsiveness, where available (weak recommendation, low quality of evidence).
6. We recommend an initial target mean arterial pressure (MAP) of 65 mm Hg in patients with septic shock requiring vasopressors (strong recommendation, moderate quality of evidence).
7. We suggest guiding resuscitation to normalize lactate in patients with elevated lactate levels as a marker of tissue hypoperfusion (weak recommendation, low quality of evidence).

B. Screening for Sepsis and Performance Improvement

1. We recommend that hospitals and hospital systems have a performance improvement program for sepsis, including sepsis screening for acutely ill, high-risk patients (BPS).

C. Diagnosis

1. We recommend that appropriate routine microbiologic cultures (including blood) be obtained before starting antimicrobial therapy in patients with suspected sepsis or septic shock if doing so results in no substantial delay in the start of antimicrobials (BPS).

   Remarks: Appropriate routine microbiologic cultures always include at least two sets of blood cultures (aerobic and anaerobic).

D. Antimicrobial Therapy

1. We recommend that administration of IV antimicrobials should be initiated as soon as possible after recognition and within one hour for both sepsis and septic shock (strong recommendation, moderate quality of evidence).
2. We recommend empiric broad-spectrum therapy with one or more antimicrobials for patients presenting with sepsis or septic shock to cover all likely pathogens (including bacterial and potentially fungal or viral coverage) (strong recommendation, moderate quality of evidence).
3. We recommend that empiric antimicrobial therapy be narrowed once pathogen identification and sensitivities are established and/or adequate clinical improvement is noted (BPS).
4. We recommend against sustained systemic antimicrobial prophylaxis in patients with severe inflammatory states of noninfectious origin (e.g., severe pancreatitis, burn injury) (BPS).
5. We recommend that dosing strategies of antimicrobials be optimized based on accepted pharmacokinetic/pharmacodynamics principles and specific drug properties in patients with sepsis or septic shock (BPS).
6. We suggest empiric combination therapy (using at least two antibiotics of different antimicrobial classes) aimed at the most likely bacterial pathogen(s) for the initial management of septic shock (weak recommendation, low quality of evidence).
7. We suggest that combination therapy not be routinely used for ongoing treatment of most other serious infections, including bacteremia and sepsis without shock (weak recommendation, low quality of evidence).

   Remarks: This does not preclude the use of multidrug therapy to broaden antimicrobial activity.
8. We recommend against combination therapy for the routine treatment of neutropenic sepsis/bacteremia (strong recommendation, moderate quality of evidence).

   Remarks: This does not preclude the use of multidrug therapy to broaden antimicrobial activity.
9. If combination therapy is used for septic shock, we recommend de-escalation with discontinuation of combination therapy within the first few days in response to clinical improvement and/or evidence of infection resolution. This applies to both targeted (for culture-positive infections) and empiric (for culture-negative infections) combination therapy (BPS).
10. We suggest that an antimicrobial treatment duration of 7 to 10 days is adequate for most serious infections associated with sepsis and septic shock (weak recommendation, low quality of evidence).
11. We suggest that longer courses are appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *Staphylococcus aureus*, some fungal and viral infections, or immunologic deficiencies, including neutropenia (weak recommendation, low quality of evidence).
12. We suggest that shorter courses are appropriate in some patients, particularly those with rapid clinical resolution following effective source control of intraabdominal or urinary sepsis and those with anatomically uncomplicated pyelonephritis (weak recommendation, low quality of evidence).
13. We recommend daily assessment for de-escalation of antimicrobial therapy in patients with sepsis and septic shock (BPS).
14. We suggest that measurement of procalcitonin levels can be used to support shortening the duration of antimicrobial therapy in sepsis patients (weak recommendation, low quality of evidence).
15. We suggest that procalcitonin levels can be used to support the discontinuation of empiric antibiotics in patients who initially appeared to have sepsis, but subsequently have limited clinical evidence of infection (weak recommendation, low quality of evidence).

E. Source Control

1. We recommend that a specific anatomic diagnosis of infection requiring emergent source control should be identified or excluded as rapidly as possible in patients with sepsis or septic shock, and that any required source control intervention should be implemented as soon as medically and logistically practical after the diagnosis is made (BPS).
2. We recommend prompt removal of intravascular access devices that are a possible source of sepsis or septic shock after other vascular access has been established (BPS).

F. Fluid Therapy

1. We recommend that a fluid challenge technique be applied where fluid administration is continued as long as hemodynamic factors continue to improve (BPS).
2. We recommend crystalloids as the fluid of choice for initial resuscitation and subsequent intravascular volume replacement in patients with sepsis and septic shock (strong recommendation, moderate quality of evidence).
3. We suggest using either balanced crystalloids or saline for fluid resuscitation of patients with sepsis or septic shock (weak recommendation, low quality of evidence).
4. We suggest using albumin in addition to crystalloids for initial resuscitation and subsequent intravascular volume replacement in patients with sepsis and septic shock, when patients require substantial amounts of crystalloids (weak recommendation, low quality of evidence).
5. We recommend against using hydroxyethyl starches (HESs) for intravascular volume replacement in patients with sepsis or septic shock (strong recommendation, high quality of evidence).
6. We suggest using crystalloids over gelatins when resuscitating patients with sepsis or septic shock (weak recommendation, low quality of evidence).

G. Vasoactive Medications

1. We recommend norepinephrine as the first-choice vasopressor (strong recommendation, moderate quality of evidence).
2. We suggest adding either vasopressin (up to 0.03 U/min) (weak recommendation, moderate quality of evidence) or epinephrine (weak recommendation, low quality of evidence) to norepinephrine with the intent of raising mean arterial pressure to target, or adding vasopressin (up to 0.03 U/min) (weak recommendation, moderate quality of evidence) to decrease norepinephrine dosage.
3. We suggest using dopamine as an alternative vasopressor agent to norepinephrine only in highly selected patients (e.g., patients with low risk of tachyarrhythmias and absolute or relative bradycardia) (weak recommendation, low quality of evidence).
4. We recommend against using low-dose dopamine for renal protection (strong recommendation, high quality of evidence).
5. We suggest using dobutamine in patients who show evidence of persistent hypoperfusion despite adequate fluid loading and the use of vasopressor agents (weak recommendation, low quality of evidence).

   Remarks: If initiated, vasopressor dosing should be titrated to an end point reflecting perfusion, and the agent reduced or discontinued in the face of worsening hypotension or arrhythmias.
6. We suggest that all patients requiring vasopressors have an arterial catheter placed as soon as practical if resources are available (weak recommendation, very low quality of evidence).

H. Corticosteroids

1. We suggest against using IV hydrocortisone to treat septic shock patients if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability. If this is not achievable, we suggest IV hydrocortisone at a dose of 200 mg/day (weak recommendation, low quality of evidence).

I. Blood Products

1. We recommend that RBC transfusion occur only when hemoglobin concentration decreases to <7.0 g/dL in adults in the absence of extenuating circumstances, such as myocardial ischemia, severe hypoxemia, or acute hemorrhage (strong recommendation, high quality of evidence).
2. We recommend against the use of erythropoietin for treatment of anemia associated with sepsis (strong recommendation, moderate quality of evidence).
3. We suggest against the use of fresh frozen plasma to correct clotting abnormalities in the absence of bleeding or planned invasive procedures (weak recommendation, very low quality of evidence).
4. We suggest prophylactic platelet transfusion when counts are $<10{,}000/mm^3$ ($10 \times 10^9/L$) in the absence of apparent bleeding and when counts are $<20{,}000/mm^3$ ($20 \times 10^9/L$) if the patient has a significant risk of bleeding. Higher platelet counts ($\geq 50{,}000/mm^3$ [$50 \times 10^9/L$]) are advised for active bleeding, surgery, or invasive procedures (weak recommendation, very low quality of evidence).

J. Immunoglobulins

1. We suggest against the use of IV immunoglobulins in patients with sepsis or septic shock (weak recommendation, low quality of evidence).

K. Blood Purification

1. We make no recommendation regarding the use of blood purification techniques.

L. Anticoagulants

1. We recommend against the use of antithrombin for the treatment of sepsis and septic shock (strong recommendation, moderate quality of evidence).
2. We make no recommendation regarding the use of thrombomodulin or heparin for the treatment of sepsis or septic shock.

M. Mechanical Ventilation

1. We recommend using a target tidal volume of 6 mL/kg predicted body weight compared with 12 mL/kg in adult patients with sepsis-induced acute respiratory distress syndrome (ARDS) (strong recommendation, high quality of evidence).
2. We recommend using an upper limit goal for plateau pressures of 30 cm H_2O over higher plateau pressures in adult patients with sepsis-induced severe ARDS (strong recommendation, moderate quality of evidence).
3. We suggest using PEEP (higher positive end-expiratory pressure) over lower PEEP in adult patients with sepsis-induced moderate to severe ARDS (weak recommendation, moderate quality of evidence).
4. We suggest using recruitment maneuvers in adult patients with sepsis-induced, severe ARDS (weak recommendation, moderate quality of evidence).
5. We recommend using prone over supine position in adult patients with sepsis-induced ARDS and a PaO_2/FIO_2 ratio <150 (strong recommendation, moderate quality of evidence).
6. We recommend against using high-frequency oscillatory ventilation in adult patients with sepsis-induced ARDS (strong recommendation, moderate quality of evidence).
7. We make no recommendation regarding the use of noninvasive ventilation (NIV) for patients with sepsis-induced ARDS.
8. We suggest using neuromuscular blocking agents (NMBAs) for <48 hours in adult patients with sepsis-induced ARDS and a PaO_2/FIO_2 ratio <150 mm Hg (weak recommendation, moderate quality of evidence).

9. We recommend a conservative fluid strategy for patients with established sepsis-induced ARDS who do not have evidence of tissue hypoperfusion (strong recommendation, moderate quality of evidence).
10. We recommend against the use of β_2 agonists for the treatment of patients with sepsis-induced ARDS without bronchospasm (strong recommendation, moderate quality of evidence).
11. We recommend against the routine use of the PA (pulmonary artery) catheter for patients with sepsis-induced ARDS (strong recommendation, high quality of evidence).
12. We suggest using lower tidal volumes over higher tidal volumes in adult patients with sepsis-induced respiratory failure without ARDS (weak recommendation, low quality of evidence).
13. We recommend that mechanically ventilated sepsis patients be maintained with the head of the bed elevated between 30 and 45 degrees to limit aspiration risk and to prevent the development of VAP (ventilator-associated pneumonia) (strong recommendation, low quality of evidence).
14. We recommend using spontaneous breathing trials in mechanically ventilated patients with sepsis who are ready for weaning (strong recommendation, high quality of evidence).
15. We recommend using a weaning protocol in mechanically ventilated patients with sepsis-induced respiratory failure who can tolerate weaning (strong recommendation, moderate quality of evidence).

N. Sedation and Analgesia

1. We recommend that continuous or intermittent sedation be minimized in mechanically ventilated sepsis patients, targeting specific titration end points (BPS).

O. Glucose Control

1. We recommend a protocolized approach to blood glucose management in ICU patients with sepsis, commencing insulin dosing when two consecutive blood glucose levels are >180 mg/dL. This approach should target an upper blood glucose level ≤180 mg/dL rather than an upper target blood glucose level ≤110 mg/dL (strong recommendation, high quality of evidence).
2. We recommend that blood glucose values be monitored every 1 to 2 hours until glucose values and insulin infusion rates are stable, then every 4 hours thereafter in patients receiving insulin infusions (BPS).
3. We recommend that glucose levels obtained with point-of-care testing of capillary blood be interpreted with caution because such measurements may not accurately estimate arterial blood or plasma glucose values (BPS).
4. We suggest the use of arterial blood rather than capillary blood for point-of-care testing using glucose meters if patients have arterial catheters (weak recommendation, low quality of evidence).

P. Renal Replacement Therapy

1. We suggest that either continuous RRT (renal replacement therapy, CRRT) or intermittent RRT (renal replacement therapy) be used in patients with sepsis and acute kidney injury (weak recommendation, moderate quality of evidence).
2. We suggest using CRRT to facilitate management of fluid balance in hemodynamically unstable septic patients (weak recommendation, very low quality of evidence).
3. We suggest against the use of RRT in patients with sepsis and acute kidney injury for increase in creatinine or oliguria without other definitive indications for dialysis (weak recommendation, low quality of evidence).

Q. Bicarbonate Therapy

1. We suggest against the use of sodium bicarbonate therapy to improve hemodynamics or to reduce vasopressor requirements in patients with hypoperfusion-induced lactic acidemia with pH ≥7.15 (weak recommendation, moderate quality of evidence).

R. Venous Thromboembolism Prophylaxis

1. We recommend pharmacologic prophylaxis (unfractionated heparin [UFH] or low-molecular-weight heparin [LMWH]) against venous thromboembolism (VTE) in the absence of contraindications to the use of these agents (strong recommendation, moderate quality of evidence).
2. We recommend LMWH rather than UFH for VTE prophylaxis in the absence of contraindications to the use of LMWH (strong recommendation, moderate quality of evidence).
3. We suggest combination pharmacologic VTE prophylaxis and mechanical prophylaxis, whenever possible (weak recommendation, low quality of evidence).
4. We suggest mechanical VTE prophylaxis when pharmacologic VTE is contraindicated (weak recommendation, low quality of evidence).

S. Stress Ulcer Prophylaxis

1. We recommend that stress ulcer prophylaxis be given to patients with sepsis or septic shock who have risk factors for gastrointestinal (GI) bleeding (strong recommendation, low quality of evidence).
2. We suggest using either proton pump inhibitors (PPIs) or histamine-2 receptor antagonists (H2RAs) when stress ulcer prophylaxis is indicated (weak recommendation, low quality of evidence).
3. We recommend against stress ulcer prophylaxis in patients without risk factors for GI bleeding (BPS).

T. Nutrition

1. We recommend against the administration of early parenteral nutrition alone or parenteral nutrition in combination with enteral feedings (but rather initiate early enteral nutrition) in critically ill patients with sepsis or septic shock who can be fed enterally (strong recommendation, moderate quality of evidence).
2. We recommend against the administration of parenteral nutrition alone or in combination with enteral feeds (but rather to initiate IV glucose and advance enteral feeds as tolerated) over the first 7 days in critically ill patients with sepsis or septic shock for whom early enteral feeding is not feasible (strong recommendation, moderate quality of evidence).
3. We suggest the early initiation of enteral feeding rather than a complete fast or only IV glucose in critically ill patients with sepsis or septic shock who can be fed enterally (weak recommendation, low quality of evidence).
4. We suggest either early trophic/hypocaloric or early full enteral feeding in critically ill patients with sepsis or septic shock; if trophic/hypocaloric feeding is the initial strategy, then feeds should be advanced according to patient tolerance (weak recommendation, moderate quality of evidence).
5. We recommend against the use of omega-3 fatty acids as an immune supplement in critically ill patients with sepsis or septic shock (strong recommendation, low quality of evidence).

6. We suggest against routinely monitoring gastric residual volumes (GRVs) in critically ill patients with sepsis or septic shock (weak recommendation, low quality of evidence). However, we suggest measurement of gastric residuals in patients with feeding intolerance or who are considered to be at high risk of aspiration (weak recommendation, very low quality of evidence).

   Remarks: This recommendation refers to nonsurgical critically ill patients with sepsis or septic shock.
7. We suggest the use of prokinetic agents in critically ill patients with sepsis or septic shock and feeding intolerance (weak recommendation, low quality of evidence).
8. We suggest placement of post-pyloric feeding tubes in critically ill patients with sepsis or septic shock with feeding intolerance or who are considered to be at high risk of aspiration (weak recommendation, low quality of evidence).
9. We recommend against the use of IV selenium to treat sepsis and septic shock (strong recommendation, moderate quality of evidence).
10. We suggest against the use of arginine to treat sepsis and septic shock (weak recommendation, low quality of evidence).
11. We recommend against the use of glutamine to treat sepsis and septic shock (strong recommendation, moderate quality of evidence).
12. We make no recommendation about the use of carnitine for sepsis and septic shock.

U. Setting Goals of Care

1. We recommend that goals of care and prognosis be discussed with patients and families (BPS).
2. We recommend that goals of care be incorporated into treatment and end-of-life care planning, utilizing palliative care principles where appropriate (strong recommendation, moderate quality of evidence).
3. We suggest that goals of care be addressed as early as feasible, but no later than within 72 hours of ICU admission (weak recommendation, low quality of evidence).

Review Questions

For questions 1 through 5 use the following clinical scenario:

A 72-year-old man is admitted to the intensive care unit (ICU) from the medical ward because of hypotension (80/40 mm Hg) and presumed severe sepsis. He was admitted to the medical floor 12 hours ago for multilobar pneumonia with a moderate oxygen requirement. His condition has progressively worsened despite broad-spectrum antibiotic coverage. He is now febrile, tachycardic, and hypotensive. The pulse oximeter reads 88% on high-flow oxygen by face mask. Physical examination is significant for confusion, a markedly increased work of breathing, and coarse breath sounds. In addition to a severe metabolic acidosis, laboratory results reveal the following: white blood cell (WBC) count, 32,000 with 47% band forms; platelet count, 105,000/mm^3; hemoglobin level, 10.8 g/dL. Two liters of normal saline solution are rapidly administered as a bolus via peripheral intravenous (IV) line, and the blood pressure improves slightly. The patient is intubated for impending respiratory failure and mechanical ventilation is initiated. After pulmonary artery catheterization is performed, the following data are available:

Arterial blood pressure (mm Hg)	90/45
Mean arterial pressure (MAP) (mm Hg)	60
Heart rate (beats/min)	105
Central venous pressure (mm Hg)	10
Pulmonary artery pressure (mm Hg)	30/18
Pulmonary capillary wedge pressure (mm Hg)	16
Cardiac index (L/min per m^2)	2.1

Use this clinical scenario to answer the next five questions about the administration of vasoactive drugs. You will be given five sets of hemodynamic parameters. Match each set of hemodynamic parameters with a corresponding vasoactive drug administered to this patient.

a. Norepinephrine
b. Dopamine at 6 μg/kg per minute
c. Dopamine at 25 μg/kg per minute
d. Dobutamine
e. Phenylephrine

Question 1 Hemodynamic parameters.

Arterial blood pressure (mm Hg)	90/45
MAP (mm Hg)	60
Heart rate (beats/min)	115
Central venous pressure (mm Hg)	8
Pulmonary artery pressure (mm Hg)	25/15
Pulmonary capillary wedge pressure (mm Hg)	12
Cardiac index (L/min per m^2)	3.3

Question 2 Hemodynamic parameters.

Arterial blood pressure (mm Hg)	110/60
MAP (mm Hg)	77
Heart rate (beats/min)	90
Central venous pressure (mm Hg)	10
Pulmonary artery pressure (mm Hg)	30/18
Pulmonary capillary wedge pressure (mm Hg)	16
Cardiac index (L/min per m^2)	1.9

Question 3 Hemodynamic parameters.

Arterial blood pressure (mm Hg)	99/55
MAP (mm Hg)	70
Heart rate (beats/min)	115
Central venous pressure (mm Hg)	10
Pulmonary artery pressure (mm Hg)	30/18
Pulmonary capillary wedge pressure (mm Hg)	16
Cardiac index (L/min/m^2)	3.1

Question 4 Hemodynamic parameters.

Arterial blood pressure (mm Hg)	118/65
MAP (mm Hg)	80
Heart rate (beats/min)	120
Central venous pressure (mm Hg)	10
Pulmonary artery pressure (mm Hg)	30/15
Pulmonary capillary wedge pressure (mm Hg)	16
Cardiac index (L/min per m^2)	3.1

Question 5 Hemodynamic parameters.

Arterial blood pressure (mm Hg)	118/65
MAP (mm Hg)	80
Heart rate (beats/min)	95
Central venous pressure (mm Hg)	10
Pulmonary artery pressure (mm Hg)	30/18
Pulmonary capillary wedge pressure (mm Hg)	16
Cardiac index (L/min per m^2)	2.4

Answers

1: d. Dobutamine is an inotrope that primarily affects β_1-adrenergic receptors, which increases inotropy, chronotropy, and cardiac output. Dobutamine has little effect on α_1-receptors and β_2-receptors, which results in overall vasodilatation and a decrease in systemic vascular resistance (SVR). These two factors produce a net effect of increasing cardiac output and decreasing SVR, and they may cause a small decrease in blood pressure owing to the overall vasodilatation. Dobutamine is best used in patients with cardiogenic shock and refractory heart failure. Note that the use of dobutamine alone in this patient without an agent to support the blood pressure resulted in worsening hypotension.

2: e. Phenylephrine is primarily a vasopressor with purely α-adrenergic agonist properties. Because it produces vasoconstriction with negligible increases in cardiac inotropy or chronotropy, the increase in SVR is mainly responsible for the increase in mean arterial pressure (MAP). This may result in a reflex bradycardia. Overall, phenylephrine increases SVR with little or no change in cardiac output. Because phenylephrine lacks β-adrenergic properties, it is useful in patients with pure vasodilatory shock with normal cardiac function. Note that the use of phenylephrine in this patient decreased the already low cardiac index by increasing afterload on the heart.

3: b. Dopamine's effects can vary with the dose of drug administered. At lower doses (1–5 μg/kg per minute), dopamine primarily acts on dopamine-1 receptors in the splanchnic bed,

which results in selective vasodilatation and increased urine output. When the dose is increased (5–10 μg/kg per minute), dopamine also has effects on the β_1-adrenergic receptors. This causes an increase in stroke volume and heart rate, which ultimately results in increased cardiac output and usually a mild increase in systolic blood pressure.

4: c. At higher doses of dopamine (>10 μg/kg per minute), the α-adrenergic receptors are predominately affected. This leads to an overall vasoconstriction and increase in SVR, as well as an increase cardiac output and systolic blood pressure through its effects on β-adrenergic receptors. At high doses of dopamine, the drug can be used as a potent vasopressor.

5: a. Norepinephrine binds to both α_1-adrenergic and β_1-adrenergic receptors, which results in both potent vasoconstriction and a slight increase in cardiac output. Norepinephrine is commonly used in sepsis because of its potency in achieving desired MAP. The expected increase in cardiac output is much less than with dopamine; therefore an additional agent for inotropic support may be required in select patients with poor cardiac contractility.

6. Which of the following statements is *most* correct regarding the use of corticosteroids in patients with septic shock?

a. Corticosteroids are contraindicated in patients with septic shock.

b. Patients with septic shock should receive hydrocortisone 100 mg IV every 8 hours.

c. Corticosteroids should be considered for patients who remain hemodynamically unstable despite aggressive fluid and vasopressor resuscitation.

d. Corticosteroids should only be used in patients who do not respond to an adrenal corticotropic hormone (ACTH) stimulation test.

Answer: c. The use of corticosteroids in septic shock has a long and controversial history. Initial use of high-dose steroids to modulate inflammation was shown to be ineffective and was abandoned in the late 1980s. More recently the concept of relative adrenal insufficiency in septic shock was proposed, leading to a resurgence of the use of corticosteroids in septic shock. Furthermore, small studies and one randomized clinical trial showed that in nonresponders to an ACTH stimulation test, the use of hydrocortisone was associated with improved mortality. However, a large multicenter study (CORTICUS) failed to show any benefit with the use of hydrocortisone in patients with septic shock. The 2016 Surviving Sepsis Campaign guidelines recommend that IV hydrocortisone not be given to patients with septic shock in whom blood pressure responds to fluids and vasopressors. However, in patients who do not respond to aggressive fluid and vasopressor resuscitation, the use of steroids (200 mg hydrocortisone continuous infusion over 24 hours a day for 7 days or until shock resolution) should be considered as an adjunct to modulate the cardiovascular response of shock. The ADRENAL study (published in 2018) randomly assigned more than 3000 patients to the hydrocortisone regimen previously described versus placebo and failed to clarify the issue with faster resolution of shock but no difference in 28-day or 90-day mortality, albeit trends favoring steroids at both time points. The APROCCHSS trial (also published in 2018) randomly assigned 1241 patients to hydrocortisone/fludrocortisone versus placebo and demonstrated a survival advantage in the steroid treated patients. Steroid therapy should be considered in the more critically ill patient requiring high doses of vasopressors.

Management

Fundamentals of Tamponade

Pericardium surrounding the heart was described in antiquity by Hippocrates (460 BCE–370 BCE) who called it "a smooth mantle surrounding the heart."[1] Galen (129 CE–210 CE) was the first to note the presence of a pericardial effusion.[2] Tamponade was described in the 17th century by the Cornish clinician Richard Lower,[2] although the first known treatment was not attempted until 200 years later when the Austrian pathologist and surgeon Franz Schuh performed a successful pericardiocentesis. The term "cardiac tamponade" was coined by a German surgeon, Edmund Rose, and its hallmark, pulsus paradoxus, by Adolph Kussmaul, both in the 19th century. Claude Beck, an American heart surgeon, described his eponymous sign in 1935.[3] In 1964, Harvey Feigenbaum and colleagues demonstrated pericardial effusion by cardiac ultrasound.[4]

Cardiac tamponade is a condition characterized by an increase in pressure external to the heart, resulting in impaired filling of the cardiac chambers. In the typical scenario, as fluid in the pericardium accumulates, cardiac output falls. The diagnosis represents a continuum from mild tamponade with subtle diagnostic findings to a critical clinical setting with imminent mortality.[5] The variability in presentation, including diagnostic findings and course, and the morbidity and mortality associated with treatment make this a particularly challenging clinical problem in critical care medicine.

Pericardial Anatomy

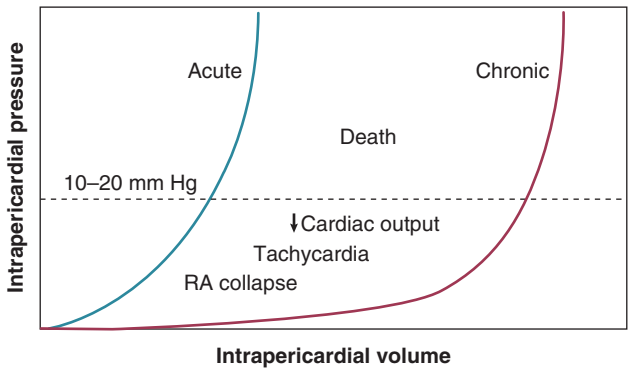
The pericardium consists of a visceral and a parietal pericardial segment, the former being composed of a single layer of cells that adhere to the cardiac epicardial surface.[6,7] The parietal pericardium is the structure responsible for the clinically relevant features of tamponade; it is a relatively noncompliant structure composed of collagen and elastin and normally is less than 2 mm thick.[8,9] The mechanical properties of the pericardium—in particular, those reflected by its pressure-volume curve (Fig. 25.1)—are responsible for the clinical features seen in cardiac tamponade.

The pericardium extends from the lower third of the superior vena cava to the apex of the heart. It is attached to the sternum, the diaphragm, and the proximal portion of the great vessels. Because it extends beyond the heart border, trauma to not only the heart but also the great vessels approaching the heart borders can lead to cardiac tamponade.[10,11] The main arterial blood supply of the pericardium is provided by the pericardiophrenic arteries which branch from the internal mammaries; the former are prominently visible when the latter have been used for bypass grafts and become occluded, and are sometimes mistaken for coronary vessels. The phrenic nerve provides sensory innervation, whereas vasomotor innervation comes from the sympathetic trunks.[12]

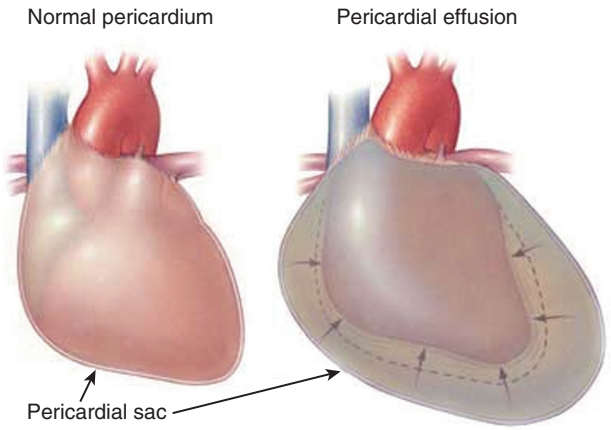
Physiology

Cardiac tamponade is a result of decreased transmural pressure (the difference between intracavitary and pericardial pressure), typically from accumulation of fluid in the pericardial space (Fig. 25.2). Other causes of "tamponade-like physiology" are related to extrinsic compression of the heart,[13] although these pathologic processes should be separated from those causing constriction rather than true tamponade. Differentiating between these two distinct physiologic entities, constriction and tamponade, is essential to diagnosis and management.

The fluid accumulating in the pericardial space can be blood, serous fluid, purulent material, clot, or rarely gas.[14] As fluid accumulates, the pericardium stretches, until it reaches a point (see Fig. 25.1) at which its degree of compliance is exhausted, so that it has become largely inelastic. At this point, any further



• **Fig. 25.1** Pressure-volume curves for normal pericardium on the *left* and compliant pericardium on the *right*. In the setting of rapid onset of effusion in the normal pericardium, low volumes, typically starting from less than 50 mL, lead to a rise in pressure that exceeds the limit of pericardial stretch, with early onset of tamponade physiology. With more compliant pericardium, a result of chronic stretching, critical extramural pressures do not result until substantially higher volumes are achieved, in some cases more than 1 L. *RA,* Right atrial.



• **Fig. 25.2** The pericardium surrounding the heart in a normal physiologic setting and in tamponade. The pericardium can be seen to extend to the proximal great vessels. Note the large amount of effusion in the image on the *right,* consistent with chronic pericardial stretch, which leads more slowly to tamponade. (Courtesy Mayo Foundation for Medical Education.)

increase in intrapericardial fluid is associated with a decrease in intracardiac chamber volume, because the total volume of pericardial fluid, heart muscle, and the cardiac chambers becomes fixed by pericardium no longer able to stretch. This in turn results in decreased filling of the heart and consequently decreased stroke volume. To maintain cardiac output, an early compensatory mechanism is an increase in heart rate. Subsequent adaptations to maintain blood flow to central end organs (heart, brain, kidneys) are venous pressure rise, peripheral vasoconstriction, increase in ejection fraction, and selective shunting of blood to preserve flow to the essential end organs. Venous pressure increase is accomplished by fluid retention and peripheral venoconstriction. In severe tamponade, equalization of right atrial, right ventricular (RV) diastolic, pulmonary diastolic, pulmonary artery wedge, and intrapericardial pressures occurs. Both pulmonary and systemic arterial and pulse pressures fall. Tamponade is a continuum, ranging from a primarily echocardiographic finding of right-sided chamber collapse to shock and pulseless electrical activity.

Pericardial Pressure

The normal pericardium contains a small amount of fluid, typically in a range of 20 to 50 mL, resulting in no more than 5 mm of separation between the visceral and the parietal pericardial surfaces. Pressure in the normal pericardium reflects intrathoracic pressure, which in turn reflects atmospheric pressure, with variation influenced by respiration. During inspiration, the pressure falls a few millimeters below atmospheric pressure (by convention, 0 mm Hg); during expiration, it increases a few millimeters above. The difference between intracardiac and intrapericardial pressures, the transmural pressure, in turn distends or compresses the cardiac chambers. Because intrapericardial mean pressure in patients breathing unassisted typically is the same as atmospheric pressure, whereas right atrial pressure is normally in the range of 2 to 8 mm Hg, the latter is the typical range of net right atrial transmural pressure. When intrapericardial pressure rises to the level of right atrial pressure, the right atrium collapses, a typical feature of early cardiac tamponade, although this nonspecific finding can be seen with hypovolemia alone.

The normal parietal pericardium, because of its limited compliance, functions to limit abrupt expansion of the heart as a whole.[15] Thus in the setting of right ventricular infarction, for example, acute dilation of the right ventricle is at the cost of left ventricular volume decrease—a ventricular interdependence phenomenon similar to that illustrated in Fig. 25.3. Acute chamber enlargement as the result of other etiologic conditions or disorders, such as abrupt volume loading or sudden onset of severe valvular regurgitation, is impeded by the constraint of pericardium that has reached the limits of its intrinsic elasticity. Because right-sided heart filling occurs preferentially with inspiration, when negative intrathoracic pressures result in increased venous return and higher right-sided chamber volume, left ventricular stroke volume, and hence systolic blood pressure, tend to fall as left atrial and left ventricular volumes are decreased. This exaggerates the normal respiratory variation, and systemic pressure falls with inspiration to a level at which pulsus paradoxus, defined by convention as a greater than 10 mm Hg decrease in systolic pressure, is seen. In addition, decreased intrathoracic pressure has a disproportionate effect on the pulmonary venous circulation, which is not exposed to the high pericardial pressures; hence a disproportionate fall during inspiration in the pulmonary vein to left atrial gradient further exacerbates the decrease in left atrial filling.[16] In fact, the fall in systolic pressure is not a paradox but rather an exaggeration of the normal respiratory variation of approximately 3%[17] with an associated inspiratory decrease in left ventricular stroke volume. With severe tamponade, total elimination of pulse pressure can be seen with individual heartbeats, as in the example in Fig. 25.4.

The inability to dilate further means that additional volume beyond the intrinsic stretch limit of the pericardium, such as from bleeding into the pericardial sac, results in increasing compression of heart chambers as volume expands in the pericardial space. Because the right-sided chambers have the lowest intracardiac pressures, in particular the right atrium, those are the first chambers to show collapse, particularly in diastole, when the tricuspid valve is open and the right atrium can decompress into the right ventricle. With progressive increase in intrapericardial pressure, compression of the right ventricle in diastole occurs during pressure equalization with the right atrium. Eventually, as intrapericardial pressure continues to rise, compression of the left-sided chambers ensues.

In contrast to acute tamponade physiology, in which hemodynamic decompensation may occur after only a modest accumulation

• **Fig. 25.3** Hemodynamic tracings from a patient with ventricular interdependence (200–mm Hg scale). With inspiration, left ventricular *(LV)* systolic pressure falls as right ventricular *(RV)* systolic pressure increases. Because of ventricular interdependence, the right ventricular and left ventricular systolic pressures trend in opposite directions (lines connecting peak systolic pressures diverge during phases of the respiratory cycle). Diastolic pressures in both ventricles are essentially identical *(green oval)*. Absence of pulsus paradoxus and preserved systolic pressure make this physiology consistent with constriction rather than tamponade. The patient had a clot in the pericardial space after prior cardiac trauma.

of fluid (generally in the range of 100–200 mL), chronic pericardial effusion results in gradual increase in distensibility of the pericardium. With increasing compliance, large amounts of fluid can accumulate at low pressure without decreasing transmural pressure or compressing the cardiac chambers (see Fig. 25.1). Even in chronic low pressure–high volume tamponade, a limit of distensibility is eventually reached that results in similar pathophysiology as with acute tamponade, in some cases only after a liter or more of fluid has accumulated. Once the steep portion of the pressure-volume curve is reached, it is important to appreciate that with accumulation of another 50 to 100 mL of pericardial fluid, hemodynamic decompensation can occur rapidly, with similar outcomes as in patients who have acute tamponade, such as is seen with penetrating trauma, coronary artery perforation, aortic dissection, or cardiac rupture.

Etiology

Pericardial effusions generally can be characterized as transudate or exudate, infectious or bloody, with tamponade occurring with variable frequency depending both on the rapidity of fluid accumulation and, to a somewhat lesser degree, on characteristics of the effusion and physiology determined by its etiology. Transudates are characteristic of congestive heart failure, radiation, and uremia; exudates are characteristic of infections, malignancy, and connective tissue disorders. Laboratory testing may help differentiate exudates from transudates; pericardial and serum protein, albumin, lactate dehydrogenase, cholesterol, and glucose should be obtained,[18] although some of the differentiating characteristics applicable to pleural effusions may not be discriminatory in pericardial effusions.[19] In addition, pericardial fluid total and differential cell count, Gram stain, aerobic and anaerobic culture, and mycobacterial and fungal evaluation should be performed along with cytology when malignancy is considered. Molecular techniques can be useful in diagnosing otherwise occult infections.[20] Amylase is reserved for cases when pancreatic disease or esophageal rupture is part of the differential diagnosis.

Conditions predisposing to slow accumulation—such as heart failure, myxedema, chronic renal failure, and connective tissue disorders in general—are less likely to cause acute tamponade, whereas those associated with rapid development, such as malignancy, infection (including bacterial, fungal, and human immunodeficiency virus–related), or particularly hemorrhage, commonly result in abrupt hemodynamic deterioration. The effect of

• **Fig. 25.4** Hemodynamic tracing of systemic pressure in cardiac tamponade, 100–mm Hg scale. Systolic pressure variation is nearly 40 mm Hg, and pulse pressure is markedly reduced during inspiration. Note the complete obliteration of the systemic pressure during deep inspiration in the beat highlighted by the *arrow.* Because of low stroke volume, cardiac output is being maintained to some extent by a high heart rate (146 beats/min).

inflammation in decreasing compliance of the pericardium exacerbates the hemodynamic effects of effusions associated with pericarditis.[21] The potential etiologic disorders are highly variable, with significant influence of demographics and geography, so that tamponade secondary to tuberculous pericardial effusion in immune-compromised patients is a not uncommon presentation in Africa,[22] whereas in industrialized nations malignant effusions are a far more common cause.[23] Large and usually benign pericardial effusions are seen frequently after heart transplantation, possibly immune-mediated.[24] Large pleural effusions can cause sufficient compression of the heart such that tamponade physiology occurs.[25] The most common etiologic disorders are listed in Table 25.1; more detailed discussion of the various causes is presented later in the chapter, organized by the hospital setting in which presentation typically is seen.

History and Physical Examination

Dyspnea is the most common symptom of tamponade, although its etiology sometimes is unexplained and it usually is not associated with significant concomitant pulmonary vascular congestion. It is likely to be secondary to decreased cardiac output and encroachment on lung volume by the expanding pericardium as well as any simultaneous pleural effusions. The patient may describe a sensation of fullness in the chest or abdomen and dysphagia, associated with venous engorgement and passive congestion, stretching of the richly innervated pericardium, and occasionally vagal stimulation.[26] Occasionally hoarseness and hiccups may be noted owing to the involvement of the recurrent laryngeal nerve and the phrenic nerve, respectively.[14] Because most patients with tamponade have comorbid conditions accounting for their effusion, additional signs and symptoms are likely to be related to pericarditis, malignancy, or other concomitant conditions.

The hallmarks of cardiac tamponade on physical examination relate to features associated with venous hypertension, low cardiac output, and effects of the layer of fluid between the heart and the chest wall. In patents with tamponade, the general appearance changes substantially during progressive increase in pericardial pressure. Because tamponade represents a continuum, some patients with early tamponade physiology look well, whereas patients with more advanced tamponade show features of a low-output state, with clinical manifestations reflecting the high catecholamine levels required to maintain cardiac output. They become progressively more anxious and agitated and less communicative and may be struggling to breathe. Patients may complain of chest pain associated with pericardial irritation, not infrequently radiating to the neck, jaw, or shoulder[27]; if venous congestion is acute, patients may experience pain from stretching of Glissen's capsule around the liver.

Pulsus Paradoxus

The physical examination in significant tamponade can include Beck's triad, composed of jugular venous distention, decreased

TABLE 25.1 Etiology of Cardiac Tamponade

Causative Disorder/Condition	Frequency (%)
Most common[a]	
Idiopathic	23
Malignancy	22
Iatrogenic	18
Acute myocardial infarction	8
Purulent (including tuberculous)	8
Renal failure	3
Miscellaneous	18
Aortic dissection	
Myxedema	
Trauma	
Connective tissue disorders	
Radiation therapy	

[a]Frequency of common etiologies of tamponade is based on 119 cases in Barcelona, Spain. Other relatively common causes of effusion include congestive heart failure, hypoalbuminemia, coagulopathy, and postcardiotomy and Dressler syndromes. Etiologies of tamponade will be dependent on geography and patient demographics and also will be strongly influenced by the presence of oncology, trauma, or dialysis units. For a comprehensive list of tamponade etiologies based on prior data, see Box 6.1.

Data from Sagrista-Sauleda J, Merce J, Permanyer-Miralda G, et al. Clinical clues to the causes of large pericardial effusions. *Am J Med.* 2000;109:95–101.

• BOX 25.1 Tamponade Settings in Which Pulsus Paradoxus May Not Be Present

- Nonrestrictive (large) atrial septal defect
- Severe aortic insufficiency
- Loculated effusion
- LV hypertrophy and other causes of elevated LV diastolic pressure
- Shock caused by hypovolemia, or profound circulatory collapse with tamponade
- Severe left ventricular dysfunction
- Low-pressure tamponade
- Right ventricular hypertrophy or other cause of impaired RV filling.
- Positive-pressure ventilation
- Arrhythmias

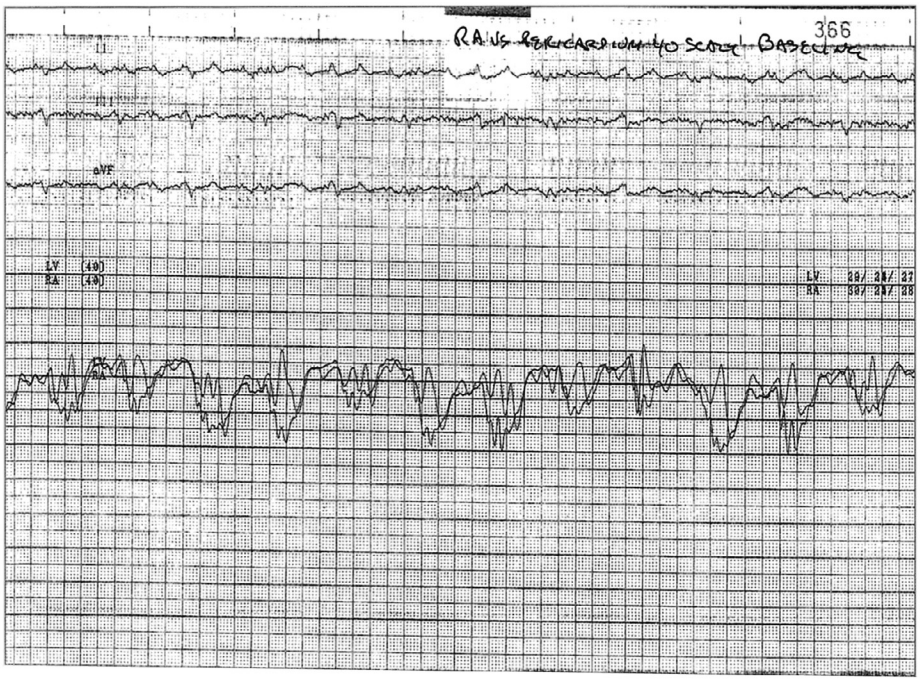
LV, *Left ventricular;* RV, *right ventricular.*

arterial pressure, and a small, quiet heart. As described earlier, pulsus paradoxus is the result of cardiac chamber interdependence and a decrease in left ventricular chamber volume with inspiration. It can be detected at the bedside by auscultation of Korotkoff sounds, identifying the highest and lowest pressures at which sounds are first heard during inspiration and expiration; alternatively, a simpler and more useful technique is to palpate the radial artery pulse with the cuff inflated to the maximum pressure at which the pulse appears and then to lower the cuff pressure in increments of 10 mm Hg to detect the pressure at which pulses are continuously noted throughout the respiratory cycle. In the patient whose systolic pressure is shown in Fig. 25.4, simple palpation of the radial pulse would detect the loss of pulse pressure in the beat indicated by the red arrow. It is important to recognize that although pulsus paradoxus is a classic feature of severe tamponade, as a diagnostic feature it is of limited sensitivity and specificity.

Various thresholds other than the relatively arbitrary 10-mm Hg threshold have been proposed to increase specificity, including a 10% decrease, rather than a 10-mm Hg fall.[28] A drop in *systolic* pressure greater than 50% of the *pulse* pressure has also been proposed.[5] Use of a 15- or 20-mm Hg fall in pressure by physical examination is a less sensitive but far more specific finding for tamponade but may result in a delayed diagnosis. Pulsus paradoxus may be present in other conditions that result in exaggerated decrease in systolic pressure with inspiration, such as massive pulmonary embolism, severe chronic obstructive pulmonary disease (which also can feature constrictive physiology because of limited expansion of the heart in the setting of hyperexpanded lungs),[28] and RV infarction.[29] Furthermore, other features of the systemic blood pressure and pulse are important to consider. With a progressive decrease in cardiac filling overall, a decline in systemic pressure (regardless of phase of the respiratory cycle) as well as a decrease in pulse pressure (the difference between systolic and diastolic pressures) occurs, reflecting decreasing stroke volume and decreasing cardiac output. Thus it may be impossible to palpate radial artery pulsations; with severe tamponade, the patient is likely to feel cool and clammy, a finding consistent with severe peripheral vasoconstriction.

Tachycardia is almost invariable, except for comorbid conditions associated with a decrease in heart rate, such as electrical conduction disturbances, severe hypothyroidism, or aggressive β-blockade. Tachycardia, a compensatory mechanism for decreased stroke volume, also is caused by high catecholamine levels and may result from pericardial irritation of the sinus node that stimulates a higher heart rate. On occasion, acute bradycardia may be seen in tamponade, and is sometimes the first finding after hemorrhage into the pericardial sac. Although a well-preserved systolic pressure and a wide pulse pressure are uncommon in tamponade, neither low pressure nor a narrow pulse pressure is completely specific. Further, early in the course of tamponade, acute surge in catecholamine levels may result in hypertension rather than shock. In addition, patients with tamponade in the setting of renal disease and chronic hypertension appear to present more often with elevated systolic pressures.[30]

The pulsus paradoxus may be absent in conditions in which ventricular interdependence is masked[31] (Box 25.1), such as a nonrestrictive atrial septal defect, in which inspiration also increases left atrial filling, or aortic insufficiency, in which left ventricular filling in diastole is increased by regurgitation from a high-pressure source: the aorta. Localized tamponade may have some general tamponade features (such as decreased stroke volume) but may not result in ventricular interdependence—hence, the clinical picture may be that of a sick patient with tamponade but without pulsus paradoxus. Markedly elevated left-sided heart diastolic pressures in severe left ventricular hypertrophy and other disease states may exceed the elevated right atrial and intrapericardial pressures in tamponade, decreasing the effect of inspiration on interdependence of right and left sides of the heart. An example in which both pulse pressure and pulsus paradoxus would be insensitive markers of tamponade is aortic dissection that combines aortic insufficiency with tamponade, in which a wide pulse pressure may be seen in some patients with partial compensation, and in which pulsus paradoxus, as discussed, may be masked. By contrast, conditions



• **Fig. 25.5** Hemodynamic tracings showing right atrial *(RA)* and intrapericardial pressures (incorrectly labeled LV) on 40–mm Hg scale. Note the equivalence of pressures as well as the high mean pressure, 27 mm Hg, consistent with tamponade and hemodynamic decompensation. The y descent is nearly absent.

resulting in impaired RV filling, such as RV hypertrophy in severe pulmonary hypertension, also may result in absence of a pulsus paradoxus[32]; furthermore, in settings such as cor pulmonale, the dramatic elevation in right-sided diastolic pressures will delay onset of the otherwise highly sensitive and early finding of right atrial and RV diastolic collapse until tamponade is severe.[33] A substantial number of case reports describe physiologic conditions in which the classic findings for tamponade are not seen or are attributable to other etiologic disorders.[34]

Venous Pressure

Because impairment of right-sided filling is usually the first manifestation of increasing pericardial pressure, high jugular venous pressure manifested by prominent venous pulsations may be the earliest finding on physical examination, occurring with increasing intrapericardial and right atrial pressures. Jugular venous distention may, however, be simultaneously absent because venoconstriction, a common finding with acute tamponade, makes detection of elevated venous pressures difficult. It also will be masked by low-volume tamponade, including volume-depleted states such as trauma, when, in addition to hemorrhage into the pericardium, significant blood loss has occurred. Other settings in which venous distention may not be observed include postdialysis patients with uremic pericardial effusions, and excessive diuresis, sometimes as part of treatment for symptoms of congestive heart failure when the cause of elevated filling pressures has not been appreciated.[35] In general, lack of venous engorgement in tamponade, particularly when the latter is acute, is not uncommon. Thus prominent jugular venous distention may suggest an alternative diagnosis, such as severe right-sided heart failure. Increased venous pressure with inspiration (Kussmaul's sign) is a feature of constriction, reflecting increased venous return to the thorax without increased right atrial filling, because the latter is constricted by the pericardium. This is in contrast to tamponade, in which negative intrathoracic pressure is transmitted through the pericardial effusion, and results in increased right-sided heart filling with decreased venous pressure. Because these findings are difficult to differentiate in most acutely ill patients, much of the subsequent description about right atrial pressure is based on catheter-based hemodynamic findings rather than the physical examination.

The y descent, in contrast with pericardial constriction in which it is prominent, typically is limited or absent (Fig. 25.5). Unlike in pericardial constriction, filling of the right ventricle (and hence emptying of the right atrium) is impaired throughout the cardiac cycle, because extrinsic compression by pericardial fluid results in elevated diastolic pressures in the right ventricle when rapid filling would otherwise occur. Because the pericardium allows additional atrial expansion during ventricular ejection (when ventricular volume decreases), the x descent (which occurs in early ventricular systole) is typically the more prominent negative pressure wave seen. The classic square root sign seen in the RV pressure tracing in constriction is absent in tamponade.

In contrast to acute tamponade, with chronic effusion the persistent elevation in pericardial pressure leads to parallel rise in central and peripheral venous pressure, as well as fluid retention with elevated intravascular volume. Venous congestion as well as peripheral edema and end-organ signs of chronic venous hypertension, such as passive congestion of the liver, become more common in this setting.

Cardiac and Chest Examination

The quiet heart in Beck's triad relates to several features that tend to muffle the intensity of heart sounds. First, the insulating effects of pericardial fluid on sound waves tend to decrease the sound

volume transmitted to the chest wall. Second, low stroke and filling volumes tend to decrease the forces that cause the sounds generated by heart valve closure, with low pulse pressure in both the aortic and the pulmonary arteries. Because the S_3 gallop is created by rapid ventricular filling, a phenomenon absent in tamponade, it would not be expected, nor would an S_4, because the hemodynamic characteristics of late diastolic atrial emptying that causes the fourth heart sound are not seen.[5] If pericarditis is involved, a pericardial friction rub may be heard. Except in severe tamponade, the pericardium around the apex of the heart may contain relatively little fluid, and left ventricular contraction typically is vigorous unless underlying left ventricular dysfunction also is present. Hence, a palpable point of maximal impulse may be felt.

A particular feature that differentiates tamponade from decompensated congestive heart failure is the typical presence of clear lungs in the case of the former. Although both right and left atrial pressures are markedly elevated, flow into the pulmonary circulation is limited, and the pressure-volume curve for the pulmonary vascular system is not affected.

Diagnostic Tests

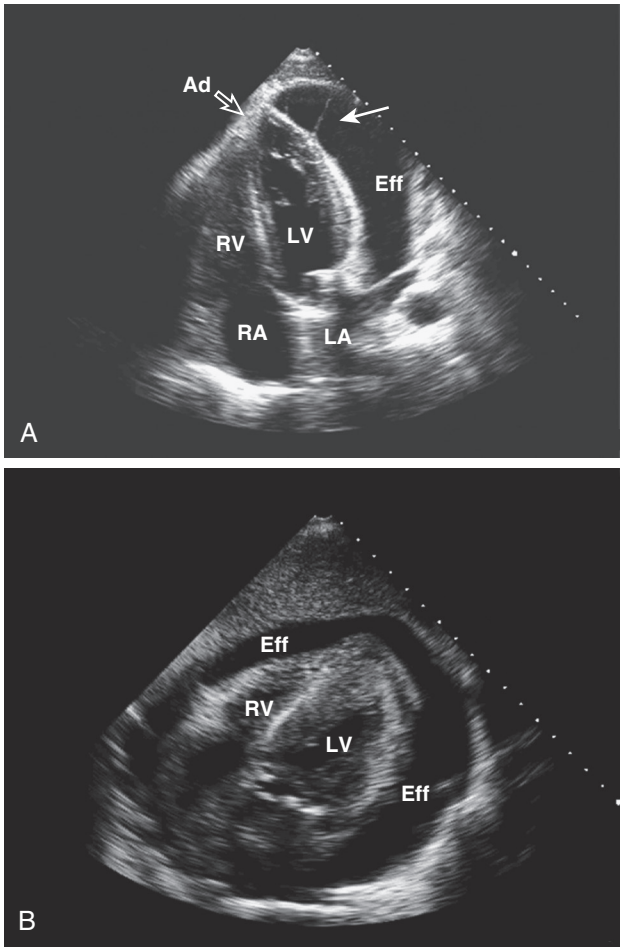
Echocardiography

Echocardiography is the most easily accessible and accurate means for the timely diagnosis of tamponade and remains the diagnostic modality of choice.[36] Besides evaluating presence and degree of chamber collapse, the echocardiogram is useful for assessing the amount and location of effusion in the pericardial space, for characterizing the fluid, and for judging the hemodynamic effect. Cardiac tamponade represents an echocardiographic continuum, from a small accumulation of fluid with at most subtle clinical findings, to large, usually circumferential[37] accumulations with resultant cardiogenic shock. Until effusions are at least moderate in size, fluid may be shifted by gravity to a location primarily posterior to the heart, because most patients are recumbent during echocardiography (Fig. 25.6).

Several echocardiographic features have been described in tamponade that result from an increase in intrapericardial pressure. These include exaggerated late diastolic right atrial collapse, early diastolic RV collapse, significant respiratory variation in Doppler inflow velocities across the tricuspid and mitral valves, plethora of the inferior vena cava (IVC), exaggerated expiratory flow reversal of the hepatic veins, and blunted diastolic flow of the inferior vena cava during expiration.[38] Since the right-sided cardiac chambers are more compliant, thin-walled, and at relatively low pressure, the increase in intrapericardial pressure will result in the collapse of these chambers first.

Immediately after atrial contraction, the right atrial volume is at its lowest, whereas RV volume is at its maximum; total pericardial volume in cardiac tamponade is relatively fixed. The increase in ventricular filling during diastole increases pericardial pressure, which prevents expansion of the right atrium during atrial relaxation (late ventricular diastole).[39] Persistence of right atrial collapse for more than one-third of the cardiac cycle is a useful marker for early tamponade physiology. This phenomenon is best appreciated from the apical or subcostal four-chamber views (see Fig. 8.42B).

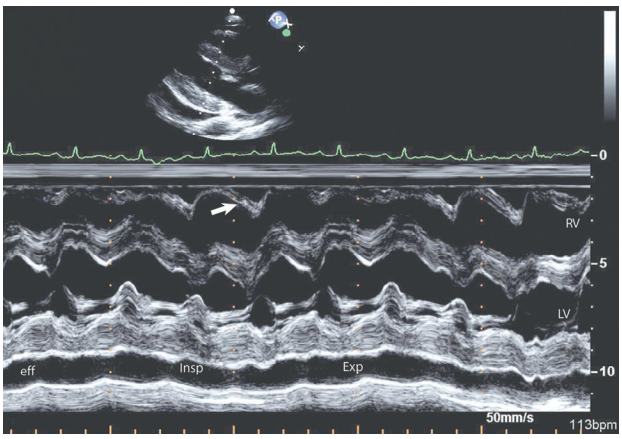
The right ventricle, conversely, is more vulnerable to collapse during early diastole, when its pressure is at its lowest as it expands after closure of the pulmonic valve. The RV outflow tract is the more compressible area of the right ventricle and hence tends to collapse first.[38] With increasing intrapericardial pressure, the collapse extends



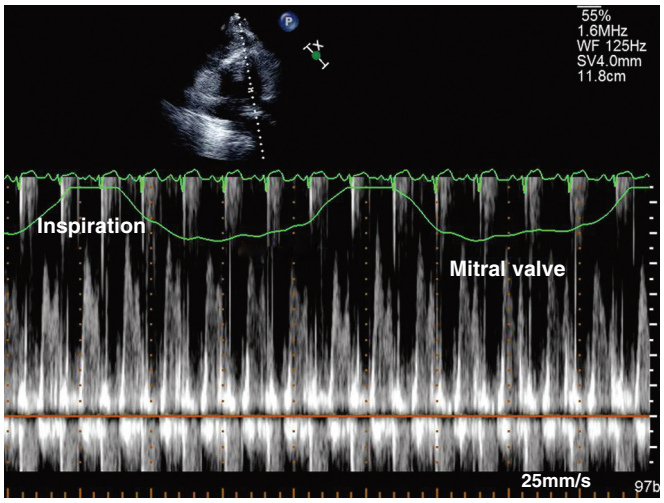
• **Fig. 25.6** Echocardiographic images of two types of pericardial effusions. A, A large posterior pericardial effusion, with relatively little fluid anterior to the heart or at the apex. The apex is adherent to the pericardial surface. The *arrow* points to a fibrous strand. This is a fairly typical appearance of a chronic postcardiotomy effusion. Needle access would be problematic. B, By contrast, this effusion is circumferential, with somewhat more fluid behind the left ventricle, a largely gravitational effect. Leaning the patient forward 20 to 30 degrees would facilitate pericardiocentesis, although the patient was not significantly hemodynamically compromised. *Ad,* Adhesion; *Eff,* effusion; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Courtesy Priscilla Peters, BA, RDCS, FASE.)

to the RV free wall, which is best appreciated on parasternal long- or short-axis views (see Fig. 8.43). This is a more specific finding for tamponade than right atrial collapse because the latter can occur in the setting of hypovolemia alone. However, RV diastolic collapse may not be seen in conditions that result in significantly elevated RV diastolic pressure (because transmural pressure is relatively high) or in RV hypertrophy. Collapse of the higher-pressure left-sided chambers, particularly the left ventricle, is uncommon, but when seen it is highly specific for tamponade. Collapse of the left atrium is not uncommon in the immediate postcardiac surgery period, frequently a result of loculated effusion causing regional tamponade.[40]

Although cardiac chamber collapse is a highly sensitive marker and is typically seen before clinical manifestations of tamponade, a number of other findings are more specific. As discussed previously, pulsus paradoxus results from exaggerated ventricular coupling. The ventricular interdependence (Fig. 25.7) can be appreciated on echocardiography by demonstration of marked respiratory variation



• **Fig. 25.7** Classic findings for ventricular interdependence in cardiac tamponade (see legend Fig. 8.44). (Courtesy Priscilla Peters, BA, RDCS, FASE.)



• **Fig. 25.8** Doppler inflow of mitral valve with tamponade, demonstrating enhancement with expiration and decrease with inspiration (see legend 8.49). (Courtesy Priscilla Peters, BA, RDCS, FASE.)

of Doppler flow across the atrioventricular or semilunar valves (see Figs. 8.49 and 8.50). During inspiration, the drop in intrathoracic pressure results in increased RV filling. As RV cavity size increases during diastole, expansion of the RV free wall is impaired by the increased intrapericardial pressure, and continued RV filling is accomplished only by diastolic expansion of the interventricular septum. The consequent bulging of the interventricular septum into the left ventricular cavity during diastole results in marked reduction in LV compliance and inspiratory filling.[21,41] These filling changes are reflected in a marked inspiratory increase in tricuspid valve Doppler inflow velocities with simultaneous inspiratory decrease in mitral valve inflow velocities. Reciprocal changes are noted during expiration (Fig. 25.8). A corollary to these respiratory changes is noted in the hepatic vein and vena cava flow patterns. Normal vena cava flow into the right atrium occurs during both ventricular systole and diastole. In tamponade, already impaired diastolic flow is further compromised in expiration by the exaggerated ventricular interdependence. This hemodynamic effect manifests on Doppler as blunted diastolic caval flow during expiration with increased expiratory flow reversal in the Doppler flow pattern of hepatic veins.[42] Although it is expected that in tamponade the IVC will be dilated and nonreactive,[43] plethora of the IVC can be seen in any condition causing elevation of right atrial pressure, including positive-pressure ventilation in an intubated patient.

Portable echocardiography, performed at the bedside, in the emergency department, or in critical care units, is highly reliable in cardiac tamponade.[44,45] However, adequate training in basic technique and fundamental anatomy is essential to avoid misdiagnosis. Epicardial fat can be confused with effusion,[46] and isolated or coexistent pleural effusions, mediastinal masses, and atelectasis can confound the diagnosis as well.[47] It is important to assess the heart from as many echocardiographic windows as possible for small but opportunistic loculated accumulations of fluid, for presence of clot, fibrinous "strandlike" material or masses, and for compression from processes outside the pericardium, such as a mediastinal hematoma and pleural effusion, all of which will have a significant impact on management.

X-Ray Studies

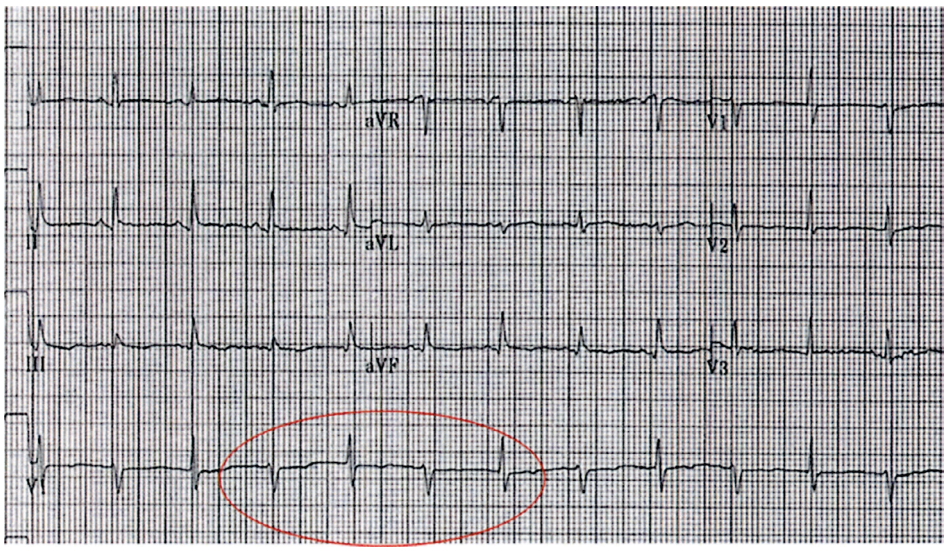
The classic "water bottle" configuration of the heart is due to a large pericardial effusion and therefore occurs only if the pressure-volume curve has altered sufficiently through chronic accumulation to allow significant increase in pericardial volume. It is a misconception that a normal-sized heart excludes tamponade; in acute tamponade the heart size can be expected to appear normal or minimally enlarged.[21] With marked enlargement of the cardiac silhouette, the finding is nonspecific and not readily distinguishable from cardiomegaly, although in tamponade pulmonary vascular congestion is usually not seen, although prominence of the vena cava may be noted. Other modalities such as computed tomographic (CT) scanning and magnetic resonance imaging show large effusions and can demonstrate chamber collapse. In addition, characterization of pericardial thickness and of the pericardial fluid to differentiate between blood and fluid of different densities can be useful. Although CT and magnetic resonance imaging show primarily anatomy rather than physiology, they can identify chamber collapse, characterize soft tissue, and demonstrate reflux into the azygous vein, a useful sign of tamponade.[48] CT scanning can provide information supplemental to that seen on echocardiography, including identification of extracardiac disease lesions,[49] and can provide additional sensitivity for detection of loculated effusions.[46] Coronary sinus compression on CT scanning is an early and specific indicator of tamponade.[50]

Electrocardiography

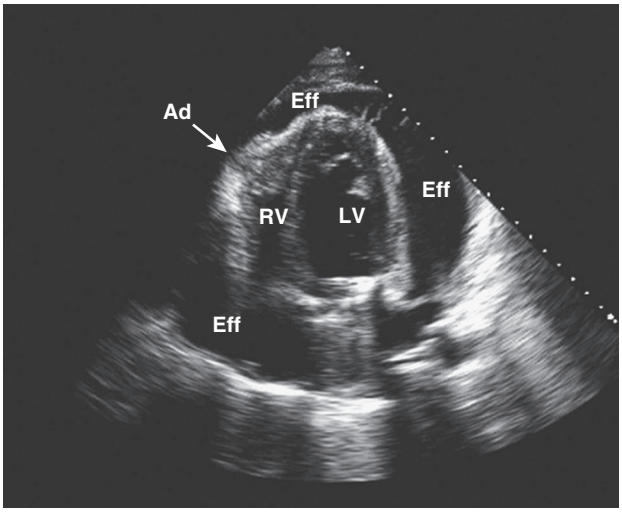
The classic electrocardiographic features include low voltage, a result of poor transmission of electrical activity across the fluid in the pericardial space, and electrical alternans, an insensitive but relatively specific finding for tamponade generated by swinging of the heart in the fluid-filled chamber (Fig. 25.9). Electrical alternans typically is seen only with large effusions in the later stages of tamponade, although the finding is related more to fluid volume and the ability of the heart to swing within the pericardial space. It may involve alternans of both QRS complexes and P waves. Thus tamponade with adhesions (Fig. 25.10), loculation, or masses that restrict heart motion may not manifest the alternans phenomenon.

Overall Assessment

In general, the severity of tamponade can be judged by the extent of hypotension, tachycardia, and pulsus paradoxus on physical



• **Fig. 25.9** Electrocardiogram demonstrating classic electrical alternans in a patient with pericardial tamponade. Note the change in amplitude of the R wave in lead V1 *(red oval)*. Similar findings are seen throughout the limb and precordial leads shown.



• **Fig. 25.10** Echocardiogram showing pericardial tamponade with right-sided collapse, adhesion of the right ventricle to the pericardium *(arrow),* and fibrous strands of early adhesions seen at the 1-o'clock position near the apex of the left ventricle. Even if the effusion accumulates further, electrical alternans would be less likely because of lack of mobility of the heart. *Ad,* Adhesion; *Eff,* effusion; *LV,* left ventricle; *RV*, right ventricle. (Courtesy Priscilla Peters, BA, RDCS, FASE.)

examination and confirmed by findings on echocardiography.[51] Mild tamponade features no hypotension or tachycardia, and no pulsus, with mild RV collapse by echocardiography. Patients with moderate tamponade have preservation of systemic pressure, but they have tachycardia, some degree of pulsus paradoxus, and clear RV collapse on echocardiography. Severe tamponade is associated with tachycardia, shock, profound pulsus paradoxus, and chamber collapse with a swinging heart on ultrasound.[29] Hemodynamic findings correlate with increasing pericardial pressure at each stage of tamponade,[52] initially less than right atrial or pulmonary wedge pressure, then equilibrating with right but less than left atrial pressure, and in severe tamponade equilibrating with both.

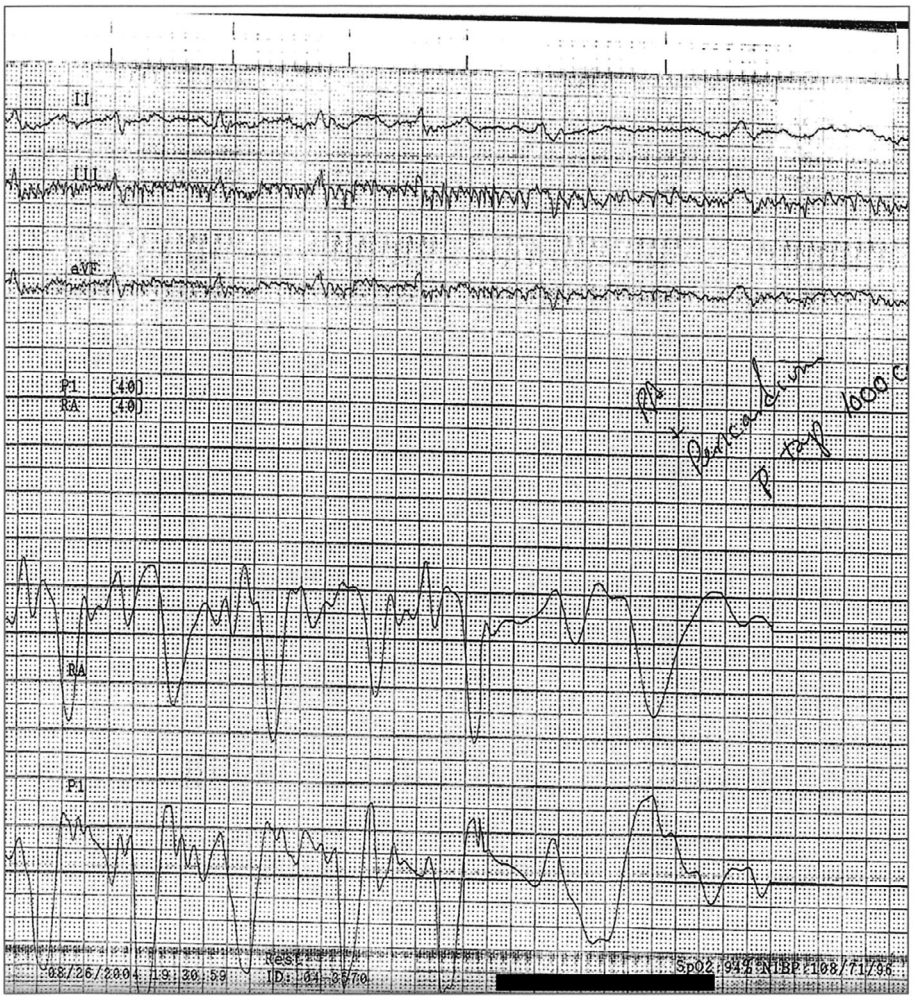
Special Syndromes in Tamponade

Although most cases of tamponade have at least some of the classic features, there are several important variants. Loculated effusions that compress the heart primarily in one region typically occur after surgery, although they may be due to neoplasms or a number of other etiologies as discussed later in the chapter. There are also a number of conditions in which pulsus paradoxus does not occur or is masked (see Box 25.1).

Effusive Constrictive Disease

This phenomenon is an important-to-recognize condition that occurs in less than 10% of patients with tamponade,[53] but in up to 40% of patients in some series. Hospitals with disproportionately high populations of oncology patients, either because of tumor metastases or postradiation pericardial involvement or tuberculosis, will have a higher percentage of tamponade patients with this diagnosis. The syndrome can occur after acute pericarditis of multiple etiologies and may even be transient.[54] The classic features of tamponade are seen on presentation, and a history of malignancy should increase the suspicion prepericardiocentesis.

Effusive constrictive disease is a setting in which careful hemodynamic monitoring is very helpful for accurate diagnosis. Monitoring of intrapericardial and right atrial or wedge pressure during pericardiocentesis demonstrates findings as seen in Fig. 25.11. In general, intrapericardial hypertension resolves with relief of tamponade, and classic respiratory variation is seen in most patients, whereas right atrial pressure remains elevated, though lower than before the pericardiocentesis. The y descent becomes prominent because of the elimination of high transmural pressures that restrict filling during early diastole in tamponade, unmasking classic constrictive physiology. Fig. 25.12 shows echocardiographic images in a typical patient with this syndrome.



• **Fig. 25.11** Hemodynamic tracings (40–mm Hg scale) obtained 1 hour after those shown in Fig. 25.5. After pericardiocentesis of 1 L of fluid, the pericardial pressure has achieved a mean equivalent to atmospheric pressure (0 mm Hg by convention), while right atrial pressure remains elevated near 22 mm Hg. This is physiology consistent with effusive-constrictive disease. On removal of the effusion, the hemodynamics, including the newly seen steep y descent, are classic for constriction. This patient had a malignant pericardial effusion. *P,* Intrapericardial pressure; *RA,* right atrium.

Low- and High-Pressure Tamponade

Low-pressure tamponade has been defined as featuring hypotension secondary to pericardial effusion but with low venous and intrapericardial pressures, most commonly in the setting of hypovolemia caused by dehydration or blood loss. A more formal definition, based on a single site experience, was described by Sagrista-Sauleda and colleagues[55] as an intrapericardial pressure less than 7 mm Hg, with a postpericardiocentesis right atrial pressure less than 4 mm Hg and equalization of intrapericardial and right atrial pressures before pericardiocentesis. Importantly, 20% of their patients with cardiac tamponade met these criteria (and 10% of their patients with large pericardial effusions), suggesting that low-pressure tamponade, previously the subject primarily of case reports and small series, may be more common than previously appreciated. Because of low pressures, there is a lack of features such as pulsus paradoxus or jugular venous distention, with only 24% demonstrating these classic findings, making the diagnosis significantly more difficult. Fluid challenge may result in more typical findings.

Patients with chronic hypertension in whom tamponade develops occasionally have high blood pressure despite tamponade physiology, presumably because of an exaggerated systemic pressure response to the catecholamine storm associated with tamponade.[56] In this setting, injudicious use of the usual medications to lower blood pressure can result in profound hemodynamic compromise.

Settings in Which Tamponade Is Seen

Emergency Department

The primary cause of tamponade in the emergency department relates to hemopericardium, although the complete range of medical etiologies can be seen in this setting. Trauma includes gunshot and stab wounds, as well as penetrating and crush wounds to the chest, including those related to automobile accidents.[57–59] Penetrating wounds are significantly more likely to result in tamponade than crush injuries.[60] Medical presentations with acute hemopericardium include aortic dissection with tamponade, post–myocardial

(Courtesy Priscilla Peters, BA, RDCS, FASE.)

infarction (MI) rupture, or leaking thoracic aneurysm, situations in which pericardiocentesis may lead to further hemodynamic decompensation,[61,62] as well as hemopericardium secondary to overanticoagulation. In general, acute hemopericardium may be associated with continued hemorrhage as well as clot in the pericardium; the latter makes complete drainage difficult. Clot alone can compress the heart and cause tamponade-like physiology. The clinical presentation of acute intrapericardial hemorrhage is typically shock, and jugular venous distention may or may not be present because of venoconstriction and hypovolemia as previously described. Use of echocardiography in the emergency department in patients with unexplained dyspnea is an important diagnostic tool.[63]

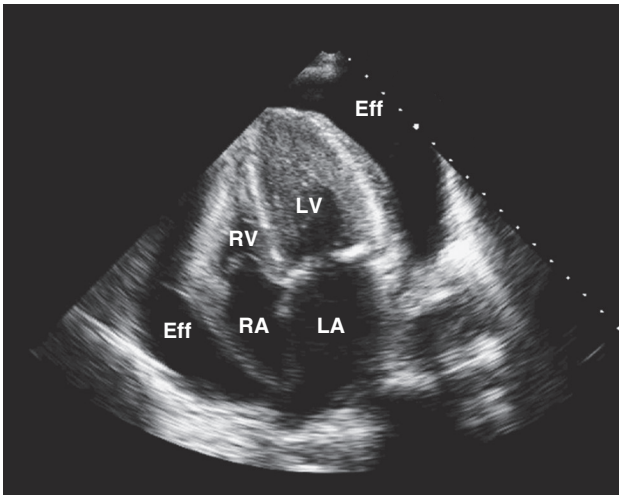
Cardiac Catheterization and Electrophysiology Laboratories

Perforation of the heart, including coronary arteries and cardiac chambers, during invasive cardiac procedures has become an increasingly important cause of pericardial tamponade.[64] Common scenarios include electrophysiology procedures, where relatively stiff catheters are placed in the relatively thin-walled structures of the right heart, including the right atrium, right ventricle, and the coronary venous system including the coronary sinus. Anticoagulation, when required for electrophysiology procedures, such as those involving left atrial ablation, raises the risk substantially. Perforation of coronary arteries occurs in particular with atheroablation devices such as those used for rotational atherectomy, directional atherectomy and lasers, with guidewires used in chronic total occlusions or injudiciously manipulated distal to the target lesion, and with oversized balloons and stents.[65] Even with normal sizing, settings such as myocardial bridges or ruptured balloons are associated with vessel perforation or rupture. A third setting is transseptal puncture, a resurgent technique because of burgeoning technologies requiring left atrial access[66] but associated with a significant risk of tamponade.[67–69] Besides left-sided ablations, mitral valvuloplasties, and percutaneous circulatory bypass (with its intake source in the left atrium), transseptal puncture is required for a rapidly expanding number of procedures, including left atrial appendage occlusion[70] and percutaneous mitral valve repair.[71] The risk of pericardial effusion and tamponade with these interventions contributes significantly to their overall morbidity and mortality.[64] However, and somewhat counterintuitively, electrophysiologists now frequently anticoagulate before transseptal puncture or perform the procedure in patients already using full oral anticoagulation.[72] This practice is driven by fear of thromboembolism rather than tamponade; the former is an important complication of left-sided ablations in particular, which can be long procedures, and is associated with clot-inducing char formation. Other endovascular procedures associated with tamponade include myocardial biopsy and central venous line placement, pacemaker lead extraction,[73] as well as erosion of devices implanted across the atrial septum or in the left atrial appendage[74–78] or acute or delayed perforation of the right ventricle from pacemaker or implantable cardioverter defibrillator lead.[79–81]

The potentially catastrophic setting of free perforation during coronary interventions is usually readily diagnosable during the procedure, with free flow in the pericardium seen during coronary injection, sometimes before the patient shows any signs of hemodynamic deterioration. This is readily treatable with balloon occlusion of the coronary artery at the perforation site, pericardiocentesis if necessary, and excluding the fenestration with a covered stent. However, lower-grade perforations that result in pooling of contrast or small adventitial craters can be more subtle. It is essential to discontinue anticoagulation in such patients and consider heparin reversal, and to ensure that personnel responsible for postprocedure management monitor the patient closely for hypotension and tachycardia. With transseptal punctures, hypotension at any time during the case, but especially after anticoagulation is administered, should raise the possibility of tamponade. A quick and relatively specific finding in the catheterization laboratory is straightening and lack of motion of the left heart border on anteroposterior fluoroscopy associated with hypotension (and sometimes reflex bradycardia); rapid intervention is essential in these patients. Hypotension after the procedure should raise the possibility that left atrial access involved a "stitch perforation" whereby the needle exited the right atrium and then entered the left atrium through the pericardial space; this mishap is possible with low punctures and frequently manifests only when catheters are removed from the fenestration at the end of the procedure. In patients who have had pacemaker placement, tamponade can develop acutely or after considerable delay as in the case of lead erosion.[82]

Critical Care Units and Medical Wards

Tamponade in the critical care unit typically is due to complications of MI, concomitant sepsis with purulent pericarditis, or hemorrhage into the pericardium because of anticoagulation (either



• **Fig. 25.13** Echocardiogram showing large circumferential pericardial effusion in myxedema. Severe tamponade is rare. *Eff,* Effusion; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Courtesy Priscilla Peters, BA, RDCS, FASE.)

iatrogenic or endogenous) or, most commonly, is secondary to neoplasms. In MI, tamponade can be acute, secondary to massive or limited rupture, or somewhat more insidious in onset as part of Dressler syndrome, with hemodynamic compromise sometimes exacerbated by anticoagulation. Tamponade also can be iatrogenic, in particular, secondary to placement of various lines through the venous or arterial circulation. Uncommon causes of tamponade, even with pericardial effusions of sometimes significant size, are viral pericarditis, congestive heart failure, uremia, myxedema (Fig. 25.13), and connective tissue disorders.

In patients with malignancy, several possible causes of tamponade are seen, including tumor involvement in the pericardium, postradiation pericarditis, graft-versus-host disease, and direct or indirect complications of therapy.[83] Patients with malignancies also are at increased risk for infectious pericarditis, coagulopathies or thrombocytopenia with secondary hemorrhage, and hypothyroid- and hypoalbuminemia-related effusions. Patients with AIDS and other immunosuppressed patients similarly are predisposed to infectious tamponade, as well as pericardial tumor involvement, including that from lymphoma. The mechanisms of pericardial effusion in cancer are varied but include direct spread to the pericardium from primary tumors such as lung, mediastinal, and esophageal cancer; hematogenous spread such as with lymphomas; and obstruction of the lymphatic drainage of the heart by tumors in the mediastinum.

Tamponade after cardiac surgery is an important phenomenon, usually occurring as a result of hemorrhagic effusion. Early postoperative tamponade is not uncommon and is important to recognize as a cause of hypotension because it has been reported to occur with a frequency of 5% to 10%, although this generally is thought to be in the 1% range in the modern era.[84] Moderate to large pericardial effusions that do not cause hemodynamic compromise have been much more common.[85] Delayed tamponade after heart surgery, with onset on average at 2 to 3 weeks postoperatively but as late as 6 months or more, occurs in less than 1% of patients but is disproportionately more common in patients undergoing valve surgery, probably related to postoperative anticoagulation in this cohort.[86,87] Delayed tamponade probably is a variant of the more common postcardiotomy syndrome.

Late tamponade typically is due to loculated effusion resulting from formation of adhesions (see Figs. 25.6 and 25.10) during recovery from surgery. Such adhesions can cause decreased cardiac output if they compress the left side of the heart, and in some cases pulmonary edema occurs if obstruction to inflow results. A variety of clinical problems related to increased right-sided heart pressure occur when tamponade involves the right side, including a clinical picture that resembles superior vena cava syndrome; several case reports have described right-to-left shunting across a patent foramen ovale as well.[88] Pericardiectomy to prevent postoperative tamponade has an uncertain risk-benefit ratio but does appear to decrease the incidence of hemodynamic compromise.[89]

Patients treated with dialysis present a special diagnostic and management problem. With underdialysis, volume overload can exacerbate chronic fluid accumulation in the pericardial space. Hypotension during or after dialysis may be secondary to inadequate intravascular volume and diminished venous pressure and needs to be avoided as well.

Management

Pericardial tamponade is life-threatening, requiring difficult diagnostic and, in particular, management decisions. When hemodynamics do not suggest significant compromise and effusion is small to moderate in volume, intervention frequently is not necessary and may involve increased risk to the patient, whereas late intervention may be fatal. Typically, the risk associated with pericardiocentesis is inversely related to the volume of accumulated fluid and also is related to the location of the effusion. Thus relatively small effusions, early in the course of tamponade, usually are located primarily posteriorly because of gravity-dependent accumulation. Waiting until the effusion is large and occupies significant volume anteriorly decreases the risk of percutaneous drainage but increases the possibility of decompensation and death before intervention. No validated risk stratification criteria for pericardiocentesis exist. A scoring system based on the etiology, the clinical presentation, and the imaging data has been proposed as a triage strategy for urgent management of cardiac tamponade by the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases.[90] Frequent monitoring of hemodynamics and application of sound clinical judgment remain essential for the timely and effective management of tamponade. Comorbid conditions such as endogenous or extrinsic anticoagulation may substantially confound the situation.[91] The clinical decision to drain the effusion percutaneously or to send the patient for thoracotomy will be a function of the clinician's assessment of risk of the former versus the potential advantages of surgery in obtaining pericardial tissue and providing a pericardial window as well. If the percutaneous approach is chosen, performing pericardiocentesis in the cardiac catheterization laboratory has significant advantages. However, the benefit of positioning the pericardial effusion anteriorly, for increased safety during needle entry into the pericardial space, requires that the patient's chest be elevated during the procedure, which typically can be accomplished only to a 20- or 30-degree angle on most catheterization tables because of the image intensifier unless the table has tilt capabilities. A moribund patient frequently needs pericardiocentesis performed at the bedside without fluoroscopic guidance, sometimes without adequate hemodynamic monitoring, and at times without echocardiographic monitoring—all of which are associated with increased risk of failed pericardiocentesis and adverse cardiac events. Patients with severe tamponade are often anxious and hypoxic; sedation is hazardous as is intubation, although the latter

is at times necessary. Because of associated positive intrathoracic pressure, intubation may cause abrupt hemodynamic deterioration because it decreases venous return to the heart.[6] Cardiopulmonary resuscitation using chest compression is unlikely to be effective; immediate pericardiocentesis or thoracotomy are ordinarily the only possibilities for survival. Further discussion of percutaneous interventions for tamponade can be found in Chapter 6.

Little in the way of medical treatment is clearly therapeutic for tamponade. Volume expansion in relatively acute tamponade will support right-sided filling in patients with low circulatory volumes, such as are seen in trauma.[92] Patients with chronic tamponade typically have considerable fluid retention, and additional hydration is unlikely to be of benefit. Pressors may be modestly helpful, but for patients with preserved cardiac function, catecholaminergic drugs provide only modest augmentation of cardiac output; patients with hemodynamically important tamponade are usually already maximally catecholamine stimulated. Vasodilator therapy is less clearly beneficial, and drugs that decrease preload, such as nitrates and nitroprusside, should be avoided if the patient is hypotensive. Reversal of anticoagulation is essential, both to stop bleeding into the pericardial space and to decrease the risk of trauma to the heart or major blood vessels during pericardiocentesis (e.g., coronary arteries, hepatic vessels). The introduction of direct thrombin inhibitors may affect this portion of the management algorithm because they are not reversible with vitamin K, and there are case reports of hemopericardium occurring after introduction of oral versions of these agents[93–96] as well as failed pericardiocentesis during PCI associated with bivalirudin administration.[97] However, a reversal agent for dabigatran was approved in 2015 and antidotes for factor Xa inhibitors are currently under investigation.[95] Antibiotic therapy in the setting of purulent pericarditis and tamponade is not expected to acutely relieve hemodynamic decompensation in most settings; postdrainage treatment is discussed in Chapter 6. A targeted approach for patients with malignant pericardial disease includes the use of sclerosing agents combined with antineoplastic drugs infused into the pericardial space, sometimes combined with radiation; a variety of such management strategies continue to be applicable for some cancer patients.[98] Leaving an indwelling drain is controversial because of the associated risk of infection, although there is some evidence that it can decrease the risk of recurrent tamponade.[99] An excellent review of the clinical approach to pericardial disease in general has been published by the European Society of Cardiology.[14]

Acknowledgment

The authors wish to acknowledge Priscilla Peters for kindly providing Figs. 25.6, 25.7, 25.8, 25.10, 25.12, and 25.13.

Key Points

- Pericardial tamponade represents a continuum, ranging from effusions associated with little or no hemodynamic compromise to hemodynamic collapse.
- The primary physiologic feature of tamponade is impairment of cardiac chamber filling owing to high intrapericardial pressure, with resultant decrease in cardiac output.
- Acute tamponade occurs after relatively limited accumulation of fluid in the setting of a nondistensible pericardium.
- Chronic tamponade may involve a pericardial effusion of 1 L or more; because hemodynamic decompensation occurs in the steep part of the pressure-volume curve, accumulation of a small amount of additional fluid can result in substantial hemodynamic deterioration.
- Pulsus paradoxus is seen in a variety of conditions besides cardiac tamponade and is absent despite tamponade in a number of settings. A large pericardial effusion and right ventricular collapse, a 10- to 20-mm Hg or larger decrease in systolic pressure with inspiration, and a significant decline in pulse pressure combined are specific for tamponade.
- Right atrial pressure, except in settings such as hypovolemia, usually is significantly elevated, but jugular venous distention may not be seen with acute tamponade.
- Despite markedly elevated right and left atrial pressures, pulmonary vascular congestion usually is not seen.
- Persistent high right atrial pressure after fluid drainage suggests effusive-constrictive disease, most commonly associated with malignancy but also seen with infection and acute pericarditis.
- Management of pericardial tamponade involves determining the optimal timing and method of intervention. Fluid and drug therapy constitute modest adjunctive care only.

Review Questions

1. Tamponade physiology usually results from:
   - **a.** Abrupt accumulation of 50 to 100 mL of fluid in a patient with normal heart and pericardium
   - **b.** Gradual accumulation of 1 L or more of fluid in a patient with chronic pericardial effusion
   - **c.** Abrupt accumulation of an additional 50 to 100 mL of fluid in a patient with chronic pericardial effusion
   - **d.** All of the above

   Answer: d. Tamponade occurs when the patient reaches the upward sloping portion of the curve in Fig. 25.1. Patients with a normal, nondistensible pericardium require very little volume to achieve a critical drop in transmural pressure. In contrast patients with slow fluid accumulation—such as those with slow-growing malignancies, uremia, and other chronic conditions—frequently accumulate a liter or more before their pericardial pressure rises dramatically. However, abrupt accumulation in the latter settings, superimposed on substantial volume already in the pericardial space, will also cause tamponade.
2. A patient with effusive-constrictive disease undergoes pericardiocentesis and 500 mL of fluid is removed; no effusion is seen on postprocedure echocardiography. The initial hemodynamics showed an intrapericardial pressure of 20 mm Hg and a right atrial pressure of 20 mm Hg. Post tap the hemodynamics are likely to show:
   - **a.** Intrapericardial pressure >5 mm Hg; right atrial pressure 5–10 mm Hg
   - **b.** Intrapericardial pressure 0 mm Hg; right atrial pressure 5–10 mm Hg
   - **c.** Intrapericardial pressure >5 mm Hg; right atrial pressure 15 mm Hg
   - **d.** Intrapericardial pressure 0 mm Hg; right atrial pressure 15 mm Hg

   Answer: d. With complete resolution of the effusion, intrapericardial pressure typically decreases to atmospheric pressure, which by definition is 0 mm Hg. However, the patient with effusive-constrictive disease will continue to demonstrate features of pericardial constriction—namely, a high right atrial pressure and a steep y descent (see Fig, 25.5 and 25.11).
3. Beck's triad incorporates:
   - **a.** Small quiet heart, pulsus paradoxus, and jugular venous distention
   - **b.** Pulsus paradoxus, jugular venous distention, tachycardia
   - **c.** Small quiet heart, tachycardia, jugular venous distension
   - **d.** Small quiet heart, jugular venous distention, hypotension

   Answer: d. Claude Beck, the first professor of cardiovascular surgery in the United States, described his triad as jugular venous distension, a small quite heart of physical examination, and low arterial pressure. The other choices shown—pulsus paradoxus and tachycardia—are also seen commonly in tamponade, but are not part of the classic triad.
4. In differentiating tamponade from congestive heart failure, both of which are associated with elevated left atrial pressures, which of the following is true?
   - **a.** Both conditions feature an S_3 gallop.
   - **b.** Rales are uncommon with acute tamponade.
   - **c.** Both conditions feature an S_4 gallop.
   - **d.** A square root sign is common with acute tamponade.

   Answer: b. A distinguishing feature of tamponade is that the patient's lungs are usually clear. This is despite the fact that left atrial pressure is typically elevated (and equal to right atrial pressure). Limited right ventricular flow into the pulmonary circulation prevents pulmonary congestion in classic acute tamponade. Neither an S_3 nor an S_4 gallop are likely given impaired inflow into the ventricular chambers. A square root sign is associated with constriction, although even in the setting of constriction plus tamponade this sign is absent while there is substantial fluid in the pericardial space because it depends on rapid inflow during early diastole.
5. On echocardiography, a finding highly specific for tamponade is:
   - **a.** Right atrial collapse during early diastole
   - **b.** Left atrial collapse after open heart surgery
   - **c.** Left ventricular collapse during diastole
   - **d.** Lack of respiratory variation in Doppler inflow velocities across the tricuspid and mitral valves

   Answer: c. Chamber collapse in tamponade is caused by diminished transmural pressure, caused by rising intrapericardial pressure. Because pressures in the right-sided chambers are typically much lower than on the left, chamber collapse occurs much earlier on the right side, and may be caused by a variety of other factors as discussed in the text. Left atrial collapse after coronary artery bypass grafting is not uncommon and is associated with fluid surrounding the left atrium after open heart surgery. Left ventricular collapse is uncommon, even in tamponade, and when it does occur, it suggests very high intrapericardial pressure; it is highly specific. Respiratory variation, not "lack of," is a consequence of ventricular interdependence (see Figs. 25.7 and 25.8) and a classic finding in tamponade.
6. An electrocardiogram finding associated with tamponade and rarely seen with other conditions is:
   - **a.** Low voltage
   - **b.** ST elevation
   - **c.** Electrical alternans
   - **d.** Respiratory variation in QRS voltage

   Answer: c. Low voltage is a very common finding, but it is seen in a wide variety of clinical settings, including pulmonary disease, infiltrative myocardial disorders, muscle loss from prior infarction, hypothyroidism, and others. ST elevation may be associated with infarction or pericarditis, but it does not suggest tamponade per se. Respiratory variation in QRS voltage is a normal finding and is exacerbated in pulmonary disease and a variety of other settings. Electrical alternans, on the other hand, is typically seen when the heart swings back and forth in a large pericardial effusion and is a relatively specific, although not sensitive, finding for tamponade.
7. Pericardiocentesis can result in worsening hemodynamic status in patients with tamponade and:
   - **a.** Aortic dissection
   - **b.** Free wall rupture after myocardial infarction
   - **c.** Leaking thoracic aneurysm
   - **d.** All of the above

   Answer: d. The presence of an intact pericardium may prevent exsanguination in all of these clinical settings. Pericardiocentesis may result in catastrophic bleeding.
8. Which of the following is true?
   - **a.** Chest compression for shock in tamponade is usually effective.
   - **b.** In respiratory decompensation with tamponade, intubation should be avoided if possible.
   - **c.** When a patient with tamponade is anxious and tachypneic, sedation is helpful.
   - **d.** Patients with tamponade should undergo aggressive diuresis.

Answer: b. Chest compression is usually ineffective because it does not significantly address the underlying pathology and is unlikely to allow a higher stroke volume to be ejected. Anxiety and tachypnea are a common occurrence with tamponade related to catecholamine release and low cardiac output; sedation may undermine one of the last remaining protective mechanisms for maintaining cardiac output and aeration. Patients need to maintain intracardiac chamber pressure; diuresis in acute tamponade is counterproductive in many cases because venous return is decreased. Intubation increases thoracic pressure, also decreasing venous return in the setting of tamponade intubation may cause sudden hemodynamic collapse.

Hypovolemia and Traumatic Shock: Nonsurgical Management

DAVID J. DRIES

CHAPTER OUTLINE

Classic Neuroendocrine Response

The Hypovolemic Patient
- Initial Management
- Fluid Resuscitation
- Vasoactive Drugs
- Resuscitation Strategy and Goals

Inflammation and Shock After Injury
- Immune Mediator Cascades
- Genomics of Injury
- Acute Coagulopathy After Trauma
- Fluid Therapy

Blood Component Therapy

Endpoints
- The Problem
- Oxygen Delivery Parameters
- Lactate
- Base Deficit
- Near-Infrared Spectroscopy
- Adrenal Insufficiency

Clinical Strategies
- Early Limited Resuscitation
- Clinical Pathway—Early Resuscitation

Management of Traumatic Shock in the ICU
- Massive Transfusion
- Tranexamic Acid
- Risks of Early Red Blood Cell Transfusion

Special Problems
- Abdominal Compartment Syndrome
- Extremity Compartment Syndrome
- Pelvic Fractures

In 1934 Blalock suggested four categories of shock: hypovolemic, vasogenic, neurogenic, and cardiogenic.[1,2] In more recent clinical practice, additional categories of shock have been proposed.[3] Hypovolemic shock, the most common, results from a reduction in circulating blood volume. Volume loss may be loss of whole blood, plasma, or extracellular fluid or a combination of all three. Vasogenic shock occurs as a result of changes in the compliance of the vascular bed so that a normal blood volume fails to occupy the available space. Neurogenic shock (spinal shock) is a form of vasogenic shock in which spinal anesthesia or spinal cord injury leads to vasodilation. Septic shock is another form of vasogenic shock in which there is increased capacitance. A decrease in peripheral arterial resistance, an increase in venous capacitance, and a peripheral arteriovenous maldistribution occur. Cardiogenic shock results from failure of the heart as a pump. Obstructive shock results from mechanical obstruction to cardiac function, as seen with tamponade, tension pneumothorax, or massive pulmonary embolism.[4] Traumatic shock includes several components of the conditions mentioned previously.[5] Hypovolemia caused by blood loss is compounded by neurogenic, cardiogenic, or obstructive shock plus the vasogenic component of maladaptive mediator cascades initiated by tissue injury. Traumatic shock involves hemorrhage in combination with soft tissue trauma and fractures. As a result, the study of pure hemorrhagic shock may have limited relevance to the pathophysiologic condition of traumatic shock. Most studies have shown significant differences in the biologic condition of traumatic shock compared with that of pure hemorrhagic shock based on the activation of mediator cascades.

Conflicting observations in literature are due at least in part to the assumption that hemorrhagic shock and traumatic shock are identical insults.[2,4] Pulmonary complications after simple hemorrhage are uncommon in clinical practice, but pulmonary dysfunction is a common comorbid condition after major trauma with attendant soft tissue or long bone injury.[2,6] Activation of mediator systems is far more intense with traumatic shock than with pure hemorrhage.[7] Conflicting data regarding changes in cytokine levels after a traumatic insult are likely due to the fact that systemic cytokine levels do not reflect local production of these mediators. Measurement of tissue levels of mediator production may be necessary to determine accurately whether there is upregulation of various mediator systems after trauma and hemorrhage.

Soft tissue injury alone upregulates mediator systems.[2,8] A small animal study with closed femur fractures showed Kupffer cell activation 30 minutes after injury.[9] Another study assessed the effects of skeletal muscle injury in combination with hemorrhage in a porcine model of hemorrhagic shock. To reach a given physiologic endpoint (reduction in cardiac index and oxygen delivery), hemorrhage of 40% of the blood volume was required in a pure hemorrhagic shock model. If skeletal muscle injury was added, hemorrhage of only 29% of blood volume was necessary to reach the same endpoint.[10] The ability to maintain cardiac function after

hemorrhage was impaired in this study by superimposition of a soft tissue injury, emphasizing the difference between hemorrhagic shock and traumatic shock. A synergy in activation of neuroendocrine and inflammatory mediator systems is likely when traumatic injury and hemorrhagic shock are present. More recent work describing coagulation changes occurring with injury emphasizes the danger of combined injury and hypoperfusion of soft tissue with failure of appropriate coagulation response.[11]

Classic Neuroendocrine Response

The essential homeostatic response to fluid volume or blood loss is preservation of cerebral and cardiac perfusion with maintenance of normal blood pressure as sensed by carotid body and aortic arch receptors. Peripheral vasoconstriction and curtailment of urine output are seen. Cardiac contractility and peripheral vascular tone also are altered. Pain, hypoxemia, acidosis, infection, changes in temperature, and availability of substrates such as glucose affect this response. A decrease in blood volume alone without hypotension may activate the hypothalamic-pituitary axis. The magnitude of neuroendocrine response depends not only on the volume of fluid lost, but also the rate at which this occurs. This response may be modified by patient age, prescribed medications, preexisting illness, and the use of ethanol or other drugs. With spinal cord transection, operative intervention below the level of injury does not produce typical activation of the hypothalamic-pituitary axis. Similarly, consciousness is unnecessary for activation of this response because it may occur with the patient under anesthesia.[2,12–14]

The initial effect seen with hemorrhage is sympathetic vasoconstriction. Capacitance of the circulatory system is reduced, and aortic arch or carotid sinus baroreceptors respond to changes in blood pressure by modulation of sympathetic tone.[15] Atrial receptors respond to changes in vascular wall stretch and pressure. Afferent vagal fibers carry signals leading to loss of tonic inhibition of heart rate and immediate activation of thoracolumbar sympathetic outflow with norepinephrine release from postganglionic sympathetic fibers. As blood loss increases, so does the role played by arterial baroreceptors. Another part of this hormonal response is corticotropin-releasing factor secreted by the hypothalamus, vasopressin release, and growth hormone–releasing factor production.[12]

The clinician sees cool extremities in response to these changes associated with hypovolemia. Venous capacitance also decreases, resulting in accelerated venous return to the heart. Selective arterial vasoconstriction maintains blood flow to the heart and brain until compensation fails. Intense triggering of sympathetic signals is seen when arterial blood pressure decreases to less than 50 mm Hg and is maximally stimulated when systolic blood pressure is less than 15 mm Hg.[2] Although metabolic vasoregulation in the heart and brain helps to avoid local vasoconstriction, blood flow to other tissues decreases dramatically. Renal blood flow may be reduced to 5% to 10% of normal with acute hypovolemia. Flow to the splanchnic circulation, skin, and skeletal muscle also decreases. These vasoconstrictor responses are mediated by epinephrine and norepinephrine from the adrenal medulla and local sympathetic activity at the vasculature. With increases in acidosis and hydrogen ion concentration, coronary vasodilation occurs as opposed to constriction of arteries in skeletal muscle and the splanchnic circulation.[3,16]

Multiple endocrine responses are seen with hypovolemia. Plasma levels of glucagon, growth hormone, cortisol, and corticotropin (adrenocorticotropic hormone) increase.[2,3,5] The renin-angiotensin-aldosterone axis is stimulated with release of vasoconstrictive angiotensin II. Vasopressin release also occurs after hemorrhage, resulting in water absorption in the distal tubule of the kidney. Vasopressin induces splanchnic vasoconstriction. Endocrine studies suggest that with ongoing volume loss, vasopressin depletion may occur, and supplements of this hormone by clinicians may be warranted. Growth hormone and glucagon promote gluconeogenesis, lipolysis, and glycogenolysis. Catecholamines that inhibit insulin release with hyperglycemia and increased blood osmolarity are thought to shift fluid from cells and the interstitium into the intravascular space. More recent data associate hyperglycemia in the setting of injury with adverse outcome, however. The cellular mechanism for this response remains unclear. Loss of fluid or salt through the kidneys also is limited by these hormonal effects, which serve to conserve the circulating blood volume.[17–19]

Compensated acute hypovolemia occurs when the aforementioned mechanisms are sufficient to avoid widespread cellular injury and organ decompensation.[2] If volume loss continues or resuscitation is inadequate, a cycle of decline occurs with regional perfusion defects, leading to tissue and microcirculatory changes. Progression from compensated to decompensated and irreversible shock is often defined in retrospect. Frequently a patient with acute irreversible hemorrhage has been hypotensive for an extended period and cannot be resuscitated despite fluid administration and use of vasoactive drugs.[2,3] Presumed mechanisms include microcirculatory failure with loss of vasomotor response and integrity of the vascular bed. Patients with subacute but ultimately irreversible shock can be resuscitated initially, but progressive organ injury and end-organ dysfunction follow.

The Hypovolemic Patient

The diagnosis of shock is based on clinical, hemodynamic, and biochemical signs that can be broadly summarized into presentation of arterial hypotension (systolic blood pressure <90 mm Hg or MAP <70 mm Hg with associated tachycardia), tissue hypoperfusion, and metabolic changes typified by elevated serum lactate reflecting abnormal cellular oxygen metabolism.[20] In a recent study in which more than 1600 patients with nontraumatic shock were randomly assigned to receive either dopamine or norepinephrine, septic shock occurred in 62% of patients, cardiogenic shock in 16%, hypovolemic shock in 16%, and other types of distributive shock in 4% and obstructive shock in 2%.[21]

In the case of injury, the cause of shock is obvious from medical history and physical examination. Shock after traumatic injury continues blood loss and a direct insult to tissues. Other forms of shock may occur but are much less common. Physical examination, including skin color and temperature, jugular venous distention, and peripheral edema, is appropriate in any patient with shock. The diagnosis of shock can be refined at the bedside with point-of-care ultrasonography, including evaluation for pericardial effusion, measurement of left and right ventricular size and function, assessment for respiratory variation in vena cava dimension, and with some techniques by calculation of aortic velocity-time integral, which is a measure of stroke volume.[20,22,23]

Initial Management

Resuscitation of the hypovolemic patient should be initiated even while investigation of details of the cause is ongoing. Unless the patient's condition is rapidly reversed, an arterial catheter should be considered for monitoring of arterial blood pressure and blood sampling plus a central venous catheter for infusion of fluids and

vasoactive agents. Data obtained through the central venous catheter may also guide fluid therapy. Initial management of shock is problem-oriented and goals are similar regardless of the etiology. Treatments used to reach these goals may be varied.

Administration of oxygen should be started immediately to increase oxygen delivery. Pulse oximetry may be unreliable because of peripheral vasoconstriction, and precise determination of oxygen requirements requires blood gas monitoring. Mechanical ventilation incorporating endotracheal intubation should be seriously considered to provide reliable support of respiration and oxygen delivery. This therapy is considered in nearly all patients with dyspnea, hypoxemia, or persistent or worsening acidemia (pH <7.30). Invasive mechanical ventilation has additional benefits in reduction of oxygen demand of respiratory muscles and decreasing left ventricular afterload by increasing intrathoracic pressure. An abrupt decrease in arterial pressure after endotracheal intubation and initiation of invasive mechanical ventilation suggests hypovolemia and a decrease in venous return.[20]

Fluid Resuscitation

Fluid therapy to improve microvascular blood flow and increase cardiac output (CO) is an essential part of the treatment of any form of shock. The patient with hypovolemic, nontraumatic shock more commonly requires crystalloid solutions than the individual with hypovolemia in the setting of significant injury. Fluid administration must be closely monitored given the risk of edema and associated consequences.[11,20,24]

The ideal resuscitation fluid should produce predictable and sustained increase in intravascular volume and replace extracellular fluid. An ideal fluid is metabolized and completely excreted without accumulation in tissues and does not produce adverse metabolic or systemic effects. Resuscitation fluid must also be cost-effective. Unfortunately, there is no such fluid currently available.

Resuscitation fluids are broadly categorized into crystalloid and colloid solutions (Table 26.1). Crystalloids are solutions of ions freely permeable but containing concentrations of sodium and chloride that determine their tonicity. Colloids are suspensions of molecules within a carrier solution relatively incapable of crossing a healthy semipermeable capillary membrane owing to the molecular weight of the molecules.

Proponents of crystalloid solutions argue that colloids, particularly human albumin, are expensive and impractical particularly under field resuscitation conditions. Crystalloids are inexpensive and widely available and have an established role as first-line resuscitation fluids. Crystalloids have been associated with clinically significant interstitial edema.

Colloid solutions are more effective in expanding intravascular volume and are retained in the intravascular space and maintain colloid oncotic pressure more effectively than crystalloids. The volume-sparing effect of colloids, compared with crystalloids, is considered an advantage that is conventionally described in a 1:3 ratio of administered colloids to crystalloids to maintain a given intravascular volume.[24]

Crystalloids

Sodium chloride is the most commonly used crystalloid solution, particularly in the United States. Normal 0.9% saline solution contains sodium and chloride in equal concentrations, making it isotonic compared with extracellular fluid. The strong ion difference of 0.9% saline solution is zero, with the result that administration of large volumes of saline solution results in hyperchloremic metabolic acidosis. Adverse effects such as immune and renal dysfunction have been attributed to this phenomenon, although the clinical consequences are less well established.[24,25]

Concern about sodium and water overload associated with saline solution resuscitation has resulted in the concept of small-volume crystalloid resuscitation with the use of hypertonic saline (3%, 5%, and 7.5%) solutions. However, early use of hypertonic saline solution for resuscitation, particularly in patients with traumatic brain injury, has not improved short-term or long-term outcomes.[24,26]

Crystalloids with a chemical composition that approximates extracellular fluid have been termed *balanced* or *physiologic* solutions and are derivatives of the original crystalloid solutions. However, none of these proprietary solutions are truly balanced or physiologic. Balanced salt solutions are relatively hypotonic because they have a lower sodium concentration than extracellular fluid. Because of the instability of bicarbonate-containing solutions in plastic containers, alternative anions such as lactate, acetate, gluconate, and malate have been used. Excessive administration of balanced salt solutions may result in hyperlactatemia, metabolic alkalosis, and hypotonicity (with sodium lactate), and cardiotoxicity (with acetate). The addition of calcium in some solutions may generate microthrombi with citrate-containing red blood cell transfusions.[24]

Given the concern regarding an excess of sodium and chloride associated with normal saline solution, balanced salt solutions are becoming more popular as first-line resuscitation fluids in patients undergoing surgery, patients with trauma, and patients with diabetic ketoacidosis. Resuscitation with balanced salt solutions is a key element in the initial treatment of patients with burns, although there is increasing concern about the adverse effects of fluid overload and a strategy of permissive hypovolemia in such patients is being investigated.[24,27–29]

A recent observational study compared major complications in patients receiving only normal saline solution with a calcium-free balanced salt solution for replacement of fluid losses on the day of surgery. The use of a balanced salt solution was associated with a significant decrease in the rate of major complications, including a lower incidence of postoperative infection, renal replacement therapy, blood transfusion, and problems associated with acidosis. Another single-center observational intensive care unit (ICU) study using a colloid-restrictive fluid strategy (lactated and calcium-free balanced solutions) to replace chloride-rich intravenous (IV) fluids (normal saline solution, 4% albumin, or succinylated gelatin) was associated with a significant decrease in acute kidney injury (AKI) and the need for renal replacement therapy.[30,31]

Colloids

Human albumin (4%–5%) in saline solution is considered the reference colloid. It is produced by fractionation of blood and is heat-treated to prevent transmission of viruses. It is an expensive solution to produce and distribute and its availability is limited in low- and middle-income countries.

Albumin has been compared to saline solution in a major recent trial conducted by investigators in Australia and New Zealand, the Saline versus Albumin Fluid Evaluation (SAFE) study, conducted in approximately 7000 ICU patients. The study assessed the effect of resuscitation with 4% albumin compared to saline solution on the rate of death at 28 days. No significant difference between albumin and saline with respect to the rate of death or development of new organ failure was identified.[24,32]

A number of subanalyses of the SAFE study data have been conducted. Resuscitation with albumin was associated with a

significant risk in the rate of death at 2 years among patients with traumatic brain injury. This outcome has been attributed to increased intracranial pressure, particularly during the first week after injury. Resuscitation with albumin was associated with a decrease in the adjusted risk of death at 28 days in patients with severe sepsis, suggesting a potential but unsubstantiated benefit in patients with severe sepsis. There was no significant between group difference in the rate of death at 28 days among patients with low albumin levels.[32–34]

In the SAFE study, no significant difference in hemodynamic resuscitation endpoints, such as mean arterial pressure (MAP) or heart rate, was observed between the albumin and saline solution groups, although the use albumin was associated with a significant but clinically small increase in central venous pressure (CVP). The ratio of volume of albumin to the volume of saline solution administered to achieve comparable resuscitation endpoints was observed to be 1:1.4.[32]

Another important study conducted in sub-Saharan Africa, the Fluid Expansion As Supportive Therapy (FEAST) study, compared the use of boluses of albumin or saline solution with no boluses in resuscitation fluid for approximately 3000 febrile children with impaired perfusion. In this study, bolus resuscitation with albumin or saline produced similar rates of death at 48 hours, but there was a significant increase in the rate of death at 48 hours associated with both therapies compared with no bolus therapy. The principal cause of death in these patients was cardiovascular collapse rather than fluid overload or neurologic causes, suggesting an adverse interaction between bolus fluid resuscitation and compensatory neurohormonal responses. Although this trial was focused on a pediatric population with limited critical care facilities, the results call into question the role of bolus fluid resuscitation in populations of critically ill patients.[35,36]

In acute illness, it appears that hemodynamic effects and effects on patient-centered outcomes of albumin are largely equivalent to those of saline solution. Examination of these fluids in specific populations of patients continues.

Semisynthetic Colloids

The limited availability and relative expense of albumin have prompted development of semisynthetic colloid solutions.[24] Globally, semisynthetic colloids are known as hetastarch, succinylated gelatin, urea-linked gelatin polygeline preparations, and dextran solutions. The use of dextran solutions has largely fallen out of favor.

Hydroxyethyl starch solutions are produced by hydroxyethyl substitution of amylopectin obtained from sorghum, maize, or potatoes. A high degree of substitution on glucose molecules protects against hydrolysis by nonspecific amylases in the blood—thus prolonging intravascular volume expansion—but this action increases the potential for hydroxyethyl starches to accumulate in the reticuloendothelial tissues such as the skin and kidney. The use of hydroxyethyl starch, particularly high-molecular-weight preparations, is associated with alterations in coagulation, specifically changes in viscoelastic measurements and fibrinolysis, although the clinical consequences of these effects in specific patient populations such as those undergoing surgery or trauma are unclear. A small number of studies have questioned the safety of concentrated hydroxyethyl starch solutions in patients with severe sepsis, noting increased risks of death, AKI, and the use of renal replacement therapy.[37,38]

Currently readily available hydroxyethyl starch solutions have reduced concentrations and are available with various types of crystalloid carrier solutions. Hydroxyethyl starch solutions are widely used in patients undergoing anesthesia for major surgery, particularly as a component of goal-directed perioperative fluid management strategies, as a first-line resuscitation fluid in military theaters, and particularly in patients in the ICU. Because of the potential for fluid accumulation in tissues, limits are recommended for maximal daily doses of hydroxyethyl starch solutions.

Two important recent trials demonstrate no significant difference in short-term hemodynamic resuscitation endpoints when hydroxyethyl starch solutions are compared to saline solution. The observed ratio of hydroxyethyl starch to crystalloids in these trials was approximately 1:1.3, consistent with the ratio of albumin to saline solution reported in the SAFE study previously described.[24,39,40]

Hydroxyethyl starch solutions are associated with increases in urine output in patients at low risk for AKI but with parallel increases in serum creatinine levels in patients at increased risk for AKI.[24] The use of hydroxyethyl starch solutions was associated with an increased use of blood products and an increased rate of adverse events, particularly pruritus.

There are a variety of other semisynthetic colloid solutions such as gelatins and polygeline preparations that have not been studied. However, another recent observational study has raised concern about the risk of AKI associated with the use of gelatin solutions. These solutions have not been studied in high-quality trials to date. In light of current evidence of lack of clinical benefit, potential nephrotoxicity, and increased cost, the use of semisynthetic colloids for fluid resuscitation in critically ill patients is difficult to justify.[24,41,42]

Vasoactive Drugs

If hypotension is severe or persistent despite fluid administration, vasoactive drugs may be considered (Table 26.2). It is acceptable to administer a vasoactive drug temporarily while fluid resuscitation is ongoing with the aim of discontinuing the vasoactive medication after hypovolemia has been corrected.

Adrenergic agonists are first-line vasopressors because of rapid onset of action, high potency, and short half-life. Norepinephrine is widely considered to be the vasopressor of choice. It has predominantly α-adrenergic properties but modest β-adrenergic effects to help maintain CO. Administration generally results in a clinically significant increase in MAP with little change in heart rate or CO. The usual dose is 0.1 to 2.0 μg/kg of body weight per minute.[20]

Dopamine has predominantly β-adrenergic effects at lower doses and α-adrenergic effects at higher doses. Its effects are relatively weak. Dopaminergic effects at very low doses (0.5–2 μg/kg per minute given intravenously) may selectively dilate the hepatosplanchnic and renal circulation, but controlled trials have not shown a protective effect of this agent on renal function. Dopaminergic stimulation may also have undesired endocrine effects on the hypothalamic-pituitary system resulting in immunosuppression, particularly through reduction in prolactin release. In recent trials, dopamine had no advantage over norepinephrine as a first-line vasopressor. Dopamine induced more arrhythmias and was associated with an increased 28-day rate of death among patients with cardiogenic shock. Dopamine is no longer recommended for treatment of patients with shock.[20,21,43]

Epinephrine has predominantly β-adrenergic effects at low doses and α-adrenergic effects becoming more significant at higher doses. Epinephrine administration may be associated with increased frequency of arrhythmias and a decrease in splanchnic blood flow. This agent can also increase blood lactate levels, presumably by increasing cellular metabolism. Prospective, randomized trials have

TABLE 26.2 Vasoactive Agents Commonly Used in Shock Resuscitation

Agent	Dose Rate (μg/kg/min)	Physiologic Action	Intended Effects	Adverse Effects
Dopamine				
Low	<5	DA_1 receptor	Selective vasodilation	↑ HR
Medium	5–15	β_1 receptor	↑ CI, ↑ MAP, ↑ CWP	Arrhythmia
High	>15	α_1 receptor	↑ MAP	
Dobutamine	5–20	α_1, β_1, β_2 receptors	↑ CI, ↓ PCWP	↑ HR, ↓ MAP, arrhythmia
Norepinephrine	0.01–0.05	α_1, α_2, β_1 receptors	↑ CI	↑ Afterload
	>0.05	α_1 receptor	↑ MAP	Vasoconstriction
Nitroprusside	0.25–10	NO donor	↓ Afterload, ↑ CI	↓ MAP, ↓ Pao_2 thiocyanate toxicity
Phenylephrine	0.2–0.9	α_1 receptor	↑ MAP	Vasoconstriction

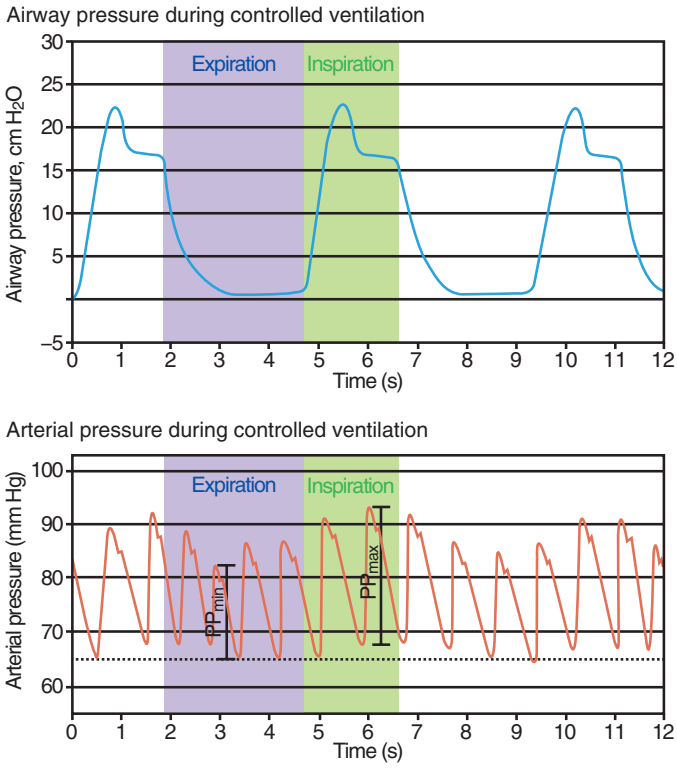
not shown beneficial effects of epinephrine over norepinephrine in septic shock. Epinephrine is a second-line agent for severe cases.[20,44]

Vasopressin deficiency may develop in patients with hyperkinetic forms of distributive shock or hypovolemia. Administration of low-dose vasopressin may result in substantial increases in arterial pressure. In studies of patients with sepsis, administration of low-dose vasopressin in addition to norepinephrine was safe. Comparable data in the hypovolemic patient are not available. Typically, if used, vasopressin should not be given at doses at higher than 0.04 U/min and should be administered in patients with high CO.[20,45]

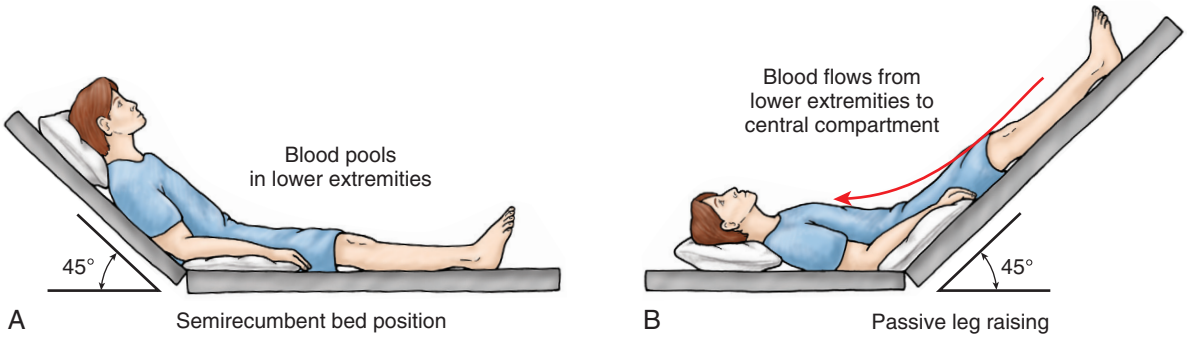
Dobutamine is the inotropic agent of choice for increasing CO regardless of whether norepinephrine is also being given. It is predominantly a β-adrenergic stimulus with less likelihood to induce tachycardia than agents such as isoproterenol. A very low dose may substantially increase CO. IV doses in excess of 20 μg/kg per minute provide little additional benefit. Dobutamine has limited effects on arterial pressure, although pressure may increase slightly in patients with myocardial dysfunction as the primary abnormality or may slightly decrease in patients with hypovolemia. Phosphodiesterase type III inhibitors such as milrinone combine inotropic and vasodilating properties by decreasing the metabolism of cyclic adenosine monophosphate. These agents may reinforce the effects of dobutamine. Unacceptable adverse effects are seen in patients with hypotension, and long half-lives of these agents compromise moment-to-moment dose adjustment.[20]

Resuscitation Strategy and Goals

Endpoints for fluid resuscitation are difficult to define. In general, CO should become preload-independent but this is difficult to evaluate clinically. Patients supported by mechanical ventilation may show signs of fluid responsiveness from beat-to-beat stroke volume measurements with the use of CO monitors or indirectly from observed variation in pulse pressure on the arterial pressure tracing during the ventilator cycle (Fig. 26.1). All



• **Fig. 26.1** Representation of airway pressure changes with positive pressure of ventilation and corresponding changes in arterial pressure waveform as expiration and inspiration are compared. Changes in systolic and diastolic pressure increase in the hypovolemic patient. (From Bentzer P, Griesdale DE, Boyd J, et al. Will this hemodynamically unstable patient respond to a bolus of intravenous fluids? *JAMA.* 2016;316:1298–1309.)



• **Fig. 26.2** Illustration shows patient positions for straight leg-raising test as a means to evaluate responsiveness to a fluid challenge. Raising the patient's legs with enhanced venous return serves as the fluid challenge in this technique. (From Bentzer P, Griesdale DE, Boyd J, et al. Will this hemodynamically unstable patient respond to a bolus of intravenous fluids? *JAMA.* 2016; 316:1298–1309.)

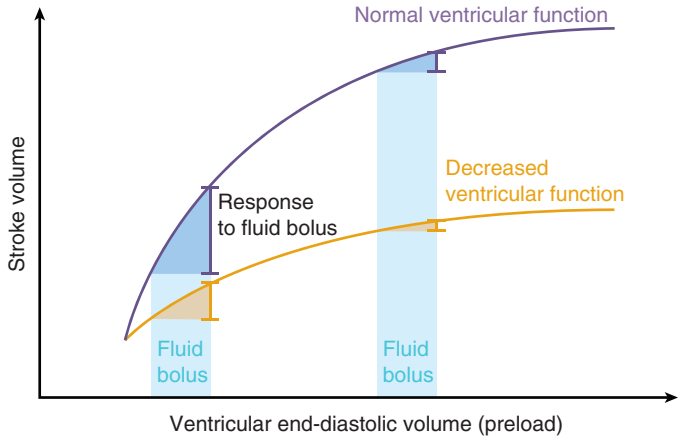
such bedside assessments have limitations and may be unreliable in patients with changing types and degree of organ system support.[20]

The fluid challenge technique has been advocated to determine a patient's actual response to fluids while limiting the risks of complications associated with fluid administration (Fig. 26.2). The fluid challenge requires definition of its elements. First, the type of fluid must be selected. Crystalloid solutions (discussed later) are the first choice because they are well tolerated and inexpensive. The use of albumin to correct severe hypoalbuminemia is reasonable in some patients. Second, the rate of fluid administration must be defined. Fluid should be infused rapidly to induce a rapid response but not so fast that an artificial stress response develops. Typically, 300 to 500 mL of fluid is administered during a period of 20 to 30 minutes. Third, the objective of the fluid challenge must be defined. In hypovolemic shock, the objective is usually an increase in systemic arterial pressure, although surrogates include a decrease in heart rate or an increase in urine output. Finally, safety limits must be defined. Pulmonary edema is the most serious complication of fluid administration. Some clinicians advocate limiting CVP changes to a few millimeters of mercury above baseline to prevent dangerous fluid overload.[20]

In the historical approach to resuscitation that emphasized protocolized care, critically ill and injured patients frequently received large amounts of crystalloids regardless of hemodynamic status. Recent trials suggest that aggressive fluid resuscitation produces severe tissue edema, compromising organ function and leading to increased mortality and morbidity. A recently completed important global survey suggests that the aggressive approach to fluid resuscitation studied in more than 40 countries is arbitrary, without basis and evidence, and is potentially harmful.[46,47]

Fluid Responsiveness

Patients are given a fluid challenge to increase stroke volume and CO. If an increase in stroke volume cannot happen, fluid administration serves no useful purpose and is possibly harmful. The patient is considered fluid-responsive if his or her stroke volume increases by at least 10% after a fluid challenge (usually 500 mL of a crystalloid solution). Fluid administration will increase stroke volume only if the fluid bolus increases stressed blood volume. This will cause the mean circulating filling pressure to increase greater than the increase in CVP, which increases the gradient for venous return, and if both ventricles are functioning, the gradient on the ascending limb of the Frank-Starling curve[46,48] (Fig. 26.3).



• **Fig. 26.3** Examples of Frank-Starling–type curves for the setting of normal ventricular function and decreased ventricular function. Note that stroke volume increases in either case but the maximum gain in stroke volume is less with compromised ventricular performance. (From Bentzer P, Griesdale DE, Boyd J, et al. Will this hemodynamically unstable patient respond to a bolus of intravenous fluids? *JAMA.* 2016; 316:1298–1309.)

A growing number of trials in critically ill and injured patients and those undergoing surgery demonstrate that approximately 50% of hemodynamically unstable patients are fluid responsive. This fundamental point is not widely appreciated and challenges the widely accepted notion that fluid administration is the cornerstone of resuscitation. Patients who are fluid responsive should be resuscitated with limited fluid boluses. Thus determination of fluid responsiveness is essential in managing resuscitation of critically ill patients.[46,48–50]

Although clinical signs such as hypotension, tachycardia, narrow pulse pressure, poor skin perfusion, and slow capillary refill are helpful in identifying inadequate perfusion, these signs are unable to determine volume status or fluid responsiveness.[51] Change in CVP after a fluid challenge is no more accurate in predicting fluid responsiveness than flipping a coin and should be abandoned for this purpose.[46,48] It should also be recognized that the change in MAP after a fluid bolus is poorly predictive of fluid responsiveness.[48] Ultrasonography of the vena cava and its respiratory variation are frequently no more predictive than the CVP for assessing fluid responsiveness. Echocardiography has limited ability for assessing volume and fluid responsiveness. Transthoracic measurements of

left ventricular outflow tract velocities for estimation of stroke volume require considerable expertise as for other ultrasound-based studies and are not easily obtained or reproduced in the critical care setting. Ultrasound-based technologies are not ideal for detecting rapid changes in stroke volume after passive leg-raising maneuvers or fluid challenges.[46]

Fluid Challenge

Currently there are two techniques that are readily available, practical, easy to perform, and physiologically based that can be used to determine fluid responsiveness with a relevant degree of accuracy.[46,48] These techniques are passive leg raising and actual fluid administration as a fluid challenge (see Fig. 26.2). These techniques are best combined with minimally invasive or noninvasive CO monitors that can track changes in stroke volume in real time. The passive leg-raising maneuver is simple to perform and takes less than 5 minutes to compete. Beyond ease of use, this method has the advantage of reversing its effects once the legs are returned to the horizontal position. A meta-analysis that pooled the results of 21 trials confirmed excellent diagnostic value of the passive leg-raising maneuver to predict fluid responsiveness in critically ill patients. The gold standard to determine fluid responsiveness is change in stroke volume after a fluid challenge. As crystalloids redistribute rapidly, the fluid bolus should be given as quickly as possible and ideally in 30 minutes or less. A bolus between 300 and 500 mL is recommended. Larger fluid boluses (20–30 mL/kg), although still widely recommended, may be unphysiologic and have an increased risk of volume overload with tissue edema.[46–52]

Fluid boluses are most frequently administered to patients with hypotension. It is not widely recognized, however, that the hemodynamic response to a fluid challenge is usually small and short-lived. In a recent study of patients with circulatory shock, 65% of patients were fluid responders, defined as those with a cardiac index increase by 25% at the end of infusion (30 minutes). Further, cardiac index had returned to baseline 30 minutes after the end of infusion.[53] Another systematic review that examined the hemodynamic response to fluid boluses in patients with sepsis reported that although MAP increased by approximately 8 mm Hg immediately after a fluid bolus, this parameter had returned to baseline at 1 hour with no increase in urine output.[54] Other data from the ARDSNet demonstrated an increase of MAP of only 2 mm Hg after a fluid bolus with no increase in urine output. Fluid boluses are generally ineffective for management of hypotension, circulatory shock, and oliguria.

Critically ill and injured patients and patients undergoing surgery do not need to be pushed to the top of their Frank-Starling curve. Patients should receive a fluid bolus if they are preload responsive and are likely to benefit from the fluid bolus, which is to say that the potential benefits and risks should be evaluated before each fluid bolus. Patients should receive fluid boluses only if the hemodynamic benefits are likely to outweigh the risks of an accumulating positive fluid balance.[46,48] Patients should not receive repeated fluid boluses until they are no longer fluid responsive. As patients' results ascend on the Frank-Starling curve, the adverse effects of fluid bolus administration outweigh the benefits as atrial pressures increase with increasing hydrostatic edema. Because of the short-lived effect of a fluid bolus, it may be preferable to treat the fluid-responsive septic patient with norepinephrine as this agent will increase venous return, stroke volume, and MAP while limiting tissue edema.[46,55] Comparable data for the patient with hypovolemia shock are not available.

Finally, organ blood flow is driven by the difference between the arterial and venous pressures in the circulation. The MAP minus the CVP is the driving force for organ blood flow. When MAP is in an organ autoregulatory range, the CVP becomes a factor determining organ and microcirculatory perfusion.[46,56] The kidney is particularly affected by increased venous pressure, which leads to increased renal subcapsular pressure and lowered renal blood flow and glomerular filtration rate. Physiologic studies have demonstrated a linear relationship between increasing CVP and AKI with a high CVP being the only hemodynamic variable independently associated with AKI. In critically ill patients and those with heart failure, CVP greater than 8 mm Hg has been demonstrated to be predictive of AKI. A growing body of data supports the primary hemodynamic goal in critically ill and injured patients and those undergoing surgery is an MAP above 65 mm Hg and a CVP less than 8 mm Hg. Ironically, fluid loading of oliguric patients with a low CVP with a goal of increasing CVP to more than 8 mm Hg may also increase the risk of progression to AKI.[46,48,57–59] Fluid administration should be guided by assessment of fluid responsiveness combined with determination of benefits and harms of fluid administration. Large fluid boluses should be avoided.

Inflammation and Shock After Injury

In addition to blood loss, extensive research suggests that trauma may be considered an inflammatory disease.[60–63] It has been shown that a variety of mediators and indicators of inflammatory response are elevated in severely injured patients. For many of these factors, it could be shown that markers of inflammation were significantly elevated in patients eventually dying compared with survivors, and that prediction of outcome is possible with a significant degree of accuracy. Peak inflammatory activity as measured by plasma values has been noted within hours of injury. Although it cannot at present be decided which of these parameters may play a direct pathophysiologic role in development and promotion of inflammatory response and consecutive organ dysfunction, and which is an indicator of this reaction, inflammatory mediators may reflect pathophysiologically relevant disturbances set off by tissue injury and blood loss with consecutive ischemia and reperfusion incidents.[64]

Shock after trauma differs from pure hypovolemic shock in that effects of release of mediators by tissue injury are superimposed on hypovolemia. It also is clear that not all damage after shock is the result of tissue hypoxia and that cellular damage follows reperfusion and subsequent inflammation. Loci of this inflammatory response are the wound, with activation of macrophages and production of proinflammatory mediator, and the microcirculation, with activation of blood elements and the endothelium.[64,65]

Immune Mediator Cascades

Although a variety of initiating events may occur, the subsequent inflammatory response is qualitatively similar.[2] Local activation of the complement cascade produces anaphylatoxins, which are strong attractants and stimulants of neutrophils. Local endothelium expresses endothelial leukocyte adhesion molecules, which attract the neutrophil population. Activated neutrophils also express adhesion molecules, leading to aggregation, margination in the vascular endothelium, and migration through vessel walls at the area of injury. This inflammatory response produces a respiratory burst with formation of oxygen radicals and synthesis of proteolytic

enzymes. Local release of bradykinin, histamine, and prostaglandin induces local vasodilation and increased capillary permeability from macromolecules, resulting in a protein-rich exudate. Local phagocytes release messenger molecules, such as granulocyte-macrophage colony-stimulating factor and macrophage colony-stimulating factor, which activate the bone marrow to produce more inflammatory cells. Neutrophils injure otherwise healthy tissues.[2,66,67]

In a slower response, the monocyte population is attracted to the site of injury, where it differentiates to macrophages and contributes to the inflammatory process by consuming and killing bacteria or disposing of necrotic tissue or both. Macrophages are activated further by triggers such as hypoxia or C5a, macrophage-activating factor, and interleukin (IL)-1–like activity from neutrophils. On stimulation, macrophages release a variety of classes of secretory products, which may be proinflammatory (proteolytic enzymes, oxygen radicals, IL-1, IL-6, tumor necrosis factor) or antiinflammatory (IL-10, prostaglandin E_2). Macrophage mediators, such as prostaglandin E_2, tumor necrosis factor, IL-1, IL-2, and IL-6, provide systemic signals adapting metabolic and defense mechanisms. Macrophages take several days after activation to develop full inflammatory capacity. They also may release nitric oxide and cytotoxic radicals. In the setting of injury, this local inflammatory process spills over to cause an exaggerated systemic response with inflammatory damage to otherwise healthy cells and organs distant to the site of injury. Secondary infection may occur in the compromised host, leading to generalized inflammation and multiorgan dysfunction (Box 26.1).[2,68,69]

Catecholamines are neurotransmitters that affect immune response humorally through circulating adrenal-derived epinephrine and locally through neuronal release of norepinephrine. The functional effects of catecholamines on cells of the immune system have been confirmed in human volunteers. In addition, relevance of this control mechanism and the implications for dysregulation have been shown by rapid systemic release of IL-10 and the high incidence of infection in patients with sympathetic storm from accidental or iatrogenic brain trauma.[70] Although detrimental effects of sustained and exaggerated sympathetic nervous system activation on cardiovascular and metabolic homeostasis have long been recognized, attention is now directed to the likelihood of immune dysregulation as well.

The neuroimmune axis is a bidirectional network composed of descending pathways linking the central nervous system (CNS) to peripheral immune tissues and a parallel afferent arm linking the immune system with the CNS. The integrity of this loop allows for communication between the CNS and peripheral immune system integrating neuronal and immune signals in the periphery and in the CNS. Cells from the immune system express functional receptors and signal transduction pathway components for several neuroendocrine mediators, allowing functional cellular responses to agonist stimulation. Similarly, cells in the CNS are capable of synthesizing, secreting, and responding to inflammatory and immune molecules. There is considerable evidence that the peripheral immune system can signal the brain to elicit a sickness response during infection, inflammation, and injury. Peripheral immune molecules such as cytokines influence CNS action through mechanisms, including entry into the brain through a saturable transport mechanism or through areas that lack the blood-brain barrier. Afferent neurons of the vagus nerve also are activated (Fig. 26.4).[71–73]

Severe trauma is characterized by the classic activation of the sympathetic nervous system and the recently recognized contribution of the inflammatory and neuroimmune response to injury.[70] The sympathetic nervous system has significant anatomic and functional interaction with cells of the immune system and plays an important role in control of the magnitude of early inflammatory response to injury by ensuring expression of adequate cytokine balance. Sympathetic neural pathways exert direct effects on cells of the immune system, affecting cytokine expression, lymphocyte function, and cytotoxic activity. In return, the inflammatory mediators released communicate with the CNS through stimulation of sensory and vagal afferents or by crossing the blood-brain barrier through active transport mechanisms and pathways allowing access to hypothalamic-pituitary structures. Immune-derived mediators, such as cytokines and chemokines, can modulate neurotransmission affecting activation of descending autonomic and neuroendocrine pathways.[70]

[a]*A variety of inflammatory mediators are associated with soft tissue injury, bony injury, and blood loss associated with various forms of trauma. The time course of mediator appearance in limited studies completed to date is suggested in this box. In experimental models and limited clinical data, the presence of soft tissue or bony injury in addition to hemorrhage accelerates and magnifies the production of these mediators over clinical and experimental models in which hemorrhage alone is seen.*

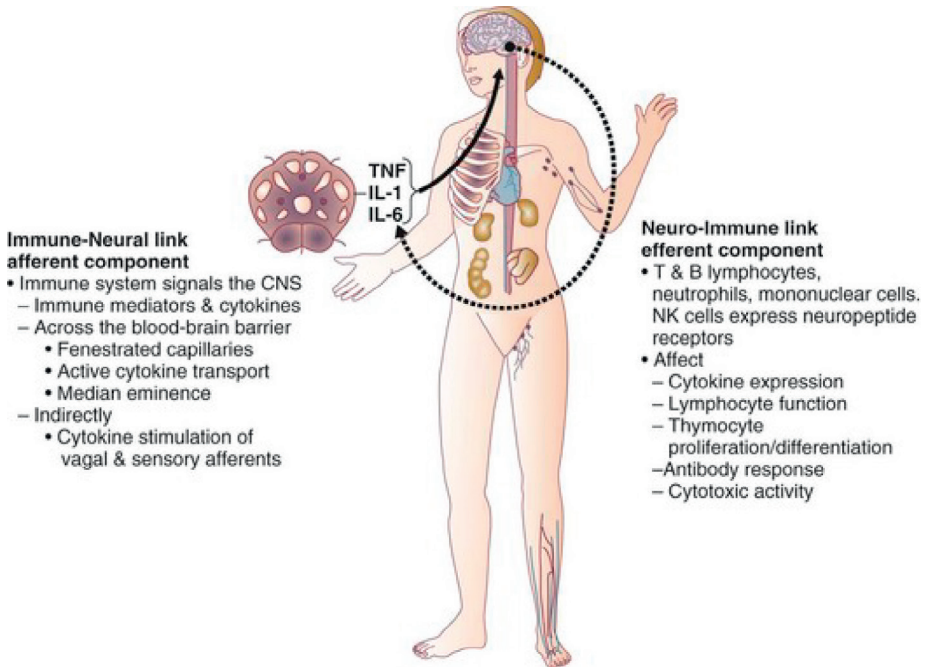
Genomics of Injury

A series of elegant clinical studies evaluated gene response to injury in a multicenter trial in patients receiving comparable resuscitation.[74] When leukocytes of normal volunteers were compared to those sustaining blunt injury, a "*genomic storm*" was identified. This work is taken from the Inflammation and the Host Response to Injury investigations[75] (Fig. 26.5).

Genes examined by these workers clustered into 30 groups by similarity to temporal patterns. One group of genes featured



• **Fig. 26.4** Endocrine, neurologic, and immunologic responses to injury are linked through afferent and efferent arcs as described in the text and shown in this figure. Patients sustaining blunt injury or soft tissue loss in addition to hemorrhage show clinical evidence of increased cytokine and inflammatory mediator production with acceleration of the process described here. The best clinical data in support of this pair of arcs are from patients with traumatic brain injury. *CNS,* Central nervous system; *IL-1,* interleukin 1; *IL-6,* interleukin 6; *NK,* natural killer; *TNF,* tumor necrosis factor. upregulation of proinflammatory cytokines such as IL-1β and tumor necrosis factor α. This pattern of gene expression resolved within the early days after injury. Other gene upregulation patterns took a longer period of time. Gene expression for IL-10 is an example of a gene with prolonged expression after injury. Some genes remained highly expressed up to 28 days after injury, whereas genes favoring proinflammatory cytokines tended to be upregulated for short periods of time. Other genes were downregulated, a response that could be seen for many days after injury. Immunoglobulin response is such an example.[75]

Fig. 26.5 shows the most significantly regulated pathways of the most upregulated pathways in circulating white blood cells. Eight of the 10 featured pathways are components of the innate immune system, which is consistent with a massive innate immune response seen after injury. Of the downregulated pathways, 9 of the 10 are included in the adaptive immune system.[75] Many of these downregulated pathways involve antigen processing. Patients with complicated clinical trajectories followed by this group of investigators demonstrated persistence of cellular necrosis, apoptosis, and autophagy in directly damaged tissues and remote tissues after trauma. Other examples of upregulated genes are those coding Toll-like receptors. These upregulated genes reflect receptors that are an important component of the innate immune system, which is immediately available but relatively nonspecific in nature. Changes in these receptors are seen with the classic inflammatory response frequently observed after injury.

Of the genes significantly modified by injury, only 63 of the thousands studied were different between injured and normal cohorts at all time points. Two-thirds of these genes were directly related to protective immunity. Adaptive immunity pathways showed suppression of genes involved in antigen presentation such as HLA-DR (human leukocyte antigen–antigen D related) and with interferon and interferon-inducible genes.[76]

This genomic work suggests a paradigm to describe patient response to severe injury. From the standpoint of gene transcription, there is an immediate genomic response triggering upregulation of the innate immune response and a downregulation of the adaptive immune response. These transcriptional changes are more dramatic and long-lasting in patients with complicated injury. This genomic storm translates into the early inflammatory response and subsequent immune suppression seen in the critical care unit. In particular, immune suppression is not compensatory and transcriptional responses for this portion of immune response are continuous and do not wax and wane.[74–76] Thus interventions to affect immune response to injury must be planned for early hours and days after the traumatic insult.

Acute Coagulopathy After Trauma

Historical Perspective

Hemorrhagic shock accounts for a significant number of deaths among patients arriving at hospitals with acute injury. Patients with uncontrolled hemorrhage continue to die despite adoption of new surgical techniques with improved transport and emergency care. Coagulopathy, occurring even before resuscitation, contributes significantly to the morbidity associated with bleeding.[77–80] Recognition of the morbidity associated with bleeding and coagulation abnormality dates to the Vietnam conflict. At that time, standard tests including prothrombin time (PT) and partial thromboplastin time (PTT) correlated poorly with effectiveness of acute resuscitation efforts. Similar work in the late 1970s was performed in civilian patients receiving massive transfusion. Again, PT, PTT, and bleeding time were helpful only if markedly prolonged.[81,82]

Studies in the 1970s and 1980s provided additional detail regarding the limitation of simple laboratory parameters and factor levels.[81–83] In a study of multiple patients requiring massive transfusion, platelet counts fell in proportion to the size of transfusion, although factors V and VIII correlated poorly with the volume of blood transfused. When coagulopathy appeared, patients seemed to respond to platelet administration. In subsequent studies, patients receiving a large number of blood products were followed for microvascular bleeding. Moderate deficiencies in clotting factors were common, but they were not associated with microvascular bleeding. Microvascular bleeding was associated with severe coagulation abnormalities such as clotting factor levels less than 20% of control values. In statistical analysis, clotting factor activities less than 20% of control levels were predicted by significant prolongation of PT and PTT. These earlier investigators also suggested that empiric blood replacement formulas available at the time were not likely to prevent microvascular bleeding because consumption of platelets or clotting factors did not consistently appear and simple dilution caused by resuscitation fluids frequently did not correspond to microvascular bleeding.[82,83]

The attention of the American trauma community was drawn to coagulopathy after trauma with the description of the "bloody vicious cycle" by the Denver health team more than 20 years ago.[79] These investigators noted the contribution of hypothermia, acidosis, and hemodilution associated with inadequate resuscitation and excessive use of crystalloids. Subsequent work extended these observations describing early coagulopathy that could be independent of clotting factor deficiency.[84] In a more recent trial, early coagulopathy was noted in the setting of severe injury that was present in the field before emergency department arrival and initiation of fluid resuscitation. Coagulopathic patients were at increased risk for organ failure and death.

In a study questioning historical transfusion practice emphasizing administration of packed red blood cells (PRBCs) in the setting of massive trauma, Hirshberg and coworkers, using clinical data, developed a computer model designed to capture interactions among bleeding, hemodynamics, hemodilution, and blood component replacement during severe hemorrhage. Resuscitation options were offered in this model and their effectiveness evaluated.[85] After setting thresholds for acceptable loss of clotting factors, platelets, and fibrinogen, the authors modeled behavior of coagulation during rapid exsanguination without clotting factor or platelet replacement. The PT reached a critical level first followed next by fibrinogen and platelets. If patients were resuscitated with small amounts of crystalloid, leaving overall blood volume reduced, the effective life of components in the coagulation cascade was increased. More aggressive fresh frozen plasma (FFP) replacement in the patient with significant bleeding was supported by this model. The optimal ratio for administration of FFP to PRBCs in this analysis was 2:3. Delayed administration of FFP led to critical clotting factor deficiency regardless of subsequent administration of FFP. Fibrinogen depletion was easier to correct. After administration of 5 units of PRBCs, the hemostatic threshold for fibrinogen was not exceeded if a FFP-to-PRBC ratio of 4:5 was used. Analysis of platelet dilution demonstrated that even if platelet replacement was delayed until 10 units of PRBCs were infused, critical platelet dilution was prevented with a subsequent platelet-to-PRBC ratio of 8:10.[85]

The essential message of this work is that massive transfusion protocols, emphasizing PRBCs, in existence when this study was performed provide inadequate clotting factor replacement during major hemorrhage and neither prevent nor correct dilutional coagulopathy.

Recent Studies

Brohi and coworkers from the United Kingdom helped to reinvigorate discussion of coagulopathy after injury by adding new coagulation laboratory techniques to previous clinical observations.[86] After reviewing more than 1000 cases, patients with acute coagulopathy after injury had higher mortality rates throughout the spectrum of Injury Severity Scores (ISS). Contrary to historical teaching that coagulopathy was a function of hemodilution with

massive crystalloid resuscitation, these authors noted that the incidence of coagulopathy increased with severity of injury but not necessarily in relationship to the volume of IV fluid administered to patients. Brohi and others helped to reemphasize the observation that acute coagulopathy could occur before significant fluid administration, which was attributable to the injury itself and proportional to the volume of injured tissue. Development of coagulopathy was an independent predictor of poor outcome. Mediators associated with tissue trauma, including humoral and cellular immune system activation with coagulation, fibrinolysis, complement, and kallikrein cascades, have been associated with changes in hemostatic mechanisms similar to those identified in the setting of sepsis.[86–88]

Factors contributing to coagulopathy in the setting of injury have been further reviewed.[89] Hypothermia relates to development of coagulopathy by reduction in platelet aggregation and decreased function of coagulation factors in nondiluted blood. Patients with temperature reduction below 34°C had elevated PT and PTT. Coagulation, like most biologic enzyme systems, works best at normal temperature. Similarly, acidosis occurring in the setting of trauma as a result of bleeding and hypotension also contributes to clotting failure. Animal work shows that a pH less than 7.20 is associated with hemostatic impairment. Platelet dysfunction and coagulation enzyme system changes are noted when blood from healthy volunteers is subjected to an acidic environment.[90,91]

We are now seeing that with or without hypothermia and acidosis, posttraumatic coagulopathy may develop in a significant number of patients. Although dilution-driven coagulopathy must be considered, loss of clotting factors has been associated with exaggerated inflammation in association with injury.

Hess and coworkers, as part of an international medical collaboration, developed a literature review to increase awareness of coagulopathy independent of crystalloid administration following trauma.[88] The key initiating factor is volume of tissue injury. Patients with severe tissue injury but no physiologic derangement, however, rarely present with coagulopathy and have a lower mortality rate.[92,93] Tissue damage initiates coagulation as endothelial injury at the site of trauma leads to exposure of subendothelial collagen and activation of the coagulation cascade.

Hyperfibrinolysis is seen as a direct consequence of the combination of tissue injury and shock. Endothelial injury accelerates fibrinolysis because of direct release of tissue plasminogen activator.[88,94] Tissue plasminogen activator expression by endothelium is increased in the presence of thrombin. Fibrinolysis is accelerated because of the combined effects of endothelial tissue plasminogen activator release with ischemia and inhibition of plasminogen activator inhibitor in shock. Although hyperfibrinolysis may focus clot propagation on sites of actual vascular injury, with widespread insults, this localization may be lost.

A number of important cofactors must be present to stimulate coagulopathy in the setting of injury.[88] Shock is a dose-dependent cause of tissue hypoperfusion. Elevated base deficit has been associated with coagulopathy in as many as 25% of patients in one large study. Progression of shock appears to result in hyperfibrinolysis. One mediator implicated in coagulopathy after injury is activated protein C. Immediate postinjury coagulopathy is likely a combination of effects caused by large volume tissue trauma and hypoperfusion (Fig. 26.6).[88]

As discussed later, equivalent ratios of FFP, PRBCs, and platelets are now considered for management of significant hemorrhage with coagulopathy after injury. Hypothermia and acidemia must be controlled to reduce their impact on enzyme systems.[95] Similar to the case with sepsis, crosstalk has been noted between coagulation and inflammation systems with injury. Activation of coagulation proteases may induce inappropriate inflammation with activation of cascades such as complement and platelet degranulation.[96,97] Trauma patients are initially coagulopathic with increased bleeding. This condition may progress to a hypercoagulable state, putting them at risk for thrombotic events. This late thrombotic state bears similarities to coagulopathy of severe sepsis and depletion of protein C. Injured patients and those with sepsis share a propensity toward multiple organ failure and prothrombotic states.[98,99]

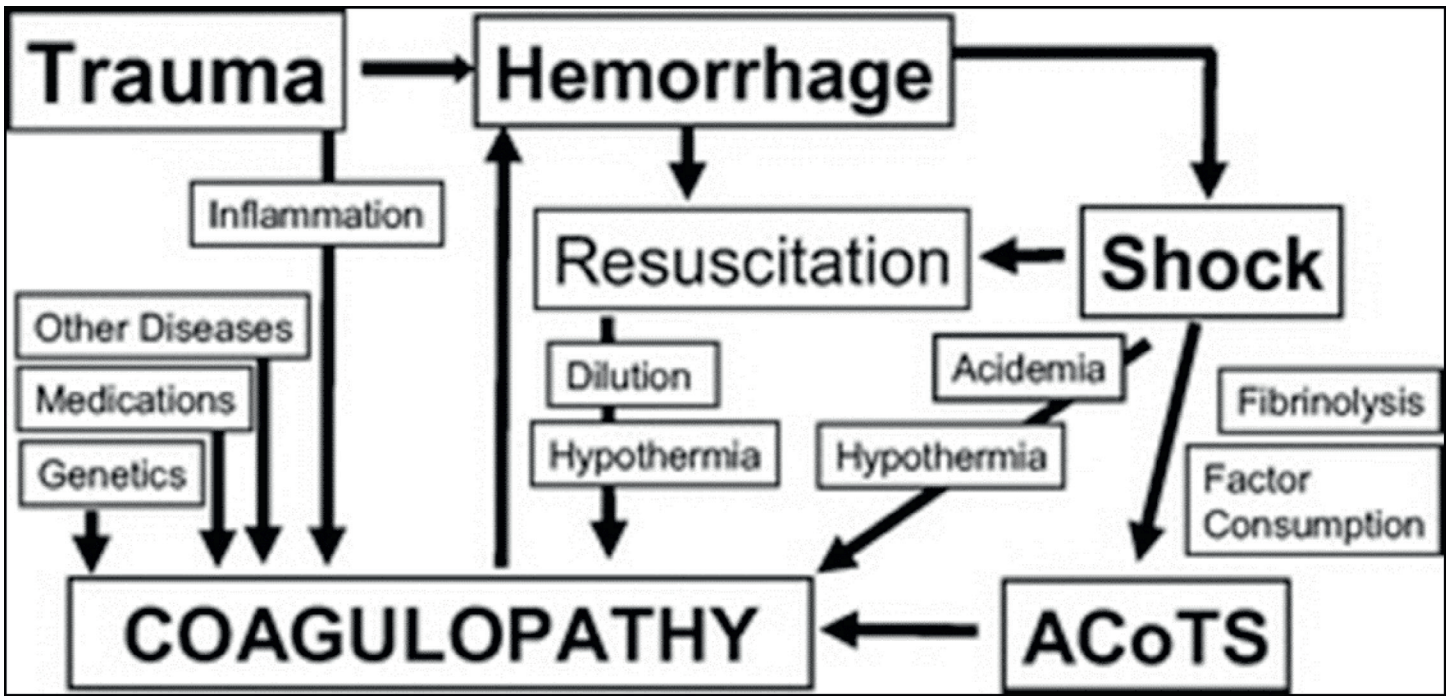
Fluid Therapy

Warmed isotonic electrolyte solutions are recommended for initial resuscitation of traumatic shock by the Committee on Trauma of the American College of Surgeons. This type of fluid provides transient intravascular expansion and stabilizes the intravascular volume by replacing accompanying fluid losses into the interstitial and intracellular spaces. Lactated Ringer solution is the initial fluid of choice. Normal saline solution is the second choice. Normal saline solution has the potential to cause hyperchloremic acidosis. This complication is more likely if renal function is compromised (Table 26.3).[100]

An initial warm fluid bolus is given rapidly—usually 1 to 2 L for an adult and 20 mL/kg for a child.[100] Patient response is observed during this initial fluid resuscitation and subsequent therapeutic decisions are based on this response. The required amount of fluid and blood is difficult to predict on initial evaluation of the patient. A rough guideline promulgated by the American College of Surgeons for the total amount of crystalloid volume acutely required is 3 mL of crystalloid fluid to replace each 1 mL of blood loss, allowing for restitution of plasma volume lost into interstitial and intracellular spaces. It is most important, however, to assess patient response to fluid resuscitation and evidence of adequate end-organ perfusion as measured by urine output and level of consciousness rather than providing fluid based on a specific formula. If the amount of fluid required to restore or maintain adequate end-organ function exceeds the previously mentioned estimates, careful reassessment of the situation and exploration for unrecognized injuries, bleeding, or other causes of shock are necessary (Table 26.4).

In clinical practice, large-volume resuscitation with lactated Ringer solution has become common in trauma care. However, recent military and laboratory work features a growing concern about tissue edema from large-volume resuscitation. The Inflammation and the Host Response to Injury investigators identify increased mortality, ICU and hospital length of stay, and a variety of infections in patients receiving more aggressive early crystalloid resuscitation. In recent years, a persisting picture of acute lung injury due to increase filtration across pulmonary microcapillaries with pulmonary inflammation has emerged. This event is seen as the acute respiratory distress syndrome (ARDS). Other observations include increased interstitial fluid in gut and cardiac tissues, abdominal compartment syndrome, extremity compartment syndrome in uninjured extremities, and pericardial effusion.[101]

Hemorrhage is a multifactorial disease; circulatory and inflammatory effects of hemorrhagic shock occur simultaneously. Unfortunately, laboratory studies have repeatedly shown that the choice of resuscitation fluid may worsen hemorrhage-induced cellular dysfunction, immune modulation, and inflammation. Fluids affect neutrophil activity by changing life span, activation, and gene expression. Resuscitation fluids also enhance the inflammatory cascade through upregulation of cellular receptors and



• **Fig. 26.6** A diagram showing some of the mechanisms leading to coagulopathy in the injured. Trauma can lead to hemorrhage, which can lead to resuscitation, which in turn leads to dilution and hypothermia causing coagulopathy and further hemorrhage. This is classic "dilution coagulopathy." Hemorrhage can also cause shock, which causes acidosis and hypothermia that in turn lead to coagulopathy, the "fatal triad." Trauma and shock can also cause the acute coagulopathy of trauma shock *(ACoTS)* associated with factor consumption and fibrinolysis. Coagulopathy is further associated with trauma-induced inflammation and modified by genetics, medications, and acquired diseases. (From Hess JR, Brohi K, Dutton RP, et al. The coagulopathy of trauma: a review of mechanisms. *J Trauma.* 2008;65:748–754.)

TABLE 26.3 Estimated Blood Loss and Other Critical Measures for Patients in Each Class of Shock[a]

Parameter	Class I	Class II (Mild)	Class III (Moderate)	Class IV (Severe)
Approximate blood loss	<15%	15%–30%	31%–40%	>40%
Heart rate	↔	↔/↑	↑	↑/↑↑
Blood pressure	↔	↔	↔/↓	↓
Pulse pressure	↔	↓	↑	↓
Respiratory rate	↔	↔	↔/↑	↑
Urine output	↔	↔	↓	↓↓
Glasgow Coma Scale score	↔	↔	↓	↓
Base deficit[a]	0 to –2 mEq/L	–2 to –6 mEq/L	–6 to –10 mEq/L	–10 mEq/L or less
Need for blood products	Monitor	Possible	Yes	Massive transfusion protocol

proinflammatory mediators. The choice of fluid also affects cellular gene expression, apoptotic cell death, and extracellular matrix integrity.[102–105]

Hypertonic Saline Solution in Trauma

Increased transmembrane sodium gradient caused by hypertonic saline solution generates intravascular volume expansion similar to hyperoncotic colloids and superior to conventional isotonic crystalloids such as lactated Ringer solution and normal saline solution. Animal models suggest that hypertonic saline solutions dilate precapillary arterioles and shunt oxygen to vital organs.[106,107] Hypertonic saline solutions also have fewer proinflammatory properties than other clinical crystalloids and colloids. Hypertonic saline solution does not induce expression of inflammatory cytokine

TABLE 26.4 General Guidelines for Establishing the Amount of Fluid and Blood Likely Required During Resuscitation[a]

	Rapid Response	Transient Response	Minimal or No Response
Vital signs	Return to normal	Transient improvement, recurrence of decreased blood pressure and increased heart rate	Remain abnormal
Estimated blood loss	Minimal (<15%)	Moderate and ongoing (15%–40%)	Severe (>40%)
Need for blood	Low	Moderate to high	Immediate
Blood preparation	Type and crossmatch	Type-specific	Emergency blood release
Need for operative intervention	Possibly	Likely	Highly likely
Early presence of surgeon	Yes	Yes	Yes

[a]If the amount of fluid required to restore or maintain adequate oxygen perfusion and tissue oxygenation exceeds these estimates, reassess the situation and search for unrecognized injuries and/or other causes of shock. The usual initial dose of resuscitation fluid in the adult is 1 L of warmed isotonic fluid. Absolute volumes of resuscitation fluid are based on patient response to fluid administration, keeping in mind that this initial fluid amount includes any fluid given in the prehospital setting.
From American College of Surgeons. Responses to initial fluid resuscitation. In: *Advanced Trauma Life Support Student Manual*. 10th ed. Chicago: American College of Surgeons; 2018.

receptor genes in multiple studies and blunts hemorrhage-induced increase in plasma levels of proinflammatory cytokines, IL-10, and granulocyte-macrophage colony-stimulating factor. Hypertonic saline solution also does not increase apoptotic cell death in liver, lung, or bowel.[102]

What about the impact of hypertonic saline solution and associated hypernatremia in the setting of injury?[108] Studies in experimental animals and humans suggest that hypertonic saline solution may be highly effective in treating head injury, either alone or associated with hemorrhagic hypotension. Tissue swelling in a closed cranium threatens to cause pressure-induced brain damage or death, and concomitant hemorrhagic hypotension reduces cerebral oxygen delivery, resulting in a secondary ischemic insult. Historical data suggest a twofold higher incidence of adverse outcomes in patients with brain injury combined with hypotension. Patients are frequently treated with hypertonic saline solution for rapid intracranial pressure control. However, hypertonic saline solution has not seen general use in trauma resuscitation.[109,110]

Colloids in Trauma

Hyperoncotic colloid solutions have also been studied in resuscitation roles for traumatic hemorrhage. The natural colloid albumin does not induce neutrophil oxidative burst and may confer a protective immunologic effect by decreasing neutrophil expression of adhesion molecules.[111] At present, albumin has little application in resuscitation at the scene of injury but has been investigated in critical care practice.

An artificial colloid, 6% hetastarch, has been found to have a number of deleterious resuscitation effects in animal models, including increased neutrophil oxidative burst and pulmonary apoptosis. Beneficial effects include decreased neutrophil migration. At present, natural and artificial colloids have failed to show clinical benefits compared to crystalloid solutions.[112,113] Laboratory concerns and lack of a positive clinical outcome argue against the use of colloids in early resuscitation of hemorrhagic shock.

Recent reviews suggest important differences in safety among colloids. Examination of data comparing colloids with crystalloids must take into account the materials used. When albumin was used as a reference, the incidence ratio for anaphylactoid reactions was 4.51 after administration of hydroxyethyl starch, 2.32 after dextran, and 12.4 after gelatin. Artificial colloid administration was consistently associated with coagulopathy and clinical bleeding, most frequently in cardiac surgery patients receiving starches. Albumin had the lowest rate of total adverse events and serious adverse events.[114] Life-threatening anaphylactoid reactions were infrequent for all colloids. Hydroxyethyl starch, compared with albumin, more than quadrupled the incidence of anaphylactic reactions, whereas dextran more than doubled them. The incidence of these reactions in recipients of gelatin was greater by an order of magnitude than after albumin infusion. Because artificial colloids are derived from nonhuman source materials, they may be recognized as foreign and are more likely to provoke this immune-mediated response. The foreign nature of artificial colloids also may hinder metabolic clearance and promote tissue deposition. On the basis of extensive evidence, albumin is the safest colloid for consideration in resuscitation of traumatic shock.[114] Although factors such as desirability of anticoagulant activity may favor other artificial colloids, this is not true in the setting of injury.[115–117]

Multicenter data comparing albumin and saline solution for fluid resuscitation were obtained in Australia and published in 2004 (SAFE trial).[32] Nearly 7000 patients were randomly assigned to administration of 4% albumin or normal saline solution for intravascular fluid resuscitation procedures. Mortality rate and the incidence of single- and multiple-organ dysfunction were comparable in the two groups. Subset analysis suggests, however, poorer outcomes in the setting of injury. In the subgroup of 140 patients included with principal diagnoses of trauma, a treatment effect seemed to favor administration of saline solution. In this trial, the increased relative risk of death among patients with trauma compared with patients without trauma resulted from an excess number of deaths among patients who had trauma with brain injury. The difference in mortality rates between the albumin and saline solution groups among patients with trauma involving brain injury must be viewed cautiously because the number of involved subjects is small. In the SAFE study, patients with traumatic brain injury constituted only 7% of the study population, and the excess number of deaths in the albumin group was 21. Other parameters that could be helpful in evaluation of the impact of albumin in the setting of brain injury, such as functional neurologic status, were not provided. In contrast to the experience in trauma, the Australian trial suggests some evidence

of treatment benefit favoring administration of albumin in patients with severe sepsis. Given contemporary resuscitation technology, factors influencing the choice of resuscitation for critically ill patients include specific clinician concerns, treatment tolerance, safety, and cost.

Crystalloids Versus Colloids

Plasma and blood were the fluid replacements of choice in traumatic shock until the early 1960s, when a variety of investigators showed the need to replace the extracellular fluid deficit with crystalloid solutions. These observations were followed by a variety of clinical studies comparing colloid, typically albumin, solutions with crystalloids, typically lactated Ringer solution. Consistent with early studies, colloids, when given on an equal volume basis, more effectively increase CO and oxygen transport. Another finding of this early work was the need to administer crystalloids in far greater quantities than colloids to achieve consistent hemodynamic objectives.[118,119]

Later studies from the Vietnam era compared resuscitation of patients who were given whole blood and crystalloids with patients given whole blood plus 5% albumin. Fluid infusion volumes were far higher in the patients given crystalloid solutions. There was no evidence of pulmonary edema, and patients treated with crystalloids seemed to fare better than patients treated with resuscitation containing albumin. Albumin seemed to have less effect on restoration of renal function with suggestion of detrimental effects in pulmonary response, myocardial contractility, and coagulation. Large animal models suggested that pulmonary compromise could relate to increased capillary permeability with albumin. Increased losses of albumin to the heart, kidneys, liver, and brain also were reported.[118,120] More extensive studies in injured patients supported reservations regarding the use of albumin. Evaluation of patients randomly selected to receive 150 g of albumin per day intraoperatively and postoperatively noted poorer outcomes than in patients receiving lactated Ringer solution. Both groups received whole blood and FFP. Patients treated with albumin required greater ventilator support and had poorer oxygenation.[118,121,122] In another carefully conducted trial of patients with multiple trauma, no differences in cardiopulmonary function between patients resuscitated with lactated Ringer solution and patients given 5% albumin and lactated Ringer solution were identified.[123] Normal cardiac index was used as a therapeutic endpoint. To maintain adequate CO, patients who received crystalloids required far more resuscitation volume than patients treated with albumin. A clear cost advantage of crystalloids was identified.[118]

Guyton and Lindsey[124] examined the effect of colloid oncotic pressure on pulmonary edema. They observed that reducing the serum protein level lowered the threshold of left atrial pressure at which pulmonary edema could occur. Zarins and colleagues[125] subsequently showed that a low colloid oncotic pressure alone did not cause an elevation in extravascular lung water. Because of the remarkable efficiency of pulmonary lymphatics, arterial blood gases, shunt fraction, and lung compliance were unchanged despite a 14% increase in body weight caused by infusion of lactated Ringer solution to maintain high pulmonary artery occlusion pressures. No pulmonary edema was created despite the presence of ascites and marked peripheral edema. Demling and coworkers[126] confirmed these findings with a chronic lung lymph fistula in sheep. Holcroft and coworkers[127] produced pulmonary edema in baboons during resuscitation from hemorrhage by continuously administering large volumes of lactated Ringer solution sufficient to elevate pulmonary artery occlusion pressures 15 mm Hg above baseline levels. With cessation of infusion, filling pressure rapidly returned to normal.

Blood Component Therapy

Despite work from multiple groups suggesting that simple replacement of PRBCs was not a sufficient answer for the most severely injured patient, particularly in the setting of coagulopathy, the concept of combination blood component replacement remained outside the mainstream of trauma care for more than 20 years.[79,83,128] It took armed conflicts and experience in a multinational group of trauma centers to bring awareness of the need for multiple blood component therapy in massive bleeding to the level of general trauma practice.

The 1970s and 1980s saw several groups propose resuscitation of significant hemorrhage with combinations of blood components. Kashuk and Moore proposed multicomponent blood therapy in patients with significant vascular injury.[79] In a study of patients with major abdominal vascular injury, Kashuk and coworkers noted frequent deviation from a standard ratio of 4:1 or 5:1 for units of PRBCs to units of FFP. The ratio was 8:1 in nonsurvivors and 9:1 when overt coagulopathy was noted. In this series 51% of patients were coagulopathic after vascular control was obtained. Using multivariate analysis, Ciavarella and coworkers from the Puget Sound Blood Center and Harborview Medical Center proposed aggressive supplementation of platelets in the setting of massive transfusion. These investigators noted that platelet counts below 50×10^9/L correlated highly with microvascular bleeding in trauma and surgery patients. Fibrinogen repletion was also emphasized. Guides to resuscitation included fibrinogen level, PT, and PTT. Supplemental FFP or cryoprecipitate was recommended for low fibrinogen levels.[83] Weaver and colleagues, summarizing extensive preclinical and clinical studies, suggested administration of FFP after 6 units of PRBCs had been infused. Additional FFP was recommended for every five additional PRBC transfusions. Monitoring included platelet count, PT, and PTT after each 5 units of PRBCs are administered. Platelet transfusion is generally unnecessary unless the platelet count falls below 50,000 platelets per µL of blood.[128]

Another view of damage control hematology comes from Vanderbilt University Medical Center in Nashville, Tennessee. This group implemented a trauma exsanguination protocol involving acute administration of 10 units of PRBCs with 4 units of FFP and 2 units of platelets. In an 18-month period, 90 patients received this resuscitation and were compared with a historical set of control subjects. The group of patients receiving the trauma exsanguination protocol as described by these investigators had lower mortality rates, higher blood product use in initial operative procedures, and more frequent use of products in the initial 24 hours, although overall blood product consumption during hospitalization was decreased.[129]

The strongest multicenter civilian data report examining the impact of plasma and platelet administration along with red blood cells on outcome in massive transfusion comes from Holcomb and coworkers.[130] These investigators describe more than 450 patients from 16 adult and pediatric centers. Overall survival in this group is 59%. Patients were gravely ill as reflected by an admission base deficit of −11, pH 7.2, Glasgow Coma Scale (GCS) score of 9, and a mean ISS of 32. Examination of multicenter data reflects an improvement in outcome as the ratio of FFP to PRBCs administered approaches 1. FFP, however, is not the sole solution to improved coagulation response in acute injury. These workers also examined the relationship of aggressive plasma and platelet administration in

these patients. Optimal outcome in this massive transfusion group was obtained with aggressive platelet as well as plasma administration. Worst outcomes were seen when aggressive administration of plasma and platelets did not take place. When either FFP or platelets were given in higher proportion in relationship to PRBCs, intermediate results were obtained. Not surprisingly, the cause of death that was favorably affected was truncal hemorrhage.

A summary statement comes from Holcomb and a combination of military and civilian investigators.[87,88] These workers identify a patient group at high risk for coagulopathy and resuscitation failure owing to hypothermia, acidosis, hypoperfusion, inflammation, and volume of tissue injury. In the paradigm proposed by these authors, resuscitation begins with prehospital limitation of blood pressure at approximately 90 mm Hg preventing renewed bleeding from recently clotted vessels. Intravascular volume resuscitation is accomplished using thawed plasma in a 1:1 or 1:2 ratio with PRBCs. Acidosis is managed by use of tromethamine and volume loading with blood components as hemostasis is obtained. A massive transfusion protocol for these investigators included delivery of packs of 6 units of plasma, 6 units of PRBC, 6 units of platelets, and 10 units of cryoprecipitate in stored individual coolers. These coolers are supplied until discontinuation by the trauma team. Even in causalities requiring resuscitation with 10 to 40 units of blood products, Holcomb and coworkers found that as little as 5 to 8 L of crystalloid is used during the first 24 hours, representing a decrease of at least 50% compared with standard practice. The lack of intraoperative coagulopathic bleeding allowed surgeons to focus on surgical hemorrhage. The goal is arrival of the patient to the ICU in a warm, euvolemic, and nonacidotic state. International normalized ratio approaches normal and edema is minimized. Subjectively, patients treated in this manner are more readily ventilated and easier to extubate than patients with a similar blood loss treated with standard crystalloid resuscitation and smaller amounts of blood products. Holcomb and others suggest that massive transfusion will be required in 6% to 7% of military patients and 1% to 2% of civilian trauma patients.

A summary statement regarding transfusion in the trauma patient has been made by the Inflammation and the Host Response to Injury investigators[131] (Fig. 26.7). In hemodynamically stable patients, administration of PRBCs should be performed with a hemoglobin level below 7 g/dL. If the hemoglobin level is above 7 g/dL and there is evidence of hypovolemia, appropriate crystalloid fluid should be given to achieve normovolemia. If administration of IV fluids to achieve normovolemia decreases the hemoglobin concentration to less than 7 g/dL, then additional red blood cells may be administered.

If the patient is normovolemic and the hemoglobin level is above 7 g/dL, then the clinical state of a patient should be assessed to determine whether there is any clinical or laboratory evidence of impaired oxygen delivery. Based on evidence of impaired oxygen delivery, such as low mixed venous oxygen saturation, persistent base deficit, or the presence of lactic acidosis, additional administration of PRBCs may be appropriate with monitoring of oxygen delivery.[131]

Endpoints

The Problem

Severely injured trauma patients are at high risk of developing multiple-organ failure or dying. Initial treatment priorities include appropriate fluid administration and rapid hemostasis.[132,133] Inadequate tissue oxygenation leads to anaerobic metabolism and tissue acidosis. Depth and duration of shock are associated with cumulative oxygen and metabolic debt. Resuscitation is incomplete until the metabolic debt is paid, and tissue acidosis is eliminated with restoration of aerobic metabolism. Many patients seem to be adequately resuscitated based on normalization of vital signs but have occult hypoperfusion and ongoing tissue acidosis (compensated shock). These individuals are at risk for later organ dysfunction and death.[100]

As stated in the Advanced Trauma Life Support protocol, the standard of care remains restoration of normal blood pressure, heart rate, and urine output.[100] When these parameters remain abnormal (uncompensated shock), the need for additional resuscitation is obvious. After normalization of these parameters, however, many trauma patients still have evidence of inadequate tissue oxygenation. Recognition of this state and its reversal are crucial to reduce the risk of organ dysfunction or death. The optimal marker of adequate resuscitation in injury remains unclear.[134]

Not all patients can be managed in the same way. More recent literature describing management of neurologic trauma suggests poor outcome with any degree of hypotension during prehospital care, resuscitation, or subsequent in-hospital course. Episodes of hypotension and hypoxia were associated with poor neurologic outcome in a review of more than 700 patients from the Traumatic Coma Data Bank with a GCS score less than 9. In this large study, patients without hypotension or hypoxia had a 27% risk of death and a 51% chance of favorable recovery. In the presence of hypotension, with or without hypoxia, the risk of death increased to 65% to 75%. Contrary to the needs of patients with penetrating trauma in whom early aggressive resuscitation may lead to increased bleeding, hypotension should be avoided in patients with head injuries. Resuscitation parameters specific to many types of injury have not been reported.[135–137]

Oxygen Delivery Parameters

Shoemaker and various coworkers provided early stimulus to optimization of hemodynamic management in high-risk surgical patients by examining hemodynamic profiles of survivors of surgical shock states versus patients who died.[138] Survivors had significantly higher oxygen delivery and cardiac index values than nonsurvivors. Values correlating with survival included cardiac index greater than 4.5 L/min per m^2, oxygen delivery greater than 600 mL/min per m^2, and oxygen consumption equal to or greater than 170 mL/min per m^2. These initial observations led to a series of reports from this group suggesting reduction in resource consumption and improvement in morbidity and mortality rates with resuscitation to supranormal oxygen delivery parameters. Initial augmentation of oxygen delivery came with volume loading followed by dobutamine and blood transfusions as needed to a hemoglobin level of 14 g/dL.[139–141]

Attempts by other investigators to replicate these findings met limited success. Moore and coworkers used a resuscitation protocol aimed at maximizing oxygen delivery and found no benefit with resuscitation to achieve supranormal oxygen delivery.[134,142] A variety of studies suggested that patients who did not reach resuscitation goals were at increased risk for multiple organ failure. Other workers noted that patients who did not obtain supranormal oxygen delivery values were at high risk of developing organ failure regardless of treatment strategy.[143,144] Obtaining hemodynamic and oxygen transport parameters seems to be more predictive of survival than

Transfusion Guideline for Trauma Patient*
Inflammation and the Host Response to Injury

1. Identify critically ill patient will hemoglobin <7 g/dL (or Hct <21%).
2. If hemoglobin <7 g/dL transfusion of PRBCs is appropriate.
   a. For patients with severe cardiovascular disease, a higher transfusion trigger may be appropriate.
3. If hemoglobin >7 g/dL assess the patient for hypovolemia.
   a. If the patient is hypovolemic, administer IV fluids to achieve normovolemia.
   b. If the patient is not hypovolemic, determine whether there is evidence of impaired oxygen delivery (low Svo_2, persistent/worsening base deficit, presence/worsening of lactic acidosis).
4. If impaired O_2 delivery present, consider pulmonary artery catheter placement, measure cardiac output, and optimize O_2 delivery.
5. If impaired O_2 delivery not present, monitor hemoglobin as clinically indicated.

A ** This protocol assumes that acute hemorrhage has been controlled, the initial resuscitation has been completed, and the patient is stable in the ICU without ongoing hemorrhage.*

useful as a goal for resuscitation, particularly if fluid administration is adequate.

In addition to conflicting outcomes in oxygen transport trials, technical concerns have been raised. These studies cannot be totally blinded. Patients in control groups often obtain physiologic endpoints similar to those in treatment groups. Other aspects of care were sometimes inconsistent, and entrance criteria varied among investigators. There also is potential mathematical coupling of oxygen delivery and consumption because both are calculated values that share many of the same measured variables.[135] Some clinicians argue that the pathologic relationship between oxygen delivery and consumption trials cannot be accepted with confidence, unless oxygen consumption is measured directly. Finally, the use of traditional oxygen delivery and consumption as resuscitative endpoints requires a pulmonary artery catheter and special expertise for operation and insertion. Routine use of pulmonary artery catheterization or central venous catheters has not been a part of acute trauma resuscitation or emergency medical management.[100,134,135]

Lactate

As an indicator of shock, blood lactate has proved accurate at assessing severity, predicting mortality risk, and assessing response to resuscitation in the hands of various workers.[134,135] At the cellular level, the explanation is based on oxygen transport principles. With shock and inadequate oxygen delivery, mitochondrial respiration is impaired. The primary cellular fuel, pyruvate, is shunted from its normal aerobic path (conversion by pyruvate dehydrogenase to acetyl coenzyme A and subsequent entry into the tricarboxylic acid cycle) to the anaerobic pathway (conversion to lactate by lactate dehydrogenase). Anaerobic metabolism makes inefficient use of cellular substrate, and high-energy phosphate stores are rapidly depleted. During cellular ischemia, lactate is released into the bloodstream and ultimately converted to glucose in the liver and kidney via the Cori cycle. Because it directly reflects anaerobic metabolism, lactate is thought to serve as a mirror of global hyperperfusion because increasing lactate levels indicate increasing oxygen debt.[135,145]

Initial and peak lactate levels and duration of increased lactate concentration correlate with development of multiorgan dysfunction after trauma.[135] In a study of trauma patient resuscitation, patients who had normalized lactate levels at 24 hours survived, whereas patients who had normalized lactate levels between 24 and 48 hours had a 25% mortality rate; patients who did not have normalized levels by 48 hours had an 86% mortality rate.[146] More recent data come from a systematic review of lactate levels in the emergency department. Elevated emergency department lactate levels were associated with mortality and other outcomes, including injury severity, ICU admission, length of hospitalization, organ failure, blood product requirement, catecholamine support, and emergency operation.[147]

Base Deficit

Inadequate oxygen delivery to tissues leads to anaerobic metabolism. The degree of anaerobiosis is proportional to the depth and severity of hemorrhagic shock, which should be reflected in lactate and base deficit. Arterial pH is not as useful because compensatory mechanisms attempt to normalize this parameter. Serum bicarbonate levels offer better correlation with base deficit (removal or addition of base in the blood).[134,148,149]

Similar to lactate, base deficit has been carefully studied.[134] A greater base deficit has been associated with blood pressure reduction, increased blood loss, and transfusion requirements. A series of studies by Davis and coworkers link base deficit to resuscitation requirements and end-organ dysfunction, such as ARDS, renal failure, and coagulopathy. Cytokine and adhesion molecule changes also have been found to parallel changes in base deficit.[150–156]

Base deficit may vary with patient populations. Concern remains in older patients that base deficit is nonspecific and may reflect metabolic acidosis owing to a variety of causes, including renal dysfunction and diabetes.[134,135] Similar to temporal changes in lactate, base deficit variation over time may add to the value of this parameter.[148] Patients with elevated base deficit also showed impaired oxygen use reflected in lower oxygen consumption. The timing of base deficit measurement also is important. One study suggested that the worst base deficit in the initial 24 hours was predictive of mortality rate along with blood pressure and estimated blood loss.[154] Some workers debate whether alcohol intoxication may worsen base deficit for similar levels of injury severity and hemodynamics after trauma. In a large database survey, use of alcohol did not change the significant predictive value of admission lactate and base deficit.[157,158] Resuscitation with normal saline solution (hyperchloremic metabolic acidosis) or lactated Ringer solution (accumulation of D-lactate) may increase base deficit independent of injury severity. Acidosis associated with hyperchloremia is associated with a lower mortality rate than that from other causes, particularly anaerobic metabolism.[134,159] Base deficit levels and time to normalization of base deficit are similar to data for lactate in that correlation has been established with the need for resuscitation and risk of organ dysfunction and death after injury. Specific thresholds for outcome have not been determined.

Near-Infrared Spectroscopy

Measurement of skeletal muscle oxyhemoglobin levels by near-infrared spectroscopy offers a noninvasive measurement for evaluating adequacy of resuscitation from normalization of tissue oxygenation.[134,135,160] This technology allows simultaneous measurement of tissue partial pressure of oxygen (PO_2), partial pressure of carbon dioxide (PCO_2), and pH. In human volunteers, cerebral cortex and calf oxygen saturation as measured by near-infrared spectroscopy decreased in proportion to blood loss. Studies in injury suggest correlation of tissue oxygen saturation with systemic oxygen delivery, base deficit, and lactate.[161]

This technology provides information regarding mitochondrial function. Normally, tissue oxyhemoglobin levels reflecting local oxygenation are tightly coupled to cytochrome function, reflecting mitochondrial oxygen consumption. In small studies, when patients showed a change in mitochondrial function, even in the absence of abnormality in systemic oxygen transport, multiple organ failure was more likely.[162] Nonetheless, at this time, work in this area is limited, and a role for this technology in routine management of traumatic shock has not been defined.

Adrenal Insufficiency

Adrenal insufficiency is reviewed in Box 26.2.

Clinical Strategies

Clinical observations of shock in injury have been made for hundreds of years, but the optimal treatment continues to be

• BOX 26.2 Adrenal Insufficiency

Check adrenal function in patients who fail to respond to resuscitation.[a–c] Adrenal insufficiency, a rare occurrence in the general population (<0.01%), is seen in 28% of seriously ill patients and 60% of severely injured trauma patients in contemporary series.[d] Severe illness and stress activate the hypothalamic-pituitary-adrenal axis and stimulate the release of corticotropin (adrenocorticotropic hormone) from the pituitary, which stimulates release of cortisol from the adrenal cortex. This action is an essential component of general adaptation to illness and contributes to maintenance of cellular and organ homeostasis.[a,c]

Although a growing body of literature reviews adrenal insufficiency in critical illness with an emphasis on sepsis, we have seen a significant incidence of adrenal insufficiency, reflected by low serum cortisol levels, in severe injury with or without direct trauma to the brain.[e,f]

We suspect adrenal insufficiency in patients who are young and otherwise healthy and require vasoactive drugs in addition to large amounts of resuscitation fluid. Our approach to making the diagnosis of acute adrenal insufficiency is a spot cortisol level. Although a variety of treatment protocols for hormonal replacement exist, we provide 50 mg of hydrocortisone every 6 hours or 100 mg of hydrocortisone every 8 hours for 5 days. Consistent with the treatment threshold reported by Marik and Zaloga,[b,f] we treat if a random cortisol concentration is less than 25 μg/dL. Severely injured patients have been reported to have random cortisol levels greater than 30 μg/dL.[d] Although outcome data are unavailable to suggest the value of adrenal replacement in critically stressed young trauma patients, we have seen the effectiveness of this intervention repeatedly in our own practice.

debated.[133] Early observations are attributed to Paré, Le Dran, Latta, and Gross.[163,164] Crile and Henderson were among the first to attribute the hemodynamic instability of shock to decreased intravascular volume and to propose therapy based on restoration of intravascular volume with administration of IV fluid.[164] During the First World War, physiologists Cannon and Bayliss observed patients in clinical shock.[6] These observers noted that patients with crush injuries despite absence of obvious blood loss also developed signs and symptoms of shock.[165,166] Cannon later suggested the concept of deliberate hypotension in the treatment of wounds to the torso during war with the intent of minimizing internal bleeding until the time at which operative intervention could control the hemorrhage.[167,168] In later studies, other authors reported laboratory models of ongoing arterial hemorrhage and concluded that regardless of the means used to increase blood pressure, either fluid resuscitation or vasopressor, bleeding would increase with subsequent death.[169,170]

Current guidelines for the treatment of hypotension secondary to hemorrhage after trauma recommend rapid infusion of crystalloid solutions to restore blood pressure.[100,168] This premise is based in part on clinical studies and laboratory data showing that hemorrhagic shock in animals produced with controlled blood loss was reversible when blood loss was replaced with two to three times that volume of a crystalloid solution.[171–173] Although controlled hemorrhage is a well-defined laboratory model, resuscitation of a patient with multiple injuries and active or uncontrolled bleeding may represent very different pathophysiology.[133]

In 1950 Wiggers[174] developed a standard hemorrhagic shock model in dogs. He and others showed that severe hypotension over several hours produced a condition in which infusion of withdrawn blood restored arterial pressure only temporarily.[133] After intervals ranging from 30 minutes to 3 hours, arterial pressure declined again. Additional infusions of blood were followed by progressively poorer recovery and more rapid development of circulatory failure, ultimately resulting in the demise of the animal. This decompensation point in shock, defining a time at which reinfusion of shed blood could not resuscitate the animal, led to the concept of irreversible shock.[175] The approach to resuscitation of cellular, organ, and organism changes after hemorrhagic shock using the Wiggers model has been applied to all types of injury based in part on the elegant experiments of Shires and colleagues[171] and a series of other investigators.[102]

Early Limited Resuscitation

Animal Studies

Several large animal studies explored the use of varying degrees of fluid resuscitation in animals receiving injuries leading to uncontrolled hemorrhagic shock. Bickell and coworkers[176] created infrarenal aortotomy using a stainless steel wire in 16 anesthetized Yorkshire swine weighing 23 to 40 kg that had been instrumented with pulmonary artery and carotid artery catheters. When the wire was pulled, a 5-mm aortotomy with subsequent intraperitoneal hemorrhage followed. Animals were alternately assigned to an untreated control group or a treatment group receiving 80 mL/kg of lactated Ringer solution as an IV bolus. The volume of blood loss and the mortality rate were significantly increased in animals treated with lactated Ringer solution relative to the untreated control group. All control animals survived, whereas animals treated with lactated Ringer solution died in less than 2 hours. The volume of hemorrhage identified in treated animals exceeded 2 L, whereas control animals lost on average less than 800 mL of blood.

Several observations may be made in relation to this widely cited report. First, the mortality rate in the control group was low, leading one to question the severity of injury in the animal model. Second, fluid resuscitation administered, although consistent with replacement of two to three times the volume loss in blood with crystalloid, far exceeds standard resuscitation for a human patient of comparable weight. In addition, the rapidity of fluid administration may have served to diminish further any potential positive impact of fluid administration in this model of injury. The effect seen was reproduced, however, with other types of fluid administration in a comparable injury model. Other large animal studies of hypotensive resuscitation used graded resuscitation protocols.[177,178]

Stern and coworkers[177] examined a swine model combining femoral artery hemorrhage via a catheter to an MAP of 30 mm Hg with subsequent intraabdominal aortic laceration producing a 4-mm tear and uncontrolled intraperitoneal hemorrhage. Three groups of animals were resuscitated to mean arterial pressures of 40, 60, and 80 mm Hg. No untreated control group was used. Resuscitation was begun when the pulse pressure of each animal reached 5 mm Hg. Animals were resuscitated with saline solution at 6 mL/kg per minute to a maximum of 90 mL/kg, after which resuscitation fluid was changed to shed blood at 2 mL/kg per minute to a maximal volume of 24 mL/kg. Animals were observed for 60 minutes or until death. As noted previously, the mortality rate was significantly higher in animals receiving the most aggressive resuscitation compared with less aggressively treated groups. Animals resuscitated most aggressively had higher volumes of intraperitoneal hemorrhage than the two other experimental groups. In addition, oxygen delivery, which was monitored in these animals, was significantly greater in the group resuscitated to an MAP of 60 mm Hg than in the two other experimental groups. Similar observations were made in a second report from this same group in a study by Kowalenko and colleagues.[178]

Clinical and preclinical studies focused on early limitation of crystalloid resuscitation and hemorrhagic shock focus on penetrating torso trauma but do not address initial care of patients with head injury, a leading cause of traumatic death in the United States. Historically, when shock accompanies head injury, the incidence of adverse outcome doubles. Because of the vulnerability of the injured brain to even brief periods of reduced perfusion, guidelines for the management of head injury state that delayed resuscitation cannot be considered applicable in head trauma.[137] Nonetheless, in a large animal model using a standard cerebral injury along with uncontrolled hemorrhage secondary to aortotomy, there was no evidence of increased secondary cerebral ischemia with delayed resuscitation. Conventional resuscitation with lactated Ringer solution resulted in signs of increased secondary brain injury.[179]

Clinical Studies

Martin and coworkers[180] provided preliminary data in patients on the effect of aggressive versus delayed prehospital resuscitation of uncontrolled hemorrhagic shock after penetrating injury. These workers evaluated the effect of delaying fluid resuscitation until surgical intervention could control the source of hemorrhage on outcome of hypotensive trauma victims. Injury severity was similar in standard resuscitation and delayed resuscitation groups. The rate of survival to hospital discharge was 69% in the delayed resuscitation group and 56% in the standard resuscitation group. The difference between these groups did not reach statistical significance owing to small sample size.

Much attention has been directed to resuscitation of patients after injury after a report from Bickell and associates[181] that appeared in the *New England Journal of Medicine.* The authors reported a prospective clinical trial of adults with penetrating truncal trauma who were hypotensive in the field as indicated by a systolic blood pressure less than 90 mm Hg. Patients were randomly assigned to placement of intravascular catheters with standard prehospital and trauma center fluid resuscitation using lactated Ringer solution or an experimental group in which vascular catheters were placed but IV fluids were not administered until patients reached the operating room. Patients were excluded from this trial if they were noted to have a field revised trauma score of zero consistent with cardiopulmonary arrest or had sustained fatal gunshot wounds to the head with neurologic injury that precluded long-term survival. In addition, patients with penetrating truncal injury who did not require operation were excluded. After 1069 patients were screened during the 37 months of this study, 598 patients were enrolled—309 in an immediate resuscitation group receiving standard fluids according to Advanced Trauma Life Support protocols and 289 in a delayed resuscitation group, which did not receive IV fluids until reaching the operating room.[100]

The immediate and delayed resuscitation groups were well matched with respect to age, gender, and anatomic injury as measured by the ISS, Revised Trauma Score (physiologic response to injury), and systolic blood pressure.[182,183] Field response times for prehospital providers in this trial were short, averaging 30 minutes or less. The trauma center interval (i.e., the interval in the hospital before operation) was surprisingly long: 44 minutes in the immediate resuscitation group and 52 minutes on average in the group receiving delayed resuscitation. Prehospital fluid administration averaged less than 900 mL in the immediate resuscitation group versus less than 100 mL in the delayed resuscitation cohort. Fluid administration in the trauma center before operation averaged greater than 1600 mL of fluid in the immediate resuscitation group, whereas the delayed resuscitation patients averaged 283 mL of fluid received. Operative blood loss between the study groups was not different. Among the 289 patients who received delayed fluid resuscitation, 203 (70%) survived and were discharged from the hospital. Of the 309 patients who received immediate fluid resuscitation, 193 (62%) survived ($P = 0.04$). Patients in the delayed resuscitation group displayed a trend toward reduced postoperative complications, including ARDS, sepsis syndrome, acute renal failure, coagulopathy, wound infection, and pneumonia, compared with patients in the immediate resuscitation group ($P = 0.08$).

The value of what we now call "hypotensive resuscitation" has been confirmed in subsequent studies of injured patients and victims of vascular insults such as aneurysm rupture. Placement of increased vascular access at the scene and rapid fluid administration has been associated with increased mortality.[184]

Although these early clinical studies represent a remarkable accomplishment in design, organization, and data analysis, many questions remain unanswered. None of the studies reported was blinded, and a randomization scheme was not used. In the trial by Bickell and colleagues, in which the difference in mortality rate rested in a difference in survival of a small number of patients in the experimental groups, 22 patients in the delayed resuscitation group were given IV fluids in violation of study design.[181] Although these individuals were appropriately included in an intent-to-treat analysis, the impact of selected fluid administration on study outcome is unclear. The authors also have been criticized for excluding patients *after* randomization because of injuries considered too minor (no operative therapy) or too severe (Revised Trauma Score of 0). Exclusion of these patients may invalidate the statistical approach used and increase the difficulty of the clinician seeking guidance from this work. Finally, time spent in the trauma center by these hypotensive patients with injuries requiring operation was surprisingly long. Although the resuscitation groups described differed statistically in vital signs and hematologic parameters, it is unclear whether the differences observed had clinical significance.

We await additional data on the military approach to resuscitation, which requires innovation and effectiveness in austere environments.[185] Contemporary recommendations include limitation of fluid administration unless systolic blood pressure is less than 80 to 85 mm Hg or is rapidly falling. Another clinical indicator for fluid resuscitation is decreasing mentation without evidence of head injury. Key assessment parameters are mental status and the presence of a radial pulse. In many settings, no fluids are administered in the presence of a strong radial pulse and normal mentation. Indicators for intervention are pulse deterioration or decreasing level of consciousness. When fluids are given, a number of small-volume colloids with high tonicity or colloids in combination with saline solution are being investigated. Even early hospital resuscitation is designed to emphasize the use of blood products and minimize crystalloids and nonblood colloids in the setting of major injury.

Clinical Pathway—Early Resuscitation

In all of the preclinical and clinical work described, the mechanism of injury and survival remains unclear. Among considerations is the impact of fluid resuscitation on early clot formation in the setting of uncontrolled hemorrhage.[133,177] Other workers suggest that rapidity in resuscitation of pulse pressure may relate to mechanical disruption of initial thrombus. Fluid resuscitation may contribute to dilution of clotting factors in the setting of exaggerated bleeding in uncontrolled hemorrhage.[168] The data to support these observations are limited. Coagulopathy proportional to volume of injured tissue and severity of shock may be seen even before resuscitation fluids are provided.[11]

Despite provocative preclinical and clinical data, there is insufficient evidence to propose practice guidelines or make recommendations. "Uncontrolled" hemorrhage itself remains undefined. This problem is best seen as injury with blood loss occurring in the absence of surgical or mechanical hemostasis or the "control" provided by regulated blood removal through a vascular cannula. It is unclear whether a vascular injury after a torso gunshot wound and a shattered spleen after an automobile crash are different in this regard. The message from all of the studies is that elevation of the blood pressure to normal or supranormal levels results in resumption of bleeding from the uncontrolled site, and rebleeding leads to recurrent shock and death of the experimental animal. Other work shows that animals subjected to shock could be successfully resuscitated at lower than "normal" mean arterial pressures if the bleeding site was controlled as part of the resuscitation program. Shock victims resuscitated with electrolyte solutions are subject to progressive hemodilution, and this may lead to death. The lessons that clinicians should learn from this body of data are as follows[11,100,133]:

1. Operation to control bleeding is part of resuscitation.
2. Blood pressure levels are convenient but possibly misleading endpoints for shock resuscitation in that resuscitation to normal or supranormal pressures may be harmful if the effort delays

operation to control bleeding or the pressure elevation causes rebleeding. Better endpoints (e.g., tissue oxygenation or other metabolic parameters) are needed.

3. Blood loss is increased in the setting of significant soft tissue insults combined with shock. Early administration of blood products should include use of a balanced administration strategy with PRBCs, FFP, and platelets given in equal proportions.
4. Resuscitation of traumatic shock, similar to fluid management of a burned patient, requires repeated observation, judgment, and skill and cannot be accomplished by recipe or formula.

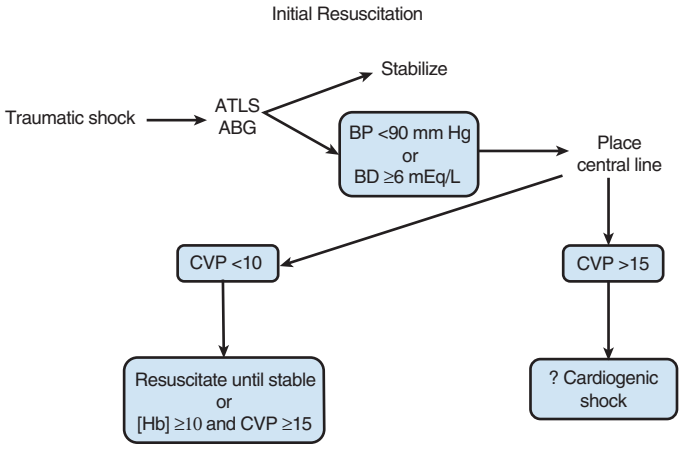
A protocol from the investigators on the Inflammation and the Host Response to Injury Project is shown in Fig. 26.8. Variables driving decision-making include systolic blood pressure, heart rate, base deficit, CVP, hemoglobin level, and clinical judgment.[186]

Patients with major trauma arriving with a systolic blood pressure below 90 mm Hg and/or a heart rate above 130 beats/min are initially managed using Advance Trauma Life Support fluid administration. Routine monitoring includes frequent vital signs, continuous electrocardiogram, and pulse oximetry with assessment of core body temperature. Arterial blood gas analysis is obtained in all patients presenting in traumatic shock. Patients with major torso trauma with evidence of shock (early systolic blood pressure <90 mm Hg and/or base deficit ≥6 mEq/L) and who require ongoing resuscitation should have a central venous catheter placed while they are in the emergency department. CVP measurements should be used to differentiate the type of shock and assist with monitoring of shock resuscitation. Early CVP above 15 mm Hg before extensive volume loading suggests cardiac insufficiency. Differential diagnosis of cardiovascular insufficiency after blunt trauma includes tension pneumothorax, myocardial contusion or infarction, pericardial tamponade, and infrequently, air embolus.[186]

CVP less than 10 mm Hg despite volume loading indicates persistent hypovolemia consistent with ongoing bleeding. The endpoint of initial resuscitation is controversial as described earlier. These investigators recommend hypotensive resuscitation to systolic blood pressure above 90 mm Hg and heart rate below 130 beats/min with moderate volume loading until hemorrhage control is accomplished. They recommend this approach as standard care for patients with penetrating trauma and believe it is most likely safe as well for patients with blunt torso trauma who do not have significant coexistent brain injuries.

Blood should be administered when lactated Ringer infusion exceeds 30 mL/kg. Earlier empiric blood transfusion is indicated in patients, especially the elderly, who arrive in severe shock or have injuries associated with significant bleeding, such as vertical shear pelvic fractures or bilateral femur fractures. Institution protocols for massive transfusion should be established and used in these patients. Coagulopathy is among the complications of massive blood and fluid administration. Stored blood is deficient in factors V and VIII and platelets. Timely administration of FFP and platelets reduces the risk of coagulopathy after massive transfusion. Presumptive factor replacement is usually not indicated in the early phase of resuscitation, but it may be appropriate in patients with massive hemorrhage caused by significant intracavitary bleeding or an unstable pelvic fracture.[186]

Before admission to the critical care unit, resuscitation is directed at maintaining blood pressure and reducing heart rate through simple volume loading with crystalloid and blood products as necessary. Simple clinical endpoints are used as described earlier. This approach should be adequate for the vast majority of injured patients.

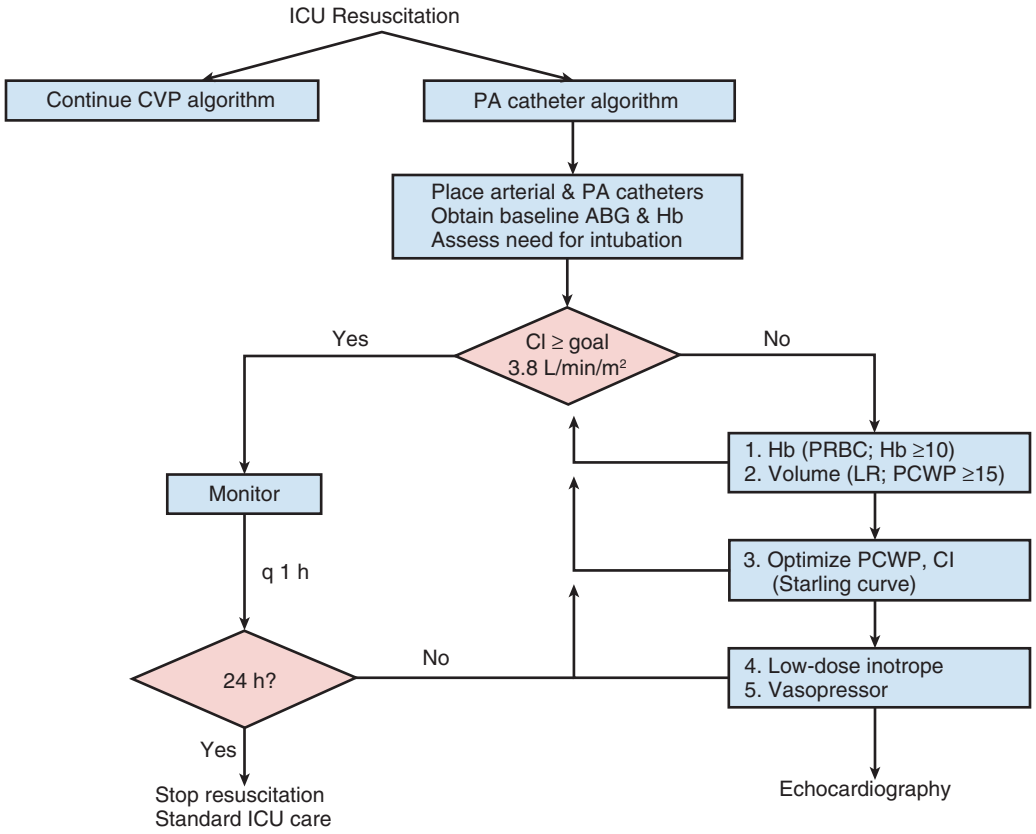


• **Fig. 26.8** Initial approach to resuscitation based on work from the Inflammation and the Host Response to Injury project. ATLS is resuscitation per the Advanced Trauma Life Support Program described earlier. Simple clinical goals are provided which are modified based on observed patient response. *ABG,* Arterial blood gas; *ATLS,* Advanced Trauma Life Support; *BD,* base deficit; *BP,* blood pressure; *CVP,* central venous pressure; *Hb,* hemoglobin. (From Moore FA, McKinley BA, Moore EE, et al. Inflammation and the Host Response to Injury, a large-scale collaborative project: patient-oriented research core-standard operating procedures for clinical care. III. Guidelines for shock resuscitation. *J Trauma.* 2006;61:82–89.)

Management of Traumatic Shock in the ICU

In a series of studies characterizing resuscitation of injured patients in the ICU, Moore and coworkers used the pulmonary artery catheter to describe response to fluid administration.[187–189] Criteria identifying patients considered for placement of a pulmonary artery catheter and need for ICU resuscitation include major injury (two or more abdominal organs, two or more long bone fractures, complex pelvic fractures, flail chest, or major vascular injury), blood loss (anticipated need for >6 units of PRBCs during the first 12 hours after hospitalization), and metabolic stress (arterial base deficit >6 mEq/L during the first 12 hours after hospital admission). A trauma patient older than 65 years with any two of the previous criteria also warrants consideration of pulmonary artery catheter insertion and ICU resuscitation. Patients with these criteria who also incurred severe brain injury, defined as GCS score less than or equal to 8 in the trauma ICU and abnormality on brain computed tomography scan, were not resuscitated by protocol during development of this approach unless assessed by the attending neurosurgeon to be at low risk of secondary brain injury with these procedures.[187–189] In my practice, I find that the brain, similar to other organs, benefits from aggressive resuscitation.

Hemorrhage control is of paramount importance in initial management of patients with major torso trauma who arrive in shock. It is assumed that this issue has been addressed in the vast majority of patients by the time of ICU admission. Priorities in early ICU care are optimization of resuscitation; correction of hypothermia, coagulopathy, and acidosis; and monitoring for ongoing bleeding requiring operative or interventional radiology procedures.[186] As indicated in Fig. 26.9, an important early decision is to determine whether placement of a pulmonary artery catheter and an arterial catheter is necessary. The vast majority of patients do not require a pulmonary artery catheter. I do note, however,



• **Fig. 26.9** ICU resuscitation model based on the consensus documents of the Inflammation and the Host Response to Injury project. As noted in the text, it is unusual for patients to require a pulmonary artery *(PA)* catheter. Reasoned choices for vasoactive drugs are given earlier in this chapter. *ABG,* Arterial blood gas; *CI,* cardiac index; *CVP,* central venous pressure; *Hb,* hemoglobin; *ICU,* intensive care unit; *LR,* lactated Ringer; *PCWP,* pulmonary capillary wedge pressure; *PRBC,* packed red blood cells. (From Moore FA, McKinley BA, Moore EE, et al: Inflammation and the Host Response to Injury, a large-scale collaborative project: Patient-oriented research core-standard operating procedures for clinical care. III. Guidelines for shock resuscitation. J Trauma 2006; 61:82–89.)

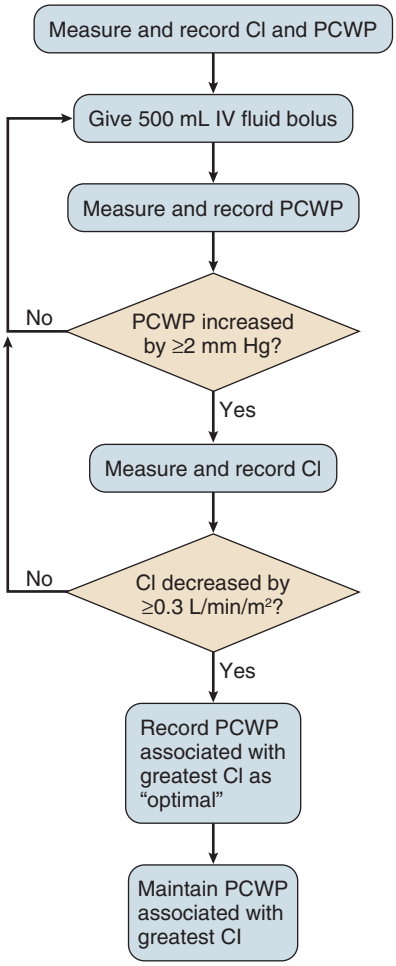
that CVP is a very indirect monitor of hemodynamic function and changes in CVP do not necessarily indicate propriety of fluid administration.

A pulmonary artery catheter could be considered for patients unresponsive to ongoing volume administration including blood transfusion by demonstrating low MAP or persistent high base deficit and/or demonstrating secondary organ dysfunction, such as worsening oxygenation or decreasing urine output[186] (see Fig. 26.9). The possibility of an impending abdominal compartment syndrome must also be considered if crystalloid fluid volume exceeds 10 L or PRBC transfusion exceeds 10 units. Periodic urinary bladder pressure measurements should be obtained to monitor for the onset of abdominal compartment syndrome. Urinary bladder pressure of 25 mm Hg or higher indicates significant abdominal hypertension and the need to consider decompressive laparotomy. I note that bladder pressures must be obtained in sedated, relaxed patients. Neuromuscular blockade may be required.

It is assumed that most patients treated by this protocol will be intubated. If they are not intubated and require ongoing volume loading, intubation should be considered because worsening pulmonary function is likely. If intubated and ventilator settings include positive end-expiratory pressure of 12 cm/H_2O or higher, the effects of high mean airway pressure on cardiac function may become important. This may also reflect the need to consider a pulmonary artery catheter or other CO monitor.

A general cardiac index goal is 3.8 L/min per m^2. Hemodynamic variables are assessed hourly and possibly more frequently as needed. Laboratory variables, including hemoglobin, blood gas data, and coagulation parameters, should be determined every 4 hours and possibly more frequently until the patient is fully resuscitated and stable. Most young patients easily exceed the cardiac index goal of 3.8 L/min per minute with crystalloid volume loading and blood transfusion. There is no need to increase cardiac filling pressures to high levels in responsive patients, but the hemoglobin level should be maintained at 10 g/dL or higher during acute resuscitation where bleeding may still be ongoing. Once acid-based status is normalized and the need for ongoing volume loading has resolved, a lower hemoglobin level is acceptable.[186]

Pulmonary capillary wedge pressure (PCWP) may not accurately reflect left ventricular end-diastolic volume, and increase in PCWP to 15 mm Hg or higher may enhance cardiac performance. The optimal relationship between PCWP and cardiac index may be determined by incrementally increasing left ventricular preload followed by measurement of CO response. In this process, a Starling curve is developed (Fig. 26.10).



• **Fig. 26.10** This simple algorithm describes a Starling curve protocol for optimization of filling pressures as a part of resuscitation of severely injured patients in the critical care unit where a pulmonary artery catheter is employed. *CI,* cardiac index; *IV,* intravenous; *PCWP,* pulmonary capillary wedge pressure. (From Marr AB, Moore FA, Sailors RM, et al. Preload optimization using "Starling curve" generation during shock resuscitation: can it be done? *Shock.* 2004;21:300–305.)

After obtaining optimal PCWP, if CO is below 3.8 L/min per m^2, infusion of a vasodilating inotropic agent should be considered. If a vasodilator is deemed appropriate, dobutamine is recommended with dosing beginning at 5 μg/kg per minute and increased in increments of 2.5 μg/kg per minute to a maximum of 20 μg/kg per minute to increase cardiac index. If the patient does not tolerate the vasodilatation associated with this agent, dopamine may be considered. Occasionally, an inotropic agent with vasocontrictive effects may be needed to maintain MAP at 60 mm Hg or higher, enhance myocardial contractility, and maintain coronary perfusion pressure. Norepinephrine is recommended as the preferred agent in this setting. Norepinephrine infusion should be started at 0.05 μg/kg per minute and increased in increments of 0.05 μg/kg per minute as needed to obtain a cardiac index above 3.8 L/min per m^2 and maintain MAP above 60 mm Hg. The maximum recommended norepinephrine dose rate is 0.2 μg/kg per minute. Adrenal insufficiency in patients requiring norepinephrine to maintain MAP must be considered. Low-dose vasopressin may complement the administration of norepinephrine and allow reduction in doses of this agent.[186]

The protocol-driven approach described has provided a variety of observations.[190] First, even elderly patients respond to ICU resuscitation after injury.[188] In general, the maximal oxygen delivery response is less than that of younger patients, and elderly patients have a greater requirement for inotropic support.[191] Second, a Starling curve generation approach is feasible and reliably improves hemodynamic resuscitation from major trauma. Supranormal resuscitation is neither necessary nor desirable in the management of patients with trauma associated with shock.[192] Third, aggressive resuscitation, particularly in the setting of ongoing bleeding, increases the risk of elevated intraabdominal pressure and abdominal compartment syndrome.[193] Preload-driven resuscitation may cause bowel edema with subsequent venous obstruction, declining CO, decreased urinary output, and compromise of systemic oxygenation. Finally, although many endpoints for interventions for goal-directed resuscitation in critical injury exist, systemic oxygen transport is the current state of the art in the most severely injured patients and is the basis for future development of clinical processes for resuscitation of shock caused by major trauma.[190]

The utility of the pulmonary artery catheter in the management of patients with severe injury is suggested by a study using data obtained in the National Trauma Data Bank.[194] From more than 450,000 records, 53,000 patients were reviewed. These patients were admitted between January 1994 and December 2001. Patients survived more than 48 hours and underwent at least one diagnostic or therapeutic procedure. The patients were 16 to 90 years old and distinguished by ISS and initial base deficit. Approximately 2000 patients who had insertion of a pulmonary artery catheter during hospitalization were compared with 51,000 patients who did not. Logistic regression analysis was used to develop a model that examined mortality rate after injury. Factors included in the model were use of a pulmonary artery catheter, age, emergency department base deficit, ISS, comorbid conditions, mechanism of injury, and specific injury patterns as identified by the Abbreviated Injury Scale. Overall, patients managed with a pulmonary artery catheter were older and had a higher ISS, greater emergency department base deficit, and higher mortality rates (29.7% with pulmonary artery catheter vs. 9.8% without pulmonary artery catheter). Patients with spine, abdominal, chest, or head injury and patients with at least one Abbreviated Injury Scale score of 3 or higher were more likely to be managed with a pulmonary artery catheter.

Pulmonary artery catheter use was associated with an increased mortality rate in all subgroups of ISS, emergency department base deficit, and age. As age, base deficit, and ISS increased, however, the risk of death associated with pulmonary artery catheter use decreased, and an apparent benefit of pulmonary artery catheter use emerged. In contrast, less severely injured trauma patients (ISS 16–24) and severely injured patients without high admission base deficit (greater than −5) had an increased mortality rate associated with pulmonary artery catheter placement regardless of age.

Although these observations are from a large database, retrospective study design and subgroup analysis are not optimal for definitive hypothesis testing. Finally, neither timing of placement for pulmonary artery catheters nor cause of death and specific relationship to placement of the pulmonary artery catheter could be conclusively examined by analysis of the National Trauma Data Bank. Nonetheless, these data suggest that carefully selected patients may derive benefit from pulmonary artery catheter–guided resuscitation to avert complications related to persistent perfusion deficits. Further focused examination of patients with risk factors for poor outcome is warranted.[194]

Massive Transfusion

Independent of mechanism of injury, hemorrhagic shock consistently is the second leading cause of early death among injured patients, with only CNS injury consistently more lethal.[195] Primary CNS injury is devastating and has a high rate of prehospital mortality; prevention is the best strategy.[196] Hemorrhagic shock accounts for 30% to 40% of trauma deaths and is more amenable to interventions to reduce mortality and morbidity rates.[195] In addition, approximately 25% of CNS injuries are complicated by hemorrhagic shock.[197,198] Hemorrhage contributes to death during the prehospital period in 33% to 56% of cases, and exsanguination is the most common cause of death among individuals found dead on arrival of emergency medical services personnel.[47] Hemorrhage accounts for the largest proportion of mortality within the first hour of trauma center care and more than 80% of operating room deaths after major trauma.[195,199] Although the need for massive transfusion (defined as administration of ≥10 units of PRBCs in <24 hours) is probably necessary in 5% or less of patients in busy trauma centers, this intervention can be lifesaving, and available data suggest that early aggressive administration of blood products reduces morbidity and mortality rate and decreases overall product use.[200]

Numerous general observations can be made.[200–202] Most patients receiving massive transfusion are treated initially with crystalloid fluids followed by non–cross-matched type O red blood cells. Plasma therapy is typically delayed while waiting for blood typing and plasma to thaw. Platelets frequently are not given until patients have received multiple units of PRBCs. Coagulopathy is common and difficult to correct. Plasma and platelets are inadequately used and greater emphasis is needed on plasma and platelet administration.

A typical massive transfusion protocol begins in the emergency department when the senior trauma practitioner orders transfusion of O-negative PRBCs and invokes an organization-specific massive transfusion protocol.[202,203] This is followed by administration of 4 to 6 additional typed or O-negative units of PRBCs and a similar number of units of FFP and platelets. Therapy continues with containers sent from the blood bank, each containing red blood cells, plasma, and platelets. Goals are normalization of the PT and elevation of the platelet count to 50 to 100×10^9/L. The fibrinogen level is checked after 6 to 12 units of PRBCs, and cryoprecipitate is given if the fibrinogen level is less than 1 g/L. Once a common component of massive transfusion strategies, recombinant activated factor VII has been deemphasized in both military and civilian practice.[204,205]

Major trauma centers have developed transfusion protocols to address rapid blood loss and trauma-associated coagulopathy. This strategy has demonstrated improved survival in severely injured trauma patients. Although many centers have implemented massive transfusion protocols, a standardized initiation policy has not been defined. Frequently, activation of massive transfusion protocols is provider dependent and variability exists among high-volume centers.

Several scoring systems have been developed to rapidly predict the patient requiring massive transfusion.[206–208] Of these scores, the ABC (assessment of blood consumption) score, which incorporates penetrating mechanism of injury, positive results on ultrasound examination of the abdomen in the emergency department, arrival systolic blood pressure of 90 mm Hg or less, and arrival heart rate of 120 beats/min or more, has been reported and validated in large patient sets. Although multiple more sophisticated criteria have been proposed, an ABC score of two or more criteria correctly classified the patient requiring massive transfusion in up to 85% of cases. Other investigators point out that hypotension and evidence of coagulopathy are the strongest predictors of massive transfusion. Additional data from military and civilian practice continues to clarify appropriate transfusion triggers.

Tranexamic Acid

Tranexamic acid is a derivative of the amino acid lysine that inhibits fibrinolysis by blocking binding sites on plasminogen. This agent has been used in a variety of surgical trials and has been demonstrated to reduce blood transfusion requirement. The massive CRASH-2 (Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage 2) study, incorporating more than 20,000 patients, evaluated tranexamic acid as a means to address fibrinolysis occurring as a component of coagulopathy after trauma.[209,210] CRASH-2 was conducted in more than 250 hospitals and 40 countries. More than 20,000 patients with significant bleeding or at risk for significant bleeding were assigned within 8 hours of injury to receive either tranexamic acid or matching placebo. All-cause mortality rate was significantly reduced with tranexamic acid. Specific risk of death due to bleeding was also significantly reduced. This remarkable outcome was accomplished without a significant increase in thrombotic events. Subsequent analysis of the CRASH-2 data, however, reveals that greatest efficacy came when treatment was initiated within 3 hours after injury. In fact, treatment after 3 hours seemed to increase the risk of death owing to bleeding. A recent review of military experience with tranexamic acid, the MATTERs (Military Application of Tranexamic Acid in Trauma Emergency Resuscitation) trial, also demonstrates improved outcomes with early administration of this inexpensive drug shortly after injury. This military experience with tranexamic acid suggests improvement in outcome in patients receiving as little as 1 unit of PRBCs. Incremental risk with administration of tranexamic acid was not demonstrated.[211]

The role for tranexamic acid in trauma systems where massive transfusion protocols incorporate FFP containing indigenous antifibrinolytic elements in plasma remains unclear. In developed trauma systems, the best place for tranexamic acid may actually be in the prehospital environment as this material can readily be maintained in helicopter and road transport programs. Prehospital administration of blood products, especially plasma, is not routine in civilian settings; thus tranexamic acid offers an early opportunity to manage coagulopathy.[212] Opportunities for use of this promising material in the critical care setting are being defined.

Risks of Early Red Blood Cell Transfusion

Blood transfusion in trauma has been identified as an independent predictor of multiple-organ failure, systemic inflammatory response syndrome, increased postinjury infection, and increased mortality rate in multiple studies.[213] Cumulative risks have been related to the number of units of PRBCs transfused, increased storage time of transfused blood, and possibly the presence of leukocytes in donor blood. Many authors have concluded that blood transfusion in an injured patient should be minimized when possible.[214]

Large single-institution data sets examined the impact of blood transfusion in postinjury multiple-organ failure.[215,216] Variables identified as early independent predictors of multiple organ failure included age older than 55 years, ISS of 25 or higher, and more than 6 units of PRBCs in the first 12 hours after admission. Base deficit greater than 8 mEq/L in the first 12 hours and lactate greater than 2.5 mol/L also were independent predictors of multiple-organ failure. Subsequent prospective work confirmed the

importance of blood transfusion as an independent risk factor for postinjury multiple-organ failure after controlling for other indices of shock, including base deficit and lactate. Additional studies of blood product use after injury associate blood transfusion with increased mortality rate. Potential confounding shock variables, including base deficit, serum lactate, age, gender, race, GCS score, and ISS, were controlled in this analysis.

Factors contributing to complications associated with red blood cell transfusion include storage time, increased endothelial adherence of stored red blood cells, nitric oxide binding by free hemoglobin in stored blood, donor leukocytes, host inflammatory response, and reduced red blood cell deformability.[212,217] Nonetheless, transfusion of an injured patient with balanced blood component therapy is the only option for treatment of severe hemorrhagic shock. Although other hemoglobin-based oxygen carriers hold promise and ultimately may provide better outcomes for injured patients, these materials have not come into routine use. In an effort to reduce adverse events, attempts to minimize the use of blood transfusion in injury are appropriate outside major hemorrhage.

Special Problems

Abdominal Compartment Syndrome

A compartment syndrome is a condition in which increased pressure within a confined anatomic space adversely affects the function and viability of tissues contained within. Confined anatomic spaces associated with compartment syndromes are fascial spaces of the extremities, the globe as in glaucoma, and the cranial cavity as in epidural or subdural hematoma. Abdominal compartment syndrome is a condition in which sustained pressure within the abdominal wall, pelvis, diaphragm, and retroperitoneum adversely affects the function of the gastrointestinal tract and related extraperitoneal organs. Abdominal compartment syndrome is receiving increasing recognition as a complication of massive resuscitation after trauma, burns, or other surgical procedures (Box 26.3). Operative decompression is frequently required. Pressures around 5 to 7 mm Hg in the peritoneal cavity are normal. Short-duration pressure increases frequently occur with coughing, Valsalva maneuvers, defecation, and weightlifting. Intraabdominal pressure can be nonpathologically increased in obese individuals. Elevated intraabdominal pressure is a common finding among critically ill medical and surgical patients.[218–220]

A consensus conference on abdominal compartment syndrome has created improved definitions of this problem (Table 26.5). For standardization, intraabdominal pressure should be expressed in mm Hg and measured at end-expiration with the patient supine after ensuring that abdominal muscle contractions are absent. The transducer is zeroed at the midaxillary line. The current reference standard for intraabdominal pressure measurement is pressure measured via an indwelling urinary drainage catheter within the bladder. The recommended technique for measuring intraabdominal pressure is to clamp the urinary catheter and instill a maximal volume of 25 mL of sterile, room-temperature saline solution into the bladder with the patient in the supine position. After zeroing a transducer and a stabilization period of at least 30 to 60 seconds, the mean intraabdominal pressure can be read on a bedside monitor or as the height of the fluid column in urinary drainage tubing.

Intraabdominal hypertension is defined by a sustained or repeated intraabdominal pressure greater than 12 mm Hg or an abdominal perfusion pressure less than 60 mm Hg, where abdominal perfusion pressure is MAP minus intraabdominal pressure. Abdominal compartment syndrome is present when organ dysfunction occurs as a result of intraabdominal hypertension. Abdominal compartment syndrome is further defined by sustained or repeated intraabdominal pressure greater than 20 mm Hg or abdominal perfusion pressure less than 60 mm Hg in association with new-onset single- or multiple-organ system failure. In contrast to intraabdominal hypertension, abdominal compartment syndrome is not graded but rather is considered an "all-or-none" phenomenon.[220,221]

Intraabdominal hypertension has a variety of physiologic effects. In experimental preparations, animals die as a result of congestive heart failure as abdominal pressure passes a critical threshold. Increased intraabdominal pressure decreases CO and left and right ventricular stroke work, while increasing CVP, PCWP, and systemic and pulmonary vascular resistance. Abdominal decompression reverses these changes. As both hemidiaphragms are displaced upward with increased intraabdominal pressure, decreased thoracic volume and compliance are seen. Decreased volume within the pleural cavity causes atelectasis and decreases alveolar clearance. Pulmonary infections also may result. Ventilated patients with abdominal hypertension require increased airway pressure to deliver a fixed tidal volume. As the diaphragm protrudes into the pleural cavity, intrathoracic pressure increases with reduction in CO and increased pulmonary vascular resistance. Ventilation and perfusion abnormalities result, and blood gas measurements show hypoxemia, hypercarbia, and acidosis.[222]

Elevation in intraabdominal pressure also causes renal dysfunction. Inadequate renal perfusion pressure and renal filtration gradient

• BOX 26.3 Risk Factors for Intraabdominal Hypertension and Abdominal Compartment Syndrome

Acidosis (pH < 7.2)
Hypothermia (core temperature <33°C)
Polytransfusion (>10 units packed red blood cells/24 h)
Coagulopathy (platelets <55,000/mm^3 *OR* activated partial thromboplastin time 2× normal *OR* higher or prothrombin time <50% *OR* international standardized ratio >1.5)
Sepsis (American-European Consensus Conference definitions)
Bacteremia
Intraabdominal infection or abscess
Peritonitis
Liver dysfunction or cirrhosis with ascites
Mechanical ventilation
Use of positive end-expiratory pressure (PEEP) or the presence of auto-PEEP
Pneumonia
Abdominal surgery, especially with tight fascial closures
Massive fluid resuscitation (>5 L colloid or crystalloid/24 h)
Gastroparesis, gastric distention, or ileus
Volvulus
Hemoperitoneum or pneumoperitoneum
Major burns
Major trauma
High body mass index (>30)
Intraabdominal or retroperitoneal tumors
Prone positioning
Massive incisional hernia repair
Acute pancreatitis
Distended abdomen
Damage control laparotomy
Laparoscopy with excessive inflation pressures
Peritoneal dialysis

TABLE 26.5 Consensus Definitions List

Definition 1	IAP is the steady-state pressure concealed within the abdominal cavity.
Definition 2	APP = MAP − IAP.
Definition 3	FG = GFP − PTP = MAP − 2 × IAP.
Definition 4	IAP should be expressed in mm Hg and measured at end-expiration in the complete supine position after ensuring that abdominal muscle contractions are absent and with the transducer zeroed at the level of the midaxillary line.
Definition 5	The reference standard for intermittent IAP measurement is via the bladder with a maximal instillation volume of 25–50 mL sterile saline solution.
Definition 6	Normal IAP is approximately 5–7 mm Hg in critically ill adults.
Definition 7	IAH is defined by a sustained or repeated pathologic elevation in IAP ≥12 mm Hg.
Definition 8	IAH is graded as follows: grade I (IAH 12–15 mm Hg); grade II (IAP 16–20 mm Hg); grade III (IAP 21–25 mm Hg); grade IV (IAP >25 mm Hg).
Definition 9	ACS is defined as a sustained IAP >20 mm Hg (with or without an APP <60 mm Hg) that is associated with new organ dysfunction/failure.
Definition 10	Primary ACS is a condition associated with injury or disease in the abdominopelvic region that frequently requires early surgical or interventional radiologic intervention.
Definition 11	Secondary ACS refers to conditions that do not originate from the abdominopelvic region.
Definition 12	Recurrent ACS refers to the condition in which ACS redevelops after previous surgical or medical treatment of primary or secondary ACS.

ACS, Abdominal compartment syndrome; *APP*, abdominal perfusion pressure; *FG*, filtration gradient; *GFP*, glomerular filtration pressure; *IAH*, intraabdominal hypertension; *IAP*, intraabdominal pressure; *MAP*, mean arterial pressure; *PTP*, proximal tubular pressure.
From Malbrain ML, Cheatham ML, Kirkpatrick A, et al. Results from the International Conference of Experts on Intra-abdominal Hypertension and Abdominal Compartment Syndrome. I. Definitions. *Intensive Care Med.* 2006;32:1722–1732.

have been proposed as critical factors in the development of renal insufficiency associated with elevated intraabdominal pressure. The filtration gradient is the mechanical force across the glomerulus and equals the difference between glomerular filtration pressure and proximal tubular pressure. In the presence of intraabdominal hypertension, proximal tubular pressure may be assumed to equal intraabdominal pressure. Glomerular filtration pressure may be estimated as MAP minus intraabdominal pressure. Changes in intraabdominal pressure may have a greater impact on renal function and urine production than changes in MAP. Oliguria is thought to be one of the first signs of intraabdominal hypertension. Control of intraabdominal pressure leads to reversal of renal impairment. Oliguria may be seen with intraabdominal pressure of 15 to 20 mm Hg. Deterioration in CO plays a role in diminished renal perfusion, but even with maintenance of CO, impairment of renal function persists in intraabdominal hypertension.[218,223–225]

Other organs affected by increased intraabdominal pressure include the liver, where hepatic blood flow has been shown to decrease with abdominal hypertension.[226,227] It may be assumed that hepatic synthesis of acute-phase proteins, immunoglobulins, and other factors of host defense may be impaired by reduced hepatic blood flow. Other gastrointestinal functions may be compromised by increased intraabdominal pressure. Splanchnic hypoperfusion may begin with an intraabdominal pressure of 15 mm Hg. Reduced perfusion may create changes in mucosal pH, translocation, bowel motility, and production of gastrointestinal hormones. Finally, intracranial hypertension is seen with chronically increased intraabdominal pressure. Intracranial hypertension has been shown to decrease when intraabdominal pressure is reduced in morbidly obese patients and in intracranial injury.

Operative decompression is the method of choice for treatment of patients with intraabdominal hypertension and associated evidence of organ dysfunction. After decompression, improvements in hemodynamics, pulmonary function, tissue perfusion, and renal function have been shown in a variety of clinical settings. To prevent hemodynamic decompensation during decompression, intravascular volume should be restored, oxygen delivery should be normalized, and hypothermia and coagulation defects should be corrected. The abdomen should be opened in patients with adequate venous access and controlled ventilation. Adjunctive measures to combat reperfusion washout from by-products of anaerobic metabolism include acute use of vasoconstrictor agents to avoid sudden changes in blood pressure. After decompression of the abdomen, the fascial gap is left open using one of a variety of temporary abdominal closure methods.

In a recent report, Cheatham and Safcsak review their experience with percutaneous, ultrasound-guided drainage of ascitic fluid contributing to abdominal hypertension and abdominal compartment syndrome.[228,229] These investigators suggest that in patients with significant fluid accumulation creating abdominal hypertension, percutaneous drainage can avoid the need for decompressive laparotomy with its associated morbidity and occasional complications. Additional reports from other centers are required. To date, apart from the large experience described previously, percutaneous control of fluid accumulation to manage abdominal hypertension and compartment syndrome is limited to case reports.

Extremity Compartment Syndrome

The numerous causes of extremity compartment syndrome include complications of open and closed fractures, arterial injury, temporary vascular occlusion, snakebite, drug abuse, burns, physical exertion, and gunshot wounds. The most common cause of compartment syndrome is muscle injury leading to edema, which is correlated to the amount of tissue damage. Pressure is increased within the closed fascial space first by intracellular swelling followed by hematoma formation if a fracture is present. Because extremities, particularly at the calf, are composed of relatively unyielding fascial compartments, circulatory compromise occurs as tissue pressure increases with resulting ischemia and tissue damage. Leakage of intracellular fluid follows, and a further increase in intracompartmental pressure is seen.[230]

When extremity injuries produce complete ischemia, skeletal muscle that is deprived of oxygen may survive for 4 hours without irreversible damage. Total ischemia of 8 hours' duration produces irreversible change. Peripheral nerves conduct for 1 hour after onset of total ischemia and can survive for 4 hours with only neurapraxic damage. After 8 hours, irreversible damage occurs. Ischemia caused by reduction or cessation of blood flow occurs

when the perfusion gradient to a muscle compartment falls below a critical level. Perfusion is related to the compartment pressure. When intracompartmental blood pressure is 25 mm Hg, tissue perfusion in injured tissues is substantially decreased.[230–232]

Fasciotomy should be performed when intracompartmental pressure approaches 30 mm Hg, or if an extremity has been completely ischemic for 6 hours, the patient's clinical condition is worsening, substantial tissue injury is present, or tissue pressure is increasing.[232] Prophylactic treatment is valuable because fasciotomy does not reverse changes caused by initial extremity injury but can prevent changes resulting from secondary ischemic insults.

Pain, pallor, paralysis, paresthesias, and pulselessness are the classic hallmarks of extremity compartment syndrome. If treatment is not initiated until all of these signs are present, poor results are obtained. Pain and aggravation of pain by passive stretching of the muscles in the involved compartment is the most sensitive clinical finding. Assessment of pain is useful when patients are conscious and can respond cognitively to examination. In unconscious patients at risk for compartment syndrome, tissue pressure measurements may be the only objective criteria for diagnosis. Measurement of compartment pressures is obtained in all extremity compartments at risk and proximal and distal to any fractures. The highest pressure noted should serve as the basis for determining the need for fasciotomy.

Pelvic Fractures

Substantial blunt force is required to disrupt the pelvic ring. The extent of injury is related to the direction and magnitude of force applied. Associated abdominal, thoracic, and head injuries are common. Force applied to the pelvis can cause rotational displacement with opening or compression of the pelvic ring. Other types of displacement seen with pelvic fractures are vertical with complete disruption of the ring and the posterior sacroiliac complex.[233]

Patients with pelvic ring injuries are easily divided into two groups on the basis of clinical presentation—patients who are hemodynamically stable and patients who are hemodynamically unstable.[233] There is a dramatic difference in mortality rates between patients with pelvic fracture who are hypotensive and patients who are hemodynamically stable. Hemodynamic stability and biomechanical pelvic instability are separate though related issues, which tends to confuse the clinical picture. The source of bleeding may be multifactorial and not directly related to the pelvic fracture itself. Blood loss secondary to a pelvic fracture that contributes to hemodynamic instability is a significant risk factor, however. Early fracture diagnosis and stabilization using external skeletal fixation are sometimes essential in the acute phase of patient management.[233] Treatment of the patient also is directed by response to initial fluid resuscitation. Retroperitoneal bleeding in a pelvic fracture usually arises from a low-pressure source—the cancellous bone at the fracture site or adjacent venous injury. Significant retroperitoneal arterial bleeding occurs in approximately 10% of patients. Clinical evidence has suggested that provisional fracture stabilization using external fixation devices or even wrapping the fractured pelvis in a bed sheet can control low-pressure venous bleeding. Continued, unexplained bleeding after provisional fracture stabilization suggests an arterial source. Angiography with embolization of the involved vessel is indicated. Therapeutic angiography balloon occlusion of the aorta and preperitoneal pelvic packing also may be required with abdominal exploration if a rapidly expanding retroperitoneal hematoma is encountered.[234,235]

Key Points

- Although flaws in current crystalloid resuscitation preparations exist, a clear benefit of routinely available colloids has not been shown.
- A variety of hemodynamic, metabolic, and oxygen transport endpoints for resuscitation have been identified. None of the available resuscitation endpoints is consistently effective to limit or guide therapy after injury at this time. Guides to drive resuscitation in injury will vary from those used for hypovolemia not caused by injury.
- Shock after trauma is not the same as simple hemorrhage. Blood loss is combined with an inflammatory component.
- Because of inflammation associated with hemorrhage, the rate and amount of resuscitation are increased after injury compared with hemorrhage outside the setting of trauma.
- The classic neuroendocrine response leading to conservation of salt and water in traumatic shock can be linked to neuroimmune feedback loops, which modulate inflammatory response.
- Resuscitation to supranormal oxygen transport parameters does not improve outcome after injury. A staged approach using a pulmonary artery catheter, which should be necessary in less than 5% of injured patients, may be helpful.
- Although massive transfusion reduces overall blood product requirements in patients with rapid blood loss, limited resuscitation and blood product conservation are seen as appropriate in many injured patients.

Review Questions

1. A 19-year-old, 90-kg man sustains a grade IV splenic laceration caused by a motor vehicle collision. Because of hemodynamic instability, he is taken from the emergency department to the operating room, and there he undergoes damage control laparotomy. He is brought to the intensive care unit (ICU) for ongoing resuscitation. His vital signs on arrival include a blood pressure of 80/40 mm Hg and a heart rate of 125 beats/min, and he has urine output of 15 mL/h. After resuscitation with crystalloid and blood products, his blood pressure is 117/75 mm Hg, heart rate 99 beats/min, urine output 100 mL/h. The lactate level is 5.2 mmol/L and base deficit is −9. Which of the following statements is most correct?

- **a.** Given the normalization of his vital signs and urine output, this patient's resuscitation is complete, and further aggressive resuscitation should be withheld.
- **b.** His base deficit should be corrected by the administration of sodium bicarbonate.
- **c.** Despite normalization of vital signs and urine output, he continues to have evidence of tissue hypoperfusion and likely still warrants aggressive resuscitation.
- **d.** This patient should have a pulmonary artery catheter placed to better define his hemodynamics and titrate his resuscitation.

Answer: c. Despite some strong feelings on this topic, the fact is that the optimal endpoint for trauma resuscitation is not known. Although it is a good sign that urine output and vital signs are normalized, what is known is that if resuscitation stops there, a significant percentage of patients are left underresuscitated ("cryptic shock") and at risk for multiorgan failure and death. It is likely that the most prudent strategy involves combining the entire clinical picture with multiple markers of hypoperfusion to include vital signs, physical examination, urine output, lactate, base deficit, mixed venous oxygen saturation, and so on while weighing the risk/benefit ratio of ongoing fluid and product administration (e.g., potential for worsening oxygenation or abdominal compartment syndrome). Base deficit has been studied in the trauma population, with a correlation to outcome. However, these data are not robust and no specific threshold level or correction time frame can be reported with any confidence. Furthermore, base deficit is a crude marker of hypoperfusion that can be highly influenced by treatment provided, such as chloride administration. There is no role for a pulmonary artery catheter in this patient.

2. A 25-year-old man sustains a stab wound to the upper abdomen with omentum visible on examination. He arrives at the emergency department with a systolic blood pressure of 86 mm Hg and is answering questions appropriately. Which of the following should be done for this patient?

- **a.** Given his normal mental status, he should be taken for computed tomography (CT) scan of the chest and abdomen to better define his injury and for operative planning.
- **b.** Large-bore intravenous (IV) access should be obtained and crystalloid and packed red blood cell transfusion should be immediately undertaken until blood pressure is normalized.
- **c.** Emergent local wound exploration should be performed to assess the need for operation.
- **d.** Large-bore IV access should be obtained and the patient should be allowed to be hypotensive with no resuscitative efforts until reaching the operating room.

Answer: d. The concept of permissive hypotension and delayed resuscitation for penetrating trauma has gained increased traction since a landmark study published in the 1990s showed that this strategy reduced mortality rate. By increasing blood pressure with initial resuscitative efforts, there is a concern that the initial friable clot will be dislodged and lead to increased rebleeding. Therefore, unless this patient's blood pressure falls further or his mental status is lost, he should be taken immediately to the operating room, and then resuscitation should commence. There is no role for CT scan or local wound exploration in this patient, as it is obvious that his injury violates the peritoneum.

3. A 31-year-old man is brought to the ICU after emergent laparotomy for blunt trauma. In the operating room, he was found to have liver, bowel, and splenic injuries that required bowel resection and reanastomosis and splenectomy. He received 25 units of packed red blood cells, 15 units of fresh frozen plasma, 6 units of platelets, and 4 units of crystalloid. He requires ongoing resuscitation for reversal of tissue hypoperfusion while in your ICU. Two hours later, his abdomen is distended and his bladder pressure is elevated. What constellation of signs would be most congruent with abdominal compartment syndrome?

- **a.** Central venous pressure (CVP) 25 cm H_2O, elevated peak and plateau airway pressures, oliguria, bladder pressure 25 mm Hg
- **b.** CVP 25 cm H_2O, elevated peak and plateau airway pressures, oliguria, bladder pressure 6 mm Hg
- **c.** CVP 5 cm H_2O, elevated peak pressure, normal plateau airway pressure, normal urine output, bladder pressure 15 mm Hg
- **d.** Bladder pressure 30 mm Hg with no other significant findings

Answer: a. This patient is an example of a classic setup for abdominal compartment syndrome: blunt trauma to the abdomen requiring massive resuscitation. Normal intraabdominal pressure is 5 to 7 mm Hg and should be measured at end-expiration, in the supine position, absent of abdominal muscle contraction, with a zeroed transducer at the level of the midaxillary line. Intraabdominal hypertension can exist without abdominal compartment syndrome in conditions such as morbid obesity and ascites. Abdominal compartment syndrome is the presence of intraabdominal hypertension (>20 mm Hg) associated with new or worsening organ dysfunction. Abdominal compartment syndrome can affect most all organ systems. This patient has some of the classic findings. CVP will be elevated. Owing to a reduction in compliance, both peak and plateau airway pressures will increase, and ventilation will become increasingly difficult. Of note, an elevated peak airway pressure and normal plateau pressure would be indicative of a resistance problem, such as endotracheal tube occlusion or bronchoconstriction. Owing to a reduction in perfusion pressure to the kidney, oliguria will occur. Option b is not correct as the bladder pressure is normal. Other causes for deterioration should be sought. Option b could be caused by something such as acute respiratory distress syndrome with concomitant acute cor pulmonale.

4. A 19-year-old man sustains a severe crush injury in an industrial accident. His injuries include a severe closed head injury, pelvic fracture, and crush injury to the right leg. Which one of the following statements is most correct regarding the evaluation and management of this patient?

a. Absence of a Cushing reflex (bradycardia and hypertension) virtually rules out significant elevations of intracranial pressure.

b. For laterally displaced pelvic fractures, using a bed sheet to circumferentially wrap and compress the pelvis with traction is as effective as external fixation in stopping blood loss.

c. Loss of a palpable pulse in the crushed extremity is an early sign of impending compartment syndrome.

d. Compartment pressures above 30 mm Hg in a crushed extremity indicate a need for close follow-up with serial compartment pressures measurement.

Answer: d. Intracranial hypertension can cause a Cushing reflex, resulting in a rise in blood pressure with a drop in the heart rate producing bradycardia. However, the absence of a Cushing reflex does not exclude intracranial hypertension. Pelvic fractures can be associated with massive blood loss producing shock. Closed pelvic fractures can cause a patient to lose 50% of his or her circulating blood volume. Laterally displaced (i.e., "open book") pelvic fractures need emergency stabilization of the fracture to achieve control of the blood loss. This can be accomplished with an external fixator. Alternatively, using a bed sheet to circumferentially wrap and compress the pelvis with traction is equally effective at stopping blood loss in the acute resuscitation setting. Continuing blood loss after fixation of the pelvic fracture likely requires angiographic embolization to stop the bleeding. In cases of compartment syndrome after a crush injury, loss of a palpable pulse is a late (not early) finding. Loss of a palpable pulse would be preceded by pain, pallor, paresthesias, and paralysis. A markedly elevated compartment pressure at 30 mm Hg would be an indication for performing fasciotomy, not serial examinations.

Severe Heart Failure

FREDRIC GINSBERG AND JOSEPH E. PARRILLO

CHAPTER OUTLINE

Definition, Epidemiology, and Staging of Heart Failure

Pathophysiology

Diagnosis and Serum Natriuretic Peptides
- Prognosis in Acute Heart Failure

Acute Heart Failure Syndromes
- Initial Evaluation and Therapy
- Indications for Invasive Hemodynamic Monitoring
- Evaluation for Etiology of Heart Failure Exacerbation

Pharmacologic Management of Acute Heart Failure
- Intravenous Diuretics
- Vasopressin Inhibitors
- Parenteral Basodilators
- Angiotensin-Converting Enzyme Inhibitors
- Inotropic Drugs
- Vasopressors
- Ultrafiltration

Transition to Chronic Pharmacologic Therapy for Severe Heart Failure
- Oral Diuretic Therapy
- β-Blockers
- Angiotensin-Converting Enzyme Inhibitors
- Angiotensin Receptor Blockers
- Combination Angiotensin Receptor/Neprilysin Inhibitor
- Aldosterone Antagonists
- Combination Hydralazine/Isosorbide Dinitrate
- Digoxin
- I_f Channel Blocker

Acute Coronary Syndromes and Acute Heart Failure: Special Considerations

Heart Failure With Preserved Left Ventricular Ejection Fraction (Diastolic Heart Failure)

Myocarditis and Acute Heart Failure
- Fulminant Myocarditis

Device Therapy for Heart Failure and Ventricular Tachyarrhythmias: Implanted Cardioverter Defibrillator and Cardiac Resynchronization Therapy
- Implanted Cardioverter Defibrillator Therapy
- Cardiac Resynchronization Therapy

Severe Heart Failure and Mechanical Circulatory Support
- Temporary "Nondurable" Support
- Durable Mechanical Support

Definition, Epidemiology, and Staging of Heart Failure

Heart failure is defined as the inability of the heart to provide cardiac output adequate to meet the metabolic demands of the body at a normal filling pressure. Normal cardiac output is maintained with mild heart failure, but more severe heart failure is associated with reduced cardiac output. Physiologic abnormalities lead to excessive salt and fluid retention and signs and symptoms comprising the heart failure syndrome. Heart failure is a progressive illness with a high mortality rate. Death can occur after chronic progressive worsening of heart failure, or suddenly and unexpectedly in patients who appear clinically stable. Appropriate therapies for heart failure, including medications, revascularization, and devices, have the potential to reverse the processes that cause heart failure and improve cardiac performance, stabilize the patient's symptoms, enhance functional status, and improve survival.

Heart failure is a very common illness. Approximately 6.5 million Americans are affected, females as frequently as males. It is estimated that 2.5% of the adult population of Americans are affected by heart failure, and more than 20% of hospital admissions in patients older than 65 years of age are due to heart failure. The population with heart failure is expected to increase to 8 million by 2030. Almost 1 million new cases are diagnosed annually. In those younger than 75 years, the incidence of heart failure is higher in black and Hispanic populations. In the United States, there are nearly 1 million hospital discharges yearly, a volume that did not change during the decade 2000 to 2010. There were 509,000 visits to the emergency department for heart failure in 2012. More than 56,000 people in the United States died in 2007 with heart failure as the

primary cause. The treatment of heart failure incurs a very large economic burden on the U.S. health care system. Estimated direct and indirect cost of heart failure in 2012 was estimated at $30.7 billion. The majority of this cost was related to the treatment of patients hospitalized with heart failure. Epidemiologic data show significant increases in both the incidence and prevalence of heart failure in the United States, likely influenced by the aging of the population, a high prevalence of hypertension, and improved treatment and survival of patients with ischemic heart disease.[1,2]

Patients hospitalized with acute heart failure are usually elderly, with a mean age in the early 70s. In the United States, roughly 80% of patients have a previous history of heart failure and in European studies one-third of patients had a new diagnosis of heart failure[3]; 40% to 55% of patients have normal or relatively normal left ventricular systolic function, which occurs more commonly in females than in males. Coronary heart disease is present in 50% to 60% of patients and hypertension in 72% of patients. Comorbidities are common, including renal disease in 30% of patients, diabetes mellitus in 43%, and chronic obstructive pulmonary disease in roughly 30%.[3,4] The prognosis of heart failure remains more serious than is generally appreciated. Only 50% of patients survive 5 years after the initial diagnosis of heart failure. Mortality is often due to associated noncardiac conditions. Risk factors for mortality include the presence of coronary artery disease, diabetes, hypertension, and cigarette smoking.[1]

In the American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for the diagnosis and management of chronic heart failure, four stages in the development of heart failure are recognized (Fig. 27.1). This staging system emphasizes the following details. (1) Heart failure may be preventable. Several common medical conditions, such as hypertension and diabetes mellitus, place patients at high risk for developing left ventricular dysfunction and heart failure. Appropriate management of these conditions may prevent the development of heart failure. (2) Left ventricular dysfunction and heart failure are conditions that worsen over time. (3) In patients with left ventricular dysfunction but who have not yet developed heart failure, medical therapy can delay or prevent the development of heart failure. (4) There are evidence-based guidelines for therapy for each stage.[5]

Stage A represents patients at high risk for heart failure but without structural heart disease or symptoms of heart failure. These include patients with hypertension, atherosclerotic heart disease, diabetes, obesity, patients exposed to cardiotoxic medications, or those with a family history of cardiomyopathy. Antecedent hypertension exists in 75% of patients who develop heart failure. Stage B patients have structural heart disease, but without signs or symptoms of heart failure. This group includes patients who have had a myocardial infarction, those with abnormal left ventricular ejection fraction (LVEF) but no symptoms of heart failure, and those patients with asymptomatic valvular heart disease. Stage C patients have structural heart disease with prior or current symptoms of heart failure. Stage D patients have refractory symptoms of heart failure at rest despite maximal medical therapy. They require specialized or extraordinary interventions, such as cardiac transplantation or mechanical circulatory support (MCS), or end-of-life care.

Pathophysiology

Heart failure can be due primarily to left ventricular systolic dysfunction or abnormal diastolic function, although both abnormalities are often present. In addition, right ventricular dysfunction may accompany left ventricular dysfunction or may be the primary problem. The syndrome of systolic heart failure—or "heart failure with reduced ejection fraction" (HFrEF)—results from depressed left ventricular contractility caused by loss of myocytes and myocardial fibrosis with reduced LVEF. The left ventricle is often dilated. Diastolic heart failure is now preferentially termed "heart failure with preserved ejection fraction" (HFpEF). It is caused by reduced left ventricular diastolic compliance and abnormal relaxation. Impaired diastolic filling leads to a higher left ventricular diastolic pressure to maintain cardiac output, with elevation of pulmonary capillary wedge pressure (PCWP) (Fig. 27.2).

Many conditions can cause damage to left ventricular myocardium and result in systolic heart failure. The most common are myocardial infarction and chronic myocardial ischemia caused by atherosclerotic coronary artery disease. Other common etiologies include hypertension, familial and idiopathic cardiomyopathy, viral myocarditis, and valvular heart disease, including aortic stenosis, aortic insufficiency, and mitral regurgitation. Peripartum cardiomyopathy, transient apical ballooning syndrome ("takotsubo" or stress cardiomyopathy), cardiomyopathy associated with prolonged tachycardia, and cardiomyopathy related to cardiotoxic cancer chemotherapy are less common. Uncommon causes are alcoholic cardiomyopathy, diabetic cardiomyopathy, and a cardiomyopathy seen in some patients with hyperthyroidism or severe obesity.[6–8]

Myocardial damage and loss of myocytes result in a series of maladaptive systemic responses modulated by the autonomic and hormonal systems, termed *neurohormonal activation.* Two major systems involved in neurohormonal activation are the renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system. Activation of the renin-angiotensin system leads to elevated levels of renin, angiotensin II, and aldosterone, which have deleterious consequences on cardiac structure, function, and hemodynamics.[2,9] Effects of neurohormonal activation include salt and fluid retention, endothelial dysfunction, myocyte hypertrophy, myocardial fibrosis, and myocyte apoptosis (programmed cell death). Sympathetic nervous system activation results in tachycardia, arrhythmias, increased myocardial oxygen consumption, and peripheral vasoconstriction.[10] Increased circulating norepinephrine levels contribute to myocyte injury and death. Renal effects of sympathetic nervous system activation lead to further activation of the RAAS.

Weakened left ventricular contractile force and neurohormonal activation lead to changes in cardiac structure termed *ventricular remodeling.* The left ventricular chamber becomes progressively more dilated, the shape of the left ventricle changes from ellipsoid to more spherical, and there is a reduction in LVEF.[2,9] In addition, the change in left ventricular geometry may lead to an increase in the size of the mitral annulus and altered coaptation of mitral valve leaflets, which causes mitral regurgitation and worsening heart failure (see Fig. 27.2). A detrimental positive feedback loop is established, where further left ventricular dysfunction leads to intensification of maladaptive responses, progressive deterioration in left ventricular structure and performance, and worsening heart failure.

Conditions commonly associated with HFpEF include hypertension, left ventricular hypertrophy, and acute coronary ischemia. HFpEF is common in elderly populations, especially in women, owing in part to progressive diastolic compliance abnormalities seen with aging. Uncommon conditions leading to diastolic heart failure include infiltrative and restrictive cardiomyopathies, such as amyloid cardiomyopathy, and chronic constrictive pericarditis.

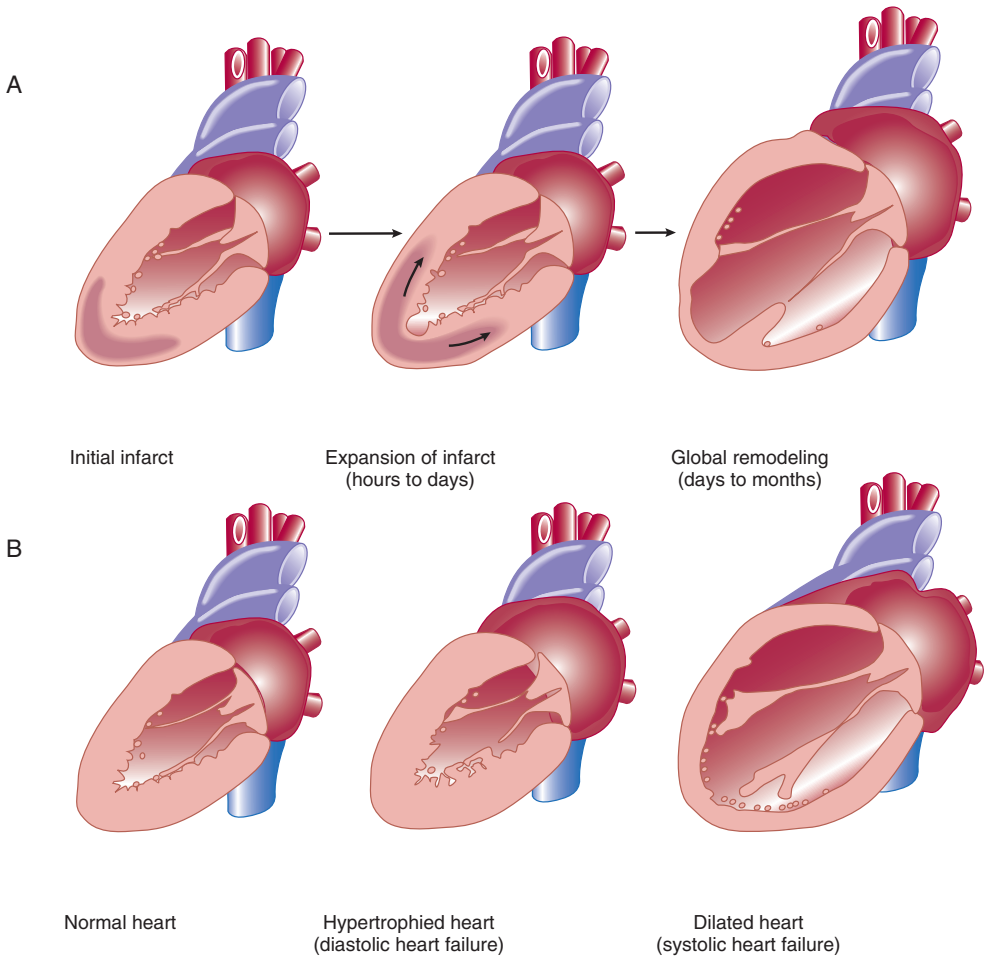
Diagnosis and Serum Natriuretic Peptides

Heart failure is a clinical diagnosis, determined after evaluation of a patient's symptoms and physical examination and supported

A report on the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for Evaluation and Management of Heart Failure): Developed in collaboration with the American College of Chest Physicians and the International Society for Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. *Circulation.* 2005;112: 1825–1852.)

by results of ancillary testing, including serum biomarkers, chest x-ray, and echocardiography. Symptoms of heart failure caused by pulmonary or systemic venous congestion are shortness of breath with exertion or at rest, cough, swelling of legs and/or abdomen, orthopnea, and paroxysmal nocturnal dyspnea. Fatigue, anorexia, and change in mental status are symptoms caused by low cardiac output. Physical examination findings include pulmonary rales, elevated jugular venous pressure, signs of cardiomegaly, cardiac murmurs (especially mitral regurgitation), S_3 gallop, hepatic enlargement, ascites, and edema. An S_3 gallop and elevated jugular venous pressure are the most specific signs of heart failure; absence of rales is not infrequent in patients with acute heart failure, and chest radiography may not show obvious congestion.[11] Manifestations of more severe heart failure on physical examination include marked dyspnea at rest possibly resulting in respiratory failure, cyanosis, cool extremities, and altered mental state. A careful evaluation for the presence of pulsus paradoxus is important if cardiac tamponade is suspected. However, these signs and symptoms are not specific for heart failure, and coexisting conditions, such as obesity, chronic lung disease, and deconditioning, can add uncertainty to the clinical diagnosis. Heart failure is often both underdiagnosed and overdiagnosed in outpatient and emergency department settings.

Studies have shown that serum assays of B-natriuretic peptide (BNP) and N-terminal pro-BNP (NTpro-BNP) improve the accuracy of diagnosing heart failure. BNP is a 32–amino acid

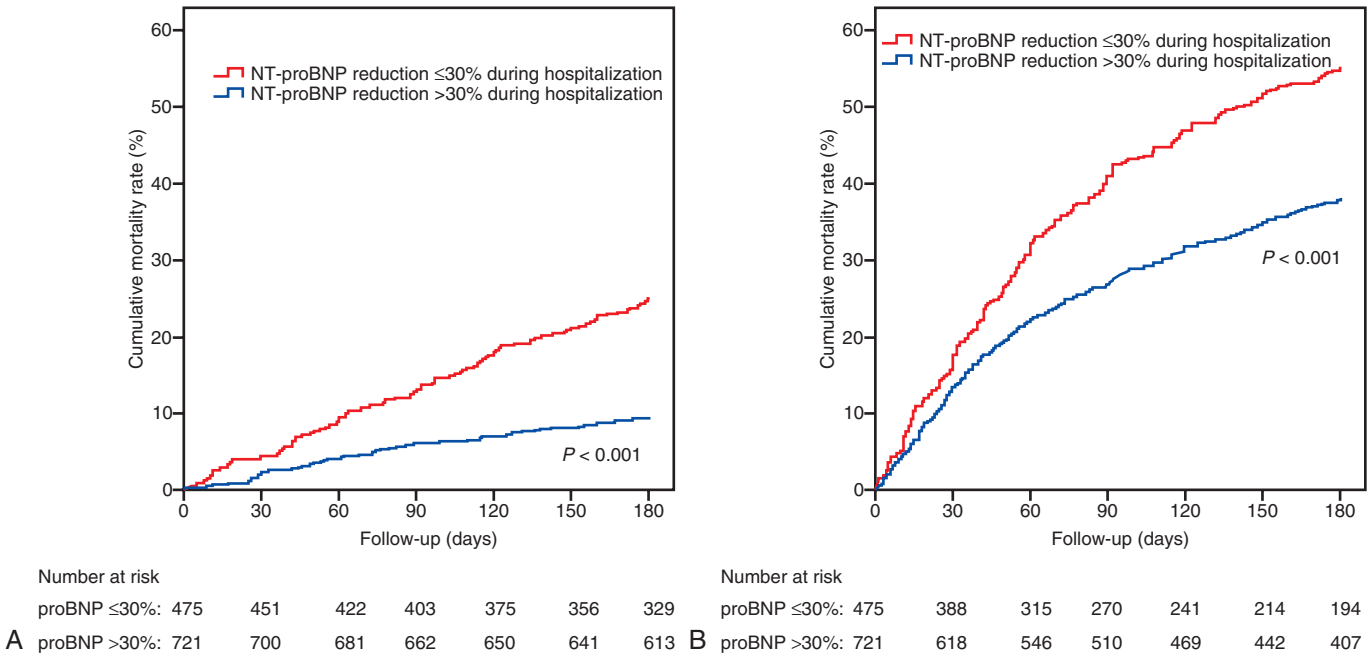


• **Fig. 27.2** A, Left ventricle (LV) remodeling after acute myocardial infarction, resulting in a dilated LV with global systolic dysfunction. B, Ventricular remodeling in diastolic and systolic heart failure. Note differences in LV morphology in diastolic versus systolic heart failure. (Redrawn from Jessup M, Brozena S. Heart failure. *N Engl J Med.* 2003;348:2007–2018.)

peptide produced by cardiac myocytes in response to pressure-induced wall stretch and tension.[12] Physiologic actions of BNP include arterial and venous dilation and natriuresis. A study of 1530 patients presenting to the emergency department with dyspnea showed that knowledge of BNP serum levels resulted in improved diagnostic accuracy of heart failure from 65% to 74% to 81% when compared with clinical judgment alone.[13] BNP levels above 100 pg/mL had a sensitivity of 90%, specificity of 76%, and diagnostic accuracy of 81.2% for the diagnosis of heart failure. Determination of BNP was very useful for discriminating patients with dyspnea owing to uncomplicated lung disease who had BNP values below 100 pg/mL.[14] Patients with BNP values below 100 pg/mL were very unlikely to have heart failure as the cause of dyspnea. Levels between 100 and 400 pg/mL can be seen in patients with primary right ventricular failure owing to cor pulmonale with chronic lung disease, idiopathic pulmonary hypertension, and acute pulmonary embolism. Left ventricular failure is the likely diagnosis when levels are above 400 pg/mL. BNP levels should always be interpreted in conjunction with all other clinical data to arrive at a correct diagnosis.

Evaluating BNP levels in heart failure patients in the emergency department was shown to decrease the need for hospitalization and decrease the need for intensive care unit (ICU) admissions, without affecting 30-day mortality rates. Total hospital stay was shortened by 3 days, cost of treatment was significantly reduced, and time to initiation of definitive therapy in the emergency department was shortened by 30 minutes.[15]

BNP levels correlate with disease severity. Higher levels are seen in patients with more severe heart failure and with worse left ventricular systolic function. Higher levels are correlated with a poorer prognosis and can predict an increased rate of functional deterioration and mortality.[16] In a study of 114 patients admitted to the hospital with class IV heart failure, of all variables evaluated, predischarge BNP level was most strongly associated with death or readmission within 6 months; BNP levels higher than 350 pg/mL had high sensitivity and specificity.[17] BNP is also elevated in patients with diastolic heart failure and renal failure. Stable patients with chronic left ventricular systolic dysfunction and compensated heart failure often have chronically elevated BNP levels; however, an increase of more than 30% over this "baseline" does reflect worsening heart failure status.[18] BNP levels may initially be low in patients with "flash" pulmonary edema, as they may present to the hospital more quickly than the time required for significant rises in serum BNP to occur. Obese patients tend to have lower levels of BNP and may have "falsely low" levels in the setting of heart failure.



• **Fig. 27.3** Kaplan-Meier curves for all-cause mortality (A) and composite endpoint (B) at 180 days according to NT-proBNP during hospitalization. *NT-proBNP,* N-terminal pro-B-type natriuretic peptide. (From Salah K, Kok WE, Eurlings LW, et al. Competing risk of cardiac status and renal function during hospitalization for acute decompensated heart failure. *JACC Heart Fail.* 2015;3:751–761.)

NTpro-BNP can also be used for the diagnosis of heart failure. The precursor hormone pro-BNP is cleaved to form BNP and NTpro-BNP, which is physiologically inactive. NTpro-BNP has a longer half-life than BNP. It is cleared from the serum by the kidneys, so levels are higher in patients with coexisting renal disease. Levels of NTpro-BNP rise significantly in older populations. A cutoff level of NTpro-BNP below 300 pg/mL yielded a negative predictive value of 98% for exclusion of the diagnosis of heart failure.[19,20] The diagnosis of heart failure is very likely at levels above 450 pg/mL in patients younger than age 50, above 900 pg/mL in patients between 50 and 75 years, and above 1800 pg/mL in patients older than age 75. NT pro-BNP levels can also be used to guide therapy. In patients admitted to hospital with acute heart failure, a more than 30% reduction in NTpro-BNP predicted a reduction in the risk of mortality and readmission with heart failure (Fig. 27.3).[21]

Prognosis in Acute Heart Failure

Hospitalization for acute heart failure is associated with a poor prognosis. In-hospital mortality is high, with mortality rates of 4% to 8%. There is 9% mortality at 60 to 90 days, and 1-year mortality of 29%.[3,22–24] In a European heart failure database, in-hospital mortality was 6.9%, the 12-week readmission rate was 24%, and total mortality at 12 weeks was 13.5%.[4] More recent data indicate no major change in 30-day risk-standardized mortality after hospitalization for heart failure—11.5% in 2009–2010 and 11.3% in 2013.[25] Randomized trials of pharmacologic therapy reported an annual mortality of 10% in all patients with class II-III symptoms and 20% to 50% in class IV patients. Most recent data from the United States in the Medicare population show a 1-year mortality of 29.6% over 1 year after a heart failure hospitalization.[1] The mortality rate at 5 years continues to be around 50% despite recent advances in treatment. In the groups with the most severe chronic heart failure—patients awaiting cardiac transplantation—1-year mortality was 75% with 2-year mortality of 92%.[26] The prognosis for patients with cardiogenic shock caused by acute myocardial infarction (AMI) continues to be poor. Hospital mortality remains 40% to 50% even with aggressive supportive therapy and emergency revascularization strategies.[27] Rehospitalization rates are also high, averaging 20% to 25% at 30 days, although only half of rehospitalizations are caused by heart failure.

Several clinical factors have been shown to identify patients with a poorer prognosis. These include lower LVEF, low blood pressure on admission, and PWCP. In the United States the Acute Decompensated Heart Failure National Registry (ADHERE) database of 62,275 admissions for acute heart failure, blood urea nitrogen (BUN) more than 43 mg/dL, admission systolic blood pressure less than 115 mm Hg, and creatinine level more than 2.75 mg/dL were the three factors that indicated a higher in-hospital mortality. The presence of an elevated BUN was associated with a fourfold increase in hospital mortality to 8.35%. The presence of all three factors yielded an in hospital mortality of 19.8%[23] (Box 27.1).

Other factors that have been associated with increased mortality rates include hyponatremia, higher serum BNP level, and elevation of serum troponin.[28] In ADHERE, higher levels of serum BNP on admission were associated with a higher in-hospital mortality, ranging from 1.9% in the lowest quartile to 6.0% in the highest quartile (BNP > 1730 pg/mL). The ability of BNP to predict prognosis was present even after multivariate adjustment for coexisting conditions and was also true for patients with normal and abnormal LVEF.[29] Serum troponin is elevated in 6% to 10.4% of patients admitted with acute heart failure (with serum creatinine <2.0 mg/dL). Troponin elevation was associated with a lower blood pressure, lower ejection fraction, and longer hospital length of

• BOX 27.1 Factors Indicating a Poor Prognosis in Acute Heart Failure

Hypotension (systolic blood pressure <115 mm Hg on admission)
Presence of coronary artery disease
Elevated blood urea nitrogen and creatinine
Hyponatremia
Low left ventricular ejection fraction
Poor functional capacity
Marked elevation of B-natriuretic peptide, elevated troponin
Anemia
Diabetes mellitus

stay. Hypothetical mechanisms of troponin release in chronic heart failure include ischemia, cytokine activation, oxidative stress, and apoptosis. Hospital mortality was 8.0% in troponin-positive patients and 2.7% in troponin-negative patients. The ability of troponin elevation to predict mortality also was independent of other variables and was true even in patients with nonischemic etiologies of heart failure.[30] The coexistence of kidney disease significantly worsens the prognosis of patients with heart failure. Kidney disease aggravates the tendency to volume overload and heart failure decompensation, and heart failure often worsens renal function. Worsening renal function (WRF) during therapy and evidence of diuretic resistance also indicate patients with poorer outcomes. A meta-analysis of 16 large studies of heart failure patients revealed that 29% of heart failure patients had moderate to severe impairment of renal function. These patients had more than 100% increased relative mortality risk. Any degree of renal impairment had an approximately 50% increased relative mortality risk.[31]

Acute Heart Failure Syndromes

Initial Evaluation and Therapy

Acute heart failure is a common, life-threatening emergency. It is the cause of more than 1 million hospitalizations yearly in the United States. It is defined as either the new onset of sudden, severe heart failure symptoms or a gradual worsening of a chronic heart failure syndrome that has progressed in severity to require urgent and intensive therapy. Fifty percent to 60% of patients are male with an average age of 70 to 73 years.[32] Acute heart failure can occur in patients with systolic dysfunction or in patients with heart failure with HFpEF. Although in-hospital mortality and length of stay have been reduced, the prognosis remains poor, with 30% mortality at 1 year after hospitalization and 50% mortality at 5 years. This prognosis is affected by the high incidence of serious comorbid conditions as well as end-organ complications, including renal dysfunction, hepatic congestion, and thromboembolic conditions.

Acute heart failure requires urgent and simultaneous initiation of diagnostic testing and therapeutic interventions. Several different schemes are used to classify acute heart failure; these enable the clinician to assess the etiology and optimize initial diagnostic and therapeutic strategies. Blood pressure on presentation can often quickly differentiate the etiology, as acute heart failure with hypertension is considered a hypertensive emergency, mandating urgent blood pressure lowering. Acute heart failure with normal blood pressures suggests coronary artery disease as an etiology. Hypotension may indicate cardiogenic shock or advanced severe chronic heart failure. Another approach to the initial assessment is to evaluate for the likelihood of acute coronary ischemia as the etiology of acute heart failure to assess the need for and timing of revascularization strategies.[33,34]

A classification system recommended by the European Society of Cardiology identifies several distinct clinical syndromes of acute heart failure[22] (Table 27.1):

1. Acute worsening or decompensation of chronic heart failure symptoms, either in the setting of known chronic cardiovascular illness or de novo. These patients do not have shock or pulmonary edema. This is the most common presentation of acute heart failure requiring admission to hospital, occurring in approximately 70% of patients with acute heart failure.
2. Acute pulmonary edema with normal blood pressure, often caused by AMI or acute coronary ischemia.
3. Acute pulmonary edema associated with elevated blood pressure, often in the setting of chronic severe hypertension and chronic kidney disease. Pulmonary edema (syndromes 2 and 3) accounts for roughly 25% of acute heart failure admissions.
4. Cardiogenic shock with heart failure, usually the result of AMI. This is the most severe presentation of acute heart failure and is associated with high in-hospital mortality rates. This accounts for about 5% of acute heart failure cases.
5. High cardiac output heart failure in the setting of sepsis, hyperthyroidism, or cardiac arrhythmia. This is the least common presentation, occurring in a small percentage of patients.
6. Acute right ventricular failure, occurring with acute right ventricular myocardial infarction, massive pulmonary embolism, or cardiac tamponade. This presentation may be more subtle, marked by fatigue, dyspnea, hypotension, tachycardia, and signs of systemic venous congestion. This is also a relatively infrequent presentation of acute heart failure.

Symptoms of acute heart failure include severe shortness of breath, orthopnea, wheezing, and symptoms of hypoxemia including restlessness and confusion. Symptoms of tissue hypoperfusion, such as fatigue, weakness, mental status changes, nausea, and anorexia, may be subtle but are important to recognize as they may herald impending cardiogenic shock. Chest pain may indicate acute coronary ischemia. Physical examination often shows pulmonary rales and wheezes, an S_3 gallop, and elevation of jugular venous pressure. Peripheral pulses are weak and thready with diminished cardiac output states. A low cardiac output is reliably predicted by a low "proportional pulse pressure," which is calculated by the pulse pressure (systolic blood pressure minus diastolic blood pressure) divided by systolic blood pressure. A ratio below 0.25 predicts a cardiac index below 2.2 L/min per m^2.[35,36] The skin may be cool and clammy with cyanosis. Peripheral edema and ascites may indicate concomitant right ventricular failure of longer duration.

History and physician examination may not be sensitive or specific for the diagnosis of acute heart failure and is supplemented by urgent laboratory and radiologic testing. Complete blood cell count, electrolytes, renal and liver function, thyroid profile, and cardiac biomarkers (troponin I or troponin T) are routinely tested. Natriuretic peptide levels assist in the diagnosis of heart failure in patients presenting with dyspnea, and can be followed serially to assess effectiveness of therapy. An arterial line is helpful in managing patients with hypotension or cardiogenic shock. Electrocardiographic (ECG) evidence of acute ischemia or infarction will mandate a therapeutic approach targeted at optimizing myocardial blood flow. Chest radiography can show alveolar edema, interstitial edema, pleural effusions, and cardiomegaly, but may be unremarkable in

TABLE 27.1 Acute Heart Failure Symptoms

Syndrome	Onset	Signs and Symptoms	Hemodynamics
Acute decompensated heart failure	Days–weeks	Weakness Dyspnea Rales Third heart sound (S_3) gallop Edema	↑ PCWP ↓ CI Normal or ↑ RAP ↑ SVR
Acute pulmonary edema, normal BP	RV failure	Severe dyspnea Diffuse rales Cyanosis S_3 gallop	↑↑ PCWP Normal or ↓ CI Normal RA Normal or ↑ SVR
Acute pulmonary edema with hypertension	Acute	Severe dyspnea Diffuse rales	↑↑ PCWP Normal CI Normal RAP ↑↑ SVR
Cardiogenic shock	Acute	Hypotension Cyanosis Lethargy Cool, clammy	↑↑ PCWP ↑ RAP ↓↓ CI ↑ SVR

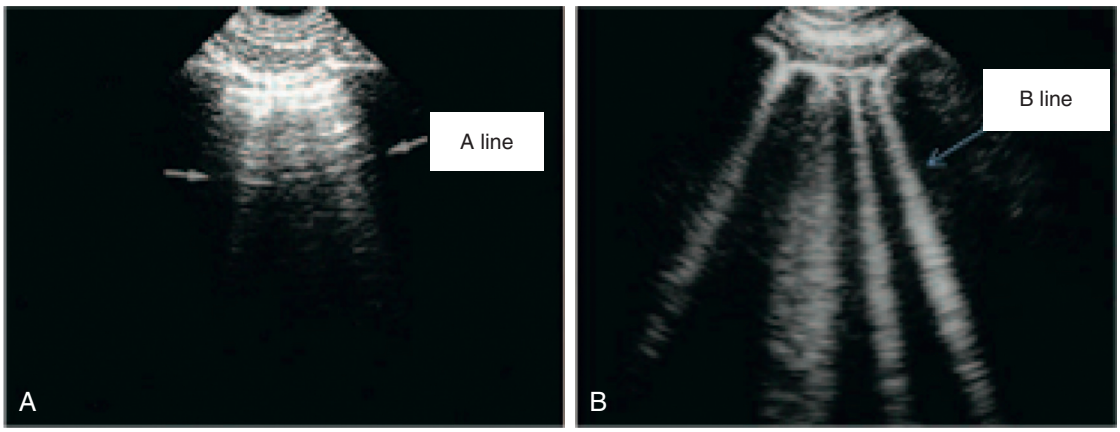
20% of patients with heart failure. Thoracic ultrasound is being used more frequently to assess for interstitial lung edema (Fig. 27.4).[32] Echocardiography should be performed emergently in unstable patients or can be performed after initial stabilization. It is essential to evaluate left ventricular size and function, right ventricular function, valve function, and the presence of pericardial effusion. Doppler echocardiography affords assessment of ventricular filling pressures, right ventricular systolic pressure, cardiac output, and the severity of valve lesions.

Rapid assessment of heart rate, blood pressure, cardiac rhythm, oxygen saturation, chest radiography, and ECG is necessary to initiate urgent therapies. Initial management is focused on providing adequate oxygenation and ventilation, optimizing blood pressure, stabilizing cardiac rhythm, treating myocardial ischemia when present, and reversing end-organ dysfunction. Initial therapy includes supplemental oxygen if the patient is hypoxemic. Patients with pulmonary edema often require ventilatory assistance with noninvasive positive airway pressure ventilation or endotracheal intubation. Noninvasive ventilation improves oxygenation and pulmonary compliance and decreases work of breathing. The use of continuous oxygen administration alone was prospectively compared with the use of continuous positive airway pressure ventilation (CPAP) and noninvasive intermittent positive pressure ventilation in 1069 patients who presented with acute cardiogenic pulmonary edema. No difference among these therapies was noted in the primary endpoint of death at 7 days or in the secondary endpoint of death plus endotracheal intubation at 7 days. Noninvasive ventilation did result in more rapid improvement in dyspnea, tachycardia, hypercapnia, and acidosis. There was no difference in safety or efficacy between CPAP and noninvasive intermittent positive pressure ventilation.[37] However, a Cochrane meta-analysis of 32 studies that enrolled 2916 patients concluded that in patients with acute cardiac pulmonary edema, the early use of noninvasive positive-pressure ventilation *was* associated with lower hospital mortality and lower need for subsequent endotracheal intubation. Noninvasive ventilation was associated with a shorter ICU stay and fewer neurologic complications.[38] Endotracheal intubation may be required for patients who demonstrate marked fatigue or severe hypercapnea and respiratory acidosis (Fig. 27.5).

There are few controlled trial data to arrive at evidence-based guidelines for the treatment of acute heart failure. Many recommendations are based on small studies, experience, observation, and consensus of opinion.[39] Initial medical therapy has historically included intravenous morphine because of its favorable vasodilator effect and relief of psychological distress. However, an analysis of registry data concluded that use of morphine was associated with increased need for endotracheal intubation and higher hospital mortality.[40] Therefore morphine should not be given routinely and its use should be individualized. Intravenous loop diuretics, such as furosemide, offer rapid and effective symptom relief and are almost always first-line therapy. Intravenous vasodilators are very useful, especially in patients with severe hypertension; intravenous nitroglycerin and intravenous nitroprusside are used most commonly. β-Blockers can be administered in the setting of acute myocardial



• **Fig. 27.4** Thoracic ultrasound images in normal and patients with acute heart failure. Recommendations on pre-hospital and early hospital management of acute heart failure: a consensus paper from the Heart Failure Association of the European Society of Cardiology, the European Society of Emergency Medicine and the Society of Academic Emergency Medicine. *Eur J Heart Fail.* 2015; 17:544–558.)

ischemia, hypertension, or tachyarrhythmias. They should be withheld initially in patients with severe heart failure, hypotension, shock, bradycardia, or heart block. Calcium channel blocking agents are generally contraindicated in acute heart failure.

Urgent treatment of arrhythmias is often necessary. Rapid atrial fibrillation is a common problem in acute heart failure. In the EuroHeart Failure Study, 9% of patients hospitalized with acute heart failure had atrial fibrillation during the hospitalization, and 42% had a history of paroxysmal atrial fibrillation.[41] Other studies report atrial fibrillation in 25% to 30% of hospitalized heart failure patients.[31] Control of the ventricular response to atrial fibrillation is vitally important, especially in patients with diastolic heart failure. This can rapidly be achieved with the use of intravenous β-blockers such as metoprolol or esmolol, parenteral digoxin, or intravenous amiodarone. Intravenous diltiazem can be used in patients whose left ventricular systolic function is known to be normal or near normal.

Indications for Invasive Hemodynamic Monitoring:

Right heart and pulmonary artery (PA) catheterization enables accurate measurement of PWCP, right atrial pressure, cardiac output, and mixed venous oxygen saturation. This helps to more precisely define hemodynamic derangements because findings on physical examination are often nonspecific or misleading. The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial evaluated the *routine* use of PA catheterization in patients hospitalized with acute exacerbation of chronic heart failure and left ventricular systolic dysfunction. There was no difference in the primary endpoint of days alive out of the hospital during the 6 months after discharge in groups managed with or without a PA catheter. Importantly, there were no significant adverse effects with PA catheter use. There were no subgroups identified in which use of the PA catheter was beneficial.[42] Based on this study and clinical experience, the routine use of PA catheters in the setting of acute heart failure is not recommended.

However, there are circumstances when the use of a PA catheter is of great assistance in the management of patients with acute severe heart failure, either for initial determination of hemodynamics or to better gauge response to therapy. Indications for PA catheter use include cardiogenic shock, differentiating pulmonary from cardiac causes of dyspnea or abnormalities on chest radiography, uncertainty of a patient's hemodynamic status by clinical assessment, severe heart failure with worsening renal function, managing parenteral vasodilator therapy, and in patients whose conditions are deteriorating despite therapy. PA catheter placement is also necessary as part of the evaluation for cardiac transplantation or the implantation of a ventricular assist device (Box 27.2).

Therapies with vasodilators and inotropes, tailored to the response in hemodynamic measurements, have been advocated as effective methods to obtain more rapid and sustained improvement in patients with the most severe heart failure.[43,44] Goals of treatment include lowering PCWP less than 16 mm Hg and right atrial pressure less than 8 mm Hg, reducing systemic vascular resistance to less than 1200 dynes/s per cm^{-5}, raising cardiac index to more than 2.6 L/min per m^2, and maintaining systolic blood pressure above 80 mm Hg. PCWP can be lowered to a normal value of 10 to 12 mm Hg in many patients with significant left ventricular dysfunction without untoward effects.[45] In a group of patients referred for cardiac transplantation, a combination of aggressive parenteral therapy, targeted to optimal hemodynamics, followed by conversion to appropriate oral therapy, resulted in clinical improvement so that 30% of these patients were able to be removed from transplant lists.[44]

• BOX 27.2 Indications for Invasive Hemodynamic Monitoring With a Pulmonary Artery Catheter in Acute Heart Failure

1. Cardiogenic shock
2. Cardiac versus pulmonary cause of dyspnea uncertain
3. Uncertainty regarding severity of heart failure
4. Worsening renal function during heart failure therapy
5. Guiding parenteral vasodilator therapy
6. Deteriorating clinical status despite appropriate therapy
7. Evaluation of concomitant pulmonary hypertension
8. Evaluation before cardiac transplantation

• BOX 27.3 Causes of Acutely Decompensated Heart Failure

Environmental Causes
Excess salt and fluid intake
Excess alcohol consumption
Medication noncompliance or misunderstanding
Emotional or physical stress

Adverse Medication Effects
Calcium channel blockers
Antiarrhythmic agents (types 1A, 1C)
Nonsteroidal antiinflammatory drugs
Corticosteroids
Metformin, thiazolidinediones
Cancer chemotherapy

Cardiovascular Conditions
Acute ischemia/infarction
Pulmonary embolism
Uncontrolled hypertension
Arrhythmia
Worsening valvular regurgitation
Endocarditis

Sepsis, infection, hypoxia
Renal failure, urinary obstruction
Thyroid disease
Anemia, blood loss
Obstructive sleep apnea
Bilateral renal artery stenosis
Worsening of chronic lung disease

Evaluation for Etiology of Heart Failure Exacerbation

In patients with chronic systolic heart failure who experience acute decompensation, the specific reason for deterioration must be searched for and corrected when possible (Box 27.3). Environmental

factors such as excessive salt and fluid intake or alcohol consumption are common. Lack of adherence with outpatient heart failure therapies is also common, as complex and expensive drug regimens pose obstacles to consistent adherence. Emotional and physical stressors should be corrected when feasible.

Concomitant administration of medications for noncardiac conditions may aggravate heart failure. The most common are corticosteroids and nonsteroidal antiinflammatory drugs (NSAIDs), which promote fluid retention and aggravate hypertension. NSAIDs also interfere with the beneficial renal effects of angiotensin-converting enzyme (ACE) inhibitors, and can lead to acute renal injury and interfere with the action of loop diuretics.[46] The use of NSAIDs has been reported to increase the risk of hospitalization for heart failure by 10-fold in patients with a history of heart failure.[4] In patients with diabetes, metformin and thiazolindinediones can contribute to water retention and exacerbate heart failure. Cardiac toxicity owing to anthracyclines or other chemotherapies such as tyrosine-kinase inhibitors, a newer class of cancer chemotherapy, may cause or aggravate heart failure by direct toxic effects on the myocardium.[47] Cardiac medications such as calcium channel blockers and type 1A and 1C antiarrhythmic drugs (propafenone, flecainide) and dronedarone are contraindicated in patients with acute decompensated heart failure.

Acute and chronic comorbid medical conditions often play a role in heart failure decompensation. Renal failure often has etiologies similar to heart failure (e.g., hypertension, vascular disease) and WRF will often aggravate heart failure. Other common conditions include infections, such as pneumonia, influenza or sepsis, pulmonary embolus, worsening anemia often owing to blood loss, hyperthyroidism or hypothyroidism, and obstructive sleep apnea. Progression of underlying cardiovascular conditions is often the cause of heart failure exacerbation. Examples include progression of coronary artery disease with acute ischemia, uncontrolled hypertension, and cardiac arrhythmias. Worsening valve regurgitation, endocarditis, and bilateral renal artery stenosis are less common causes of acute heart failure exacerbation.

Pharmacologic Management of Acute Heart Failure

Urgent, short-term goals of treatment of heart failure are to relieve dyspnea, reverse acute hemodynamic decompensation, and preserve myocardial function. After the patient's condition has stabilized and improved, then long-term objectives become paramount. These are preventing rehospitalization, improving functional status, and prolonging survival. Pharmacologic therapies shown to improve long-term survival by preventing or attenuating chronic left ventricular remodeling should be instituted or intensified before discharge from the hospital (Box 27.4).

Pharmacologic treatment of heart failure is aimed at achieving these goals by improving fluid balance and reversing the neurohormonal activation responsible for the progressive decline in left ventricular function. Therapy usually involves combinations of multiple medications. Several drugs have been shown to improve symptoms and functional capacity, decrease the need for repeated hospitalizations, and improve mortality. Careful serial assessment of patients is mandatory to guide pharmacologic therapy. In addition to assessment of symptoms, frequent assessment of weight, urinary output, blood pressure, cardiac rhythm, pulmonary rales, the presence of an S_3 gallop, jugular venous pressure, pulse oximetry, electrolytes, and renal function is mandatory.

• BOX 27.4 Goals of Therapy During Hospitalization for Acute Heart Failure

Clinical

1. Improve oxygenation, resolution of dyspnea and orthopnea
2. Decongestion: Effective diuresis, fluid weight loss, resolution of lung and peripheral edema

Laboratory

1. Normalized serum electrolyte levels
2. Optimized renal function
3. Reduce serum B-natriuretic peptide <30% from baseline

Hemodynamics

1. Reduce pulmonary capillary wedge pressure to <16 mm Hg
2. Reduce right atrial pressure <8 mm Hg
3. Optimize cardiac output, maintain systolic BP above 80 mm Hg

Improve Prognosis

1. Treat myocardial ischemia
2. Initiate guideline recommended pharmacologic therapy
3. Evaluation for device therapy (cardiac resynchronization, ICD)

TABLE 27.2 Loop Diuretics Used for the Treatment of Acute, Severe Heart Failure

Agent	Oral Dose (mg)	Initial Intravenous Dose (mg)	Maximum IV Bolus Dose (mg)	Continuous IV Dose (mg/h)
Bumetanide	0.5–2.0	1.0	4–8	0.5–2
Furosemide	20–80	40–80	160–200	5–40
Torsemide	10–40	10	100–200	5–20

Intravenous Diuretics

Although no randomized clinical trials exist, the use of loop diuretics is supported by a long history of clinical success. These agents increase renal excretion of salt and water. The onset of action of intravenous bolus furosemide is 30 minutes, with peak action at 1 to 2 hours. The half-life of the medication is 6 hours, so twice-daily dosing is usually required.[46] Other loop diuretics often used are bumetanide and torsemide (Table 27.2). Lower doses of loop diuretics are effective in patients with a new diagnosis of heart failure who are not using long-term diuretic therapy, but more aggressive initial diuretic dosing is recommended in patients with exacerbation of chronic heart failure to obtain effective pulmonary and systemic venous decongestion and to achieve more rapid symptom relief.[32,33] Subsequent dosing should be titrated to the response of the patient's fluid status and symptoms. Dosage reduction may be considered when clinical status improves. Hypokalemia, alkalosis, and hypomagnesemia are frequent side effects of loop diuretics and can potentiate the occurrence of arrhythmias, so electrolyte levels must be carefully monitored during aggressive diuretic therapy.

Several small clinical trials suggested that a constant infusion of a loop diuretic resulted in superior diuresis when compared with intermittent bolus dosing,[48,49] although other studies did not confirm this.[50] The Diuretic Optimization Strategies Evaluation (DOSE) trial (diuretic strategies in patients with acute decompensated heart failure) was a large, randomized controlled study performed in patients hospitalized with acute decompensated heart failure who

were taking a high dose of furosemide before admission. Patients were randomly assigned within 24 hours of admission to bolus dosing or constant infusion and were also randomly assigned to the usual daily outpatient dose (given intravenously) versus high dose (2.5 times the usual daily dose). No significant differences were noted in prespecified outcomes between bolus and infusion administration. However, the higher-dose group had better relief of dyspnea and more fluid and weight loss than the lower-dose group; 23% of the high-dose group had a significant deterioration in renal function, but at 60 days there was no difference in renal function between the two groups.[51]

An association between administration of high-dose loop diuretics and worse prognosis has been observed. There has been concern that this may be mediated by adverse renal effects and further activation of the RAAS by loop diuretics. However, in one retrospective analysis using propensity matching, hospital mortality was not different between low-dose and high-dose diuretic groups.[52] In another study, greater RAAS activation at baseline, as defined by higher levels of renin and aldosterone, was associated with worse initial heart failure status. However, higher diuretic doses did not correlate with further RAAS activation, and RAAS activation was not predictive of worse outcomes at 60 days.[53] In another study, daily furosemide doses of more than 160 mg were not associated with poorer outcomes after multivariate analysis and adjustment for disease severity.[54] Thus it is likely that poorer outcomes associated with high-dose diuretic are not due to the drug itself but reflect a greater severity of heart failure illness.[55]

The complex interaction of severe heart failure and WRF is called the *cardiorenal syndrome.* Up to 50% of patients hospitalized with heart failure demonstrate a glomerular filtration rate (GRF) less than 60 mL/min per m^2. WRF is often defined as a rise in serum creatinine of more 0.3 mg/dL or a 30% increase over baseline. This is seen in approximately one-third of hospitalizations for acute heart failure.[56] There is increasing evidence that the most common hemodynamic alterations that lead to WRF in heart failure are elevated systemic venous pressure and increased intraabdominal pressure.[57] In a retrospective study of patients with acute heart failure who had right heart catheterization, elevated central venous pressure was associated with reduced GFR and higher all-cause mortality. These findings were independent of the measured cardiac output.[58] Patients at particular risk for developing WRF are those with lower LVEF, lower blood pressure, diabetes mellitus, a history of hypertension, and older age. These patients have longer hospital stays and higher readmission and mortality rates. The best treatment strategy for these patients is not clear, as patients with significant renal impairment have generally been excluded from large randomized pharmacologic heart failure trials. Aggressive diuresis is often associated with WRF but is often necessary to relieve congestion. WRF is associated with worse outcomes only when accompanied by persistent congestion.[59] Indeed, poorer outcomes have been associated with failure to achieve adequate decongestion at hospital discharge, which may be present in 24% to 44% of patients. WRF with persistent congestion is associated with more severe hemodynamic abnormalities.[40,54,60]

Patients with chronic heart failure with or without renal dysfunction may exhibit resistance to loop diuretics, defined as an acute reduction in diuretic efficacy after repeated loop diuretic dosing. With chronic loop diuretic use, there is an increase in sodium reabsorption in the distal nephron and stimulation of aldosterone release. In edematous states there is delayed oral absorption of the drug. With renal dysfunction there may be reduced levels of drug delivered to the renal tubule. This resistance is associated with a poorer prognosis. Diuretics that act distally in the renal tubule, such as metolazone or hydrochlorothiazide, or aldosterone blockers such as spironolactone, can be added. Combination diuretic therapy induces a greater diuresis than simply increasing the dose of loop diuretic further. The response may be delayed for 48 to 72 hours. Combining diuretics often augments diuresis even in the setting of significant chronic kidney disease, and a good response can be expected in more than 70% of patients. Particular attention must be given to monitoring renal function and electrolytes when combination diuretic therapy is prescribed[61] (Table 27.3).

TABLE 27.3 Treatment of Refractory, Diuretic-Resistant Heart Failure

Supplemental Diuretic	Usual Dose
Hydrochlorothiazide	20–50 mg once or twice daily
Metolazone	2.5–5.0 mg once or twice daily
Spironolactone	12.5–50 mg once daily

Vasopressin Inhibitors

The use of vasopressin inhibitors has been evaluated in clinical trials of treatment of acute heart failure.[62] Vasopressin is a hormone synthesized in the hypothalamus; its major effect is to control free water clearance. It acts through V1a receptors in vascular smooth muscle and myocardium, leading to peripheral and coronary vasoconstriction, myocyte hypertrophy, and positive inotropy. Vasopressin also acts through V2 receptors at the renal tubule collecting ducts to cause free water retention and hyponatremia. Levels of vasopressin are increased in patients with chronic heart failure, and higher vasopressin levels correlate with worse heart failure severity. Vasopressin release is stimulated by changes in serum osmolality and cardiac output and leads to further vasoconstriction and retention of free water.[63,64] Inhibition of vasopressin's effects would have theoretic benefits in patients with heart failure. In contrast to loop diuretics, inhibition of vasopressin theoretically would not cause hypotension or neurohormonal activation and would not aggravate cardiac arrhythmias owing to electrolyte depletion.

Conivaptan is a vasopressin antagonist that inhibits V1a and V2 receptors. Tolvaptan and lixivaptan are antagonists selective for the V2 receptor. These medications increase urine volume and free water excretion, with a rise in the serum sodium concentration. The use of conivaptan in patients with class III-IV heart failure was associated with increased urine output, and decreases in PCWP and right atrial pressure, without changes in cardiac output.[4] Oral use of tolvaptan was associated with fluid loss and diuresis without change in heart rate, blood pressure, or serum creatinine. Hemodynamic effects of tolvaptan included rapid reduction in PCWP and right atrial pressure.[65]

In a large, multicenter, placebo-controlled randomized trial, Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study With Tolvaptan (EVEREST), tolvaptan was administered to patients hospitalized with heart failure. There were no adverse consequences on heart rate, blood pressure, or serum electrolytes and there was more rapid improvement in dyspnea and signs of heart failure compared with usual therapy. Hyponatremia improved. However, at 10 months' follow-up after hospitalization, there was no improvement in mortality or readmission rates.[66,67] A more recent trial in patients hospitalized with dyspnea caused by systolic

heart failure or HFpEF evaluated administration of 2 doses of 30-mg tolvaptan at 24 and 48 hours after hospital admission, compared with standard diuretic therapy. Despite greater fluid loss in the patients receiving tolvaptan, there was no improvement in dyspnea relief, and there was an increased risk for WRF. There also was no difference in posthospitalization outcomes.[68]

Currently tolvaptan is approved for treatment of heart failure if there is hypervolemia and severe hyponatremia (i.e., serum sodium < 125 mEq/L) or less severe hyponatremia if associated with symptoms and not responding to fluid restriction. Cases of severe liver injury have been reported. A course of therapy with tolvaptan should not exceed 30 days, and its use is contraindicated in patients with significant liver disease.

Parenteral Vasodilators (Table 27.4)

Intravenous vasodilator therapy is often added to diuretic therapy to obtain more rapid improvement in severe heart failure. There is limited controlled trial evidence on which to base recommendations for their use.[69] The Acute Heart Failure Global Registry of Standard Treatment (ALARM-HF) enrolled patients hospitalized with heart failure in eight countries. A retrospective analysis of unadjusted and propensity-matched data studied in-hospital mortality related to use of vasodilators. The adjusted data showed a lower in-hospital mortality when a vasodilator was combined with a diuretic, compared with diuretic therapy alone (hospital mortality 7.8% vs. 11.0%, $P = 0.016$).[70] In the European Society of Cardiology 2012 Heart Failure Guidelines, a IIa indication (level of evidence B) is given to intravenous nitrates administered for relief of dyspnea, whereas the ACC Foundation/AHA 2013 guidelines give a IIb indication (level of evidence A) to vasodilators.[5,22] A clear indication for vasodilators is acute pulmonary edema with severe hypertension. Their use should also be considered in patients who are not responding to intravenous diuretics combined with standard oral heart failure medications. Blood pressure response to these medications needs to be carefully monitored as hypotension is common. Improvement in hemodynamics has been obtained with aggressive intravenous vasodilator therapy using intravenous nitroprusside, intravenous nitroglycerin, or nesiritide. The choice of agents depends on matching the patient's clinical picture and hemodynamics with the predicted effects of each vasodilator.[71,72]

Nitroglycerin

Intravenous nitroglycerin is an effective systemic and coronary vasodilator. It is very useful in heart failure caused by acute coronary ischemia because it improves coronary blood flow. Intravenous nitroglycerin acts as a venodilator at lower doses, lowering preload and PCWP, thereby reducing pulmonary congestion, without increasing oxygen demand. It is also an arterial dilator at high doses, but it is less effective at reducing afterload than nitroprusside.[33] Dose ranges between 5 and 200 μg/min. Headache is a frequent side effect. A major limitation of the use of intravenous nitroglycerin is tachyphylaxis, the rapid development of tolerance to the drug's effect, which often occurs after only 24 hours of therapy. Prescribing a "nitrate-free" period during the daily dosage regimen has been advocated to limit the development of tolerance, but this is not feasible in patients receiving parenteral therapy. Nitrates have not been shown to improve long-term prognosis.

Nitroprusside

Intravenous sodium nitroprusside is a powerful venous and arterial dilator. It is a drug of choice in treating hypertension-related heart failure with pulmonary edema and severe heart failure owing to acute mitral regurgitation. The use of nitroprusside requires hospitalization in the ICU and invasive monitoring with a PA catheter and arterial line. This drug causes a significant reduction of afterload and preload, lowering right atrial pressure, systemic vascular resistance, mean systemic blood pressure and PCWP, and increased cardiac output in patients with heart failure owing to left ventricular systolic dysfunction. Limitations of nitroprusside use include inducing a coronary "steal" syndrome in patients with active coronary ischemia and facilitating pulmonary ventilation-perfusion mismatch.[46] Accumulation of the toxic metabolites thiocyanate and cyanide may occur with more prolonged administration in patients with renal or hepatic disease. The dosage range is 0.3 to 5.0 μg/kg per minute.

Nesiritide (B-Naturetic Peptide)

Human BNP manufactured by recombinant DNA technology is available as an intravenous medication, nesiritide, for heart failure therapy. BNP is a hormone produced by ventricular and atrial

TABLE 27.4 Hemodynamic Effects of Parenteral Vasodilators

	Nitroglycerin	Nitroprusside	Nesiritide
Starting dose	10–20 μg/min	0.3 μg/kg/min	
Infusion	May increase up to 200 μg/min	May increase up to 5 μg/kg per minute	0.01 μg/kg per minute

myocytes in response to stretch from cardiac chamber dilatation. Hemodynamic effects include venous and arterial dilation, coronary vasodilation, and natriuresis. Initial trials showed greater reduction in PCWP and right atrial pressure compared with intravenous nitroglycerin.[71] It is not proarrhythmic and does not induce tolerance.[73] It may potentiate the effects of loop diuretics. Significant hypotension may limit its use in some patients.[46] Because the hypotensive effects of nesiritide are less marked than those of nitroprusside, nesiritide can be used without invasive hemodynamic monitoring and can be initiated in emergency department settings. Nesiritide is initiated as an intravenous bolus dose of 2 μg/kg followed by infusion of 0.01 μ/kg per minute.

Nesiritide was compared with dobutamine in patients with severe heart failure. Nesiritide infusion was associated with less tachycardia and ventricular arrhythmia.[74] A meta-analysis of three randomized trials of nesiritide suggested a slight increase in mortality in patients given nesiritide versus a placebo control group, possibly mediated through an adverse effect on renal function.[75,76] A retrospective review of patients receiving intravenous vasoactive medications for acute heart failure indicated mortality rates, adjusted for clinical variables, were equivalent for patients receiving nitroglycerin or nesiritide. Patients who received intravenous nesiritide or intravenous nitroglycerin had a lower in-hospital mortality compared with patients who received dobutamine or milrinone.[77]

A randomized, placebo-controlled international study, Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure (ASCEND-HF), was performed to evaluate the effect of nesiritide on relief of dyspnea, mortality, and renal function in patients hospitalized with acute heart failure; 7141 patients were enrolled. More than 90% of patients received loop diuretics and 15% received vasodilator therapy. Patients who received nesiritide had slightly better relief of dyspnea at 6 and 24 hours, although this did not meet a prespecified significant improvement in dyspnea score. There was no significant difference in hospital mortality, 30-day mortality, or death or rehospitalization at 30 days. There was no significant worsening of renal function in the nesiritide group. Hypotension was significantly more common in the nesiritide group (26.6%) compared with the control group (15.3%). The authors concluded that nesiritide was not useful for routine use in the management of patients with severe heart failure.[78] The Renal Optimization Strategies Evaluation (ROSE) trial evaluated the use of a low dose of nesiritide (0.005 μg/kg per minute) with diuretic therapy, compared to low-dose dopamine and diuretics alone, in patients with decompensated systolic heart failure. The study showed no improvement in urine volume, change in renal function (as measured by serum cystatin C level), or improvement in decongestion using nesiritide dosing strategy.[79] Nesiritide thus is used only in patients with acute decompensated heart failure to relieve dyspnea when more conventional therapies are ineffective.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are of limited use as parenteral therapy in patients with acute severe heart failure in the urgent setting. *Enalaprilat* is an intravenous bolus formulation that can be used in patients with chronic heart failure who are taking chronic oral ACE inhibitor therapy and who are unable to take oral medication. The maximal action occurs 1 to 4 hours after administration, with a six-hour duration of action.

Inotropic Drugs (see Table 27.5)

Dobutamine is a potent β_1-agonist. It also has β_2-agonist properties. Its major effects are increased myocardial contractility and increased cardiac output. It increases myocardial oxygen demand. It also has venodilator properties. At doses of 2.5 to 15 μg/kg per minute, dobutamine will lower systemic vascular resistance and PCWP and cause a slight increase in heart rate. It has rarely been associated with eosinophilia and fever.

In patients with heart failure, β-receptors may be chronically downregulated. Therefore the effects of dobutamine may be attenuated in patients with chronic heart failure. Dobutamine may be detrimental in patients with severe coronary artery disease or after myocardial infarction, as it increases myocardial oxygen demand and can aggravate ischemia and increase heart rate and induce arrhythmias.[74] Tolerance to the effects of dobutamine has been demonstrated in patients with infusions lasting more than 24 to 72 hours, theoretically owing to induction of β-receptor downregulation.[80] In studies of more prolonged dobutamine use, mean 14 days, a higher 6-month mortality

TABLE 27.5 Hemodynamic Effects of Inotropic Drugs and Vasopressors

	Dobutamine	Milrinone	Levosimendan	Dopamine	Norepinephrine
Bolus dose	No	25–75 μg/kg over 10–20 min	12 μg/kg over 10 min (optional)	No	No
Infusion dose	2–20 μg/kg per minute	0.375–0.75 μg/kg per minute	0.05–2.0 μg/kg per minute	3–10 μg/kg per minute	0.2–1.0 μg/kg per minute

was observed with dobutamine when compared with a vasodilator, without improvement in quality of life.[81]

Milrinone is an inhibitor of myocyte phosphodiesterase. This leads to increased intracellular cyclic adenosine monophosphate and calcium. It is a noncatechoamine inotropic agent that acts "downstream" from the β-receptor, so it is more useful than dobutamine in patients being treated with β-blockers. It may improve diastolic function. Hemodynamic effects include reduction of right atrial pressure and vasodilation with reduction in pulmonary and systemic vascular resistance. In heart failure, stroke volume and cardiac output are increased with a slight fall in mean systemic arterial pressure. Milrinone acts as a coronary vasodilator, and there is no net increase in myocardial oxygen consumption. Arterial blood pressure and PCWP tend to be lowered more than with dobutamine, and milrinone's action is more prolonged. There is no tolerance or attenuation of its effect. Milrinone is started as an infusion at 0.125 μg/kg per minute, avoiding bolus doses, with a maintenance infusion of 0.375 to 0.75 μg/kg/minute. It is cleared through the kidneys, so doses need to be reduced in patients with renal disease. Its use is limited in patients with hypotension or severe kidney disease.

Levosimendan is available for use in Europe but not in the United States. It is an inotropic drug that acts by enhancing sensitivity of troponin C to calcium. It also improves diastolic function and has vasodilator properties. Initial dose is 0.1 μg/kg per minute, which can be increased to 0.4 μg/kg per minute over 4 hours. In one trial, levosimendan was associated with more short-term clinical improvement compared with placebo, but with more hypotension and arrhythmias and without improvement in 90-day mortality.[82] Another trial compared levosimendan use to dobutamine and found no difference in 180-day mortality and no improvement in other secondary outcomes.[83]

The choice of milrinone versus dobutamine depends on specific clinical circumstances. Dobutamine tends to cause a slight rise in heart rate and has little effect on mean arterial pressure, whereas milrinone often lowers systemic arterial pressure owing to more prominent lowering of systemic vascular resistance.[84–86] Patients who do not respond to dobutamine may have a favorable response to milrinone. In the setting of acute heart failure, milrinone is used more often than dobutamine in view of its more potent vasodilator properties. In addition, its effects are not primarily mediated through β-receptors, which is an important consideration in patients receiving concomitant β-blocker therapy. However, dobutamine has a much shorter half-life than milrinone, so dobutamine-induced hypotension can be more rapidly reversed by discontinuing the drug.

Vasopressors (Table 27.5)

Dopamine effects include vasodilation and increased renal blood flow at low doses, 1 to 3 μg/kg per minute, via stimulation of dopaminergic receptors. At moderate doses, 3 to 10 μg/kg per minute, increased myocardial contractility and increased heart rate are seen via stimulation of β-receptors. High-dose dopamine, 10 to 20 μg/kg per minute, is associated with vasoconstriction owing to α-adrenergic activation.[81] Dopamine is a less useful agent for treatment of heart failure because it causes tachycardia, coronary vasoconstriction, increased afterload, and increased oxygen consumption. Dobutamine generally will lead to a greater rise in cardiac output than dopamine in systolic heart failure. Dopamine can be used when significant hypotension is present and it is necessary to restore adequate arterial pressure for end-organ perfusion. Although dopamine at low doses had been advocated to be used as add-on therapy to inotropic agents in an attempt to increase renal blood flow and augment diuresis, no controlled trials have demonstrated significant improvement in heart failure outcomes with this strategy. The ROSE trial demonstrated no improvement in urine output, decongestion, or protection of renal function in heart failure patients treated with "renal dose" dopamine, 2 μg/kg per minute.[79] No significant benefit of low-dose dopamine has been shown in preventing acute renal failure in high-risk patients or in the treatment of established renal failure.[80]

Norepinephrine is a sympathomimetic agent with strong α-agonist and weaker β-agonist effects. In patients with heart failure, the main effect of norepinephrine is to raise blood pressure by causing vasoconstriction with little effect on cardiac output. It will increase inotropy somewhat and increase myocardial oxygen demand. Its use in the setting of heart failure is restricted to patients with the most severe hypotension, unresponsive to dopamine, or in patients with complicating illnesses such as sepsis.[80] Norepinephrine should be weaned and discontinued as early as possible. The dosage range is 0.2 to 1 μg/kg per minute.

Norepinephrine and dopamine were compared in a randomized, controlled trial of 1679 patients with shock, 280 (16.7%) of whom had cardiogenic shock. In the entire group, there was no difference in survival at 28 days if patients were treated with norepinephrine or dopamine. However, in a predefined subgroup analysis of patients with cardiogenic shock, dopamine use was associated with a significantly increased mortality. In addition, in the entire group, dopamine was associated with significantly higher rates of arrhythmia, especially atrial fibrillation (24% vs. 12.4% with norepinephrine), which led to stopping the vasopressor more frequently. There was also a higher rate of severe arrhythmia with dopamine (6.1%) compared with norepinephrine (1.6%).[87] Based on the results of this study, norepinephrine is the preferred vasopressor in patients with cardiogenic shock.

An algorithm for the approach to the evaluation and therapy of acute heart failure is presented in Fig. 27.6.

Considerations Regarding the Use of Inotropes and Vasopressors

There is clear evidence that inotropic drugs are associated with more coronary ischemia, more arrhythmia, poorer outcomes, and increased mortality. Several clinical studies that evaluated the usefulness of routine inotropic therapy, comparing milrinone or dobutamine with placebo, showed no evidence for improved short-term or medium-term outcomes with inotropic therapy. In fact, the use of inotropic agents has been consistently associated with a *worse* prognosis for survival.[46] In the Flolan International Randomized Survival Trial (FIRST) study of patients with class III–IV heart failure, an average 14-day infusion of dobutamine was associated with an increased risk of morbid events and higher short-term mortality.[88] The use of a 48-hour infusion of milrinone was evaluated as routine therapy in patients admitted with class III–IV heart failure, when inotropic therapy was not considered essential. In The Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) when compared to standard therapy without milrinone, no improvement in symptom relief, hospital length of stay, or rehospitalization rate within 60 days was demonstrated. Milrinone was associated with more hypotension and atrial arrhythmia than placebo, without improvement in short-term or 60 day mortality.[86] The ALARM-HF registry showed that adjusted in-hospital mortality was 1.5 times higher in patients treated with dobutamine or

(Adapted from Pang PS. Acute heart failure syndromes. *Emerg Med Clin North Am.* 2011;29:675–688.)

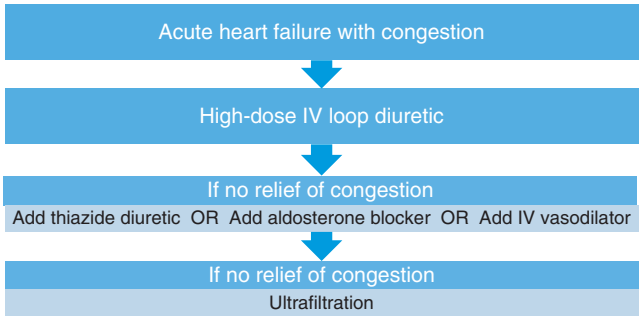
dopamine and 2.5 times higher in patients treated with norepinephrine. Levosimendan therapy had a minimally higher mortality.[70] These negative outcomes with inotropic agents are thought to be related to their propensity to stimulate sympathetic nervous system activation, increase myocardial oxygen demand, aggravate myocardial ischemia, increase the risk of serious cardiac arrhythmias, and cause myonecrosis by stimulation of chronic hibernating myocardium.

Therefore inotrope use is limited to patients in a critical care unit who have symptomatic low cardiac output and hypotension owing to reduced left ventricular systolic function and signs of end-organ hypoperfusion or cardiogenic shock.[81,89] If use of an inotrope is necessary, the shortest duration of therapy should be attempted (i.e., <72 hours) or the addition of MCS should be considered. Patients with end-stage heart failure may become inotrope-dependent, when weaning the drug leads to aggravation of the heart failure syndrome. Inotropes can be used as a bridge to heart transplantation or MCS. ACC/AHA guidelines for evaluation and management of chronic heart failure indicate that long-term intermittent infusions of a positive inotropic drug as therapy for symptomatic systolic dysfunction is *contraindicated.*[5] Continuous inotrope infusion can also be recommended for palliation of symptoms in patients with refractory end-stage heart failure (stage D). These patients will have been deemed poor candidates for advanced therapies such as MCS or heart transplantation. In this setting, quality of remaining life takes precedence over prolonging life. In one report of patients with refractory end-stage heart failure, median survival of patients receiving continuous inotrope infusion was 3.4 months, with 26% of patients surviving to 6 months.[90] The decision to use inotropic agents in this circumstance is one that should be carefully individualized.

Ultrafiltration

Venovenous ultrafiltration has been advocated for use in treating severe heart failure. This process removes iso-osmolar extracellular fluid via a convection process and is not associated with changes in serum electrolytes.[91] Newer ultrafiltration systems use peripheral arm veins without the need for central venous access. Systemic anticoagulation is necessary. In a pilot study of 40 patients admitted with heart failure, usual care for heart failure with diuretic therapy was compared with usual care combined with ultrafiltration. At 24 hours, average fluid loss with diuretic therapy was 2838 mL compared with 4650 mL with ultrafiltration. Weight loss and improvement in dyspnea was similar with the two therapies. Ultrafiltration was not associated with significant changes in heart rate or blood pressure.[92]

More recent larger trials have failed to demonstrate long-term survival benefit or renal sparing effects with ultrafiltration. The Ultrafiltration versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) trial investigated the use of ultrafiltration compared with intravenous diuretic therapy in 200 patients admitted with acute decompensated heart failure. Ultrafiltration was associated with more rapid weight loss and fluid loss. At 90 days, there were fewer rehospitalizations for heart failure in the ultrafiltration group, without change in mortality. There was no difference with respect to renal function in the 2 groups.[93] In the Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) trial, patients with acute decompensated heart failure, worsening renal function, and persistent congestion were treated with either ultrafiltration for 28 to 67 hours or aggressive diuretic therapy. No advantage was seen with ultrafiltration. Primary endpoint analysis showed that ultrafiltration was associated with a slight worsening of renal function, significantly more than with diuretic therapy. Fluid weight loss was similar in the two groups. Serious adverse events were common in both groups but slightly more frequent in the ultrafiltration group (72% vs. 57%, $P = 0.03$).[94]



• **Fig. 27.7** A systematic approach to decongestion therapy. *IV,* Intravenous.

Additional factors to consider are the higher cost, need for anticoagulation, potential vascular access complications, and greater nursing training and support with ultrafiltration.[40,95] Current ACC heart failure guidelines give a IIb recommendation (level of evidence B) for ultrafiltration in patients with severe heart failure for the relief of severe congestion.[5] It should not be used routinely as a substitute for diuretics. European Society of Cardiology guidelines also give a IIa indication for ultrafiltration in the setting of refractory volume overload in the setting of acute kidney injury.[22] A systematic approach to decongestion therapy is presented in Fig. 27.7.

Transition to Chronic Pharmacologic Therapy for Severe Heart Failure

After improvement in acute heart failure status is achieved, drug regimens for treating chronic heart failure are initiated and optimized, depending on the etiology of heart failure. The medical treatment of chronic systolic heart failure is based on results of many large, randomized, placebo-controlled trials (see following text). Long-term prognosis is directly related to reduction in left ventricular size, improvement in left ventricular systolic function and restoration of more normal left ventricular geometry, a process called "reverse remodeling." Optimal drug regimens combining several classes of medication help to achieve these ends by reversing the neurohormonal activation responsible for left ventricular remodeling and progressive decline in left ventricular function. Clinical goals of medical therapy include improved survival, reduction in the rate of rehospitalization, and improvement in functional capacity, exercise tolerance, and quality of life. It has been shown that initiating these medical therapies while patients are in the hospital improves long-term adherence.

Oral Diuretic Therapy (Table 27.6)

Loop diuretics are routinely used in patients with signs or symptoms of fluid retention. Diuretics are continued even after patients are euvolemic to prevent reaccumulation of fluid and symptoms of congestion. A flexible dosing schedule, based on daily weights, assessment of symptoms, and close telephone contact with a heart failure treatment team member, can be very effective in maintaining a euvolemic state while reducing the frequency of side effects.

TABLE 27.6 Oral Diuretics Recommended for Use in the Treatment of Fluid Retention in Chronic Heart Failure

Drug	Initial Daily Dose(s)	Maximum Total Daily Dose	Duration of Action
Loop Diuretics			
Bumetanide	0.5–1.0 mg once or twice	10 mg	4–6 h
Furosemide	20–40 mg once or twice	600 mg	6–8 h
Torsemide	10–20 mg once	200 mg	12–16 h
Thiazide Diuretics			
Chlorothiazide	250–500 mg once or twice	1000 mg	6–12 h
Chlorthalidone	12.5–25 mg once	100 mg	24–72 h
Hydrochlorothiazide	25 mg once or twice	200 mg	6–12 h
Indapamide	2.5 mg once	5 mg	36 h
Metolazone	2.5 mg once	20 mg	12–24 h
Potassium-Sparing Diuretics			
Eplerenone	12.5 mg once	20 mg	24 h
Spironolactone	12.5–25 mg once	50 mg[a]	2–3 days
Triamterene	50–75 mg once	200 mg	7–9 h

[a]Higher doses may occasionally be used with close monitoring of serum creatinine and potassium levels.

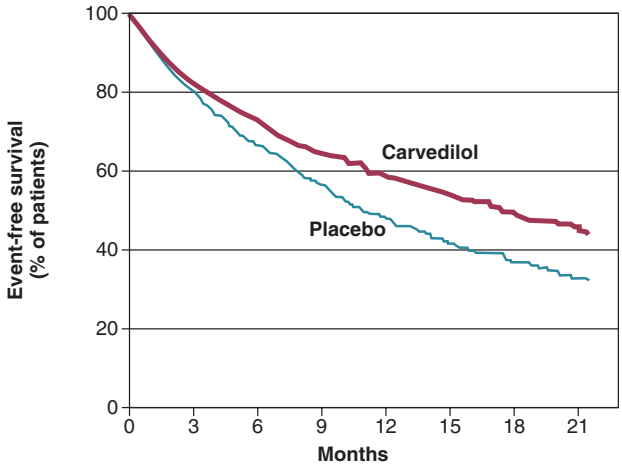
Modified from Hunt S, Abraham WT, Chin M, et al. ACC/AHA 2005 Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult—Summary Article. A report on the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Update the 2001 Guidelines for Evaluation and Management of Heart Failure). Developed in collaboration with the American College of Chest Physicians and the International Society of Heart and Lung Transplantation: Endorsed by the Heart Rhythm Society. *Circulation. 2005*;112:1825–1852.

Furosemide is the most common loop diuretic used. Bumetanide or torsemide may be helpful in patients with suboptimal responses to furosemide owing to their more consistent absorption after oral administration. Metolazone or a thiazide diuretic can be used in addition to a loop diuretic in patients with more severe heart failure because of their synergistic effects. Patients must be periodically monitored for side effects of these agents, including azotemia, hypokalemia, alkalosis, hyponatremia, and hypomagnesemia.

β-Blockers

Catecholamine levels are increased in heart failure, and higher levels correlate with worse disease severity. Catecholamines have direct negative effects on the myocardium, including induction of myocyte hypertrophy and apoptosis.[10] Clinically these effects are evident as left ventricular dilation, increased ischemia, peripheral vasoconstriction, and arrhythmia. β-Blockers interfere with catecholamine-mediated activation of cardiac β-receptors, and thereby attenuate β-receptor–mediated increases in heart rate and oxygen consumption. Sympathetic nervous system–mediated effects on remodeling can be prevented or attenuated. In addition, carvedilol blocks β-receptors and α-receptors, which mediate vasoconstriction and increased cardiac contractility.

Multiple large trials using β-blockers in thousands of patients with chronic heart failure, or in post–myocardial infarction patients with reduced LVEF, have demonstrated significant and consistent improved survival and reductions in the need for repeat rehospitalization for heart failure. The Beta-Blocker Heart Attack Trial (BHAT) showed a relative 26% reduction in mortality at 2 years in post–myocardial infarction patients treated with propranolol.[96,97] The Cardiac Insufficiency Bisoprolol Study II (CIBIS-II) trial using bisoprolol showed a 34% relative risk reduction at 16 months of therapy in the combined endpoint of hospitalizations and mortality.[98] The Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF) study showed a relative reduction of 33% in these endpoints at 12 months using metoprolol succinate.[99] Patients with more severe heart failure, symptom class III-IV, with severely reduced ejection fractions (< 25%) were studied in the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial. These patients began therapy with carvedilol during hospitalization. At mean follow-up of 10.4 months, a 35% relative mortality reduction was seen, with improvement in mortality beginning as early as 3 weeks after initiation of therapy (Fig. 27.8).[100]



No. of Patients at Risk

Placebo	1133	767	513	377	262	154	88	55
Carvedilol	1156	789	559	431	318	208	122	81

• **Fig. 27.8.** All-cause mortality rate in patients with class III to class IV heart failure, ejection fraction less than 25%, demonstrating significant survival benefit with carvedilol. (Redrawn from Packer M, Coats A, Fowler M, et al. Effect of carvedilol on survival in severe chronic heart failure. *N Engl J Med.* 2001;344:1651-1658.)

In these trials, β-blockers were well tolerated, with a frequency of side effects not different from placebo; there was also no increased risk of heart failure exacerbation owing to β-blocker therapy even in the early phases of drug administration.[101] Trials have shown an approximate 6% absolute increase in LVEF after 2 years of therapy with carvedilol.[102]

The specific β-blockers recommended as supported by clinical trial evidence are metoprolol succinate, bisoprolol, and carvedilol. They should be initiated once patients are stable and euvolemic. Doses should be titrated up to maximal recommended doses (e.g., metoprolol succinate 200 mg daily or carvedilol 25 mg bid) or maximally tolerated doses as heart rate and blood pressure permit. They are useful in patients with both ischemic and nonischemic cardiomyopathy. β-Blockers are recommended for left ventricular dysfunction even in the absence of symptoms (stage B patients) and in patients who appear compensated and stable while not using this medication, as these patients have a high likelihood of disease progression to symptomatic heart failure within 12 months. This therapy should be combined with other recommended heart failure pharmacologic therapy. Contraindications to β-blocker use include severe bradycardia or bronchospastic lung disease (Table 27.7).

For patients who are already using β-blocker therapy and who are hospitalized with acute decompensation of heart failure, β-blocker therapy should be continued unless hypotension, shock, severe bradycardia, or advanced heart block is present. In patients with a severe heart failure exacerbation, temporary reduction of the chronic dose by 50% can be considered. Discontinuation of this medication has been associated with higher short-term mortality and more frequent rehospitalizations for heart failure in observational studies.[103] In a meta-analysis of 6 trials that included 2554 patients, stopping β-blocker therapy was associated with an increased risk of in-hospital mortality (relative risk 3.72) and mortality at 6 months (relative risk 1.78)[104] (Fig. 27.9). If β-blockers are temporarily withheld, they should be reinstituted before discharge unless there are ongoing specific contraindications, as patients who are not using this drug at hospital discharge tend to not have it resumed at subsequent outpatient visits.[105,106]

TABLE 27.7 Treatment for Patients With Heart Failure and Low Ejection Fraction

Drug	Initial Dose	Target Maximal Dose
β-Blockers		
Metoprolol succinate	25 mg daily	200 mg daily
Carvedilol	3.125 mg bid	25 mg bid
Bisoprolol	1.25 mg daily	10 mg daily
ACE Inhibitors		
Captopril	6.25 mg tid	50 mg tid
Lisinopril	2.5 mg daily	40 mg daily
Enalapril	2.5 mg bid	20 mg bid
Ramipril	2.5 mg daily	10 mg daily
Angiotensin Receptor Blockers		
Losartan	25 mg daily	100 mg daily
Valsartan	40 mg bid or 80 mg daily	160 mg bid or 320 mg daily
Candesartan	4 mg daily	32 mg daily
Aldosterone Antagonists		
Spironolactone	12.5 mg daily	50 mg daily
Eplerenone	12.5 mg daily	50 mg daily
ARNI		
Valsartan/sacubitril	24/26 mg bid	97/103 mg daily
Hydralazine + isosorbide dinitrate	37.5 mg + 20 mg tid	75–100 mg + 40 mg tid
Selective Sinus Node Inhibitor		
Ivabradine	5 mg bid	7.5 mg bid

ACE, Angiotensin-converting enzyme; *ARNI*, angiotensin receptor blocker valsartan plus the neprilysin inhibitor sacubitril; *bid*, twice a day; *tid*, three times a day.

Angiotensin-Converting Enzyme Inhibitors

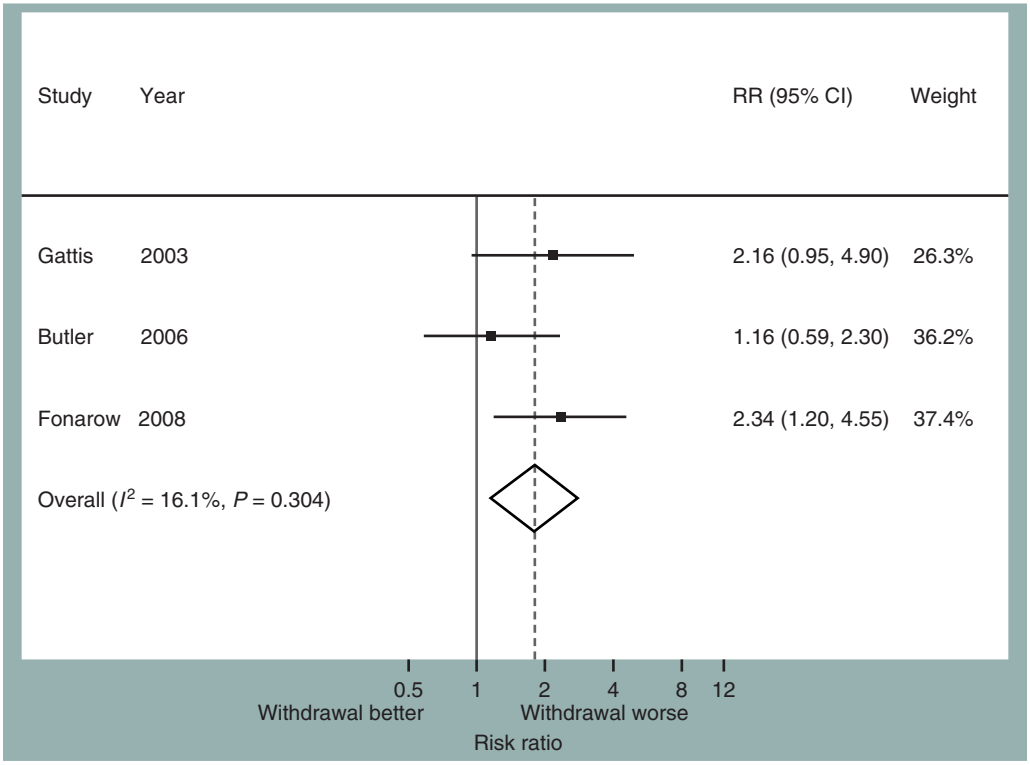
Many studies have shown benefits of ACE inhibitor therapy in post–myocardial infarction patients as well as patients with cardiomyopathy and heart failure. The Studies of Left Ventricular Dysfunction (SOLVD) trial using enalapril in patients with class II-III heart failure and LVEF below 35% showed a 10% relative risk reduction in mortality at 3.5 years.[107] Enalapril given to patients less ill, with asymptomatic left ventricular dysfunction (ejection fractions <35%) in the companion SOLVD trial showed a reduction in the clinical diagnosis of heart failure and a statistically significant reduction in heart failure hospitalizations at 3 years.[108] A meta-analysis performed of 32 trials, involving 7105 patients, using captopril, enalapril, ramipril, quinapril, or lisinopril found that ACE inhibitors reduce the risk of death and hospitalization caused by heart failure.[109] These results indicate that the positive effects of ACE inhibitors are likely to be a class effect and not specific to a particular agent (see Table 27.7).

Side effects of these agents include cough, WRF in patients with underlying renal disease or renal artery stenosis, angioneurotic edema, and hyperkalemia. The dose of ACE inhibitors should be increased as renal function and blood pressure allow. Studies have shown that medium doses of ACE inhibitors, compared with low doses, significantly reduce hospitalization rates for heart failure. However, higher doses given routinely do not significantly reduce cardiovascular events further.[110] Additional improvement in symptoms and mortality is thus best achieved by adding β-blocker and other heart failure therapy rather than increasing ACE inhibitors to the highest doses.[111]

Angiotensin Receptor Blockers

Angiotensin receptor blockers (ARBs) work to counter the effects of angiotensin II at the tissue level by blocking angiotensin II receptors. Multiple studies have shown benefits of these medications in patients with heart failure. Large numbers of patients in controlled trials have been studied, and these drugs have been as well studied as the ACE inhibitors. Trials included use of ARBs as a substitute for ACE inhibitors or in combination with ACE inhibitors and β-blockers.

The RESOLVD trial, using candesartan in heart failure patients with a mean ejection fraction of 27%, showed equivalent mortality rates and similar exercise tolerance and functional class to patients treated with enalapril at 3.5 years.[112] The Evaluation of Losartan in the Elderly II (ELITE II), a study using losartan compared with captopril in patients with ejection fractions less than 40%, showed no difference in mortality or congestive heart failure admissions. Losartan was better tolerated because of the lower incidence of problematic cough.[113] The Valsartan Heart Failure Trial (Val-HeFT



• **Fig. 27.9** Discontinuation of β-blockers was associated with a significantly increased risk of death. (From Prins KW, Neill JM, Tyler JO, et al. Effects of Beta-blocker withdrawal in acute decompensated heart failure: a systematic review and neta-analysis. *JACC Heart Fail.* 2015;3:647–653.)

2001) showed that valsartan as a substitute for ACE inhibitor therapy was associated with a relative 33% risk reduction in mortality when compared with placebo.[114] In the Candesartan in Heart failure-Assessment of moRtality and Morbidity (CHARM) study, candasartan was prescribed for patients with ejection fractions less than 40%. A 17.5% relative risk reduction in cardiovascular death and congestive heart failure admissions was seen when this ARB was used as a substitute for ACE inhibitors.[115] When candesartan was added to therapy with ACE inhibitors and β-blockers, a small 10% relative risk reduction in rehospitalizations was seen without improved mortality[116] (see Table 27.7).

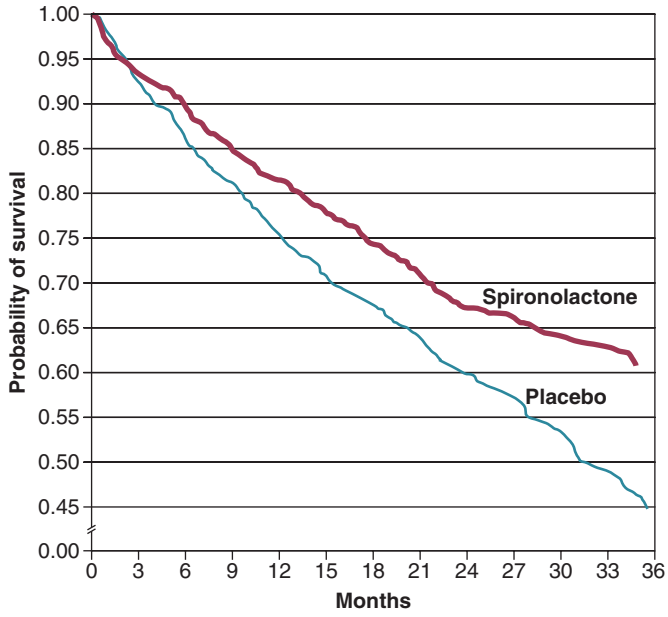
ARBs are an appropriate choice for patients who cannot be maintained with ACE inhibitors because of side effects such as cough. Patients with angioneurotic edema during ACE inhibitor therapy can often be successfully treated with ARBs without developing this complication.[117] Adding ARB therapy to ACE inhibitors and β-blockers is not generally recommended, and only small additional benefit may be achieved with a greater risk of renal dysfunction and hyperkalemia.

Combination Angiotensin Receptor-Neprilysin Inhibitor

Sacubitril is an inhibitor of the neutral peptidase called neprilysin, which degrades and inactivates the natriuretic peptides, bradykinin, and adrenomedullin. Inhibition of the actions of neprilysin results in greater activity of these vasoactive peptides, causing vasodilation and reduced sodium retention in patients with heart failure. A trial of 8442 patients with class II, III, and IV systolic heart failure with LVEF less than 40% compared enalapril with the combination of the ARB angiotensin receptor blocker valsartan plus the neprilysin inhibitor sacubitril (ARNI). Patients had to be able to tolerate the medication during a run-in phase before enrollment. After 27 months of therapy, treatment with ARNI was associated with an absolute reduction in the primary endpoint of all-cause mortality and hospitalization for heart failure by 4.7% (26.5% compared with 21.8%, $P < 0.001$). The rates of all-cause death and death from cardiovascular cause were also significantly reduced by ARNI.[118] In the updated ACC/AHA/Heart Failure Society of American 2016 Heart Failure Guidelines, use of ARNI in place of ACE inhibitors or ARBs was given a class I indication for patients with chronic systolic heart failure to reduce symptoms and improve mortality. A class I indication is also given for ARNI as a replacement of ACE inhibitor or ARB therapy in patients with chronic symptomatic systolic heart failure, functional class II or III, to further reduce morbidity and mortality. When switching from an ACE inhibitor to ARNI, a washout period of at least 36 hours is indicated to prevent the occurrence of angioedema, which is common with concomitant use of ARNI and ACE inhibitors. ARNI should not be administered to patients with a history of angioedema.[119] If heart failure biomarkers are being followed during ARNI therapy, NTpro-BNP should be used as BNP levels rise as a result of this therapy.

Aldosterone Antagonists

Aldosterone antagonists counteract the salt and water retention caused by aldosterone. In addition, aldosterone is considered to be involved in the progressive myocardial fibrosis that occurs as part of the remodeling process. In the Randomized Aldactone



No. at risk

Placebo	841	775	723	678	628	592	565	483	379	280	179	92	36
Spironolactone	822	766	739	698	669	639	608	526	419	316	193	122	43

• **Fig. 27.10** Kaplan-Meier analysis of the probability of survival among patients in the placebo group and patients in the spironolactone group, treated for class III to class IV heart failure and left ventricular dysfunction. The risk of death was 30% lower among patients in the spironolactone group than among patients in the placebo group ($P < 0.001$). (Redrawn from Pitt B, Zannad F, Remme W, et al The effect of spironolactone on morbidity and mortality in patients with severe heart failure. *N Engl J Med.* 1999;341:709–717.)

Evaluation Study (RALES), the aldosterone antagonist spironolactone was given to patients with severe, class III-IV heart failure with ejection fraction below 35%. A 24% relative risk reduction in mortality was seen in treated patients over 2 years, with reduced cardiovascular death and reduced need for rehospitalization[120] (Fig. 27.10). Thus these agents are effective at improving outcomes in patients with the most severe chronic heart failure. Aldosterone antagonists are contraindicated in patients with renal insufficiency and creatinine levels above 2.5 mg/dL (or GFR <30 mL/min) or in patients with baseline potassium levels above 5.0 mmol/L. Spironolactone should be initiated at low doses, such as 12.5 mg daily or every other day, especially in elderly patients.

An analysis of a large Canadian health care database showed a substantial increase in the frequency of spironolactone use after the RALES trial was published. This increased use was temporally associated with a twofold to threefold increased rate of hospitalization for hyperkalemia.[121] This highlights the need for careful monitoring of serum electrolytes after aldosterone blockers are initiated.

Eplerenone is an aldosterone blocker similar to spironolactone except that it has fewer antiandrogen effects and thus is free of the side effect of gynecomastia in men. It has been found effective in treating heart failure after AMI (see later text). It was subsequently tested and found to be very effective in patients with chronic heart failure. In the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) study, a placebo-controlled randomized study of 2737 patients with LVEF below 35% and class II heart failure, eplerenone was added to therapy with ACE inhibitors and β-blockers at a target dose of 25 to 50 mg daily. Mean follow-up was 21 months. Eplerenone reduced the occurrence of the primary endpoint of cardiovascular death plus hospitalization for heart failure from 25.9% to 18.3% ($P < 0.001$), with improvement in other clinical endpoints. Serious hyperkalemia that necessitated drug discontinuation occurred in only 1.1% of patients.[122]

Aldosterone blockade appears to result in beneficial effects in heart failure independent of its potassium-sparing and diuretic effects.[123] Aldosterone blockers are an important therapy for heart failure and should be routinely added to ACE inhibitors and β-blockers in patients with symptomatic heart failure with low LVEF (see Table 27.7).

Combination Hydralazine/Isosorbide Dinitrate

Combination therapy with the vasodilators hydralazine and isosorbide dinitrate (ISDN) was associated with improvement in mortality when compared with placebo in one study in the era preceding the advent of ACE inhibitors and β-blocker therapy for heart failure.[123] A retrospective analysis of this study suggested that African American patients may have benefited preferentially. To evaluate this finding prospectively, the African-American Heart Failure Trial (A-Heft) study enrolled more than 1000 self-described African American patients with class II-IV heart failure and ejection fractions below 45%. The use of the combination of hydralazine with ISDN, titrated to a dose of 75 mg hydralazine plus 40 mg ISDN given 3 times daily, was associated with a 40% relative risk reduction in mortality at 10 months and a 33% relative risk reduction in first hospitalization for heart failure. This therapy was added to treatment with β-blockers, ACE inhibitors, and spironolactone.[124] Hydralazine-ISDN is approved for treatment of African American patients with heart failure and left ventricular systolic dysfunction.

Digoxin

Digoxin is a relatively weak inotropic agent. It works by inhibiting the myocyte sarcolemmal sodium-potassium pump, leading to increased intracellular calcium levels and increased inotropy. It also has vagotonic effects.[81] The use of digoxin in heart failure was studied in large numbers of patients in sinus rhythm and LVEF <45% in the Digitalis Investigation Group (DIG) trial. A decreased

need for rehospitalization for heart failure was seen with this therapy. However, there was no improvement in overall mortality.[125] A post hoc analysis of this data concluded that patients with lower serum digoxin levels (0.5–0.9 ng/dL) did have lower mortality and lower rates of heart failure hospitalization when compared with those with levels above 1.2 ng/mL.[126] Serum digoxin levels should be obtained more than 6 hours after a dose. It is hypothesized that lower digoxin doses may have beneficial neurohormonal (sympatholytic) effects without the detrimental effects of inotropic stimulation. Another post hoc analysis of the DIG trial results suggested that women (who made up 22% of the study population) assigned to treatment with digoxin had a higher cardiovascular and heart failure mortality compared to those assigned to placebo.[127]

Digoxin is indicated only for patients with symptomatic heart failure, stages C and D, to reduce the rate of hospitalization and not to improve mortality.[5] It is also useful in heart failure patients with atrial fibrillation to help control the ventricular rate. Digoxin is not useful in the setting of acute heart failure, and it should be avoided in patients with hypokalemia, bradycardia, or heart block.

I_f Channel Blocker

Ivabradine is a selective sinus node inhibitor that works via the I_f channel to slow heart rate. It has no effect on atrioventricular node conduction or myocardial contractility. Epidemiologic studies have shown that in patients with chronic heart failure a higher resting heart rate is associated with increased mortality. Therefore ivabradine was used to treat 6505 patients with chronic heart failure, mostly functional class II and III, with LVEF below 35% and in sinus rhythm with resting heart rate above 70 beats/min. This therapy was in addition to β-blockers and RAAS inhibition. At 2 years, treatment with ivabradine significantly reduced heart failure hospitalizations (from 21% to 16%), with a slight reduction in heart failure deaths (5% to 3%, not statistically significant). Average heart rate reduction with this medication was 15 beats/min. These results support the hypothesis that reducing resting heart rate is an important therapeutic goal in patients with chronic systolic heart failure.[128] The 2016 ACC Foundation/AHA guidelines give a IIa indication for the use of ivabradine to reduce heart failure hospitalizations for patients with symptomatic stable chronic systolic heart failure.[119]

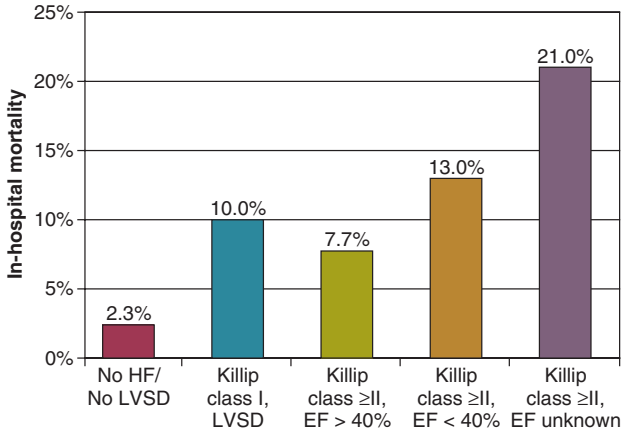
Acute Coronary Syndromes and Acute Heart Failure: Special Considerations

Coronary artery disease can lead to acute heart failure via several different mechanisms. (1) Acute ischemia leads to impaired myocardial relaxation, acute diastolic dysfunction, and sudden elevation of left ventricular filling pressure. (2) Acute ischemia can cause "stunning," defined as myocardial dysfunction caused by severe, prolonged ischemia without infarction. After normal blood flow is restored, normal function recovers in days or weeks. (3) AMI and necrosis lead to acute left ventricular systolic dysfunction owing to loss of contractile tissue. (4) Mechanical complications of AMI include acute, severe mitral regurgitation and papillary muscle ischemia, infarction, and rupture. Another mechanical complication is infarction and rupture of the interventricular septum with acute left-to-right shunting. (5) AMI involving the right ventricle causes acute right ventricular heart failure. (6) Chronic ischemia can cause myocardial dysfunction that can be reversed with revascularization, a process termed "hibernation."

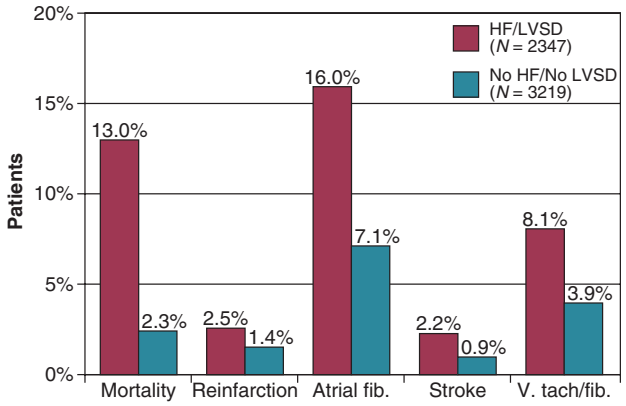
Acute myocardial ischemia is often superimposed on a ventricle impaired by chronic ischemia and infarction, so that multiple mechanisms are often present in patients with chronic coronary disease presenting with acute heart failure.[129] Acute heart failure may develop even without evidence for significant left ventricular systolic dysfunction on echocardiography and without acute necrosis documented by myocardial enzyme determinations. With effective therapy, the majority of patients with heart failure owing to an acute coronary syndrome do not have left ventricular systolic dysfunction at discharge, and only a minority will develop chronic heart failure.

In a European observational study of acute heart failure complicating acute coronary syndromes (ACS), in patients without previous history of heart failure, 13% of ACS patients presented with heart failure on admission.[130] Heart failure developed later during hospitalization in an additional 5.6% of patients. The incidence of acute heart failure of 15.6% was identical in patients with ST-segment elevation myocardial infarction (STEMI) and non–STEMI. Eight percent of patients with unstable angina developed heart failure.

Acute heart failure accompanying ACS identifies patients who are at high risk for adverse outcome. In-hospital mortality and postdischarge morbidity and mortality are worse. In a large registry of patients with AMI, event rates, therapies, and outcomes between 1996 and 2008 were analyzed. The overall incidence of heart failure in ACS declined from 46% in 1996 to 28% in 2008. In the most recent years, incidence of heart failure was identical if patients presented with STEMI or nSTEMI. In 2008, in-hospital mortality and 30-day mortality were 17% and 31%, respectively. 30% of these patients had normal LVEF. Women represented about 46% of the AMI with heart failure population, a higher proportion than in AMI without heart failure. Risk factors for developing heart failure included female gender, older age, a history of prior myocardial infarction, diabetes, hypertension, and the presence of chronic heart failure. In-hospital mortality rate for these patients was 13%, versus 2.3% for patients with AMI but without heart failure or left ventricular dysfunction (Fig. 27.11). Mortality rates



• **Fig. 27.11** In-hospital mortality rate in patients admitted with acute myocardial infarction, according to the presence of heart failure and left ventricular ejection fraction. *EF,* Ejection fraction; *HF,* heart failure; *Killip class I,* patients without evidence of heart failure on physical examination; *Killip class II,* patients with evidence of heart failure on physical examination; *LVSD,* left ventricular systolic dysfunction. (Redrawn from Velazquez EJ, Francis GS, Armstrong PW, et al. An international perspective on heart failure and left ventricular systolic dysfunction complicating myocardial infarction: the VALIANT Registry. *Eur Heart J.* 2004;25:1911–1919.)



• **Fig. 27.12** In-hospital clinical events among patients with and without heart failure *(HF)* or left ventricular systolic dysfunction *(LVSD)* ($P < 0.001$ for all events except reinfarction). *Atrial fib.,* Atrial fibrillation; *V. tach/fib,* ventricular tachycardia/ventricular fibrillation. (Redrawn from Velazquez EJ, Francis GS, Armstrong PW, et al. remain three times higher during the first year in the heart failure group. Other complications also occurred more commonly in these patients, including atrial and ventricular arrhythmias, reinfarction, and stroke[131] (Fig. 27.12).

Therefore early aggressive pharmacologic therapies are necessary, including intravenous diuretics, intravenous nitroglycerin, and β-blockers. Urgent cardiac catheterization ("early invasive" approach) is usually indicated. Intraaortic balloon counterpulsation or other MCS should be used in patients with signs and symptoms of continued ischemia despite aggressive medical therapies or who have cardiogenic shock. In patients with acute heart failure owing to AMI, rapid reperfusion is the cornerstone of therapy. This may be achieved with thrombolytic therapy (in the minority of patients with STEMI), percutaneous coronary intervention (PCI), or urgent coronary artery bypass surgery. Percutaneous or surgical reperfusion should always be considered when coronary anatomy is appropriate. In the Global Registry of Acute Coronary Events (GRACE) study, revascularization therapies were associated with lower mortality in patients with ACS and acute heart failure.[130]

In patients in whom heart failure develops or who have significant left ventricular systolic dysfunction after myocardial infarction, several medications have been shown in large placebo-controlled randomized studies to improve mortality and reduce the risk of repeat hospitalizations. β-Blockers should be part of standard post–myocardial infarction heart failure therapy. In the Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction (CAPRICORN) study, the use of carvedilol led to a significant reduction in all cause and cardiovascular mortality.[132] The SAVE study was the first trial to show that the use of an ACE inhibitor (captopril) was beneficial in post–myocardial infarction patients with ejection fraction below 40%.[133] There was a 5% absolute mortality reduction after 42 months of follow-up. In the Acute Infarction Ramipril Efficacy (AIRE) trial, treatment with the ACE inhibitor Ramipril, started 3 to 10 days after myocardial infarction in patients with heart failure, resulted in a significant mortality benefit at an average of 15 months of follow-up.[134] In the Valsartan in Acute Myocardial Infarction (VALIANT) study, the ARB valsartan was as effective as an ACE inhibitor in improving survival and reducing cardiovascular morbidity in patients with left ventricular dysfunction after myocardial infarction.[135] Therefore β-blockers and ACE inhibitors should be started early and continued over the long term in patients with reduced LVEF after AMI. Angiotensin receptor blockers are recommended in patients who are intolerant to ACE inhibitors.

Aldosterone blockers have also been shown to be effective in improving prognosis in patients with heart failure or left ventricular dysfunction after myocardial infarction and are recommended for these patients. The Eplerenone Post–Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) showed that eplerenone significantly reduced all-cause mortality and repeat hospitalizations at 16 months after AMI.[136] Reduction in mortality and sudden cardiac death was noted as early as 30 days after initiation of eplerenone.[137]

In the SWEDEHEART (Swedish Web-System for Enhancement and Development of Evidence-Based Care in Heart Disease Evaluated According to Recommended Therapy) data, the use of dual antiplatelet therapy, β-blockers, ACE inhibitors, and statins all increased between 1996 and 2008. In the latter years of the analysis, more than 90% of revascularizations were performed by PCI. More frequent utilization of these effective therapies resulted in improved outcomes, with in-hospital mortality declining from 19% in 1996 to 13% in 2008, with 1-year mortality also declining from 36% to 31%.[131]

Heart Failure With Preserved Left Ventricular Ejection Fraction (Diastolic Heart Failure)

Heart failure can occur in patients with normal or relatively normal left ventricular systolic function. HFpEF is diagnosed when patients present with typical signs and symptoms of heart failure, with LVEF above 50%, and evidence of abnormal diastolic function on Doppler echocardiography or cardiac catheterization. Some studies of HFpEF have included patients with LVEF between 40% and 50%. These patients are now considered a "borderline group" between heart failure with reduced and normal ejection fraction. HFpEF is common, occurring in approximately 50% of patients hospitalized with acute heart failure. Reported prevalence rates vary and are related to the demographics of study populations, including age, inpatient and/or outpatient status, the proportion of African Americans and females, and whether patients were evaluated at an academic referral center or in a community-based setting. The incidence appears to be increasing at a rate of approximately 1% per year.[34,138]

Compared with HFrEF, patients with HFpEF tend to be older, are more often female; have hypertension, atrial fibrillation, chronic kidney disease, obesity, and obstructive sleep apnea more often; and have significant coronary artery disease less often.[1,139] In a meta-analysis of 31 population-based studies in Europe that analyzed 41,972 patients, the average age of patients with HFpEF was 71 years compared with 66 years in HFrEF patients. Fifty percent of patients were women (compared with 28% with HFrEF), hypertension was present in 51%, and ischemic heart disease in 43% (41% and 59% in HFrEF, respectively).[140] Other studies have estimated hypertension prevalence in 60% to 89% of patients with HFpEF.[138,141–144]

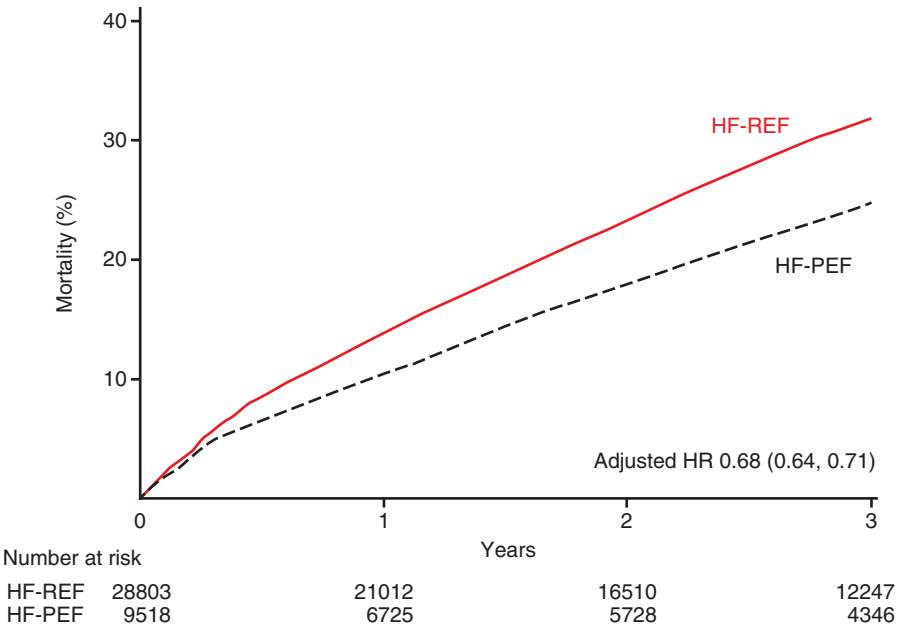
The traditional view of pathophysiology in HFpEF focused on increased left wall thickness and abnormal left ventricular geometry with increased left ventricular mass/volume ratio. Diastolic performance abnormalities included impaired ventricular filling owing

to increased wall stiffness with reduced compliance and abnormal relaxation. Myocyte hypertrophy, myocardial fibrosis, and increased collagen in extracellular matrix were responsible for the physiologic abnormalities. The hemodynamic and anatomic abnormalities include increased left ventricular end diastolic pressure, increased left atrial pressure, left atrial dilation, pulmonary venous hypertension, and pulmonary congestion.[115,117] Some patients then develop chronic pulmonary hypertension, elevated right ventricular diastolic pressure, and right atrial dilation. Patients with HFpEF usually demonstrate normal indices of left ventricular systolic performance and contractility at rest, but often the ejection fraction does not increase appropriately during exercise.[34,138,140,145,146]

A newer view of the pathophysiology of HFpEF involves systemic inflammation, coronary artery endothelial dysfunction, and primary renal abnormalities. Evidence for this includes higher levels of plasma biomarkers of inflammation in patients with HFpEF compared with HFrEF.[138] Systemic inflammation may result in pulmonary vasoconstriction and abnormal skeletal muscle oxygen utilization during exercise, and decreased renal excretion of sodium leading to plasma volume expansion. Patients with HFpEF are more sensitive to changes in volume, as heart failure is more likely to occur with volume expansion and hypotension more likely with volume contraction. Systemic inflammation may also cause oxidative stress, leading to coronary microvascular dysfunction and myocyte hypertrophy, increased numbers of myofibroblasts, increased collagen production, increased left ventricular wall stiffness, and left ventricular remodeling.[138,145]

Patients who present with heart failure owing to HFpEF have a history and physical examination indistinguishable from patients with systolic heart failure. Presenting blood pressure may be higher, and acute "flash" pulmonary edema often occurs. Common exacerbating factors include severe hypertension, medication noncompliance, myocardial ischemia, renal dysfunction, and valve dysfunction. In one study, no precipitating factors could be identified in 50% of these patients.[147] Serum BNP levels are elevated but tend to be lower than in patients with HFrEF, reflecting lower left ventricular wall stress. Up to 30% of patients with symptomatic HFpEF may have normal BNP levels, related to obesity or the presence of symptoms occurring only during exercise.[34] Diagnosis is made more difficult by the frequent coexistence of obesity and deconditioning. Common ECG abnormalities in HFpEF include atrial fibrillation, left atrial abnormality, and left ventricular hypertrophy, but these are not specific for HFpEF. Echocardiography is invaluable for determining LVEF and assessing Doppler parameters of diastolic function. Exercise testing is often helpful in the evaluation exercise tolerance and exercise-related symptoms, blood pressure response to exercise, and inducible ischemia. Invasive hemodynamic assessment is often invaluable in making the diagnosis in many patients when clinical signs are indeterminate. However, some hemodynamic findings may be misleading, as pulmonary hypertension may be due to elevated left atrial pressure or fixed pulmonary venous hypertension, and large v waves in the pulmonary capillary tracing may be due to abnormal left atrial compliance rather than severe mitral regurgitation.[34]

The prognosis of patients with HFpEF is serious. Mortality is probably not as poor as in patients with HFrEF, although one study found similar adjusted and nonadjusted mortality rates at 30 days and 1 year for hospitalized patients with heart failure and LVEF below 40% or above 50%.[148] A large European meta-analysis showed a 32% lower risk of death over 3 years in patients with HFpEF compared with HFrEF: 121 of 1000 patient-years compared with 141 of 100 patient-years (Fig. 27.13).[140] In-hospital mortality is around 4% or four times age-matched controls.[120,141,149] Annual mortality is variable and likely depends on the frequency of comorbid conditions in the cohort of patients studied; it has been reported in the range of 1.3% to 17.5%.[150] Readmission rates are



• **Fig. 27.13** Mortality for patients with heart failure with preserved left ventricular ejection fraction *(HF-PEF)* and heart failure with low left ventricular ejection fraction *(HF-REF)*, adjusted for age, gender, etiology of heart failure, hypertension, diabetes, and atrial fibrillation. *HF,* Heart failure; *HR,* heart rate. (From Meta-analysis Global Group in Chronic Heart Failure (MAGGIC). The survival of patients with heart failure with preserved or reduced left ventricular ejection fraction: an individual patient data meta-analysis. *Eur Heart J.* 2012;33:1750–1757.)

similar to those with HFrEF: as high as 50% at 1 year. Factors that identify patients with a worse prognosis include renal dysfunction, worse functional class, male gender, and advanced age.[149] Patients with HFpEF and hypertension have a worse prognosis than those with hypertension without heart failure.[146]

Unlike systolic heart failure, there are no placebo-controlled randomized studies that have demonstrated effective therapy for diastolic heart failure. The 2013 Guidelines for Treatment of Heart Failure give class I recommendations to controlling hypertension and using diuretics to control symptoms of fluid overload. A class IIa recommendation is revascularization for patients with ischemia as the major cause of HFpEF.[5]

The evidence base includes the Candesartan Cilexetil in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM)-Preserved Study, which compared the use of the ARB candesartan with placebo for treating HFpEF. After an average 3-year follow-up, the combination of death from cardiovascular cause or admission for heart failure was similar in the two groups. There was a modest impact on preventing hospitalizations due to heart failure in patients treated with candesartan.[151] The Irbesartan in Heart Failure and Preserved Ejection Fraction (I-PRESERVE) trial testing irbesartan in more than 4000 patients with heart failure and LVEF above 45% showed no beneficial effect on mortality or heart failure rehospitalizations.[152] The Treatment of Preserved Cardiac Function Heart Failure With an Aldosterone Antagonist (TOPCAT) trial evaluated treatment with spironolactone in patients with heart failure and LVEF above 45%, with follow-up for 3.3 years. There was no benefit in the primary composite endpoint of cardiovascular death, aborted cardiac arrest, or hospital admission for heart failure. There was a statistically significant benefit for spironolactone in the isolated endpoint of heart failure hospitalizations.[153] A post hoc analysis of the TOPCAT data analyzing only those patients enrolled in the Americas (the United States, Brazil, Argentina, and Canada) showed a fourfold difference compared with patients enrolled in Russia and Asian Georgia, with the rates of the primary outcome significantly improved by spironolactone in the Americas.[154] The prognostic effect of aldosterone blockade in HFpEF is still debated. Another trial showed no improvement in exercise tolerance or quality of life in HFpEF patients treated with isosorbide mononitrate.[155]

Several basic recommendations are widely agreed on. Medical therapy of HFpEF is primarily focused on alleviating symptoms. Diuretics are effective at improving pulmonary congestion. Lower doses of diuretics are generally used, as usual doses often lead to volume depletion and hypotension. Effective treatment of underlying conditions, including hypertension, diabetes mellitus, and coronary artery disease, is essential. Control of elevated blood glucose may help retard myocardial fibrosis by lessening cross-linking of myocardial collagen. Control of myocardial ischemia is important, although there are no convincing controlled data that revascularization will reliably prevent recurrences of diastolic heart failure. Maintenance of sinus rhythm and avoidance of tachycardia are also important.

β-Blockers can be useful to reduce heart rate and improve diastolic filling time. They are also effective medications for hypertension and coronary ischemia. Similarly, calcium channel blockers may improve symptoms of diastolic heart failure by treating hypertension and ischemia and improving diastolic relaxation. The use of ACE inhibitors and ARBs is indicated to lower blood pressure, reduce myocardial fibrosis, and block the adverse effects of the activation of the renin-angiotensin system. In a retrospective study of patients hospitalized with heart failure and ejection fraction below 40%, patients who were prescribed an ACE inhibitor had better quality-of-life scores, improved functional class, and lower adjusted mortality.[143] The aldosterone antagonists spironolactone and eplerenone can be used to treat hypertension and they may reduce left ventricular fibrosis (see previous text). Weight loss in obese patients and treatment of obstructive sleep apnea are important. Therapy with positive inotropic drugs or digoxin is not useful in patients with diastolic heart failure (Box 27.5).

• BOX 27.5 Treatment of Heart Failure With Preserved Left Ventricular Ejection Fraction

- Effective control of systemic hypertension
- Diuretics should be used for decongestion and symptom relief
- Evaluate for and treat myocardial ischemia, with revascularization when indicated
- Control atrial fibrillation
- Consider spironolactone use

Myocarditis and Acute Heart Failure

Myocarditis is defined as inflammation of heart muscle and is an uncommon cause of acute heart failure. Although most patients with acute myocarditis are not critically ill and make a complete recovery, a minority can develop severe left ventricular dysfunction, acute heart failure, and even cardiogenic shock.[156,157] Viral myocarditis may also cause chronic activation of immune mechanisms that over time may lead to dilated cardiomyopathy and chronic heart failure.

In most patients with myocarditis a specific cause is not found, but lymphocytic inflammation owing to a viral etiology is assumed in most cases. Coxsackie B enterovirus was considered the most common cause up to the 1990s, but human herpesvirus 6, cytomegalovirus, and parvovirus B19 have been implicated as causative agents more frequently over the past 20 years.[158] Other viral causes include influenza, Epstein-Barr virus, hepatitis C, and herpes simplex 1 and 2. The protozoa *Trypanosoma cruzi* is the cause of Chagas disease, a form of myocarditis that can lead to chronic heart failure, endemic in Central and South America. Another cause of myocarditis is autoimmune disease, including myocarditis associated with progressive systemic sclerosis, systemic lupus erythematosus, and polymyositis. Other types of myocardial inflammation are characterized by giant cells, in myocarditis complicating giant cell arteritis or isolated giant cell myocarditis, or eosinophils, seen in hypersensitivity or eosinophilic myocarditis, an uncommon entity caused by a systemic allergic reaction.

Myocarditis is a diagnosis made on clinical grounds and should be suspected in patients who present with new-onset heart failure, with or without antecedent flulike symptoms. Chest pain is often but not always present. Laboratory abnormalities include elevated leukocyte count, elevated sedimentation rate, and elevated troponin levels; sensitivity of troponin I in myocarditis is reported as 34% to 53% with specificity of 89%.[159,160] ECG changes suggestive of myocardial ischemia or infarction may be seen but are not always present. The presence of severe coronary disease often needs to be specifically excluded.

Pathologic specimens show both infiltration with inflammatory cells and myocyte necrosis. Endomyocardial biopsy (EMB) has been the traditional method used to diagnose acute myocarditis

but it has significant limitations. EMB is insensitive for diagnosis and a high degree of interobserver diagnostic variability has also been reported. In patients in whom myocarditis was suspected on clinical grounds, only 10% to 67% of patients had positive biopsies in reported series.[156,157] An AHA/ACC/European Society of Cardiology scientific statement offered recommendations concerning the appropriate use of EMB based on patients' clinical presentations. EMB was deemed useful, beneficial, and effective (class I indication) in patients with acute heart failure with severe heart failure or arrhythmias after other causes are excluded. EMB is necessary to diagnose giant cell myocarditis and eosinophilic myocarditis, as immunosuppressive therapy is mandated in these conditions. A class I indication for EMB was also given in new-onset, subacute heart failure with duration of illness of 2 weeks to 3 months, in those whose condition fails to improve with medical therapy for heart failure or who demonstrate severe ventricular arrhythmia or advanced heart block.[161] EMB should be considered if causes such as sarcoidosis or autoimmune disease are suspected.

Cardiac magnetic resonance has more recently been shown to be an important tool in the diagnosis of myocarditis.[162,163] This technique offers a noninvasive means to make this diagnosis but may be difficult to use in critically ill patients. Diagnostic criteria include (1) focal or diffuse myocardial edema in T2-weighted images; (2) early gadolinium enhancement on T1 imaging indicating inflammation and cell damage; and (3) late gadolinium enhancement in subepicardial or midmyocardial areas indicating noncoronary-related necrosis and fibrosis. Myocardial edema may be subepicardial, transmural, or global and is not always associated with late gadolinium enhancement. Signs of inflammation may be diffuse or patchy and are often confined to the lateral free wall of the left ventricle or the base of the interventricular septum (Fig. 27.14). Diagnostic accuracy of cardiac magnetic resonance is reported at 78% when two or three criteria are present and 68% when only late gadolinium enhancement is present.[164,165]

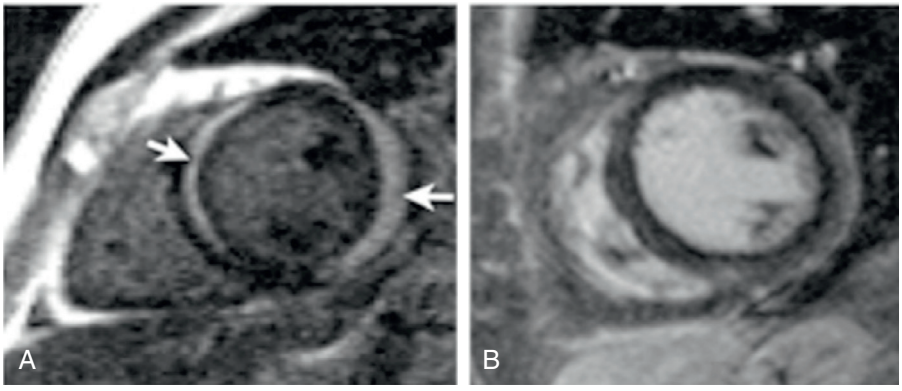
Pharmacologic management of heart failure caused by myocarditis is similar to the management of heart failure from other causes. Diuretics, ACE inhibitors, β-blockers, and aldosterone blockade should be prescribed. Many patients experience significant improvement in left ventricular function during the first 6 months after diagnosis. NSAIDs should be avoided because they may worsen myocarditis.[166] The use of immunosuppressive drugs for acute myocarditis is controversial; there is no evidence that *routine* treatment with immunosuppression is beneficial. It should be considered in patients with acute, severe heart failure or whose condition continues to worsen despite heart failure therapy. Immunosuppressive therapy should be also used in patients with myocarditis associated with autoimmune diseases. EMB should be performed and should show active inflammation and necrosis prior to initiating immunosuppressive therapy.

Fulminant Myocarditis

Myocarditis with acute, severe heart failure and cardiogenic shock is termed fulminant myocarditis. Most often there is a history of fever and other symptoms of a viral illness for several weeks, and with a distinct time of onset of heart failure symptoms. This presentation is contrasted with that of other patients with acute, severe myocarditis who have acute heart failure without cardiogenic shock with a less distinct time of onset of heart failure symptoms. Patients with fulminant myocarditis are critically ill and require intensive pharmacologic support with vasodilators and inotropes. In the most critically ill patients, mechanical circulatory may be necessary to use as a bridge to recovery or to cardiac transplantation. When supported aggressively, many patients recover fully with normal ventricular function. Therefore aggressive supportive therapy is indicated, even in gravely ill patients.[167]

Device Therapy for Heart Failure and Ventricular Tachyarrhythmias: Implanted Cardioverter Defibrillator and Cardiac Resynchronization Therapy

Sudden death is a frequent occurrence in heart failure patients, especially in patients with coronary artery disease. Sudden death is presumed to be due to sustained ventricular tachycardia or ventricular fibrillation in the majority of cases. It is estimated that 30% of patients with heart failure and ejection fractions below 30% die suddenly. In patients with heart failure and significant ventricular tachyarrhythmias, treatment with antiarrhythmic drug therapy alone is not recommended as this has been shown to be ineffective therapy (see later text). Evaluation and correction of hypoxia, electrolyte abnormalities (hypokalemia, hypomagnesemia), and ischemia is the initial approach. The medications recommended for systolic heart failure have been shown to reduce the incidence



• **Fig. 27.14** A, Subepicardial enhancement of lateral and midwall enhancement of the septal wall *(arrows)*. B, Diffuse subepicardial enhancement. (From Friedrich MG, Sechtem U, Shulz-Menger J, et al. Cardiovascular magnetic resonance in myocarditis: a JACC white paper. *J Am Coll Cardiol.* 2009;53:1475–1487.)

of sudden death. However, prophylactic therapy with antiarrhythmic drugs therapy aimed at preventing sudden arrhythmic death has been shown to be ineffective and may even worsen prognosis. In the Cardiac Arrhythmia Suppression Trial (CAST), patients with coronary artery disease, a history of myocardial infarction, and frequent premature ventricular contractions on baseline Holter monitoring had an increased mortality when treated with the antiarrhythmic drugs encainide or flecainide, despite effective suppression of the occurrence of arrhythmia on follow-up Holter monitoring.[168] This adverse effect on mortality is presumably due to the potential for these drugs to actually worsen arrhythmia ("proarrhythmia"), especially in patients with left ventricular dysfunction. Therefore class IA and IC antiarrhythmic drugs quinidine, procainamide, disopyramide, flecainide, and propafenone are not useful for prevention of sudden death and are contraindicated in patients with heart failure.

Amiodarone was also studied as primary prevention of sudden death, as the propensity for proarrhythmia is less than with type I antiarrhythmics. Six-hundred seventy-five patients with heart failure and ejection fractions below 40% were randomly assigned to treatment with amiodarone or placebo, with no survival difference between the two groups at 45 months.[169] There was a trend toward reducing mortality with amiodarone in patients with nonischemic cardiomyopathy. In another study, 1486 post–myocardial infarction patients with ejection fractions below 40% were randomly assigned to amiodarone or placebo with no difference in mortality in 21 months, although there was a suggestion of a reduction in deaths caused by arrhythmia.[170] Unlike the findings in CAST, there was no observed increased risk of death with amiodarone. Thus this medication is not helpful in the prevention of sudden cardiac death, but it is considered safe for treatment of supraventricular arrhythmias in heart failure patients.

Implanted Cardioverter Defibrillator Therapy

The implanted cardioverter defibrillator (ICD) is standard therapy for both primary and secondary prevention of life-threatening ventricular arrhythmias and sudden cardiac death in patients with severe left ventricular systolic dysfunction. This therapy is supported by the results of several large, randomized controlled trials. The use of an ICD was compared to antiarrhythmic drugs for secondary prevention of sudden cardiac death in the Antiarrhythmics Versus Implantable Defibrillators (AVID) study. These patients had been resuscitated from cardiac arrest or survived ventricular tachycardia associated with syncope and had LVEFs below 40%. A total of 1016 patients were randomly assigned to receive an ICD or antiarrhythmic drugs (>90% received amiodarone). There was a statistically improved survival with ICD therapy at 1, 2, and 3 years of follow-up.[171] Published guidelines recommend ICDs as first-line therapy in patients with ischemic and nonischemic cardiomyopathy who have survived a cardiac arrest or an episode of sustained ventricular tachycardia (secondary prevention).[5]

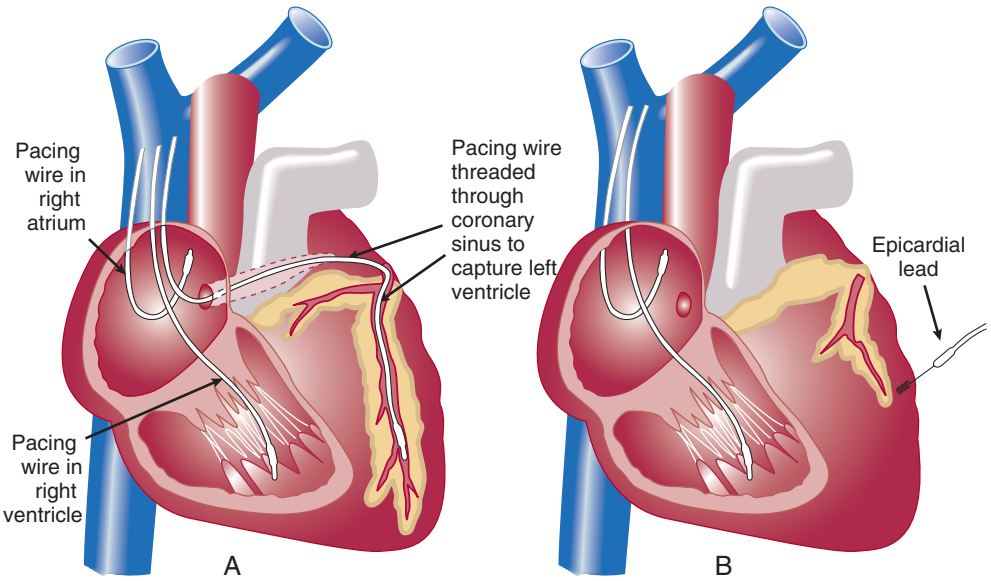
ICD therapy is also recommended as primary prevention of sudden cardiac death in patients with systolic heart failure owing to coronary heart disease and in patients with nonischemic cardiomyopathy. In the Multicenter Automatic Defibrillator Implantation Trial I (MADIT I), patients who had had a myocardial infarction, with ejection fractions below 35%, and asymptomatic nonsustained ventricular tachycardia on monitoring, were studied with electrophysiologic testing; if inducible ventricular tachycardia was present and not suppressed with antiarrhythmic therapy, then patients were enrolled and randomly assigned to ICD versus medical therapy (standard medical therapy with or without amiodarone). At 2 years of follow-up, total mortality was significantly reduced from 39% in the medically treated group to 15% in the ICD group.[172] In the Multicenter Unsustained Tachycardia Trial (MUSTT), a similar cohort of patients showed an improvement in 5-year mortality from 55% in the medication-only group to 24% in patients treated with ICDs.[173] In MADIT II, the patient population was extended to include patients with a history of myocardial infarction and ejection fractions below than 30%. Importantly, in this study, neither ventricular arrhythmias seen on monitoring nor induced at electrophysiologic study were necessary for inclusion. A statistically significant improvement in total mortality was seen in patients treated with ICDs, from 19.8% to 14.2% at 4 years.[174] Class IV heart failure patients were not included in these studies.

The Sudden Cardiac-Death-Heart Failure Trial (SCD-HeFT) enrolled patients with functional class II and III heart failure with LVEFs below 35%. This study differed from MADIT I and II in that a greater number of patients (48%) had nonischemic cardiomyopathy. Primary prevention of sudden cardiac death was compared among standard heart failure pharmacologic therapy, standard therapy combined with amiodarone, and standard therapy plus an ICD. After a mean follow-up of 45.5 months, mortality was improved from 29% in the medical group and 28% in the amiodarone group to 22% in the ICD group, which was statistically significant. This improvement was particularly notable in patients with class II heart failure.[175] Benefits of ICD therapy were seen in patients with both ischemic and nonischemic cardiomyopathy. A meta-analysis of all studies in which ICDs were used as primary prevention in patients with nonischemic cardiomyopathy indicated a statistically significant 31% relative risk reduction in favor of ICDs.[176] A more recent European study evaluated ICD therapy in 1116 patients with heart failure owing to nonischemic cardiomyopathy. Compared with the initial trials evaluating ICDs, patients enrolled in this trial had more modern heart failure medical therapy and 58% had cardiac resynchronization therapy (see later text). At an average follow-up of 67 months, there was no difference in all-cause mortality in the ICD group versus the control group (21.6% vs. 23.4%, $P = 0.28$). The incidence of sudden cardiac death was significantly decreased from 8.2% in the non-ICD group to 4.3% in the ICD group. A subgroup analysis suggested benefit from ICD therapy in younger patients (<age 59 years).[177]

The guideline-approved use of ICD therapy for prevention of sudden cardiac death includes patients with LVEF below 35%, caused by ischemic as well as nonischemic cardiomyopathy, with functional class II–III heart failure, at least 40 days after myocardial infarction, who have anticipated survival of longer than 1 year.[5]

Cardiac Resynchronization Therapy

In many patients with heart failure, there is a lack of coordination of systolic motion of the interventricular septum and left ventricular free wall, termed dyssynchrony. This often coexists with His-Purkinje conduction system disease, with QRS prolongation on ECG.[178] A left bundle branch block (LBBB) pattern with long QRS duration is associated with an increase in all-cause mortality in patients with heart failure. Pacemaker therapies have been developed to correct left ventricular dyssynchrony. This is termed biventricular pacing or cardiac resynchronization therapy (CRT). Standard transvenous pacing leads are placed in the right atrium (in the absence of chronic atrial fibrillation) and right ventricle. The left ventricular free wall is paced via a third electrode passed



• **Fig. 27.15.** A, Placement of pacing wires in biventricular pacing. B, Lack of coronary sinus venous branch necessitates epicardial placement of third lead via minimally invasive surgical procedure.

transvenously via the coronary sinus into an epicardial lateral cardiac vein. Alternatively, a left ventricular lead can be placed directly on the epicardium of the lateral wall of the left ventricle via thoracoscopy. The pacemaker is programmed to coordinate timing of septal stimulation via the right ventricular lead with left ventricular lateral wall stimulation via the coronary sinus lead (Fig. 27.15).[178,179]

In the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) trial, 453 patients with LVEF below 35%, class III-IV heart failure, and QRS duration longer than 130 msec were treated with standard medical therapy or resynchronization therapy plus medical therapy. At 6 months of follow-up, CRT resulted in a statistically significant improvement in 6-minute walking distance, quality-of-life score, and functional class, with fewer hospitalizations for recurrent heart failure.[178] In the Cardiac Resynchronization in Heart Failure (CARE-HF) study, CRT (without ICD) was evaluated in 813 patients with class III–IV heart failure caused by left ventricular systolic dysfunction, with ejection fraction below 35% and QRS duration longer than150 msec or QRS duration longer than 120 msec with signs of dyssynchrony on echocardiography. Mean follow-up was 29.4 months. The primary endpoint of all-cause mortality plus unplanned hospitalization for cardiovascular causes was reduced from 55% in medically treated patients to 39% with CRT ($P < 0.001$). All-cause mortality was reduced from 30% to 20% with CRT ($P < 0.002$). Quality-of-life scores improved and ejection fractions improved.[180] A meta-analysis of three major resynchronization trials in 1634 patients concluded that chronic resynchronization therapy was associated with a statistically significant 51% reduction in death from progressive heart failure.[181] Thus CRT can reduce mortality as well as improve symptoms in patients with chronic heart failure. The success rate of left ventricular lead placement is high. There is a low incidence of serious complications of device implantation including coronary sinus dissection or perforation.

Devices combining biventricular pacing and ICD capability were evaluated in patients with systolic heart failure and low ejection fraction. The rationale is to decrease morbidity and mortality associated with progressive heart failure as well as to decrease mortality associated with sudden life-threatening ventricular arrhythmia. Biventricular pacing does not interfere with appropriate ICD detection and termination of ventricular arrhythmias.[182] The Comparison of Medical Therapy, Pacing, and Defibrillation in Chronic Heart Failure (COMPANION) trial enrolled 1520 patients with advanced heart failure, functional class III-IV, in sinus rhythm, with QRS duration longer than 120 msec. Therapies compared were best pharmacologic heart failure therapy, best therapy with CRT, and best therapy with combination CRT plus ICD. The primary endpoints of all-cause death or hospitalization for any cause, followed over 12 months, were 68% in the drug therapy group, and 56% in both device groups, a significant difference. Death or hospitalization owing to cardiovascular cause after 1 year were 60% in the drug-alone group, with a relative risk reduction of 25% in the biventricular pacing group and 28% in the CRT plus ICD group. The authors concluded there was a significant reduction in heart failure hospitalizations with biventricular pacing, and there was an additional significant reduction in mortality when ICD therapy was added. Improvement occurred in both in patients with ischemic and nonischemic cardiomyopathy.[183]

CRT has also been studied in less ill patients, patients with functional class II and III heart failure with ejection fraction less than 30%; 1798 patients with QRS duration longer than 120 msec during native conduction, or 200 msec during ventricular pacing, were treated with an ICD alone or with ICD plus CRT. At a mean follow-up of 40 months, there was a significant improvement with CRT in the primary endpoint of all-cause mortality plus hospitalization for heart failure (33.2% with CRT-ICD vs. 40.3% with CRT alone, $P < 0.001$).[184] A meta-analysis of studies using CRT in patient with mild heart failure showed significant favorable effects on left ventricular remodeling and reduction in the progression of heart failure.[185]

Optimal response to CRT occurs more often in the presence of longer QRS duration. Current guidelines give a class I indication for CRT to patients with LVEF below 35%, functional class II-IV symptoms despite optimal medical therapy, and LBBB on ECG with QRS duration longer than 150 msec, as well as functional class I patients with LVEF below 30%. A class IIa indication is given to patients with QRS duration longer than 150 msec without

LBBB and LVEF below 35%, or in patients with LBBB with QRS duration of 120 to 149 msec.[5] CRT with ICD results in left ventricular remodeling provides symptomatic benefit and improves survival in patients with heart failure.

Severe Heart Failure and Mechanical Circulatory Support

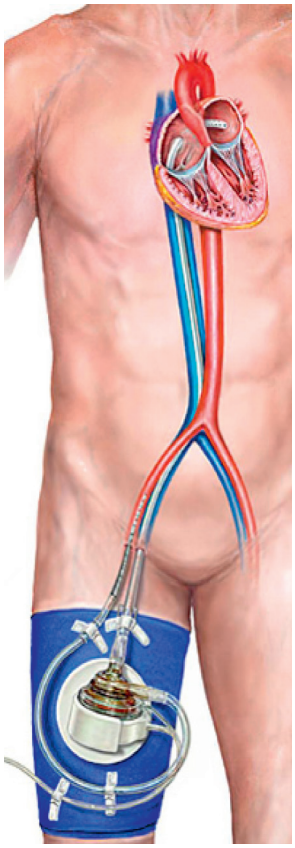
Temporary "Nondurable" Support

In patients with cardiogenic shock or refractory, severe heart failure, treatment with pharmacologic measures including inotropic agents and vasodilators is often not effective in reversing severe hemodynamic derangements. In these patients, MCS is required. Goals of mechanical supports include improved end-organ perfusion, lowering high cardiac filling pressures and relieving pulmonary edema, and preserving myocardial function by increasing coronary artery perfusion, reducing myocardial oxygen consumption, and unloading the left ventricle.[186,187] Temporary circulatory support systems can be delivered percutaneously in the cardiac catheterization laboratory or in the operating room when larger-bore cannulation is required. These systems can be placed urgently in unstable patients and can support the circulation until negative cardiac function improves or a decision is made regarding more durable mechanical support.[188] Causes of severe heart failure and cardiogenic shock in which temporary, or "nondurable," mechanical support can be considered include AMI, fulminant myocarditis, severe peripartum cardiomyopathy, stress-induced cardiomyopathy, after cardiac surgery, and for the mechanical complications of AMI.

The intraaortic balloon pump (IABP) is a form of temporary circulatory support with the longest clinical experience. This balloon catheter is placed percutaneously in the descending aorta via the femoral artery. The catheter size is 7.5F to 8.0F. Balloon inflation is timed to occur with the onset of diastole, resulting in diastolic augmentation of cardiac output and improved coronary perfusion pressure. The IABP offers modest hemodynamic support, an additional 0.5 to 1.0 L/min flow. Because timing of balloon inflation is synchronized to the ECG, marked tachycardia or frequent ventricular tachyarrhythmias results in poor augmentation of cardiac output. Complications are reported in 2.6% to 4.2% of patients and include stroke, limb ischemia, vascular injury, thrombocytopenia, or mesenteric ischemia. An IABP cannot be used in patients with moderate or severe aortic insufficiency or severe peripheral arterial disease.

The TandemHeart system (TandemLife, Pittsburgh, PA) is a form of temporary circulatory support that can offer 3.5 L/min of augmented flow via a larger, 15F catheter or 5 L/min of flow via a 19F catheter. The catheter is placed in the femoral vein and advanced to the left atrium via a transatrial septal puncture. Blood is removed from the left atrium, circulated via an extracorporeal centrifugal pump, and returned via the femoral artery (Fig. 27.16). The duration of support is approved for 6 hours (U.S. Food and Drug Administration) to 30 days (CE Mark in Europe). Hemodynamic effects include reduction of left ventricular preload and left ventricular end-diastolic pressure, decreased oxygen demand and left ventricular work, and increased afterload. Systemic anticoagulation is required. Severe peripheral arterial disease (PAD) is a contraindication.[186,187]

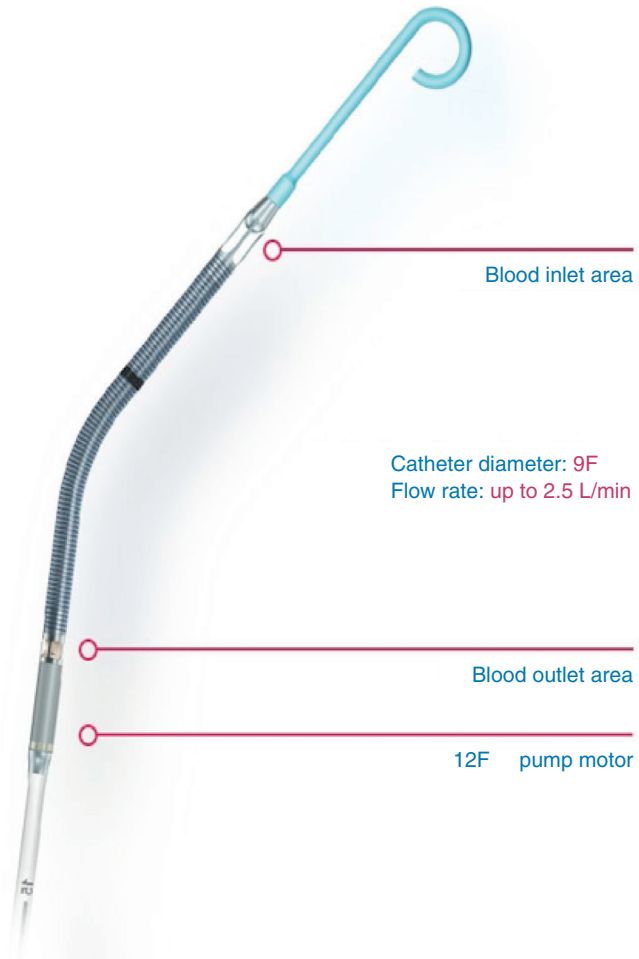
The Impella device (Abiomed, Danvers, MA) is a catheter on which is mounted a microaxial rotary pump. The catheter is placed retrograde into the left ventricle via percutaneous femoral artery catheterization. A pigtail tip stabilizes catheter position in the left ventricle. Blood is pulled from the left ventricle into an inlet area and then is expelled into the descending aorta. Flows of 2.5 L/min or 4 L/min can be delivered via percutaneously inserted 12F- or 14F-diameter catheters. A larger device delivering 5 L/min is placed via a femoral artery cutdown. Impella is approved for duration of use of 6 hour (U.S. Food and Drug Administration) to 5 days (CE Mark) (Fig. 27.17). This support system also requires cardiac electrical stability and adequate right ventricular function. Contraindications to its use include severe aortic valve disease and severe PAD. Limb ischemia and vascular injury are complications, similar to other systems using large-bore cannulas. Catheter migration, kinking, and obstruction of inflow have been reported.



• **Fig. 27.16** The TandemHeart system. (TandemHeart, Pittsburgh, PA.)

There are few data from randomized, controlled clinical trial with large numbers of patients to guide the use of these devices. In the IABP-SHOCK trial, the use of IABP was tested in 600 patients with cardiogenic shock caused by AMI who underwent urgent PCI; 83% of patients had IABPs placed after PCI was performed. There was no effect of IABP on 30-day mortality, a primary endpoint, or other secondary endpoints.[189] In another trial, the use of IABPs in patients with large anterior myocardial infarction but without shock, placed before PCI was performed, resulted in no difference in infarct size or survival at 6 months.[190] The 2013 ACC Foundation/AHA Guidelines for AMI give a IIa indication ("weight of evidence in favor of usefulness/efficacy") to the use of IABPs in cardiogenic shock because acute ST-elevation MI.[191]

Extracorporeal membrane oxygenation (ECMO) is a form of temporary circulatory support that uses an extracorporeal circuit, a centrifugal pump, and a membrane oxygenator. ECMO is not new, but improvements in technology and greater experience have resulted in more frequent use. A form of ECMO (VA ECMO



• **Fig. 27.17** The Impella device. (Abiomed, Inc., Danvers, MA.)

[venoarterial ECMO]) is used to support patients with severe heart failure. Venous blood is drawn through a femoral catheter, circulated by the pump through an oxygenator, and returned via the femoral artery. Large cannulas (19F- to 21F-diameter) are required. Additions to this circuitry are often required to ensure adequate cerebral and coronary oxygenation as well as adequate perfusion of the leg distal to catheter insertion. Systemic anticoagulation is required. Support with ECMO can be delivered for days to weeks. ECMO results in improved end-organ perfusion without increased myocardial oxygen demand. Left ventricular preload is reduced but afterload is increased. This may have deleterious effects on left ventricular function and may result in further left ventricular dilation. If this results in worsening lung edema, then unloading of the left ventricle via a left atrial or left ventricular vent catheter may be necessary.[186] Complications include bleeding (40% major or significant), thrombosis of circuitry or cannulae, infection, limb ischemia or compartment syndrome, hemolysis, and thrombocytopenia. A 5.9% incidence of stroke and 4.7% risk of amputation owing to limb ischemia have been reported (Fig. 27.18).[192]

Compared with other temporary support modalities, VA ECMO improves arterial oxygenation. Reported experience with ECMO includes the following. In an observational study of patients with cardiogenic shock caused by ST-elevation myocardial infarction, a 39% mortality was observed using ECMO, compared with 72% mortality in historical controls. Survival of 68% to ICU discharge was reported in patients with fulminant myocarditis supported with ECMO. Its use has also been reported in patients with septic shock and postcardiotomy shock. ECMO can be used as a bridge to recovery or to more durable mechanical support.[191]

Specific indications for and timing of temporary circulatory support (TCS) are evolving as technology improves and a wider experience is garnered. TCS offers greater improvements in systemic flow compared with inotropes and vasopressors, without the cost of increasing myocardial oxygen demand or increasing the risk of arrhythmia. Because the mortality associated with cardiogenic shock remains high, earlier use of TCS should be considered in patients whose conditions are not stabilizing or not improving with medical therapy and before the occurrence of severe end-organ damage or irreversible shock. Immediate use of TCS should be strongly considered in patients who present with profound shock.[187] In patients with refractory pulmonary edema or lung injury, ECMO improves oxygenation as well as support the circulation. TCS is relatively contraindicated in patients with a poor quality of life before their acute illness, a poor prognosis owing to severe comorbidities, established multiorgan system failure, severe neurologic impairment, sepsis, or high bleeding risk.

• BOX 27.6 Patients Who May Benefit From Ventricular Assist Device Therapy

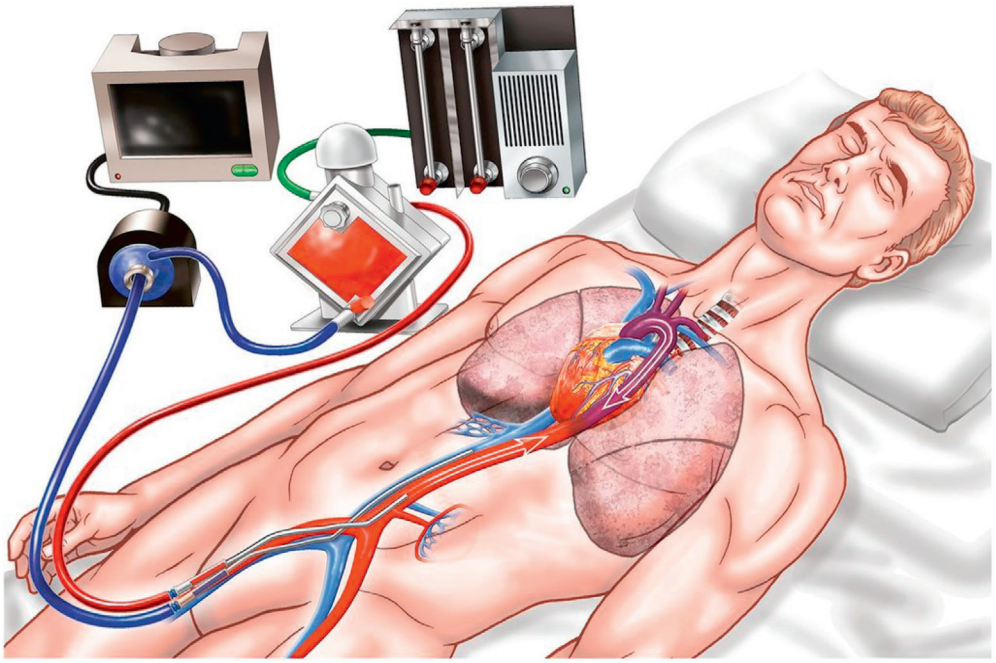
- Symptomatic functional class IV heart failure for longer than 2 months despite optimal medical and device therapy
- Two or more hospitalizations for decompensated heart failure in prior 12 months without obvious precipitating reason
- LVEF below 25%, or peak oxygen consumption less than 14 mL/kg per minute on CPET
- Dependence on inotropic therapy for more than 2 weeks
- Worsening end-organ function (renal, hepatic)
- Inability to tolerate β-blocker and/or ACE-I therapy because of hypotension
- Absence of severe RV dysfunction

ACE, *Angiotensin-converting enzyme;* CPET, *cardiopulmonary exercise testing;* LVEF, *left ventricular ejection fraction;* RV, *right ventricular.*

Durable Mechanical Support

It is estimated that more than 600,000 patients in the United States have chronic stage D, class IV heart failure. These patients have a very poor prognosis, even with appropriate pharmacologic and device therapy.[192] Cardiac transplantation offers an effective therapy for many patients with end-stage heart failure and is currently associated with a 1-year survival of more than 80% and median survival of 10.7 years.[193] However, the pool of donor hearts is currently less than 3000 per year in the United States and is not increasing.[194,195] Therefore durable MCS with ventricular assist devices (VADs) is being used with increasing frequency to support the function of the failing heart and provide normal cardiac output and flow to vital organs.

Patients considered for VAD therapy include those with refractory cardiogenic shock, patients dependent on and unable to be weaned from parenteral inotropic drugs for 14 days, those with persistent class IV symptoms despite optimal medical and device therapy for the prior 45 to 60 days, progressive cardiorenal dysfunction precluding the use of ACE inhibitors or hypotension preventing the use of ACE inhibitors and/or β-blockers, peak oxygen consumption of less than 14 mL/kg per minute on cardiopulmonary stress testing, or inability to perform this test[192,193] (Box 27.6).



• **Fig. 27.18** Femoral venoarterial extracorporeal membrane oxygenation (ECMO). When ECMO is implemented via femoral venous drainage and femoral arterial return in patients with residual native cardiac function and impaired lung function, reinfused oxygenated blood *(red arrow)*, flowing retrograde through the aorta, may meet resistance from poorly oxygenated blood flowing antegrade from the left ventricle *(purple arrow)*. Depending on the amount of cardiac function, the location of the interface between antegrade and retrograde flow will vary, and the reinfused oxygenated blood may not reach the cerebral and coronary vascular beds. (From Abrams D, Combes A, Brodie D. Extracorporeal membrane oxygenation in cardiopulmonary disease in adults. *J Am Coll Cardiol*. 2014;63:2769–2778.)

MCS can be used in clinical scenarios including the following:

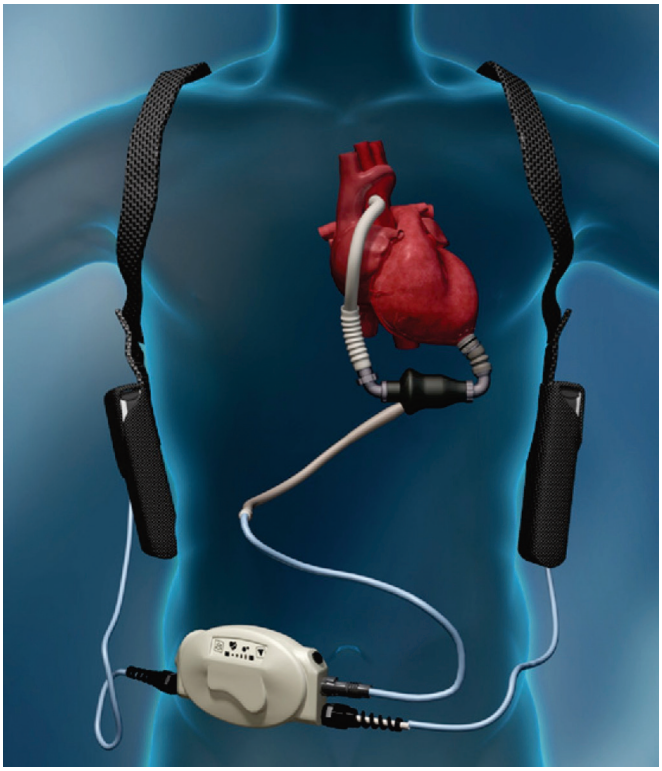
1. Bridge to cardiac transplantation. A mortality rate of 30% has been reported in patients listed for and awaiting heart transplantation, so MCS may enable many patients to survive to obtain transplantation.
2. Bridge to decision. These patients have an urgent need for support but have end-organ impairment exacerbated by heart failure, which makes transplantation a poor initial option. End-organ function may improve after a period of improved circulation with MCS, so that transplantation becomes feasible.
3. Bridge to recovery. Approximately 10% of patients have significant improvement in cardiac function during MCS such that survival is expected after removal of MCS. Examples include patients with severe peripartum cardiomyopathy and fulminant myocarditis.[167]
4. Destination therapy: long-term support with MCS. The HeartMate II (Thoratec Corp., Pleasanton, CA) continuous-flow VAD was approved for use as destination therapy in 2010. In 2014, 45.7% of VADs were implanted as destination therapy devices.[1]

Current VADs are small, implanted intracorporeally, and provide continuous, nonpulsatile flow. These continuous-flow devices function are much more durable and are associated with improved outcomes when compared with first-generation pulsatile-flow VADs. Current devices are suitable for long-term support. Battery packs are small and wearable, so that patients with VADs have freedom of movement and can participate in rehabilitation and normal daily activities (Fig. 27.19). These devices require systemic anticoagulation and antiplatelet therapy.

Appropriate patient selection for VAD use is vital. Exclusions to VAD therapy as destination therapy include the following[192,193,196]:

- Small body surface area (<1.2 m^2 or obesity with body mass index >45 kg/m^2)
- High pulmonary vascular resistance (>8 Woods units)
- Poor right ventricular function (defined by low right ventricular stroke work index or right atrial pressure/PCWP ratio >0.63),
- Serum creatinine above 3 mg/dL
- Elevated BUN
- Moderate to severe pulmonary disease
- Current cancer chemotherapy
- Inability to undergo anticoagulation
- Restrictive cardiomyopathy as cause of heart failure
- Poor social support
- Advanced liver disease (elevated transaminase, bilirubin, and international normalized ratio)
- Poor nutritional state (low albumin)
- Coagulopathy
- Neurologic deficits
- Severe anemia

Contraindications to the use of VADs include severe chronic obstructive pulmonary disease, need for hemodialysis, aortic insufficiency, or aortic valve mechanical prosthesis. Risk scores have been developed to attempt to define appropriate patient selection but need prospective validation. The incidence of major



• **Fig. 27.19** A continuous-flow left ventricular assist device. The axial, continuous-flow device is implanted within the chest and is attached to an external power source. (From Pagani FD, Miller LW, Russell SD, et al. Extended mechanical circulatory support with a continuous-flow rotary left ventricular assist device. *J Am Coll Cardiol.* 2009;54:312–321.)

complications of VAD therapy at 2 years include right ventricular failure (18%), sepsis (19%), stroke (11.7%), and bleeding (54%). Gastrointestinal bleeding is associated with an acquired von Willebrand factor deficiency and gastrointestinal arteriovenous malformations. Other complications include pump thrombosis, right ventricular failure, and left ventricular underfilling, which may cause syncope and be due to hypovolemia or a "suction event" within the left ventricle. The most common causes of death in VAD patients are multiorgan system failure, neurologic dysfunction, sepsis, and VAD removal.[188]

In patients with VADs implanted as destination therapy, current survival is 75% at 1 year and 50% at 3 years. In 2013 and 2014, there were approximately 2400 continuous-flow VAD implants per year in the United States. A classification system (the Interagency Registry for Mechanically Assisted Circulatory Support [INTERMACS] profile) is used to identify the severity of heart failure and to define suitability for VAD implantation (Fig. 27.20). Currently 80% of patients receiving VADs are in profiles 1 to 3 (critical cardiogenic shock, progressive decline despite continuous intravenous inotrope therapy, or stable on inotrope therapy). Patients in profiles 1 and 2 have a higher mortality. Current actuarial 1-year survival in all VAD recipients is 80%, with 2-year survival of 70%.[197] Device failure requiring replacement occurs in 4% to 9% of patients, most often because of pump malfunction, infection or pump thrombosis.[197] Patients with VADs have a rehospitalization rate at 1 year of 70%.[193] However, quality-of-life scores assessments shows continued improvement at 12 and 24 months after implantation.

Extending the indication for VAD therapy to less sick heart failure patients was studied in the Randomized Olmesartan and Diabetes Microalbuminuria Prevention (ROADMAP) trial. Two hundred patients with low functional class 3 or ambulatory class 4 chronic heart failure were randomly assigned to receive optimal medical therapy versus VAD therapy. At 1 year, VAD patients had improved survival on assigned therapy (80% vs. 63%) and improved 6-minute walking distance. However, VAD therapy was associated with a higher rate of adverse events (1.9 events per patient-year), most often for bleeding, with an 80% rehospitalization rate. Optimal medical therapy was associated with an adverse event rate of 0.83 events per patient-year, predominantly heart failure exacerbation, and rehospitalization rate of 63%.[198]

Future refinements in design will include further miniaturization of pumps; providing some degree of pulsatile flow, which may reduce bleeding complications; total implantability without externalized drive lines, which will reduce the risk of infection; and remote monitoring of devices. Patients can now be supported with mechanical devices for many years with satisfactory quality of life.

Key Points

- Factors that identify patients with acute heart failure who have a poorer prognosis include elevated BUN and creatinine, low systolic blood pressure, hyponatremia, markedly elevated BNP, elevated serum troponin, and lower LVEF.
- When patients with chronic heart failure are admitted to the hospital with acute decompensation, it is important to determine the reason for the acute change in status to attempt to reduce the risk of future episodes of decompensation and rehospitalization.
- Although controlled trial evidence is lacking, the use of vasodilators in combination with diuretics for acute severe heart failure is often useful, especially in patients with hypertension or those who are not adequately responding to diuretics alone.
- The use of inotrope therapy is reserved for patients with symptomatic low cardiac output and signs of end-organ hypoperfusion or cardiogenic shock.
- Defining hemodynamics with a PA catheter is often useful, especially in patients in cardiogenic shock, worsening renal function, or in whom hemodynamic status is uncertain.
- Pharmacologic therapy of chronic heart failure caused by left ventricular systolic dysfunction has been shown to improve adverse left ventricular remodeling. Medical therapies shown to improve mortality include β-blockers, ACE inhibitors, angiotensin receptor blockers with or without neprilysin inhibitors, aldosterone antagonists, and a combination of hydralazine with isosorbide dinitrate.
- Acute ischemia caused by coronary artery disease should always be considered as a potential etiology in patients presenting with acute heart failure. When ischemia is identified, aggressive revascularization therapies should be strongly considered to improve prognosis.
- Although randomized controlled trial data are lacking, the treatment of HFpEF includes aggressive control of hypertension, treating cardiac ischemia, controlling arrhythmias including atrial fibrillation, and considering the use of spironolactone.
- In patients with cardiogenic shock, newer percutaneous devices are now available that provide effective hemodynamic support for days to assess whether cardiac function is improving or if more permanent mechanical support is indicated.

INTERMACS profile descriptions	Time frame for intervention
Profile 1: Critical Cardiogenic shock	
Patient with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion, often confirmed by worsening acidosis and/or lactate levels. *"Crash and burn."*	Definitive intervention needed within hours.
Profile 2: Progressive decline	
Patient with declining function despite intravenous inotropic support, may be manifest by worsening renal function, nutritional depletion, inability to restore volume balance *"Siding on inotropes."* Also describes declining status in patients unable to tolerate inotropic therapy.	Definitive intervention needed within few days.
Profile 3: Stable but inotrope dependent	
Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support (or a temporary circulatory support device or both), but demonstrating repeated failure to wean from support due to recurrent symptomatic hypotension or renal dysfunction *"Dependent stability."*	Definitive intervention elective over a period of weeks to few months.
Profile 4: Resting symptoms	
Patient can be stabilized close to normal volume status but experiences daily symptoms of congestion at rest or during ADL. Doses of diuretics generally fluctuate at very high levels. More intensive management and surveillance strategies should be considered, which may in some cases reveal poor compliance that would compromise outcomes with any therapy. Some patients may shuttle between 4 and 5.	Definitive intervention elective over period of weeks to few months.
Profile 5: Exertion intolerant	
Comfortable at rest and with ADL but unable to engage in any other activity, living predominantly within the house. Patients are comfortable at rest without congestive symptoms but may have underlying refractory elevated volume status, often with renal dysfunction. If underlying nutritional status and organ function are marginal, patient may be more at risk than INTERMACS 4 and require definitive intervention.	Variable urgency, depends upon maintenance of nutrition, organ function, and activity.
Profile 6: Exertion limited	
Patient without evidence of fluid overload is comfortable at rest and with activities of daily living and minor activities outside the home but fatigues after the first few minutes of any meaningful activity. Attribution to cardiac limitation requires careful measurement of peak oxygen consumption, in some cases with hemodynamic monitoring to confirm severity of cardiac impairment. *"Walking wounded."*	Variable, depends upon maintenance of nutrition, organ function, and activity level.
Profile 7: Advanced NYHA II	
A placeholder for more precise specification in future, this level includes patients who are without current or recent episodes of unstable fluid balance, living comfortably with meaningful activity limited to mild physical exertion.	Transplantation or circulatory support may not currently by indicated.
Modifiers for Profiles	
TCS-Temporary Circulatory Suppor—can modify only patients in hospital (other devices would be INTERMACS devices) includes IABP, ECMO, TandemHeart, Levitronix, BVS 5000 or AB5000, Impella.	Possible Profiles to Modify 1, 2, 3 in hospital.
A-Arrhythmia—can modify any profile. Recurrent ventricular tachyarrhythmias that have recently contributed substantially to clinical compromise. This includes frequent ICD shock or requirement for external defibrillator, usually more than twice weekly.	Any profile.
FF-Frequent Flyer—can modify only outpatients, designating a patient requiring frequent emergency visits or hospitalizations for diuretics, ultrafiltration, or temporary intravenous vasoactive therapy.	3 if at home, 4, 5, 6. A frequent flyer would rarely be profile 7.

• **Fig. 27.20** A classification of heart failure syndromes, with level 1 representing the most critical illness with an urgent need for mechanically assisted circulatory support. Levels 1 through 5 include patients with New York Heart Association *(NYHA)* class IV heart failure. Levels 5 and 6 describe patients with advanced NYHA class III heart failure. (From Stevenson LW, Pagani FD, Young JB, et al. INTERMACS profiles of advanced heart failure: the current picture. *J Heart Lung Transplant.* 2009;28:535–541.)

Review Questions

1. In patients with severe, chronic systolic heart failure who are being considered for durable mechanical support with a left ventricular assist device (LVAD), which of the following would be considered a contraindication to device implant?
   - **a.** Severely abnormal left ventricle (LV) systolic function with LV ejection fraction below 10%
   - **b.** Inability to wean from inotropic medications
   - **d.** Severe pulmonary hypertension with pulmonary vascular resistance (PVR) less than 2 Woods units
   - **d.** Poor right ventricular function

   Answer: d. LVAD therapy supports only left ventricular function. Severe right ventricular dysfunction is not effectively treated with an LVAD, and if present can result in severe right ventricular failure after LVAD implantation. Severe LV systolic function (choice a) and inability to wean from inotropic therapy (choice b) are indications for LVAD therapy, not contraindications. Severe pulmonary hypertension is a contraindication to LVAD therapy in the presence of severe elevation of pulmonary vascular resistance greater than 3 Woods units. Pulmonary hypertension with less severe elevation of PVR (choice c) may reflect pulmonary hypertension caused by left heart failure and would not preclude LVAD implantation.
2. Which of the following is true regarding the use of intravenous vasodilator therapy for the treatment of acute, severe heart failure?
   - **a.** Vasodilator therapy is useful for emergency management of heart failure caused by acute severe mitral regurgitation complicating acute myocardial infarction.
   - **b.** Vasodilator therapy has been shown to preserve renal function in patients with acute heart failure.
   - **c.** Neseritide is preferred over intravenous nitroglycerin or nitroprusside.
   - **d.** Vasodilator therapy is contraindicated in acute heart failure caused by acute coronary ischemia.

   Answer: a. In patients with acute severe mitral regurgitation (for instance, caused by rupture of chordae tendineae or ruptured head of papillary muscle complicating acute myocardial infarction) vasodilator therapy can lower preload, improve pulmonary edema, and improve cardiac output by lowering LV afterload. Vasodilator therapy is an appropriate temporizing measure while preparing patients for cardiac surgery. Vasodilators have not been shown to result in consistent improvement in renal function in heart failure patients (choice b incorrect), and neseritide does not offer consistent benefits over other vasodilator drugs (choice c incorrect). In patients with acute heart failure caused by acute coronary ischemia, treatment with intravenous nitroglycerin is an effective therapy (choice d incorrect).
3. Which is the most common presentation of acute heart failure in the hospital setting?
   - **a.** Acute worsening of chronic heart failure
   - **b.** Acute pulmonary edema caused by acute coronary ischemia
   - **c.** Acute pulmonary edema caused by severe hypertension
   - **d.** Cardiogenic shock

   Answer: a. Roughly 75% of hospital admissions for acute decompensated heart failure involve acute worsening of chronic heart failure, either heart failure with normal or reduced LV ejection fraction. Acute pulmonary edema, caused by either acute ischemia or severe hypertension, accounts for roughly 25% of heart failure admissions (choices b and c incorrect). Cardiogenic shock accounts for 5% of acute heart failure admissions (choice d incorrect).

Anaphylaxis and Anaphylactic Shock

DANIEL DE BACKER

CHAPTER OUTLINE

Pathophysiology

Symptoms and Clinical Diagnosis

Treatment and Management
- Initial Management
- General Management
- Steroids and Antihistaminic Agents
- Other Agents

What Should Be Done After Recovery for Anaphylactic Shock?

The severe forms of anaphylaxis include severe cutaneous lesions, respiratory failure and upper airway obstruction, and circulatory failure (anaphylactic shock). Although respiratory symptoms or cutaneous lesions may be life-threatening, the most severe cases of anaphylaxis are related to the rapid progression into a generalized systemic reaction.

Pathophysiology

Mast cells and basophils play a prominent role in anaphylaxis. Mast cells are based primarily in tissues (skin, respiratory, and gastrointestinal tract) but are also in the blood. When these cells are activated by immunoglobulin E (IgE) and allergen, these cells degranulate and release numerous mediators, including histamine but also leukotrienes, prostaglandins, and other inflammatory mediators. Mediators from polymorphonuclear leukocytes and platelets are responsible for late-phase reactions after the initial anaphylactic event. These mediators are associated with endothelial dysfunction (manifested mostly by increased vascular permeability leading to loss of intravascular volume in conjunction with swelling and interstitial edema, and abnormal vascular reactivity leading to hypotension associated with marked skin vasodilation) and bronchial smooth muscle constriction.

Anaphylactic reactions are in many instances mediated by IgE but some severe episodes can also be related to non-IgE–mediated mechanisms (sometimes called anaphylactoid reaction). The World Allergy Organization suggested that the term *anaphylactoid* be abandoned and that all events should be called *anaphylactic episodes*, regardless of the mechanism of production.[1] They further suggested to divide these into immunologic and nonimmunologic events. Nonimmunologic anaphylactic events could be considered synonymous with the term anaphylactoid, and the immunologic events were further subcategorized as mediated and not mediated by IgE. A separate category was further added that is neither immunologic nor nonimmunologic, but rather "idiopathic."[1]

The immune-mediated IgE-dependent or IgE-independent and nonimmune-mediated mast cell degranulation-mediated anaphylactic reactions have similar clinical features. In IgE-mediated anaphylaxis, the IgE ligated to the antigen activate surface receptors that induces the release of mediators. In non-IgE–mediated anaphylactic reactions, the direct activation of surface receptors on mast cells and basophils by antigen is responsible for similar mediator release. Among the agents able to directly activate these surface receptors, iodinated contrast agents, opiates, and some antibiotics are the most common (Box 28.1).

Symptoms and Clinical Diagnosis

The symptoms of anaphylaxis are quite variable and can affect the following:
- Skin (flushing, itching, urticaria, angioedema, morbilliform rash)
- Eyes and orbits (periorbital itching, erythema and edema, conjunctival erythema, tearing)
- Mouth and mucosa (itching of lips and tongue, swelling of lips and tongue)
- Upper respiratory system (rhinorrhea, sneezing, dysphonia, hoarseness, stridor, dry cough)
- Lower airways (tachypnea, dyspnea, cough, wheezing and bronchospasm, respiratory arrest)
- Cardiovascular system (tachycardia, bradycardia [less common], hypotension and shock, cardiac arrest)

The clinical features associated with severe anaphylaxis are often associating cutaneous (rash and edema), respiratory symptoms (stridor, bronchospasm), and circulatory symptoms (hypotension or shock).

Several clinical criteria can be used to diagnose anaphylaxis (Box 28.2). These clinical criteria are mostly based on respiratory and/or circulatory compromise that occurs very acutely in the context of known or potential exposure to a causal agent.

The differential diagnosis includes vasovagal/neurocardiogenic reactions, pulmonary embolism, and septic shock for the cardiovascular symptoms. For the respiratory symptoms, the differential diagnosis includes acute respiratory decompensation from severe asthma attacks, foreign body aspiration, and vocal cord dysfunction.

When hemodynamic evaluation is available, it typically shows decreased systemic vascular resistance and low filling pressures.[2,3] Cardiac output is often low before volume replacement. Of note, the heart is often involved in anaphylaxis, either directly or under

• BOX 28.1 Agents Frequently Associated With Immune and Nonimmune Types of Anaphylaxis

Immunologic Mechanisms

IgE-mediated
- Food (nuts, shellfish, fruits, and so on)
- Venoms (stinging insects)
- Medications (β-lactam antibiotics, NSAIDs, neuromuscular blocking agents, and so on)
- Natural rubber latex
- Seminal fluid
- Radioconstrast media (in some cases)

IgE-Independent
- Radioconstrast media (in most cases)
- Dextrans
- Monoclonal antibodies (Rituximab)
- Medications (β-lactam antibiotics, NSAIDs, and so on)
- Natural rubber latex
- Seminal fluid

Nonimmunologic Mechanisms

Medications (opioids, protamine, and so on)

NSAIDs, *Nonsteroidal antiinflammatory drugs.*

• BOX 28.2 Clinical Criteria for Diagnosing Anaphylaxis[1]

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized urticaria, itching or flushing, swollen lips/tongue/uvula) and at least one of the following:
   a. Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced PEF, hypoxemia)
   b. Reduced blood pressure or associated symptoms of end-organ dysfunction (e.g. hypotonia collapse, syncope, incontinence)

OR

2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
   a. Involvement of the skin-mucosal tissue (e.g., generalized urticaria, itch/flush, swollen lips/tongue/uvula)
   b. Respiratory compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced PEF, hypoxemia)
   c. Reduced blood pressure or associated symptoms (e.g., hypotonia collapse, syncope, incontinence)
   d. Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)

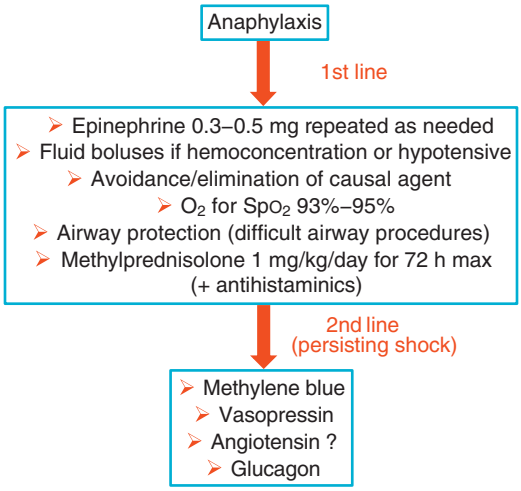
OR

3. Reduced blood pressure after exposure to known allergen for that patient (minutes to several hours)
   a. Infants and children: low systolic blood pressure (age-specific) or >30% decrease in systolic blood pressure
   b. Adults: systolic blood pressure of <90 mm Hg or >30% decrease from that person's baseline

PEF, *Peak expiratory flow.*

the influence of high levels of endogenous and exogenous catecholamines. The heart is rich in mast cells, and mediators released from activated human heart mast cells strongly influence ventricular function, cardiac rhythm, and coronary artery tone.[4] Cases of myocardial ischemia (sometimes related to coronary spasm[2] and/or stent thrombosis or occlusion by mast cells and eosinophils—the Kounis syndrome[5]) and cases of Takotsubo syndromes have been described[2,6–8]; these can be accompanied by severe depression of myocardial contractility. Arrhythmic events can also frequently occur.[2] Given this potential cardiac involvement, it is recommended to perform echocardiography to evaluate cardiac function of these patients, as in other causes of shock.[9,10]

When in doubt that the clinical pattern corresponds to anaphylaxis, it is recommended to measure mast cell tryptase as an indicator of mast cell degranulation.[11,12] Serial mast cell tryptase measurements are obtained and anaphylaxis is considered when the rise in tryptase is higher than a given threshold (peak tryptase should be >1.2 × baseline tryptase + 2 mg/L). Although this measure is not specific to the causative agent or to a mechanism (IgE-mediated or not), it allows confirmation of the anaphylactic process.[12]



• **Fig. 28.1** Management of a patient with severe anaphylaxis. O_2, Oxygen; Spo_2, oxygen saturation measured by pulse oximetry.

Treatment and Management

Case fatality register studies have demonstrated that deaths can occur within minutes of the onset of an anaphylactic reaction and that the severity of the reaction is often difficult to predict initially.[13,14] It is therefore consistently advocated by guidelines that all reactions are promptly managed by initiating a range of pharmacologic and nonpharmacologic interventions.[15] These actions are summarized in Fig. 28.1.

Initial Management

Anaphylactic shock is characterized by vasoplegia and capillary leak. Hence, initial management should include volume replacement and vasopressors. In opposition perhaps with other types of shock, prioritization is given to vasopressor and in particular to epinephrine.

Epinephrine

Epinephrine is the drug of choice as it interacts with pathophysiologic mechanisms of anaphylaxis.[16] The β-adrenergic effects of epinephrine inhibit mast cell degranulation by increasing intracellular levels of cyclic adenosine monophosphate. In addition, β-adrenergic stimulation reverses bronchospasm, whereas the

α-adrenergic vasoconstrictive properties of epinephrine may increase vascular tone and improve venous return by constriction of capacitance veins.[17] Accordingly, it increases cardiac filling and improves cardiac output. By its action on diastolic pressure, epinephrine also enhances coronary flow. Of note, epinephrine also increases myocardial contractility and increases heart rate, and these effects are not always warranted in the early phase, as it can led to obstruction of the left ventricular outflow tract. In this situation, fluid loading would help to relieve the symptoms.[18]

Even though the effect of epinephrine on mortality remains unproven by large-scale randomized studies, it is widely accepted that epinephrine should be administered as soon as possible after the onset of severe anaphylaxis,[14–16] even when shock is not present.[14] Epinephrine is recommended for self-administered therapy as an intramuscular injection[14] (usual dose 0.3–0.5 mg repeated at 5- to 10-minute intervals depending on the symptoms). In the hospital and under the supervision of emergency physicians, anesthesiologists, and/or intensivists, epinephrine should be administered intravenously in patients with shock (boluses of 0.3–0.5 mg that can be increased to 1 mg, repeated as needed).

When shock persists in the hospital setting, after administration of several boluses of 1 mg epinephrine, what would be the vasopressor agent of choice? Data are lacking to decide whether prolonged epinephrine infusion should be used or whether another vasopressor agent should be used. In many instances, physicians use either continuous infusion of epinephrine or norepinephrine. In addition, alternative agents may be considered (see additional measures).

Fluids

Fluids are also a key part of the management of anaphylactic shock. Because of the increased permeability and vascular dilation, hypovolemia is an important component of anaphylactic shock. Hemoconcentration is often present as an index of the severity of hypovolemia. Fluid replacement should thus be generous in patients with anaphylactic shock. Crystalloids should be used as a first choice, especially in patients presenting with hemoconcentration. Colloids may also be used, in combination with crystalloids. The exact amount of fluids to administer is highly variable, especially when capillary leak is ongoing. Fluid boluses are usually indicated as long as hemoconcentration persists. After correction of hemoconcentration, administration should be guided using classic hemodynamic guidance, preferring dynamic variables to predict fluid responsiveness when these can be applied.[9]

General Management

Avoidance of the causal agent is mandatory. In patients with venom exposure, it is recommended to closely look at the skin to ensure that retained stingers should not be extracted. For in-hospital exposure, it is important to stop administration of the causative agent (contrast media, antibiotic, dextran, gelatins, exposure to latex, and so on).

Airway management is crucial, and difficult intubation procedures should be used for patients with suspected laryngeal edema. Oxygen is administered to ensure a pulse oxygen saturation between 93% and 96%.

Steroids and Antihistaminic Agents

Systematic reviews are inconclusive on the use of steroids and antihistaminic agents.[19] However, these agents are used very frequently, especially in the most severe cases. Their effect on the initial insult may be limited but these seem mostly useful in limiting the secondary phase. Steroids inhibit the synthesis of histamine and therefore may limit the protraction of symptoms or biphasic reactions.[20] Methylprednisolone (1 mg/kg per 24 hours) mays be administered up to 72 hours.

Other Agents

Modulation of Guanylate Cyclase

Methylene blue inhibits guanylate cyclase and as such may not only stabilize endothelial dysfunction but also limit mastocyte degranulation. The use of methylene blue is mostly supported by experimental evidence and case reports.[21–25] In an experimental model of protamine-induced anaphylactic shock, methylene blue administration attenuated hypotension and improved cardiac function, without affecting nitric oxide levels.[26] Experimental data also suggest that the effects of the combination of epinephrine and methylene blue are much better than the effects of methylene blue in isolation.[25] Several case studies reported beneficial effects of methylene blue in epinephrine-refractory hypotension associated with anaphylactic shock.[22,23] Methylene blue may also be beneficial for respiratory symptoms refractory to epinephrine in severe anaphylaxis without hypotension.[24]

Nitric Oxide Modulation?

As anaphylactic shock is a form of severe vasodilation, inhibition of nitric oxide may sound attractive. Inhibition of nitric oxide attenuates hypotension and hemoconcentration but fails to improve myocardial contractility.[27] In an experimental model of anaphylactic shock, nitric oxide inhibition improved blood pressure but resulted in impaired myocardial function, an increase in bronchospasm and pulmonary vascular resistance, and increased mortality rate.[28] On the other hand, nitric oxide donors improve bronchospasm.[28,29] These experimental results highlight the dual role of nitric oxide in anaphylactic shock.

Vasopressin

Experimental data suggest that vasopressin levels are initially increased in anaphylactic shock in response to hypotension and that vasopressin inhibition worsens the outcome of anaphylactic shock.[30] However, when direct comparison with epinephrine is provided, epinephrine improved bronchospasm and cerebral oxygenation, whereas vasopressin had minimal effects on these aspects.[31,32] Accordingly, vasopressin should not replace epinephrine. However, combination of epinephrine and vasopressin may be considered. Administration of vasopressin in epinephrine-resistant anaphylactic shock resulted in a prompt hemodynamic stabilization in a small series of cases.[33]

Angiotensin

Angiotensin is a promising agent for refractory hypotension in septic shock.[34] Experimental data suggest that angiotensin levels are initially increased in anaphylactic shock in response to hypotension.[30] Also, patients treated with angiotensin-converting enzyme inhibitors have a worse outcome when anaphylactic shock develops,[35] possibly because angiotensin-converting enzyme inhibitors prime mast cells.[36] Hence, angiotensin administration may appear attractive, but data are lacking at this stage to support its use.

Glucagon

Glucagon inhibits histamine release.[37] In an isolated heart model submitted to anaphylaxis, glucagon provided protection from anaphylaxis-induced arrhythmias and improved coronary perfusion.[37]

In humans, the use of glucagon has been described successfully in case reports[38] but series, even retrospective, are lacking.

What Should Be Done After Recovery for Anaphylactic Shock?

The causative agent, if not yet known, should be identified by review of case history. When the cause is not identified, delayed evaluation should be conducted by an allergist or immunologist. For some of the causative agents (some foods, pollens, penicillins, venoms of stinging insects, and so on), the cause of anaphylaxis may be supported by the results of skin tests and/or in vitro IgE tests. Unfortunately, these tests are not available for the majority of medications, and the causative agent often remains speculative. The file of the patient should clearly identify the allergic agent and the patient should carry a notice of this allergy in a wallet. When the cause is not fully avoidable or when the causative agent cannot be determined, the patient should be supplied with an autoinjectable epinephrine pen.

Key Points

- Anaphylaxis is related to degranulation of mast cells and basophils after contact to an antigen.
- Classic IgE-mediated allergic reaction (type I), IgE-independent, and nonimmune anaphylactic reactions are clinically identical and respond similarly to treatment.
- The clinical consequences of anaphylaxis are related to endothelial activation with vasoplegia and increased microvascular permeability.
- Hemodynamic characteristics of anaphylaxis include tachycardia, hypotension, decreased cardiac filling pressures, and decreased systemic vascular resistance.
- Cardiac involvement is frequent in anaphylaxis. Echocardiography should be performed in severe cases to assess cardiac function.
- Anaphylaxis management includes the following actions: securing airway patency, removing the causative agent, administering epinephrine, and administering fluid to correct hypovolemia.
- Corticosteroids should be given in severe cases to prevent late-phase reactions.
- Methylene blue and vasopressin can be considered as second-line agents in addition to epinephrine.
- All patients who have experienced anaphylaxis should be referred for appropriate follow-up. These patients may require allergy testing, desensitization, and premedication strategies.

Review Questions

1. Which one of the following hemodynamic patterns is *most* likely to be found in a patient with anaphylactic shock?

	MAP	CVP	SVR	CO	HCT
a.	85	15	↑	8.0	53
b.	45	15	↓	3.5	35
c.	45	2	↓	5.5	55
d.	85	2	↑	8.0	35

CO, Cardiac output; *CVP*, central venous pressure; *HCT*, hematocrit; *MAP*, mean arterial pressure; *SVR*, systemic vascular resistance.

Answer: c. Anaphylactic shock is characterized by severe vasodilation and hemoconcentration. Even though cardiac output is usually increased, volume repletion is often required to achieve this hyperdynamic pattern.

2. A patient develops anaphylactic shock in the radiology suite. Which one of the following is the *most* appropriate first-line treatment for the patient's hypotension?

a. Norepinephrine
b. Epinephrine
c. Hydrocortisone
d. Dobutamine
e. Vasopressin

Answer: b. Epinephrine is the first-line agent, combining an antidegranulation effect through β-stimulation and a vasoconstrictive effect through α-stimulation. Dobutamine is a sympathomimetic agent with predominantly inotropic effects and would not correct the hypotension in anaphylactic shock. Norepinephrine and vasopressin are second-line agents that can be used in cases refractory to epinephrine and fluids. Steroids are used mostly to prevent late-phase reactions and have no immediate effects on hemodynamic abnormalities.

3. A patient is admitted to the intensive care unit with persistent hypotension and tachycardia in the context of anaphylactic shock, despite administration of multiple doses of epinephrine, fluids, and steroids. What are the potential second line agents? (Multiple responses are possible.)

a. Continuous epinephrine infusion
b. Norepinephrine
c. Vasopressin
d. Methylene blue
e. Glucagon
f. Esmolol

Answers: b, c, d, and e. This patient already received multiple doses of epinephrine and is quite tachycardic. Further stimulation of β-adrenergic receptors may increase tachycardia and is unlikely to have additional effects on degranulation. Norepinephrine, vasopressin, methylene blue, and glucagon can all be considered as second-line agents as an adjunct but not in replacement of first-line agents. Esmolol is contraindicated as β-blockers worsen the outcome of patients with anaphylactic shock.

Definitions

Acute coronary syndrome (ACS) refers to "a spectrum of conditions compatible with acute myocardial ischemia and/or infarction that are usually due to an abrupt reduction in coronary blood flow."[1] Therefore the ACS spectrum encompasses unstable angina (UA), non–ST-segment elevation myocardial infarction (NSTEMI), and ST-segment elevation myocardial infarction (STEMI). The presence or absence in the blood of either troponin or the MB (muscle-brain) fraction of creatine kinase (CK-MB) determines the distinction between a diagnosis of either UA or myocardial infarction (MI). (For convenience, these and other relevant abbreviations are listed in Table 29.1.) An expert consensus document titled the "Third Universal Definition of Myocardial Infarction" was published in 2012 by a joint task force of the European Society of Cardiology (ESC), the American College of Cardiology Foundation (ACCF), the American Heart Association (AHA), and the World Heart Federation.[2] The clinical diagnosis of an acute MI was defined as a rise or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit together with evidence of myocardial ischemia with at least one of the following: symptoms of ischemia, electrocardiogram (ECG) changes indicative of new ischemia (new ST-T changes or new left bundle branch block [LBBB]), development of pathologic Q waves in the ECG, or imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.[2] Definitions also exist for the diagnosis of an acute MI in three other circumstances: sudden death, after percutaneous coronary intervention (PCI), and after coronary artery bypass graft (CABG) surgery.[2]

The increased sensitivity of troponin compared with CK-MB and the new criteria for the diagnosis of acute MI dictate that many patients who were classified as having UA by the old criteria are now given a diagnosis of acute MI. Among 1851 patients enrolled in a prospective study, 538 received a diagnosis of acute MI based on dynamic changes in troponin T, compared with only 427 patients when CK-MB was used to diagnose acute MI, representing a 41% increase.[3] A retrospective analysis of 2181 patients with suspected ACS and no ST-segment elevation found that the prevalence of acute MI ranged from 9.7% to 22% based on differing troponin-based definitions, compared with 7.8% based on CK-MB alone.[4] Meier and colleagues[5] studied 493 consecutive patients with suspected ACS. Of those, 224 patients had elevated CK-MB, and an additional 51 patients had normal CK-MB but elevated troponin I levels. The latter group was characterized by a greater incidence of comorbid conditions and higher 6-month mortality. Among 29,357 patients with non–ST-segment elevation ACS (NSTE-ACS) who were enrolled in the Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes with Early Implementation of the ACC/AHA Guidelines? (CRUSADE) registry, 18% of patients were CK-MB negative and troponin positive.[6] The risk of in-hospital death was significantly increased among troponin-positive patients regardless of CK-MB status.

The Global Registry of Acute Coronary Events (GRACE) is a prospective observational registry of 26,267 patients with ACS who were admitted to 106 hospitals in 14 countries.[7] (A list of eponyms in use for various cardiac registries and drug trials is provided in Table 29.2.) Among the 10,719 patients (10.4%) with both CK-MB and troponin data, 1110 patients without elevation of CK-MB were diagnosed with acute MI by virtue of elevated troponin. Patients who were troponin negative had similar 6-month mortality regardless of CK-MB status, but patients who were CK-MB negative and troponin positive had a twofold greater hospital case-fatality rate.

The advent of highly sensitive troponin assays has contributed to further changes in the detection of acute MI in patients with myocardial ischemia.[8–10] Bonaca and colleagues[8] conducted a prospective study of the prognostic value of a sensitive assay for

Abbreviation	Definition	Abbreviation	Definition
ACC	American College of Cardiology	ICD	Implantable cardioverter-defibrillator
ACCF	American College of Cardiology Foundation	INR	International normalized ratio
ACE	Angiotensin-converting enzyme	IRA	Infarct-related artery
ACS	Acute coronary syndrome	LAD	Left anterior descending (artery)
ACT	Activated clotting time	LBBB	Left bundle branch block
AF	Atrial fibrillation	LDL	Low-density lipoprotein
AHA	American Heart Association	LMWH	Low-molecular-weight heparin
APSAC	Anisoylated plasminogen-streptokinase activator complex	LVEF	Left ventricular ejection fraction
aPTT	Activated partial thromboplastin time	MI	Myocardial infarction
ARB	Angiotensin receptor blocker	MR	Mitral regurgitation
AVB	Atrioventricular block	MRI	Magnetic resonance imaging
BMS	Bare metal stent	NNT	Number needed to treat
BNP	Brain natriuretic peptide	NO	Nitric oxide
CABG	Coronary artery bypass grafting	NSAIDs	Nonsteroidal antiinflammatory drugs
CAD	Coronary artery disease	NSTE-ACS	Non–ST-segment elevation acute coronary syndrome
HF	Congestive heart failure	NSTEMI	Non–ST-segment elevation myocardial infarction
CCTA	Coronary CT angiography	NTG	Nitroglycerin
CI	Confidence interval	PA	Pulmonary artery
CK-MB	Muscle-brain fraction of creatine kinase	PCI	Percutaneous coronary intervention
CT	Computed tomography	PCWP	Pulmonary capillary wedge pressure
DAPT	Dual antiplatelet therapy	RCA	Right coronary artery
DES	Drug-eluting stent	rPA	Reteplase
ECG	Electrocardiogram	RR	Relative risk
EF	Ejection fraction	RVMI	Right ventricular myocardial infarction
ESC	European Society of Cardiology	SK	Streptokinase
FDA	U.S. Food and Drug Administration	STEMI	ST-segment elevation myocardial infarction
GP	Glycoprotein	t-PA	Tissue plasminogen activator
HDL	High-density lipoprotein	UA	Unstable angina
HF	Heart failure	UFH	Unfractionated heparin
HIT	heparin-induced thrombocytopenia	VF	Ventricular fibrillation
IABP	Intraaortic balloon pump	VSR	Ventricular septal rupture
ICH	Intracranial hemorrhage	VT	Ventricular tachycardia
ICU	Intensive care unit		

cardiac troponin I in 4513 patients with NSTE-ACS enrolled in a randomized trial of ranolazine versus placebo. Patients with low-level increases of serum troponin I (0.04 μg/L to < 0.1 μg/L) had a significantly higher risk of death at 12 months (6.4% versus 2.4%, $P = 0.005$). Another study found that implementation of a sensitive assay for troponin I in patients with suspected ACS increased the detection of MI by 29%, identified patients who were at the highest risk of recurrent MI and death, and was associated with improved clinical management that resulted in fewer deaths and admissions with recurrent MI.[9] It is important to recognize that other conditions that occur frequently in patients with cardiovascular disease, such as heart failure (HF) and chronic kidney disease, may confound the diagnosis of ACS because they can be associated with elevated troponin levels.[10]

ST-Segment Elevation Myocardial Infarction

Clinical Manifestations

Clinical History

The initial differentiation of ACS from other causes of chest pain is based on the chest pain history, physical examination, presence of risk factors for coronary artery disease (CAD), and the ECG. Certain chest pain characteristics are associated with decreased or increased likelihoods of ACS.[11] The feature that was found to be associated with the highest risk of a diagnosis of ACS is radiation of pain to one or both shoulders or arms. A prospective study of patients who presented to an emergency department for evaluation of chest pain determined that pain relief by nitroglycerin is not a useful indicator of the presence or absence of ACS.[12] Nitroglycerin relieved chest pain in 35% of patients with active CAD, compared with 41% of patients without active CAD ($P > 0.2$).[12]

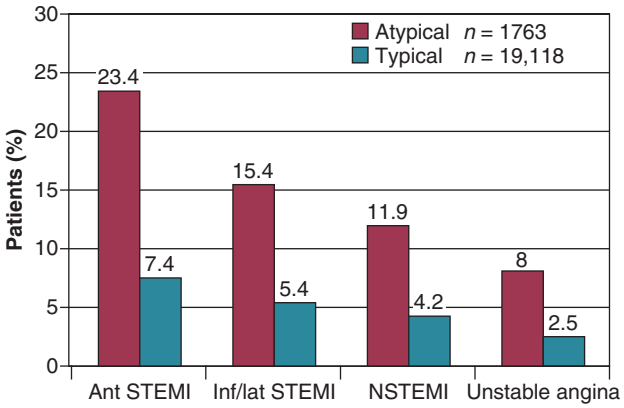
Another literature review included 15 studies published from 1989 to 2002 that identified symptoms of ACS.[13] Chest pain was the most common symptom among both men and women, but atypical symptoms were common, especially among women. Compared with men, women with ACS were significantly more likely to report back and jaw pain, nausea, vomiting, dyspnea, indigestion, and palpitations. A significant fraction of patients with acute MI do not complain of chest pain at the time of presentation.[14–16] A total of 1674 U.S. hospitals contributed patients to the National Registry of Myocardial Infarction (NRMI) 2.[14] Among 434,877 patients with confirmed MI who were enrolled in the NRMI 2 registry between June 1994 and March 1998, 142,445 (33%) did not have chest pain at the time of presentation to the hospital. There were several notable differences between the groups who presented with and without chest pain. Only 23% of patients without chest pain had ST-segment elevation on the initial ECG, compared with 47% of the patients with chest pain. The group of patients who presented without chest pain was older (74 years vs. 67 years) and had a higher proportion of women (49% vs. 38%). A subsequent analysis of 1,143,513 patients enrolled in the registry found that the proportion of patients who presented without chest pain was significantly higher for women than men (42% vs. 30.7%; $P < 0.001$).[16] The gender differences in clinical presentation without chest pain diminished with increasing age.[16]

The absence of chest pain has a major impact on hospital management and outcomes, even among patients who present with ST-segment elevation.[14–16] A report from the GRACE registry compared 6385 patients with STEMI and typical symptoms with 541 patients whose presenting symptoms did not include chest pain.[15] Patients without chest pain were significantly less likely to receive reperfusion therapy (i.e., fibrinolysis or primary PCI), β-blockers, and aspirin. Perhaps as a consequence of undertreatment, hospital mortality was significantly greater among patients with STEMI and no chest pain than among patients with chest pain (18.7% vs. 6.3%; $P < 0.001$) (Fig. 29.1).

There is a long-standing belief that diabetes is associated with silent myocardial ischemia and painless MI owing to autonomic neuropathy. Nevertheless, in the NRMI 2 registry, only 33% of the patients with painless MI had diabetes mellitus, and in the GRACE registry, only 32% of patients with painless ACS had diabetes.[14,15]

Physical Examination

The initial physical examination provides important prognostic information in patients with acute MI. Killip and Kimball published their classic study in 1967.[17] Among 250 patients with acute MI, 81 patients (33%) had no HF (Killip class I), 96 (38%) had mild HF (Killip class II), 26 (10%) had pulmonary edema (Killip class III), and 47 (19%) had cardiogenic shock (Killip class IV). Respective mortality rates were 6%, 17%, 38%, and 81%. Although the overall mortality for acute MI has decreased since 1967, the Killip class on admission remains a powerful predictor of outcome among patients treated with reperfusion therapy.[18,19] DeGeare and coworkers[19] performed an analysis of 2654 patients with acute MI who were enrolled in three primary angioplasty trials. Patients in Killip class IV were excluded. Increasing Killip class was associated with an increased need for intraaortic balloon counterpulsation and a greater incidence of renal failure, major arrhythmias, and major bleeding. After controlling for confounding variables, the Killip class on admission remained a multivariate predictor of both in-hospital and 6-month mortality.



• **Fig. 29.1** In-hospital mortality rate in subgroups with acute coronary syndrome (ACS) according to presenting symptoms. *Ant,* Anterior; *Inf/lat,* inferior or lateral; *NSTEMI,* non–-ST-segment elevation myocardial infarction; *STEMI,* ST-segment elevation myocardial infarction. (From Brieger D, Eagle KA, Goodman SG, et al. Acute coronary syndromes without chest pain, an underdiagnosed and underreated high-risk group: Insights from the Global Registry of Acute Coronary Events. *Chest.* 2004;126:461–469.)

The physical examination also may provide clues to the diagnosis of causes of chest pain other than ACS. A pericardial friction rub may be audible in patients with pericarditis. Aortic dissection may be associated with diminished or absent pulses. Both diagnoses are important to exclude because they are contraindications to fibrinolytic therapy.

Diagnostic Approach

The ACCF/AHA Task Force on Practice Guidelines and the ESC have published detailed recommendations for the diagnosis and management of patients with ACS.[1,20–24] Conditions for which there is evidence, general agreement, or both that a given procedure or treatment is useful and effective are categorized as class I[1,24] (not to be confused with Killip class I). Conditions for which there is conflicting evidence or divergence of opinion are categorized as class II. The weight of evidence or opinion is in favor of usefulness or efficacy for class IIa conditions, whereas usefulness or efficacy is less well established for class IIb conditions. Class III conditions are those for which there is evidence or general agreement that a procedure/treatment is not useful or effective and may be harmful in some cases.

Electrocardiogram

The 2004 iteration of the ACC/AHA Guidelines for the Management of Patients with ST-Elevation Myocardial Infarction include three class I indications for an ECG.[20] The first is that all patients with chest discomfort or other symptoms suggestive of STEMI should have a 12-lead ECG within 10 minutes of arrival in the emergency department (and it should be interpreted by an experienced physician). The second is that serial ECGs should be performed at intervals of 5 to 10 minutes in patients with a nondiagnostic initial ECG if the patient remains symptomatic and there is a high clinical suspicion of STEMI. The third is that right-sided ECG leads should be obtained to screen for right ventricular MI in patients with inferior STEMI. A fourth class I indication for a 12-lead ECG was included in the 2013 ACCF/AHA Guideline for the Management of ST-Elevation Myocardial Infarction.[24] It recommended that a 12-lead ECG be performed by emergency medical services personnel at the site of first medical contact in patients with symptoms consistent with a STEMI.

The electrocardiographic diagnosis of acute MI in the presence of an LBBB is problematic.[25,26] Angiographic studies have demonstrated a low prevalence of acute MI among patients with a new LBBB.[27–30] Analysis of the Mayo Clinic's primary PCI database found that only 12 of 36 patients with a new LBBB and clinical symptoms suspicious for an MI met troponin criteria for an MI, resulting in emergency activation of the cardiac catheterization laboratory for a false-positive diagnosis of acute MI in two-thirds of patients with a new LBBB.[28]

Sgarbossa and associates[31] devised an algorithm for the diagnosis of acute MI in patients with LBBB that used three electrocardiographic criteria: ≥1-mm ST-segment elevation concordant with the QRS complex; ≥1-mm ST-segment depression in leads V_1, V_2, or V_3; and ≥5-mm ST-segment elevation discordant with the QRS complex. Several subsequent studies investigated the utility of the so-called Sgarbossa criteria.[26,29] A study that enrolled 83 patients with LBBB and symptoms suggestive of acute MI found that the ECG algorithm based on the Sgarbossa criteria had a sensitivity of only 10%.[26]

Patients with an acute MI who present with an LBBB that is new or of indeterminate age have a worse prognosis than patients without an LBBB. A bundle branch block was present on the admission ECG in 4% of the patients with a suspected acute MI who were included in a meta-analysis of nine trials that randomly assigned 58,600 patients to either a control group or fibrinolytic therapy.[32] Mortality at 35 days for patients who were randomly assigned to the control groups was greater among patients who presented with a bundle branch block (23.6%), compared with patients who had ST-segment elevation in the anterior leads (16.9%) or inferior leads (8.4%), or ST-segment depression (13.8%).[32] Fibrinolytic therapy was associated with a 25% reduction in mortality among patients who presented with a bundle branch block on ECG.[32] The publication did not provide information regarding the age of the bundle branch block or whether the meta-analysis was limited to patients with an LBBB or also included patients with a right bundle branch block.[32] Among 3053 patients with an acute MI who were enrolled in the Primary Angioplasty in Myocardial Infarction (PAMI) trials, an LBBB was an independent predictor of in-hospital death (odds ratio [OR] 5.53; 95% confidence interval [CI] 1.89–16.1; $P = 0.002$).[33]

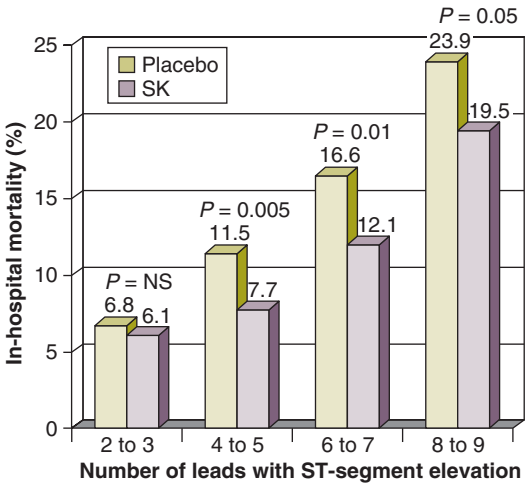
Patients with LBBB and acute MI frequently have no chest pain at the time of presentation. Chest pain was not reported by 47% of the 29,585 patients with LBBB and acute MI who were enrolled in the NRMI 2 registry.[34] Patients who presented without chest pain were less likely to receive aspirin or a β-blocker and four times less likely to receive reperfusion therapy (OR 0.25).[34] This may explain why patients with acute MI and LBBB who presented without chest pain had a 47% greater in-hospital mortality rate than patients who presented with chest pain (27% vs. 18%; $P < 0.001$).[34]

A new or presumably new LBBB in patients with symptom onset within the prior 12 hours was designated as a class I indication for either fibrinolytic therapy or PCI in the guidelines for the management of acute MI issued by the American College of Cardiology (ACC)/AHA Task Force on Practice Guidelines in 2004.[20] According to the most recent revision of the practice guidelines for ST-segment elevation MI, a new or presumably new LBBB "should not be considered diagnostic of acute MI in isolation."[24] The risks of fibrinolytic therapy may be increased in patients with LBBB owing to older age and a higher prevalence of hypertension. Therefore the most prudent strategy in patients with LBBB and a suspected acute MI may be immediate coronary angiography, both to diagnose an acute coronary artery occlusion and to eliminate the risk of fibrinolytic therapy in patients who cannot benefit from it (i.e., patients with a NSTEMI or a noncardiac condition). A more detailed discussion of the management of patients with LBBB and suspected MI can be found in an excellent review article published in 2012.[25]

The ECG provides additional important information in patients with acute MI. Patients with acute inferior STEMI who have ST-segment depression in the precordial leads have larger infarctions, more post-MI complications, and a higher mortality rate than patients without precordial ST-segment depression.[35] The presence of Q waves in the infarct territory on the initial ECG is an independent predictor of greater 30-day mortality irrespective of the infarct location or time between symptom onset and administration of fibrinolytic therapy.[36] Nevertheless, substantial myocardial salvage is possible despite Q waves on the initial ECG.[37]

The electrocardiographic leads with ST-segment elevation have been correlated with occlusions of the left anterior descending (LAD), left circumflex, or right coronary arteries.[38,39] The number of leads with ST-segment elevation before reperfusion therapy and the degree of resolution of ST-segment elevation after either fibrinolytic therapy or primary angioplasty confer useful prognostic information. The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI) trial investigators reported that in-hospital mortality was directly related to the number of leads with ST-segment elevation for both the patients treated with streptokinase and the control group.[40] Treatment with streptokinase significantly reduced in-hospital mortality among patients with ST-segment elevation in four or more leads, but not among patients with ST-segment elevation that was confined to two or three leads[40] (Fig. 29.2). Early ST-segment recovery is associated with improved infarct zone wall motion[41] and greater myocardial salvage as assessed by technetium-99m sestamibi scintigraphy.[42] Also, resolution of ST-segment elevation within 90 minutes after either primary angioplasty or fibrinolytic therapy identifies patients with lower mortality at 30 days and 1 year and 5 years after STEMI.[43–46] Continuous ECG monitoring is customary for the detection of arrhythmias and conduction abnormalities.

It is important to recognize that ST-segment elevation occurs in numerous conditions other than acute MI.[47] The list includes left ventricular hypertrophy, LBBB, acute pericarditis, hyperkalemia, Brugada syndrome, pulmonary embolism, and left ventricular apical ballooning syndrome (takotsubo cardiomyopathy)[47,48] (Fig. 29.3).



• **Fig. 29.2** In-hospital mortality among patients randomly assigned to the streptokinase *(SK)* and control groups in the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI-1) trial. Treatment with streptokinase significantly reduced in-hospital mortality among patients with ST-segment elevation in four or more leads, but not among patients with ST-segment elevation that was confined to two or three leads. *NS,* Not significant. (Data from Mauri F, Gasparini M, Barbonaglia L, et al. Prognostic significance of the extent of myocardial injury in acute myocardial infarction treated by streptokinase (the GISSI trial). *Am J Cardiol.* 1989;63:1291–1295.)

Cardiac Enzymes

Myocardial necrosis is accompanied by the release of several biochemical markers in circulating blood, including creatine kinase, myoglobin, troponins T and I, and lactate dehydrogenase. As noted previously, a typical rise and gradual fall of troponin or more rapid rise and fall of CK-MB are required to diagnose an acute, evolving, or recent MI.[2] The ACC/AHA guidelines, however, stress that decisions such as initiation of reperfusion therapy for patients with ST-segment elevation and symptoms of STEMI should not be delayed until the results of serum cardiac biomarkers are available.[20]

Although troponin has become the preferred biomarker for myocardial necrosis, the serum troponin is frequently elevated in patients with HF[10] or chronic kidney disease.[49] Numerous other causes of an elevated troponin have been recognized, and several may be associated with chest pain or ST-segment elevation.[50] An elevated troponin in patients with pulmonary embolism is associated with right ventricular dysfunction and an increased risk of hypotension and death.[51–53] Elevated cardiac troponin also has been reported in patients with acute pericarditis, and patients with ST-segment elevation were more likely to have an elevated troponin.[54]

Echocardiography

Echocardiography may be a useful diagnostic tool under a variety of circumstances. A transesophageal echocardiogram may be useful to differentiate STEMI from aortic dissection. Both transthoracic and transesophageal echocardiography are useful in patients with HF or hypotension to evaluate left and right ventricular function, to rule out cardiac tamponade, and to diagnose ventricular septal rupture (VSR) or mitral regurgitation (MR). Mitral regurgitation is frequent among patients with uncomplicated MI. Color Doppler echocardiography was performed within 48 hours of admission in a series of 417 consecutive patients with acute MI.[55] Mild MR was present in 121 patients (29%), moderate MR in 21 (5%), and severe MR in 4 (1%).[55] Patients with any MR had higher 30-day and 1-year mortality rates, and MR was independently associated with increased 1-year mortality.[55] Echocardiography performed within 30 days after acute MI revealed MR in 50% of a cohort of 773 patients.[56] Cardiac auscultation did not detect a murmur in 54% of patients with mild and 31% of patients with moderate or severe MR.[56] Among 30-day survivors of an MI, during a mean follow-up period of 4.7 years moderate or severe MR detected by echocardiography within 30 days of MI was associated with a 55% increase in the relative risk (RR) of death independent of age, gender, left ventricular ejection fraction (LVEF), and Killip class.[56]

Hemodynamic Monitoring

The value of pulmonary artery (PA) catheterization in critically ill patients has been questioned.[57] The evidence base regarding the impact of PA catheters on outcome in patients with acute MI is limited to retrospective studies because PA catheterization in patients with acute MI has not been evaluated in a prospective, randomized, controlled trial.[58–60] Cohen and associates[60] performed a retrospective analysis of PA catheterization in patients with ACS who were enrolled in two large international randomized clinical trials, Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) IIb and GUSTO III. The study compared the outcomes in 735 patients who received PA catheters with those in 25,702 patients who did not. Except for patients with cardiogenic shock, mortality at 30 days was significantly greater among patients who received PA catheters, both before and after adjustment for baseline differences and subsequent events that may have prompted insertion of a PA catheter.

According to the ACC/AHA Guidelines, the class I indications for PA catheter monitoring are (1) progressive hypotension that either is unresponsive to fluid administration or is developing in a patient in whom fluid administration is contraindicated; and (2) a suspected mechanical complication, such as a VSR or papillary muscle rupture, if an echocardiogram has not been performed.[20] Intraarterial pressure monitoring is recommended for patients with systolic blood pressure less than 80 mm Hg, patients with cardiogenic shock, and patients receiving vasopressor and inotropic drugs.[20]

Access site bleeding is a major risk of central line insertion in patients who have received fibrinolytic drugs. The femoral route is preferred, and noncompressible sites, such as the subclavian vein, are relatively contraindicated.

Diagnostic Cardiac Catheterization and Coronary Angiography

Conditions other than STEMI can cause ST-segment elevation. Pericarditis, for example, is a relative contraindication to fibrinolytic therapy because of the risk of intrapericardial bleeding and tamponade. Therefore urgent coronary angiography and primary angioplasty if indicated would be preferable to intravenous fibrinolytic therapy if there is any suspicion of pericarditis. Similarly, diagnostic cardiac catheterization should be performed if clinical findings and noninvasive studies are unable to differentiate aortic dissection from acute MI.

Right heart catheterization and contrast ventriculography can provide useful diagnostic information in patients with suspected acute MI. Measurement of right heart pressures is useful in patients with suspected right ventricular MI and in patients with hypotension. Measurement of the oxygen content of blood in the right atrium and PA is useful in patients with a suspected VSR. A

contrast left ventriculogram provides an assessment of regional and global left ventricular function and the competence of the mitral valve. Left ventriculography was performed during the index cardiac catheterization in 1976 (95%) of 2082 patients with acute MI who were enrolled in the Controlled Abciximab and Device Investigation to Lower Angioplasty Complications (CADILLAC) trial.[61] Mild MR was present in 192 patients (9.7%), and moderate or severe MR was present in 58 patients (2.9%). Mitral regurgitation was not detected by physical examination in 50% of a cohort of 50 patients with acute MI and moderately severe or severe MR that was demonstrated by left ventriculography.[62]

Numerous studies have addressed the role of routine early angioplasty after fibrinolytic therapy.[63–68] A prospective cohort study of 21,912 patients with a first acute MI concluded that revascularization within 14 days of the acute MI was associated with a significant reduction in 1-year mortality (RR 0.47; 95% CI 0.37–0.60; $P < 0.001$).[63] Several randomized trials have shown beneficial effects of a routine invasive strategy immediately after fibrinolysis,[65] within 24 hours after fibrinolysis,[66] and 1 to 6 weeks after acute MI.[67] The most recent trials have provided support for the practice of routine early angioplasty after fibrinolytic therapy.[68–70] The Trial of Routine Angioplasty and Stenting after Fibrinolysis to Enhance Reperfusion in Acute Myocardial Infarction (TRANSFER-AMI) enrolled 1059 patients with a "high-risk" STEMI who received fibrinolytic therapy at centers that did not have the capability to perform PCI.[68] The patients were randomly assigned to either "standard" treatment (including rescue PCI or delayed angiography) or immediate transfer to another hospital for PCI within 6 hours after fibrinolysis. The primary endpoint—the composite of death, reinfarction, recurrent ischemia, new or worsening congestive heart failure, or cardiogenic shock within 30 days—occurred in 11% of the patients who were assigned to routine early PCI, compared with 17.2% of the patients who were assigned to standard treatment (RR 0.64; 95% CI 0.47–0.87; $P = 0.004$). Borgia and colleagues[69] performed a meta-analysis of seven randomized, controlled trials that compared routine early PCI after successful fibrinolysis with PCI only for patients without evidence of reperfusion (rescue PCI). After a follow-up period of

• BOX 29.1 ACC/AHA Practice Guidelines for Coronary Angiography in Patients With S-T Segment Elevation Myocardial Infarction (STEMI) Who Were Managed With Fibrinolytic Therapy or Who Did Not Receive Reperfusion Therapy

Class I

Cardiac catheterization and coronary angiography with intent to perform revascularization should be performed after STEMI in patients with any of the following:

1. Cardiogenic shock or acute severe heart failure that develops after initial presentation
2. Intermediate- or high-risk findings on predischarge noninvasive ischemia testing
3. Myocardial ischemia that is spontaneous or provoked by minimal exertion during hospitalization

Class IIa

1. Coronary angiography with intent to perform revascularization is reasonable for patients with evidence of failed reperfusion or reocclusion after fibrinolytic therapy. Angiography can be performed as soon as logistically feasible.
2. Coronary angiography is reasonable before hospital discharge in stable patients with STEMI after successful fibrinolytic therapy. Angiography can be performed as soon as logistically feasible, and ideally within 24 h, but should not be performed within the first 2–3 h after administration of fibrinolytic therapy.

STEMI, *ST-segment elevation myocardial infarction.*

From O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol. *2013;61:e78–e140.*

30 days routine early PCI after successful fibrinolysis reduced the rates of reinfarction (OR 0.55; 95% CI 0.36–0.82; $P = 0.003$), the combined end point of death and reinfarction (OR 0.65; 95% CI 0.49–0.88; $P = 0.004$), and recurrent ischemia (OR 0.25; 95% CI 0.13–0.49; $P < 0.001$). The benefits of early PCI persisted after 6 to 12 months of follow-up. D'Souza and associates[70] performed a meta-analysis of eight randomized trials that compared routine early PCI with ischemia-driven PCI after fibrinolysis in patients with STEMI. PCI within 24 hours after fibrinolytic therapy was associated with less reinfarction and recurrent ischemia.

The 2013 ACCF/AHA Guideline for the Management of ST-Elevation Myocardial Infarction includes three class I recommendations and two class IIa recommendations for coronary angiography in patients who were managed initially with fibrinolytic therapy or who did not receive reperfusion therapy[24] (Box 29.1). Coronary angiography is recommended in survivors of STEMI who are candidates for revascularization therapy with spontaneous ischemia, intermediate-risk or high-risk findings on noninvasive testing, hemodynamic or electrical instability, mechanical defects, prior revascularization, or high-risk clinical features.

Approach to Management

Fig. 29.4 presents an algorithm for the treatment of acute STEMI.

General Considerations

Patients who present to the emergency department with an acute MI will usually be diagnosed and treated before admission to the intensive care unit (ICU). It is not unusual, however, for STEMI to occur in patients receiving ICU treatment for other conditions, such as gastrointestinal bleeding or respiratory failure, or those undergoing surgical procedures. As in the patients who present to an emergency department, prompt performance and interpretation of an ECG constitute a critical initial step in management. Continuous ECG monitoring for arrhythmias is routinely practiced. Patients usually are advanced from nothing-by-mouth status to clear liquids to a low-fat, low-cholesterol diet as tolerated. Stool softeners should be used to prevent the hemodynamic effects of constipation.

Oxygen

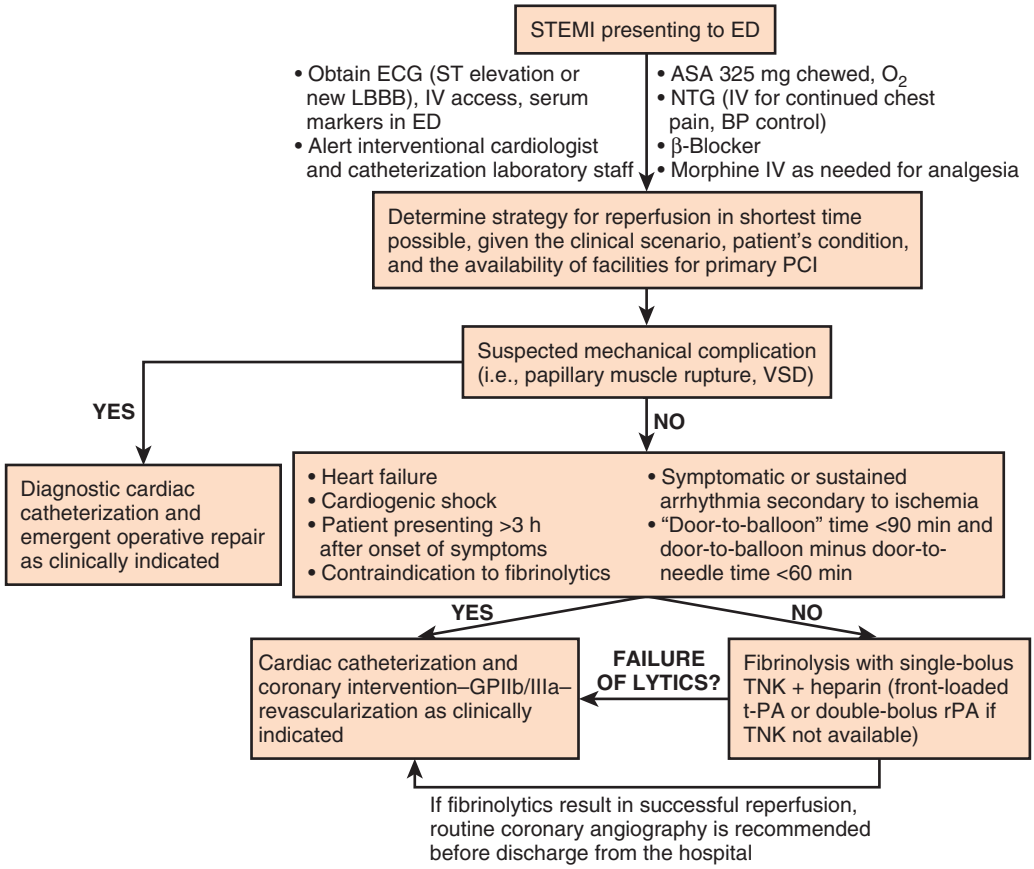
Despite both experimental and clinical studies of oxygen therapy, it remains unclear whether oxygen has beneficial, detrimental, or neutral effects in patients with acute MI. Clinical studies have shown that hyperoxia during inhalation of high concentrations of oxygen causes an increase in coronary vascular resistance and a decrease in coronary blood flow.[71] Nevertheless, in patients with an anterior STEMI who underwent PCI of the LAD, an intracoronary infusion of supersaturated oxygen for 90 minutes was associated with a significantly smaller infarct size measured by Tc^{99m}-sestamibi single-photon emission computed tomography (CT) 14 days after MI.[72] The Air Versus Oxygen in myocarDial infarction study (AVOID) randomly assigned 638 patients with a suspected STEMI to no supplemental oxygen or supplemental oxygen administered via face mask at 8 L/min by paramedics.[73] Oxygen therapy was started in the field and continued until the patient was transferred from the cardiac catheterization laboratory to the cardiac care ward. The data from 441 patients with a confirmed STEMI showed that the patients who received supplemental oxygen had greater rates of recurrent MI and cardiac arrhythmias, and a greater peak creatine kinase.[73] Among the subset of 139 patients who underwent cardiac magnetic resonance imaging (MRI) 6 months after MI, treatment with supplemental oxygen was associated with increased myocardial infarct size (2.3 vs. 13.1 g; $P = 0.04$).[73]

The DETermination of the role of OXygen in suspected Acute Myocardial Infarction (DETO2X-AMI) trial intends to randomly assign 6600 normoxemic patients with suspected acute MI to room air or supplemental oxygen at 6 L/min by mask for 6 to 12 hours.[74] The primary objective is to determine whether oxygen reduces 1-year all-cause mortality.[74]

The 2004 ACC/AHA STEMI guidelines included a class I indication for supplemental oxygen in patients with an arterial oxygen saturation less than 90%.[20] The 2004 guidelines also included a class IIa indication: "It is reasonable to administer supplemental oxygen to all patients with uncomplicated STEMI during the first 6 hours."[20] The 2013 ACCF/AHA STEMI Guidelines do not include any class I or II recommendations regarding supplemental oxygen, and state that "Oxygen therapy is appropriate for patients who are hypoxemic (oxygen saturation <90%)".[24]

Analgesia and Sedation

Relief of pain is an important goal in patients with acute MI. According to the 2013 ACCF/AHA STEMI Guideline, morphine sulfate is the drug of choice for pain relief in patients with STEMI.[24] There are no published randomized trials of morphine therapy in patients with acute MI. An analysis of the CRUSADE registry, however, revealed that use of morphine was associated with a 50% higher mortality in patients with NSTEMI even after risk adjustment.[75] In a study of 24 healthy subjects, 5 mg of intravenous morphine delayed the absorption of clopidogrel, decreased the



• **Fig. 29.4** Algorithm for the treatment of acute ST-segment elevation myocardial infarction *(STEMI). Note:* Nitroglycerin should be used with caution in patients with inferior wall myocardial infarction with possible right ventricular involvement. Nitroglycerin should be avoided altogether in hypotensive patients. *ASA,* Acetylsalicylic acid (aspirin); *BP,* blood pressure; *ECG,* electrocardiogram; *ED,* emergency department; *GP,* glycoprotein; *IV,* intravenous; *LBBB,* left bundle branch block; *NTG,* nitroglycerin; *PTCA,* percutaneous transluminal coronary angioplasty; *PCI,* percutaneous coronary intervention, *rPA,* recombinant plasminogen activator (reteplase); *TNK,* tenecteplase; *t-PA,* tissue plasminogen activator; *VSD,* ventricular septal defect.

plasma levels of the active metabolite of clopidogrel, and delayed and diminished the inhibition of platelet function.[76] Morphine has been shown to delay and attenuate the onset of platelet inhibition by either prasugrel or ticagrelor in patients with acute MI.[77–78] Therefore morphine may increase the risk of coronary reocclusion after fibrinolytic therapy and stent thrombosis after PCI. Until additional data become available, it may be prudent to limit the use of morphine to patients with persistent pain despite treatment with nitrates and a β-adrenergic antagonist.

The abundant evidence that nonsteroidal antiinflammatory drugs (NSAIDs) have adverse effects in patients with cardiovascular disease has been reviewed in great detail in multiple publications, including a scientific statement from the AHA and a meta-analysis of 31 trials that enrolled 116,429 patients.[79–81] Treatment with either a selective cyclooxygenase-2 inhibitor or a nonselective NSAID after discharge from the hospital significantly increases the risk of death and recurrent MI. A Danish study of 61,971 patients who were hospitalized for a first-time acute MI between 2002 and 2011 found that treatment with either a selective cyclooxygenase-2 inhibitor or a nonselective NSAID after discharge from the hospital significantly increased the risk of bleeding and thrombotic events, even after short-term treatment.[82] Also, the use of NSAIDs is associated with an increased risk of death or recurrent MI regardless of the time elapsed after an initial MI.[83] One possible explanation for the adverse cardiovascular effects of NSAIDs is inhibition of the clinical benefits of aspirin. An analysis of the Physicians' Health Study concluded that there was greater than a twofold increased risk of a first MI among healthy male U.S. physicians who were randomly assigned to receive aspirin and also took other NSAIDs on more than 60 days per year.[84] An important pharmacologic study demonstrated that inhibition of platelet aggregation by aspirin was blocked when ibuprofen was administered before aspirin.[85] On July 9, 2015, the U.S. Food and Drug Administration (FDA) issued a drug safety communication that announced strengthening of the existing label warning that NSAIDS increase the chance of a heart attack or stroke. According to the 2013 ACCF/AHA STEMI Guideline, NSAIDs, including cyclooxygenase-2 inhibitors, are contraindicated in patients with STEMI.[24]

Nitrates

The beneficial physiologic effects of nitrates include vasodilation of the coronary arteries, which may improve myocardial oxygen supply, especially in patients with a component of coronary spasm, and vasodilation of peripheral arteries and veins, causing reductions

in pulmonary capillary wedge pressure (PCWP), mean arterial pressure, and peripheral vascular resistance, thereby decreasing left ventricular preload and afterload and myocardial oxygen demand.[86] Severe hypotension and bradycardia have been observed after administration of either sublingual or intravenous nitroglycerin in patients with acute MI.[87] Patients with right ventricular MI may experience severe hypotension during administration of nitroglycerin because adequate right ventricular preload is required to maintain cardiac output. Nitroglycerin is contraindicated in patients who have taken phosphodiesterase inhibitors because they potentiate nitroglycerin-induced hypotension.[88]

The 2013 ACCF/AHA STEMI Guideline endorses sublingual nitroglycerin (0.4 mg) every 5 minutes for a total of three doses for relief of ischemic discomfort, and intravenous nitroglycerin for relief of ongoing ischemic discomfort, control of hypertension, or management of pulmonary congestion.[24] It has been proposed that intravenous nitroglycerin may limit myocardial infarct size and expansion.[89] Two large clinical trials, however, were unable to demonstrate significant improvements in mortality by the prolonged administration of nitroglycerin after acute MI.[90,91] The GISSI-3 trial enrolled 19,394 patients with acute MI.[90] Patients who were randomly assigned to treatment with nitroglycerin received intravenous nitroglycerin for 24 hours, followed by transdermal nitroglycerin for 6 weeks.[90] Nitroglycerin did not reduce the 6-week rate of death or clinical HF. The Fourth International Study of Infarct Survival (ISIS-4) enrolled 58,050 patients with suspected acute MI in a $2 \times 2 \times 2$ factorial study that included randomization to isosorbide mononitrate 60 mg daily or placebo for 28 days.[91] No significant effect of nitroglycerin on mortality was found after 5 weeks or 1 year.

Several studies have investigated the effect of another nitrate, nitroprusside, on hemodynamics and outcome in patients with acute MI.[92–95] Intravenous nitroprusside reduced PCWP and increased cardiac index in patients with acute MI.[92,93] A comparison of intravenous nitroprusside with intravenous nitroglycerin in 10 patients with acute anterior MI demonstrated that ST-segment elevation increased during infusion of nitroprusside, whereas it decreased during infusion of nitroglycerin.[92] Experimental data indicate that nitroprusside may exacerbate myocardial ischemia or injury by redistribution of myocardial blood flow from ischemic to nonischemic zones.[92] A Veterans Administration Cooperative Study enrolled 812 patients with acute MI and a PCWP greater than 12 mm Hg in a double-blind, randomized trial of nitroprusside infused for 48 hours.[95] Compared with the placebo group, mortality at 13 weeks was increased by nitroprusside in patients whose infusions started within 9 hours of the onset of pain. A smaller European trial randomly assigned 328 patients with acute MI to infusion of nitroprusside or 5% glucose.[94] The trial was terminated when 1-week mortality in the control group was significantly greater than in the nitroprusside group (10.9% vs. 3.1%; $P < 0.05$). The use of nitroprusside in patients with acute MI should probably be reserved for patients with severe hypertension that is unresponsive to treatment with intravenous nitroglycerin.

Aspirin

The Second International Study of Infarct Survival (ISIS-2) provided definitive evidence that aspirin reduces mortality in patients with acute MI.[96] The study used a 2×2 factorial design to randomly assigned 17,187 patients to four treatment groups: streptokinase, aspirin 160 mg daily for 1 month, both, or neither. Aspirin reduced the rate of in-hospital reinfarction both in the patients who received streptokinase and in the patients who did not receive fibrinolytic therapy. At 35 days, the vascular-cause mortality rate was 9.4% among the patients in the aspirin treatment group, compared with 11.8% among those in the placebo group, representing a 23% reduction ($P < 0.00001$). Aspirin also significantly reduced all-cause mortality. Also, the combination of aspirin and streptokinase reduced mortality more than did either agent alone. The effects of the initial dose of aspirin on short-term outcomes after fibrinolytic therapy were tested by analyzing the outcomes of 48,422 patients with STEMI who were enrolled in two large clinical trials, GUSTO I and GUSTO III.[97] Compared with an initial dose of 162 mg, an initial dose of 325 mg was associated with a significant increase in in-hospital moderate or severe bleeding, but the rates of reinfarction and death at 24 hours, 7 days, and 30 days were not significantly different.[97] The ACCF/AHA Guideline for the Management of STEMI includes a class I recommendation for a loading dose of aspirin of 162 to 325 mg before primary PCI and for patients who receive fibrinolytic therapy.[24] A second class I recommendation is for aspirin to be continued indefinitely.[24] Finally, there is a class IIa recommendation that it is reasonable to prescribe a maintenance aspirin dose of 81 mg/day in preference to higher doses after either fibrinolytic therapy or primary PCI.[24] Also, patients who are treated with ticagrelor should receive a maintenance aspirin dose of 81 mg/day because higher doses of aspirin were associated with reduced efficacy of ticagrelor.[98]

Reocclusion of a patent infarct artery after successful fibrinolytic therapy is associated with higher in-hospital mortality, reduced event-free survival after hospital discharge, and long-term impairment of regional and global left ventricular function.[99–102] There are conflicting opinions regarding aspirin's effect on reocclusion of an infarct artery.[103,104] The Antithrombotics in the Prevention of Reocclusion in Coronary Thrombolysis (APRICOT) study randomly assigned 300 patients with an open infarct artery within 48 hours after fibrinolysis to three treatment groups: aspirin 325 mg daily, warfarin, or placebo.[105] Cardiac catheterization was performed 3 months later in 248 patients. The reocclusion rates were not significantly different: 32% (24/74) with placebo, 30% (24/81) with warfarin, and 25% (23/93) with aspirin. A pooled analysis of published studies estimated that the incidence of reocclusion after streptokinase or tissue plasminogen activator (t-PA) is approximately 11% with aspirin, compared with 25% without aspirin.[103]

Inhibitors of the Platelet $P2Y_{12}$ Receptor

The combination of aspirin with inhibitors of the platelet $P2Y_{12}$ receptor has been shown to be superior to aspirin alone in patients with a STEMI.[106–108] The Clopidogrel as Adjunctive Reperfusion Therapy (CLARITY) study enrolled 3491 patients who received fibrinolytic therapy for STEMI and randomly assigned them to receive clopidogrel 75 mg daily or placebo in a double-blind fashion.[106] Coronary angiography performed at a median of 84 hours after randomization in each group demonstrated an occluded infarct-related artery (IRA) in 18.4% of the placebo group patients, compared with 11.7% of the clopidogrel group patients ($P < 0.001$). PCI was performed during the index hospitalization in 1863 (53.4%) of the patients who were enrolled in the CLARITY trial.[108] The combined incidence of cardiovascular death, recurrent MI, or stroke from PCI to 30 days after randomization was significantly lower among patients who were treated with clopidogrel and aspirin compared with the patients who received aspirin alone (3.6% vs. 6.2%; adjusted OR 0.54; 95% CI 0.35–0.85; $P = 0.008$).[108] The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) randomly assigned 45,852 patients with suspected

acute MI to receive treatment with aspirin 162 mg daily plus clopidogrel 75 mg daily or placebo.[107] The in-hospital mortality rate was significantly lower for the clopidogrel group than for the placebo group (7.5% vs. 8.1%; $P = 0.03$). The CLARITY study used a clopidogrel loading dose of 300 mg; the COMMIT study did not use a loading dose.

A multivariate-weighted logistic regression analysis of the outcomes of 8429 STEMI patients who were enrolled in 26 randomized clinical trials concluded that pretreatment with a loading dose of clopidogrel before primary PCI was an independent predictor of coronary artery patency before PCI (OR 1.51; 95% CI 1.31–1.74; $P < 0.0001$) and decreased mortality after PCI (OR 0.57; 95% CI 0.38–0.85; $P = 0.0055$).[109] Among patients with STEMI who were enrolled in the Harmonizing Outcomes With Revascularization and Stents in Acute Myocardial Infarction (HORIZONS-AMI) trial and underwent primary PCI, a clopidogrel loading dose of 600 mg ($n = 2158$), compared with 300 mg ($n = 1153$) was associated with significantly lower 30-day rates of mortality, reinfarction, and stent thrombosis and was an independent predictor of freedom from major adverse cardiac events at 30 days.[110]

Prasugrel, another inhibitor of the platelet $P2Y_{12}$ receptor, was studied in patients with ACS, including patients with STEMI, in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38.[111,112] The trial randomly assigned 3534 patients with STEMI who were undergoing either primary PCI (PCI within 12 hours of symptom onset) or secondary PCI (PCI between 12 hours and 14 days after symptom onset) to either prasugrel (60-mg loading dose and 10-mg/day maintenance dose) or clopidogrel (300-mg loading dose and 75-mg maintenance dose) for 6 to 15 months.[112] The primary endpoint of cardiovascular death, nonfatal MI, or nonfatal stroke, was significantly less frequent at both 30 days and 15 months among patients who were randomly assigned to prasugrel compared with patients who were assigned to clopidogrel.[112]

Ticagrelor, an inhibitor of the platelet $P2Y_{12}$ receptor, was studied in patients with ACS, including patients with STEMI, in the Study of Platelet Inhibition and Patient Outcomes (PLATO).[113,114] The trial randomly assigned 7544 patients with STEMI who were undergoing primary PCI to either ticagrelor (180-mg loading dose and 90-mg twice-daily maintenance dose) or clopidogrel (300-mg loading dose and 75-mg maintenance dose) for 6 to 12 months.[114] Compared with clopidogrel, treatment with ticagrelor reduced several secondary end points, including MI (hazard ratio [HR] 0.80; $P = 0.03$), total mortality (HR 0.82; $P = 0.05$), and definite stent thrombosis (HR 0.66; $P = 0.03$); major bleeding was not significantly different (HR 0.98; $P = 0.76$).[114]

The recommendations regarding adjunctive antiplatelet therapy for patients with STEMI that were endorsed by the 2013 ACCF/AHA STEMI Guideline are summarized in Box 29.2.[24] The U.S. FDA has issued several pronouncements regarding inhibitors of the platelet $P2Y_{12}$ receptor. Prasugrel is contraindicated in patients with a history of transient ischemic attack or stroke and active pathologic bleeding. Also, prasugrel should not be administered to patients older than age 75 because of an increased risk of fatal and intracranial bleeding. Finally, the maintenance dose of prasugrel should be reduced to 5 mg daily in patients who weigh less than 60 kg. Maintenance doses of aspirin above 100 mg reduce the effectiveness of ticagrelor and should be avoided. The 2013 ACCF/AHA STEMI Guideline does not reflect a label revision for clopidogrel announced by the FDA on September 16, 2016. The revision restricts the use of clopidogrel in patients with STEMI to medically

• BOX 29.2 ACCF/AHA Guideline for Antiplatelet Therapy for Patients With STEMI

Antiplatelet Therapy in Patients Who Receive Fibrinolytic Therapy

Class I

1. Aspirin (162–325-mg loading dose) and clopidogrel (300-mg loading dose for patients ≤75 years of age, 75-mg dose for patients >75 years of age)
2. Aspirin should be continued indefinitely and clopidogrel (75 mg daily) should be continued for at least 14 days and up to 1 year

Class IIa

1. It is reasonable to use aspirin 81 mg/day in preference to higher maintenance doses

Antiplatelet Therapy to Support Primary PCI in STEMI

Class I

1. Aspirin 162–325 mg should be given before primary PCI
2. After PCI aspirin should be continued indefinitely
3. A loading dose of a $P2Y_{12}$ receptor inhibitor should be given as early as possible or at time of primary PCI. Options include the following:
   a. Clopidogrel 600 mg
   b. Prasugrel 60 mg
   c. Ticagrelor 180 mg
4. $P2Y_{12}$ inhibitor therapy should be given for 1 year to patients with STEMI who receive a stent (BMS or DES) during primary PCI using the following maintenance doses:
   a. Clopidogrel 75 mg daily
   b. Prasugrel 10 mg daily
   c. Ticagrelor 90 mg twice a day

Class IIa

1. It is reasonable to use aspirin 81 mg/day in preference to higher maintenance doses
2. It is reasonable to begin treatment with an intravenous GP IIb/IIIa receptor antagonist such as abciximab, high-bolus-dose tirofiban, or double-bolus eptifibatide at the time of primary PCI in selected patients with STEMI who are receiving unfractionated heparin

Class IIb

1. It may be reasonable to administer intravenous GP IIb/IIIa receptor antagonist in the precatheterization laboratory setting to patients with STEMI for whom primary PCI is intended
2. It may be reasonable to administer intracoronary abciximab to patients with STEMI undergoing primary PCI
3. Continuation of a $P2Y_{12}$ inhibitor beyond 1 year may be considered in patients undergoing DES placement

Class III

1. Prasugrel should not be administered to patients with a history of prior stroke or transient ischemic attack.

Antiplatelet Therapy to Support PCI After Fibrinolytic Therapy in STEMI

Class I

1. Aspirin 162–325 mg should be given before primary PCI
2. After PCI aspirin 81–325 mg daily should be continued indefinitely
3. For patients who received a loading dose of clopidogrel with fibrinolytic therapy, continue clopidogrel 75 mg daily without an additional loading dose
4. For patients who have not received a loading dose of clopidogrel with fibrinolytic therapy, the loading dose of clopidogrel should be 300 mg within 24 hours and 600 mg more than 24 hours after receiving fibrinolytic therapy

Anticoagulant Therapy

The rationale for anticoagulant therapy in patients with STEMI includes promotion of infarct artery patency, and prevention of deep vein thrombosis, pulmonary embolism, left ventricular mural thrombus, and cerebral embolism. Left ventricular mural thrombus formation after acute MI occurs more commonly after anterior than nonanterior wall MI and is associated with an increased risk of systemic embolization.[115,116] Data differ regarding the incidence of left ventricular thrombus in patients who receive reperfusion therapy. The GISSI-2 study, in which all patients received fibrinolytic therapy, observed left ventricular thrombi in 51 of 180 consecutive patients with a first anterior acute MI who underwent serial echocardiography within 48 hours after the onset of symptoms and before hospital discharge.[117] Another study, however, detected left ventricular thrombi in only 6.4% of patients with acute anterior MI who underwent echocardiography on days 1, 14, and 90 after MI.[118] A double-blind, randomized trial compared a 10-day course of high-dose subcutaneous unfractionated heparin (UFH) (12,500 units every 12 hours) with low-dose subcutaneous UFH (5,000 units every 12 hours) in the prevention of left ventricular thrombus in 221 patients with acute anterior MI who did not receive fibrinolytic therapy.[119] Echocardiography 10 days after MI demonstrated left ventricular thrombi in 10 of 95 patients (11%) in the high-dose group and in 28 of 88 patients (32%) in the low-dose group ($P = 0.0004$). A meta-analysis of seven studies that enrolled 270 patients suggests that systemic anticoagulation in patients with mural thrombi reduces embolic complications.[115]

Clinical trials have evaluated both subcutaneous and intravenous UFH in patients with acute MI who were treated with various fibrinolytic agents. Randomized, controlled clinical trials have shown that adjunctive therapy with intravenous UFH increases the patency of the IRA after administration of t-PA.[120,121] A meta-analysis that included 68,000 patients enrolled in randomized trials that compared UFH plus aspirin with aspirin alone showed that only 5 lives were saved per 1000 patients who received UFH in addition to streptokinase.[122] The meta-analysis was heavily influenced by two studies, GISSI-2[123] and ISIS-3,[124,125] that enrolled 62,067 patients randomly assigned to receive fibrinolytic therapy plus either aspirin alone or aspirin plus subcutaneous UFH. Another meta-analysis was limited to six randomized controlled trials that enrolled 1735 patients who received either intravenous UFH or no heparin after fibrinolytic therapy.[126] The analysis found that the addition of intravenous UFH to t-PA or streptokinase had insignificant effects on mortality and reinfarction, but the risk of bleeding was significantly increased.[126]

Several randomized clinical trials[127–131] and meta-analyses[132,133] have been performed to compare low-molecular-weight heparin (LMWH) with placebo or UFH as adjuncts to fibrinolytic therapy in patients with STEMI. A meta-analysis of 16,943 patients enrolled in four randomized trials revealed that the endpoints of death or reinfarction at 7 days and at 30 days were significantly reduced by LMWH compared with placebo.[133] A meta-analysis of 7098 patients enrolled in six randomized trials revealed that LMWH, compared with UFH, reduced the rates of reinfarction during hospitalization and at 30 days, but the rates of death were not significantly different.[133] Neither meta-analysis included a subsequent trial, Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment (ExTRACT)-TIMI 25, that compared enoxaparin, an LMWH, with UFH in patients with STEMI who received fibrinolytic therapy.[129,130] The study was a double-blind, randomized comparison of enoxaparin given subcutaneously twice daily until hospital discharge versus intravenous UFH for 48 hours in 20,506 patients with STEMI. A fibrinolytic agent was received by 99.7% of the patients: 55% received alteplase, 20% received streptokinase, 19% received tenecteplase (TNK), and 5.5% received reteplase (rPA). The primary endpoint, death or nonfatal recurrent MI through 30 days, occurred in 12% of patients in the UFH group and in 9.9% of patients in the enoxaparin group ($P < 0.001$). The rates of major bleeding at 30 days were 1.4% in the UFH group and 2.1% in the enoxaparin group ($P < 0.001$), but the rates of intracranial hemorrhage were not significantly different (UFH 0.7%, enoxaparin 0.8%; $P = 0.14$). The enoxaparin strategy significantly reduced the risk of nonfatal MI at 1 year (5.7% vs. 6.8%; HR 0.82; 95% CI 0.73–0.92; $P < 0.001$).[130] One of the mechanisms underlying the benefit of LMWH compared with UFH may be improved patency of the infarct artery after fibrinolytic therapy.[131]

Fondaparinux, a synthetic pentasaccharide, is a factor Xa inhibitor that binds antithrombin and inhibits factor Xa. The Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS) conducted two trials to evaluate fondaparinux in patients with ACS[134] and STEMI.[135,136] The OASIS-6 trial was a randomized, double-blind comparison of fondaparinux 2.5 mg daily or control from days 3 through 9 in 12,092 patients with STEMI.[135] Forty-five percent of the patients received fibrinolytic therapy (streptokinase in 73%), 28.9% underwent primary PCI, and 23.7% did not receive any reperfusion therapy. The primary efficacy outcome—death or reinfarction at 30 days—was significantly lower in the fondaparinux group than in the control group (9.7% vs. 11.2%; HR 0.86; 95% CI 0.77–0.96; $P = 0.008$). Fondaparinux also significantly reduced the rates of death at day 9, day 30, and the end of the study (3–6 months). Significant heterogeneity in the effect of fondaparinux was observed in relation to the reperfusion strategy, with benefit observed in patients who received no reperfusion therapy or a fibrinolytic agent, but not in patients who underwent primary PCI. The rate of severe bleeding was not increased by fondaparinux.

A subgroup analysis of the OASIS-6 results was performed to compare the effects of fondaparinux with usual care (i.e., UFH or placebo) in patients with STEMI who did not receive any reperfusion therapy.[136] Fondaparinux significantly reduced the composite endpoint of death or recurrent MI, without an increase in severe bleeding or stroke, compared with UFH or placebo.[136]

The dose of fondaparinux must be adjusted in patients with renal insufficiency, but adjustment for body weight is not necessary. The anticoagulant effect of the drug cannot be monitored by conventional clotting tests, such as the activated clotting time or partial thromboplastin time. Also, the relatively long half-life of fondaparinux, 17 to 21 hours, conceivably may be viewed as an impediment to early sheath removal and ambulation after cardiac catheterization. Because of the risk of catheter thrombosis, fondaparinux should not be used as the sole anticoagulant during PCI, and an additional anticoagulant with antifactor IIa activity should be administered.[24]

Multiple randomized trials have compared bivalirudin, a direct thrombin inhibitor, with UFH in patients with STEMI.[137–142] Bivalirudin was compared with UFH plus glycoprotein (GP) IIb/IIIa inhibitors in 3602 patients with STEMI undergoing primary PCI in the HORIZONS-AMI trial.[137–139] Compared with UFH plus GP IIb/IIIa inhibitors, anticoagulation with bivalirudin was

associated with a reduced rate of net adverse clinical events and major bleeding at 30 days and 1 year.[137,138] Also, treatment with bivalirudin was associated with both cardiac and all-cause mortality rates that were significantly lower after 30 days and 1 year.[137,138] Among the 477 patients who were classified as high risk, the mortality rates at 1 year were 8.4% among patients treated with bivalirudin, compared with 15.9% among patients treated with UFH plus a glycoprotein IIb/IIIa inhibitor ($P = 0.01$).[139] A patient-level, pooled analysis of two of the randomized trials, HORIZONS-AMI and EUROMAX (European Ambulance Acute Coronary Syndrome Angiography Trial), examined the 30-day outcomes in 4935 patients with STEMI who underwent primary PCI with stent implantation and were randomly assigned to receive either bivalirudin or heparin with or without a GP IIb/IIIa inhibitor.[143] Although acute stent thrombosis (within 24 hours of PCI) was more frequent in patients treated with bivalirudin (2.5% vs. 1.6%, $P = 0.04$), the 30-day mortality attributable to early stent thrombosis occurred in 4 of 2479 (0.2%) bivalirudin-treated patients versus 16 of 2456 (0.7%) patients treated with heparin with or without GP IIb/IIIa inhibitor ($P = 0.007$).[143]

According to the 2013 ACCF/AHA STEMI Guideline,[24] "patients with STEMI undergoing reperfusion with fibrinolytics should receive anticoagulant therapy for a minimum of 48 hours and preferably for the duration of the index hospitalization, up to 8 days or until revascularization if performed." Enoxaparin is preferred over UFH if anticoagulant therapy is given for more than 48 hours because of the risk of heparin-induced thrombocytopenia (HIT) with prolonged UFH treatment. The 2013 ACCF/AHA Guideline for the Management of STEMI recommends adjustment of the dose of UFH to maintain an activated partial thromboplastic time of 1.5 to 2.0 times control.[24] Also, the platelet count should be monitored daily during treatment with UFH because there is a 3% incidence of HIT.[144] The guideline noted that bivalirudin can be used after treatment with a fibrinolytic agent in patients who develop HIT and require continued anticoagulation.[24]

For patients with STEMI who undergo primary PCI, the 2013 ACCF/AHA STEMI Guideline recommends (class I) either UFH or bivalirudin. Also, it includes a class IIa recommendation that "in patients who are at high risk of bleeding, it is reasonable to use bivalirudin monotherapy in preference to the combination of UFH and a GP IIb/IIIa receptor antagonist."[24] As noted above, a class III recommendation states that "Fondaparinux should not be used as the sole anticoagulant to support primary PCI because of the risk of catheter thrombosis."[24] Box 29.3 lists recommendations regarding the doses of UFH, enoxaparin, fondaparinux, and bivalirudin.

The 2007 Focused Update of the ACC/AHA 2004 Guidelines for the Management of Patients With ST-Elevation Myocardial Infarction included a class IIa recommendation that "it is reasonable for patients with STEMI who do not undergo reperfusion therapy to be treated with anticoagulant therapy (non-UFH regimen) for the duration of the index hospitalization, up to 8 days," but the 2013 ACCF/AHA STEMI Guideline does not include a recommendation for anticoagulation in patients who do not undergo reperfusion therapy.[21,24]

• BOX 29.3 Dosing of Anticoagulant Drugs for Patients With STEMI

Anticoagulation to Support Primary PCI in STEMI

Class I

UFH

1. With glycoprotein IIb/IIIa receptor antagonist planned: 50–70 U/kg IV bolus to achieve ACT 200–250 s
2. With no GP IIb/IIIa receptor antagonist planned: 70–100 U/kg IV bolus to achieve ACT 250–300 s

Bivalirudin

1. 0.75 mg/kg IV bolus, then 1.75 mg/kg per hour infusion with or without prior treatment with UFH. Reduce infusion to 1 mg/kg per hour with estimated creatinine clearance <30 mL/min

Class IIa

1. Bivalirudin preferred over UFH with GP IIb/IIIA antagonist in patients at high risk of bleeding

Class III

1. Fondaparinux: not recommended as sole anticoagulant for primary PCI

Anticoagulation in Patients Who Receive Fibrinolytic Therapy

Class I

Patients with STEMI undergoing reperfusion with fibrinolytic therapy should receive anticoagulant therapy for a minimum of 48 h and preferably for the duration of the index hospitalization, up to 8 days or until revascularization if performed (regimens other than UFH are recommended if anticoagulant therapy is given for more than 48 h because of the risk of heparin-induced thrombocytopenia with prolonged UFH treatment). Recommended regimens include the following:

a. UFH: initial intravenous bolus 60 U/kg (maximum 4000 U) followed by an intravenous infusion of 12 U/kg per hour (maximum 1000 U/h) initially, adjusted to maintain the activated partial thromboplastin time at 1.5 to 2 times control (approximately 50–70 s) for 48 h or until revascularization

b. Enoxaparin (provided the serum creatinine is <2.5 mg/dL in men and 2 mg/dL in women): The dose for patients younger than 75 years of age is an initial 30-mg intravenous bolus, followed 15 minutes later by subcutaneous injections of 1 mg/kg every 12 hours. For patients at least 75 years of age, the initial bolus is eliminated and the subcutaneous dose is reduced to 0.75 mg/kg every 12 hours. Regardless of age, if the creatinine clearance (using the Cockcroft-Gault formula) during the course of treatment is estimated to be <30 mL/min, the subcutaneous regimen is 1 mg/kg every 24 hours. Treatment should be continued for up to 8 days or until revascularization.

c. Fondaparinux (contraindicated if CrCl < 30 mL/min): initial dose 2.5 mg intravenously; subsequent subcutaneous injections of 2.5 mg daily starting the following day and continued for up to 8 days or until revascularization.

ACT, *Activated clotting time;* CrCl, *creatinine clearance;* GP, *glycoprotein;* IV, *intravenous;* PCI, *percutaneous coronary intervention;* STEMI, *ST-segment elevation myocardial infarction;* UFH, *unfractionated heparin.*

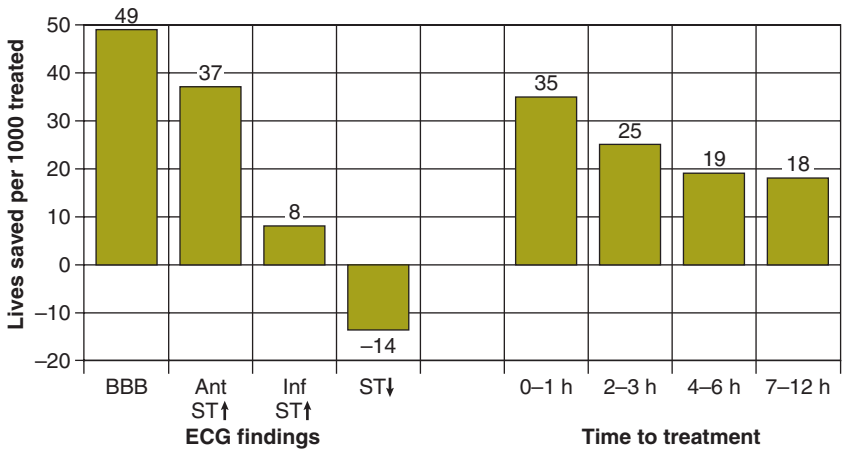
Fibrinolytic Therapy

Effect of Fibrinolysis on Survival

The landmark angiographic study performed by DeWood and coworkers[145] confirmed the presence of coronary artery thrombi in patients with STEMI. Four well-designed, multicenter randomized trials established that three fibrinolytic agents—streptokinase,[96,146,147] anisoylated plasminogen-streptokinase activator complex (i.e., anistreplase),[148] and t-PA[149]—each reduced short-term and long-term mortality in patients with acute MI. In the GISSI trial the survival benefit observed in the patients treated with streptokinase remained significant at 10 years, with an absolute benefit of 19 (95% CI 1–17) lives saved per 1000 patients treated.[147] The Fibrinolytic Therapy Trialists' Collaborative Group analyzed nine trials that randomly



• **Fig. 29.5** The impact of the presenting electrocardiogram *(ECG)* and the time to treatment on the 35-day mortality of 58,600 patients enrolled in nine randomized trials comparing streptokinase, anisoylated plasminogen-streptokinase activator complex (anistreplase), urokinase, or tissue plasminogen activator with placebo or control, expressed as the number of lives saved per 1000 patients who received fibrinolytic therapy. *Ant ST* anterior ST-segment elevation; *BBB* bundle branch block; *Inf ST* inferior ST-segment elevation. (From Indications for fibrinolytic therapy in suspected acute myocardial infarction: Collaborative overview of early mortality and major morbidity results from all randomised trials of more than 1000 patients. Fibrinolytic Therapy Trialists' [FTT] Collaborative Group. *Lancet.* 1994;343:311–322.)

assigned a total of 58,600 patients with suspected acute MI to a fibrinolytic therapy group or a control group.[150] The absolute risk of death increased with age, but absolute reductions in mortality were comparable among younger and older patients up to 75 years of age. Several trials had upper age limits for enrollment. The remaining trials enrolled 5788 patients 75 years or older and found no significant effect of fibrinolytic therapy on mortality at 35 days (25.3% for the control patients vs. 24.3% for patients who received fibrinolytic therapy).[150]

The baseline ECG findings and the elapsed time between the onset of symptoms and the initiation of treatment were significant determinants of the impact of fibrinolytic therapy on mortality at 35 days[150] (Fig. 29.5). The greatest reduction in mortality was observed in patients who presented with either bundle branch block (BBB) (control 23.6% vs. fibrinolytic 18.7%) or ST-segment elevation in the anterior leads (control 16.9% vs. fibrinolytic 13.2%).[150] Fibrinolytic therapy increased mortality among patients with ST-segment depression on the baseline ECG.

A linear relationship between the absolute reduction in mortality and the delay from symptom onset to randomization was found among the 45,000 patients who presented with ST elevation or BBB on the ECG.[150] Fibrinolytic therapy significantly reduced mortality even among patients who received treatment 7 to 12 hours after the onset of symptoms, but patients who received treatment within the first hour after the onset of their symptoms received the greatest benefit. Patients who receive fibrinolytic therapy within the first hour after symptom onset have the greatest proportional mortality reduction,[151] as well as the highest incidence of so-called aborted MI, defined as maximal creatine kinase level up to twice the upper limit of normal and typical evolution of ECG changes.[152,153] A multicenter trial of fibrinolytic therapy reported that the baseline-adjusted mortality was significantly lower among the 13.3% of patients who had an aborted MI than among those who did not.[152]

Persistent occlusion of the IRA after acute MI is associated with left ventricular remodeling, resulting in increased left ventricular end-systolic volume, a major predictor of survival after acute MI.[154,155] Some evidence suggests that reperfusion later than 6 hours after the onset of symptoms has a favorable effect on ventricular remodeling, with less ventricular dilation observed after successful reperfusion than after no reperfusion therapy.[156,157] Several clinical trials have investigated the effects of fibrinolytic therapy on clinical events in patients who received treatment more than 6 hours after the onset of symptoms. A South American multicenter trial randomly assigned 2080 patients within 7 to 12 hours after the onset of symptoms to receive streptokinase or placebo and found no significant difference in mortality rates in the hospital, after 35 days, and after 1 year.[158] The Late Assessment of Thrombolytic Efficacy (LATE) study randomly assigned 5711 patients who presented with suspected acute MI between 6 and 24 hours after the onset of symptoms to receive t-PA or placebo.[159] Treatment with t-PA significantly reduced mortality among patients who received treatment within 12 hours of symptom onset; the 35-day mortality rate was 8.9% for the t-PA group versus 11.97% for placebo, representing a relative reduction of 25.6% (95% CI 6.3%–45%; $P = 0.0229$). Mortality at 35 days was not significantly reduced by the administration of t-PA to patients who received treatment 12 to 24 hours after symptom onset.

The major causes of delayed fibrinolytic therapy for acute MI are failure of patients to seek medical care[160,161] and delays in administration of fibrinolytic therapy.[162,163] A retrospective review of data for 2409 patients hospitalized with acute MI in Minnesota in 1992 and 1993 reported that 40% of the patients delayed presentation to the hospital more than 6 hours after the onset of symptoms.[160] The ACC/AHA Practice Guidelines set a goal of initiating fibrinolytic therapy within 30 minutes of contact with the medical system.[20] A study of 3219 patients with STEMI who received fibrinolytic therapy in 178 hospitals between 2007 and 2008 found that the "door-to-needle" time was 30 minutes or less in only 44.5% of patients.[163] Female gender and age older than 75 years were associated with longer door-to-needle times.[163] A total of 5296 patients who received fibrinolytic therapy before

transfer from hospitals without PCI capability to PCI-capable hospitals were enrolled in a registry of 22,481 STEMI patients between July 1, 2008, and March 31, 2012.[164] Only 43.8% of the patients achieved a door-to-needle time within 30 minutes.[164]

Prehospital administration of fibrinolytic therapy has been investigated as one approach to reducing the delay between symptom onset and reperfusion.[165–167] A meta-analysis of six randomized trials that compared prehospital with in-hospital fibrinolytic therapy for acute MI found that the time to fibrinolytic therapy and all-cause in-hospital mortality were significantly reduced by the prehospital administration of fibrinolytic drugs.[165] An international study randomly assigned 1892 patients with STEMI who presented within 3 hours after symptom onset and who were unable to undergo primary PCI within 1 hour to either prehospital fibrinolytic therapy with bolus TNK or primary PCI.[167] All patients were transferred to a PCI-capable hospital. Emergency coronary angiography was required in 36.3% of the patients in the fibrinolysis group, and coronary angiography was performed at a median of 17 hours after randomization in the remainder of the prehospital fibrinolysis group.[167] The primary endpoint—a composite of death, shock, HF, or reinfarction within 30 days—occurred in 116 of 939 patients (12.4%) in the fibrinolysis group compared with 135 of 943 patients (14.3%) in the primary PCI group (RR 0.86; 95% CI 0.68–1.09; $P = 0.21$).[167] For the entire study group the rate of intracranial hemorrhage was greater in the fibrinolysis group than in the primary PCI group (1.0% vs. 0.2%; $P = 0.04$).[167] However, after the dose of TNK was reduced by 50% in patients 75 years of age or older, there were no additional cases of intracranial hemorrhage in that age group, and the rates of intracranial hemorrhage after the protocol amendment were 0.5% for the fibrinolysis group compared with 0.3% for the primary PCI group ($P = 0.45$).[167]

Coronary Artery Patency After Fibrinolytic Therapy

Early angiographic studies investigated the rates of coronary reperfusion after intracoronary[168–170] or intravenous administration of fibrinolytic agents.[171] The Thrombolysis in Myocardial Infarction (TIMI) Study Group devised a grading system of coronary patency that has been adopted widely[171] (Box 29.4). Fibrinolysis was judged to be successful if an IRA that was occluded (TIMI grade 0 or 1) before treatment improved to either partial perfusion (TIMI grade 2) or complete perfusion (TIMI grade 3) 90 minutes after the fibrinolytic therapy began.[171] The first TIMI trial revealed that only 31% of occluded arteries were patent (TIMI grade 2 or 3) 90 minutes after intravenous streptokinase, compared with a 62% patency rate after a 3-hour intravenous infusion of t-PA ($P < 0.001$).[172] Subsequent studies that examined the relationship between the TIMI grade flow and clinical outcome concluded that TIMI grade 3 flow, but not TIMI grade 2 flow, improves both in-hospital and long-term mortality after acute MI.[173,174] Therefore the criteria for evaluating fibrinolytic therapy were revised, and TIMI grade 2 flow is no longer considered a successful outcome.[175]

• BOX 29.4 Definitions of Perfusion in the TIMI Trial

Grade 0 (no perfusion): There is no antegrade flow beyond the point of occlusion.

Grade 1 (penetration without perfusion): The contrast material passes beyond the area of obstruction but "hangs up" and fails to opacify the entire coronary bed distal to the obstruction for the duration of the cineangiographic filming sequence.

Grade 2 (partial perfusion): The contrast material passes across the obstruction and opacifies the coronary bed distal to the obstruction. However, the rate of entry of contrast material into the vessel distal to the obstruction or its rate of clearance from the distal bed (or both) is perceptibly slower than the rate of entry into or clearance from comparable areas not perfused by the previously occluded vessel (e.g., the opposite coronary artery or the coronary bed proximal to the obstruction).

Grade 3 (complete perfusion): Antegrade flow into the bed distal to the obstruction occurs as promptly as antegrade flow into the bed proximal to the obstruction, and clearance of contrast material from the involved bed is as rapid as clearance from an uninvolved bed in the same vessel or the opposite artery.

TIMI, *Thrombolysis in Myocardial Infarction.*

From TIMI Study Group. Thrombolysis in Myocardial Infarction (TIMI) trial. Phase I findings. N Engl J Med. *1985;312:932–936.*

The GUSTO-I trial randomly assigned 41,021 patients to four fibrinolytic strategies: streptokinase plus subcutaneous UFH, streptokinase plus intravenous UFH, accelerated t-PA plus intravenous UFH, or a combination of streptokinase and t-PA plus intravenous UFH.[176] Thirty-day mortality was lowest for the accelerated t-PA–UFH regimen, 6.3%. A substudy of GUSTO-I included 2431 patients who underwent coronary angiography to assess patency of the IRA.[177,178] TIMI grade 3 flow was achieved 90 minutes after initiation of fibrinolytic therapy in 54% (157/292) of patients in the accelerated t-PA–UFH group, compared with 31% of patients who received streptokinase plus UFH (176/576). Analysis of the relationship between patency at 90 minutes and mortality at 30 days regardless of treatment assignment revealed a significant difference between the mortality rate associated with grade 3 flow and the mortality associated with grade 0 or 1 flow (4.4% vs. 8.9%; $P = 0.009$).

The relationship between time to treatment and the mortality reduction by fibrinolytic therapy may be a reflection of several factors. One is that earlier reperfusion achieves greater myocardial salvage.[179] Another factor is that time to treatment may influence the patency rate 90 minutes after administration of certain fibrinolytic drugs.[180] Patency of the IRA 90 minutes after administration of a nonfibrin-specific fibrinolytic drug, such as streptokinase, anistreplase, or urokinase, is lower when patients are first treated beyond 3 hours after the onset of symptoms than when the drugs are administered within 3 hours after onset.[172,180–182] After treatment with t-PA or rPA, fibrin-specific fibrinolytic agents, the rates of TIMI grade 3 flow are similar for patients who received treatment within 3 hours or at 3 hours or later after the onset of symptoms.[172,181,182] The time-dependent reperfusion efficacy is reflected by the rates of in-hospital mortality. A retrospective analysis of six angiographic trials that included 1174 patients found that in-hospital mortality among patients who received nonfibrin-specific drugs was twofold greater for patients treated more than 3 hours after symptom onset compared with patients treated within 3 hours.[182] Among patients who received t-PA or rPA, in-hospital mortality did not differ for patients treated within 3 hours of symptom onset or later than 3 hours after symptom onset.

More sophisticated methodologies for assessing myocardial reperfusion have been devised, such as the TIMI frame count and TIMI myocardial perfusion grade.[183–185] Application of these methods demonstrated that even among patients with TIMI grade 3 flow after fibrinolytic therapy, clinical outcomes and survival are related to the speed of epicardial flow and the state of myocardial perfusion.[183,184] Therefore a major goal of research has been to determine whether combinations of fibrinolytic and antiplatelet drugs might enhance myocardial reperfusion and achieve further reductions in mortality. Compared with full-dose t-PA or rPA, a combination of a reduced dose of either t-PA or rPA plus abciximab,

a platelet GP IIb/IIIa inhibitor, was found to increase the rates of TIMI 3 flow at 60 and 90 minutes after administration.[186,187] Unfortunately, a difference in 30-day mortality between standard-dose rPA and half-dose rPA plus full-dose abciximab was not demonstrated by a large clinical trial, GUSTO-V, that enrolled 16,588 patients with evolving STEMI.[188]

Complications of Fibrinolytic Therapy

Intracranial hemorrhage and other hemorrhagic complications are the major risks associated with the administration of fibrinolytic therapy.[189,190] The NRMI 2 database accrued 71,073 patients who received t-PA for acute MI from June 1, 1994, to September 30, 1996. Intracranial hemorrhage was confirmed by CT or MRI in 625 patients (0.88%).[190] In-hospital mortality was 53%, and 25.3% of patients with intracranial hemorrhage who survived to hospital discharge had neurologic deficits. A multivariate analysis identified several risk factors that were significantly associated with an increased risk of intracranial hemorrhage: older age, female gender, systolic blood pressure greater than 140 mm Hg, diastolic blood pressure greater than 100 mm Hg, and history of stroke. An activated partial thromboplastin time longer than 70 seconds was associated with an increased risk of hemorrhagic stroke in the GUSTO-I trial.[122] Bolus administration of fibrinolytic agents may be associated with an increased risk of intracranial hemorrhage compared with infusion.[191,192] Although phase II trials indicated a statistically nonsignificant reduction in the risk of intracranial hemorrhage, meta-analysis of phase III trials revealed a statistically significant 25% increase in the risk of intracranial hemorrhage with bolus fibrinolytic therapy.[192] According to the ACC/AHA guidelines, "The occurrence of a change in neurological status during or after reperfusion therapy, particularly within the first 24 hours after initiation of treatment, is considered to be due to intracranial hemorrhage until proven otherwise."[20] When intracranial hemorrhage is suspected, an emergency CT scan should be performed, and fibrinolytic, antiplatelet, and anticoagulant therapies should be discontinued until the diagnosis is ruled out. Cryoprecipitate or fresh frozen plasma should be given to replenish coagulation factors.[20] Protamine should be administered to patients who are receiving UFH. Neurosurgery to evacuate parenchymal hemorrhages or subdural hematomas may improve outcome.[193]

Among 40,903 patients enrolled in the GUSTO-I trial, 1.2% had severe bleeding, defined as bleeding that caused hemodynamic compromise that required treatment, and 11.4% experienced moderate hemorrhage, defined as bleeding that required transfusion but did not lead to hemodynamic compromise requiring intervention.[189] The most common sources of moderate and severe bleeding were procedure related. The rate of moderate or severe bleeding was 6% among patients who underwent no procedures, compared with 17% among patients who underwent coronary angiography, 43% among patients who received a PA catheter, and 50% among patients who received an intraaortic balloon pump (IABP) or underwent coronary artery bypass surgery. Older age, lower body weight, and female sex were the three strongest independent predictors of hemorrhage. The risk of noncerebral bleeding was greater after streptokinase than after t-PA, but the risk of intracranial hemorrhage was greater after t-PA.

Patient Selection

The 2013 ACCF/AHA Guideline for STEMI includes one class I indication for fibrinolytic therapy: in the absence of contraindications, fibrinolytic therapy should be given to patients with STEMI and onset of ischemic symptoms within the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of the first medical contact.[24] The 2013 STEMI Guideline also includes one class IIa recommendation for fibrinolytic therapy: in the absence of contraindications and when PCI is not available, fibrinolytic therapy is reasonable for patients with STEMI if there is clinical or ECG evidence of ongoing ischemia within 12 to 24 hours of symptom onset and a large area of myocardium at risk or hemodynamic instability.[24] There is a long list of absolute and relative contraindications to fibrinolytic therapy (Box 29.5). Special attention should be paid to factors that may increase the risk of intracranial hemorrhage, such as a history of such hemorrhage, recent closed head or facial trauma, uncontrolled hypertension, or ischemic stroke within the previous 3 months. PCI is preferable to fibrinolytic therapy in patients with an increased risk of intracranial hemorrhage. Active menstrual bleeding should not be considered a contraindication to fibrinolytic therapy.[194,195] The GUSTO-I trial included 12 menstruating women who received fibrinolytic therapy, 2 of whom required a transfusion for moderate vaginal bleeding.[195] Nontraumatic cardiopulmonary resuscitation also should not be considered a contraindication to fibrinolytic therapy.[194,196]

Increasing age is a risk factor for death and other adverse events after either primary PCI or fibrinolytic therapy for STEMI.[197] The risk of intracranial hemorrhage after fibrinolytic therapy also increases with advancing age.[190,198] Data are conflicting regarding

• BOX 29.5 Contraindications and Cautions for Fibrinolysis in ST-Segment Elevation Myocardial Infarction

Absolute Contraindications

Any prior intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known malignant intracranial neoplasm (primary or metastatic)
Ischemic stroke within 3 months; *exception:* acute ischemic stroke within 4.5 h
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed head or facial trauma within 3 months
Intracranial or intraspinal surgery within 2 months
Severe uncontrolled hypertension (unresponsive to emergency therapy)
For streptokinase, prior treatment within the previous 6 months

Relative Contraindications

1. History of chronic, severe, poorly controlled hypertension
2. Severe uncontrolled hypertension on presentation (systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg)
3. History of prior ischemic stroke more than 3 months earlier, dementia, or known intracranial pathology not covered in absolute contraindications
4. Traumatic or prolonged (beyond 10 min) CPR or major surgery (within 3 weeks)
5. Recent (within 2–4 weeks) internal bleeding
6. Noncompressible vascular punctures
7. For streptokinase/anistreplase: prior exposure (>5 days earlier) or prior allergic reaction to these agents
8. Pregnancy
9. Active peptic ulcer
10. Oral anticoagulant therapy

the benefit or lack of benefit of fibrinolytic therapy in patients with STEMI who are older than 75. One analysis of a Medicare database that included 2673 patients aged 76 to 86 found that fibrinolytic therapy conferred a survival disadvantage, with an HR of 1.38 for 30-day mortality.[199] Fibrinolytic therapy was associated with a 13% reduction in the composite of 1-year mortality and cerebral bleeding in a cohort of 6891 patients 75 years and older with a first STEMI who were enrolled in a Swedish registry.[200] A study performed in the Netherlands randomly assigned 87 patients with acute MI who were older than 75 to primary PCI or streptokinase.[201] The primary composite endpoint of death, reinfarction, or stroke at 30 days occurred in 4 (9%) patients in the PCI group, compared with 12 (29%) in the streptokinase group (RR 4.3, 95% CI 1.2 to 20; $P = 0.01$). After 1 year, mortality was significantly greater for the streptokinase group than for the PCI group (29% vs. 11%; RR 3.4, 95% CI 1.0 to 13.5; $P = 0.03$). One caveat regarding the study is that the mean time from hospital admission to first balloon inflation was 59 ± 19 minutes (range 33–120 minutes)—considerably shorter than door-to-balloon times in the United States.

Many patients with acute MI have contraindications to fibrinolytic therapy or do not meet eligibility criteria for fibrinolytic therapy.[202,203] Contraindications, such as recent surgery, trauma, or gastrointestinal bleeding, would be relatively frequent in patients who develop an acute MI while already hospitalized for another illness. Analysis of patients with STEMI who were enrolled in the NRMI 2, 3, and 4 databases suggested that immediate mechanical reperfusion using either PCI or coronary artery bypass surgery reduced the risk of in-hospital death among patients with contraindications to fibrinolytic therapy.[204]

Percutaneous Coronary Intervention

Numerous randomized trials and observational studies have been performed to investigate PCI in patients with acute MI. Primary PCI is defined as PCI without previous or concomitant fibrinolytic therapy After successful fibrinolysis, PCI may be performed immediately, on a routine, deferred basis, or in a selective fashion (e.g., to treat inducible ischemia). Rescue PCI refers to PCI that is performed after unsuccessful fibrinolytic therapy.

Primary Percutaneous Intervention

Dr. Andreas Gruentzig performed the first balloon angioplasty of a coronary artery in 1977.[205] Dr. K. Peter Rentrop reported his initial experience with PCI for acute MI in 1979.[206,207] O'Neill and colleagues[208] published a randomized trial of PCI compared with intracoronary streptokinase for acute MI in 1986. A meta-analysis identified 32 observational studies that included 185,900 patients with STEMI, and 23 trials that randomly assigned a total of 8140 patients with STEMI to undergo primary PCI or receive intravenous fibrinolytic therapy.[209]

Myocardial salvage and long-term mortality are correlated with both the TIMI grade flow and the myocardial blush grade achieved after primary PCI for STEMI.[210–213] TIMI grade 3 flow is achieved in a high percentage of patients who undergo primary PCI for STEMI. The largest clinical trial of PCI compared with fibrinolytic therapy for acute MI was the Danish Multicenter Randomized Study on Fibrinolytic Therapy versus the Acute Coronary Angioplasty in Acute Myocardial Infarction (DANAMI-2) study.[214–216] Immediate angiography was performed in 777 of the 790 (98%) patients who were randomly assigned to undergo PCI. The initial angiogram showed TIMI grade 0 or 1 flow in 68% of patients, and grade 3 flow in 18%. PCI was attempted in 706 patients, resulting in postprocedural flow of TIMI grade 3 in 82%, grade 2 in 16%, and grade 0 or 1 in 2%. The Zwolle Myocardial Infarction Study Group reported the outcome of 1702 patients who underwent PCI for STEMI.[217] Successful PCI, defined as TIMI grade 3 flow and a residual lumen diameter less than 50%, was achieved more often during routine hours (8 a.m. to 6 p.m.) than during off-hours (6 p.m. to 8 a.m.) (96.2% vs. 93.1%; $P < 0.01$).

Despite the presence of TIMI grade 3 flow, the myocardial blush grade, an indicator of myocardial perfusion, is abnormal in a majority of patients who undergo primary PCI for STEMI.[211,212] Among a cohort of 777 patients who underwent primary PCI for STEMI, normal myocardial blush (grade 3) was achieved in only 148 patients (19%), whereas 236 patients (30%) had blush grade 0 or 1.[211] Multivariate analysis showed that myocardial blush grade was an independent predictor of long-term mortality, with mortality after follow-up for 1.9 ± 1.7 years of 3% for grade 3, 6% for grade 2, and 23% for grade 0 or 1 myocardial blush ($P < 0.0001$).[211]

Distal Protection and Thrombectomy Devices

Distal embolization of thrombus[218] and microvascular "no reflow"[219] are two of the mechanisms of impaired myocardial perfusion after primary PCI. Distal embolization was observed in 27 of 178 patients (15%) who underwent primary PCI for STEMI.[218] Patients with distal embolization had lower LVEFs at discharge from the hospital and higher long-term mortality. Microvascular obstruction detected by MRI is a prognostic marker for cardiovascular events after acute MI, even after controlling for infarct size.[219] Numerous clinical trials have been performed to investigate various mechanical methods of protecting the coronary microcirculation during PCI for ACS or acute STEMI.[220–231] Two different distal embolic protection devices, one that consists of a distal balloon occlusion and aspiration system and another that uses a filter, failed to improve myocardial reperfusion, reduce infarct size, or improve event-free survival in patients with acute MI.[224–226] A meta-analysis of 12 clinical studies concluded that the distal embolic protection devices had no significant effect on mortality.[229]

Use of the X-Sizer thrombectomy catheter (ev3, Inc., Plymouth, MN) before coronary angioplasty or stenting appears to reduce distal embolization and improve epicardial flow, myocardial blush, and resolution of ST-segment elevation, especially in patients with angiographic evidence of intraluminal thrombus.[220–222] The AngioJet Rheolytic Thrombectomy catheter (Possis Medical, Inc., Minneapolis, MN) was evaluated in a multicenter, randomized study called the AngioJet Rheolytic Thrombectomy in Patients Undergoing Primary Angioplasty for Acute Myocardial Infarction (AIMI) study.[223] The AIMI trial randomly assigned 480 patients within 12 hours of symptom onset of STEMI to PCI alone or PCI with adjunctive rheolytic thrombectomy. No significant differences were observed in myocardial perfusion blush or resolution of ST-segment elevation. Infarct size measured by myocardial perfusion imaging was greater in the thrombectomy group, and major adverse cardiac events were more frequent in the thrombectomy group (6.7% vs. 1.7%; $P = 0.01$).[223] A meta-analysis of five randomized trials concluded that adjunctive mechanical thrombectomy with either the AngioJet catheter or the X-Sizer catheter was associated with increased mortality compared with PCI alone (5.3% vs. 2.8%; $P = 0.05$) in patients with acute MI.[229]

At least 19 clinical trials have been performed to test the effect of aspiration thrombectomy on clinical outcomes in patients with STEMI. The Thrombus Aspiration during Percutaneous Coronary Intervention in Acute Myocardial Infarction Study (TAPAS) was an open trial with a blinded evaluation of endpoints that randomly

assigned 1071 patients to either conventional PCI or thrombus aspiration using a 6F aspiration catheter during PCI.[227,228] Thrombus aspiration resulted in improved myocardial blush grade, resolution of ST-segment elevation, and lower 1-year mortality.[227,228]

Subsequently, two large trials, TASTE[230] (Thrombus Aspiration During ST-Segment Elevation MI), which enrolled 7244 patients, and TOTAL[231] (Trial of routine Aspiration Thrombectomy With PCI Versus PCI Alone in Patients With STEMI), which enrolled 10,732 patients, were unable to show a beneficial effect of aspiration thrombectomy in patients with STEMI. The TASTE[230] and TOTAL[231] trials were included in a meta-analysis of 17 trials that found no significant reduction in death, reinfarction, or stent thrombosis in patients with STEMI who underwent routine aspiration thrombectomy.[232] Also, aspiration thrombectomy was associated with a small but nonsignificant increase in the risk of stroke.[232] Therefore the 2015 ACC/AHA/Society for Cardiovascular Angiography and Interventions (SCAI) Focused Update on Primary Percutaneous Coronary Intervention for Patients with ST-Elevation Myocardial Infarction cited the TASTE[230] and TOTAL[231] trials and the updated meta-analysis[232] as the basis for a class III (no benefit) recommendation that "Routine aspiration thrombectomy before primary PCI is not useful."[23] Also, the 2015 Update on primary PCI included a class IIb recommendation that "The usefulness of selective and bailout aspiration thrombectomy in patients undergoing primary PCI is not well established."[23] Subsequently, the investigators who conducted the TAPAS, TASTE, and TOTAL trials analyzed the pooled individual patient data from these three trials that compared aspiration thrombectomy and PCI alone in patients with STEMI.[233] Although routine thrombus aspiration did not improve clinical outcomes, there were trends toward reduced cardiovascular death and increased stroke or transient ischemic attack in the subgroup of patients with a high thrombus burden, defined as TIMI thrombus grade 3 or higher.[233]

Culprit Artery–Only Versus Multivessel PCI

Multivessel CAD is common among patients with STEMI. Among the 2081 patients who underwent primary PCI for acute MI in the CADILLAC trial, only 51.2% had single-vessel CAD, whereas 33.2% had two-vessel CAD and 15.6% had three-vessel CAD, based on a definition of 70% or more occlusion of a noninfarct artery.[234] Similarly, a pooled analysis of 8 STEMI clinical trials found that 18.8% of patients had three-vessel CAD and 29.6% had two-vessel CAD, defined as a 50% or more diameter stenosis of a noninfarct artery.[235] Both studies found that multivessel disease was associated with an adverse prognosis after MI. The treatment of multivessel CAD in patients with STEMI is an area of active investigation and was addressed in the 2015 ACC/AHA/SCAI Focused Update on Primary PCI for Patients with STEMI.[23] Based on safety concerns, the 2013 ACCF/AHA STEMI Guideline recommended against PCI of nonculprit arteries at the time of primary PCI in patients who are hemodynamically stable.[24] The results of four recent randomized clinical trials served as the basis for upgrading the previous class III recommendation regarding multivessel primary PCI in hemodynamically stable patients to a class IIb recommendation for either staged multivessel PCI or multivessel PCI at the time of primary PCI.[23]

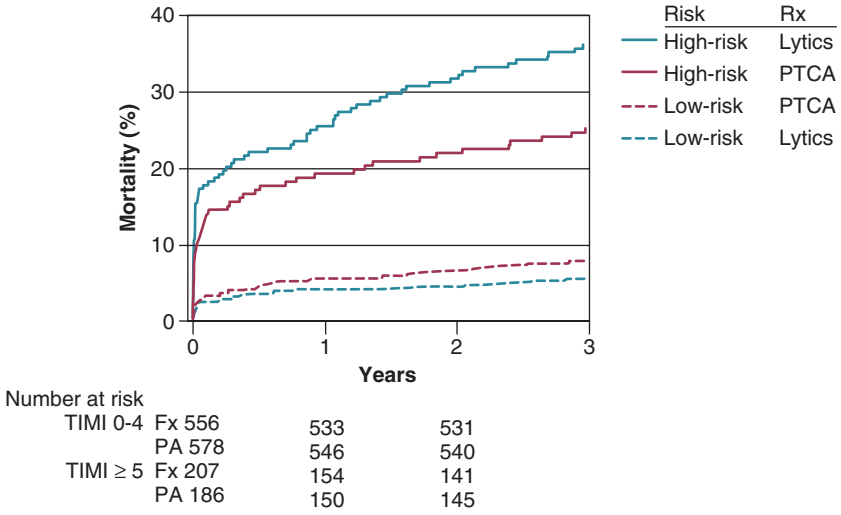
The PCI options for patients with STEMI and multivessel CAD are multivessel PCI at the time of primary PCI, culprit-only primary PCI followed by staged PCI of nonculprit arteries, or culprit-only primary PCI with PCI of nonculprit arteries only for either spontaneous ischemia or intermediate-risk or high-risk findings on predischarge noninvasive testing. Bates et al.[236] published a state-of-the-art review of the numerous randomized trials and observational studies of PCI strategies in patients with STEMI and multivessel CAD, and multiple meta-analyses have been published.[237–239] Although the studies concluded that complete revascularization is associated with improved outcomes, the data were considered insufficient to formulate a recommendation regarding the optimal timing of nonculprit artery PCI.

Primary Percutaneous Intervention Versus Fibrinoltyic Therapy

The evidence base supporting primary PCI for STEMI includes single-center series, multicenter randomized trials, large registries, and several meta-analyses. The Myocardial Infarction Triage and Intervention (MITI) Project Registry described a cohort of patients with acute MI who either underwent primary angioplasty (1050 patients) or received fibrinolytic therapy (2095 patients) at 19 hospitals in Seattle, Washington, between 1988 and 1994.[240] No significant difference in mortality was observed during hospitalization or long-term follow-up between the two groups. The MITI Registry included patients who received streptokinase, whereas a subsequent NRMI 2 report limited to patients who received t-PA also found that in-hospital outcomes were similar for both methods of reperfusion.[241] Another cohort study of 20,683 Medicare beneficiaries with acute MI concluded that 30-day and 1-year mortality rates were lower among patients who underwent primary angioplasty than among patients who received fibrinolytic therapy.[242]

The Danish Multicenter Randomized Study on Fibrinolytic Therapy versus Acute Coronary Angioplasty in Acute Myocardial Infarction (DANAMI-2) trial did not show a significant difference between PCI and fibrinolytic therapy in the rates of death or stroke at 30 days, but the rate of reinfarction at 30 days was significantly lower: 1.6% for the PCI group compared with 6.3% for the fibrinolysis group ($P < 0.001$).[214] Among 1527 patients who were enrolled in the DANAMI-2 trial, no difference in mortality was observed between low-risk patients (TIMI score 0–4) who underwent primary PCI and those who received fibrinolytic therapy (8% vs. 5.6%; $P = 0.11$) (Fig. 29.6).[215] The 3-year mortality rate was significantly lower in high-risk patients who underwent PCI than in patients who received fibrinolytic therapy (25.3% vs. 36.2%; $P = 0.02$) (see Fig. 29.6).[215]

Published meta-analyses of PCI versus fibrinolytic therapy included DANAMI-2 and 22 other randomized trials.[209,243] The trials were rather heterogeneous in design: stents were used in 12 trials, GP IIb/IIIa inhibitors were used in 8 trials, and 5 trials compared fibrinolytic therapy with PCI performed after transfer from a referral hospital to a hospital that provides invasive cardiac services. The meta-analysis by Keeley et al.[243] concluded that, compared with fibrinolytic therapy, primary PTCA was associated with lower rates of death during both short-term (7% [$n = 270$] vs. 9% [$n = 360$]; $P = 0.0002$) and long-term follow-up, and lower rates of nonfatal reinfarction (3% [$n = 80$] vs. 7% [$n = 222$]; $P < 0.0001$), and stroke (1% [$n = 30$] vs. 2% [$n = 64$]; $P = 0.0004$). Subsequently, Huynh et al.[209] published meta-analyses of the 23 randomized clinical trials and 32 observational studies. Primary PCI was associated with 34% (OR 0.66; 95% CI 0.51–0.82) lower short-term (≤6-week) mortality in randomized trials, and 23% (OR, 0.77; 95% CI 0.62–0.95) lower short-term mortality in observational studies.[209] Also, primary PCI was associated with a 63% reduction in stroke in the randomized trials and a 61% reduction in the observational studies.[209] Another analysis pooled the individual patient 6-month follow-up data from 11 randomized trials of PCI versus fibrinolytic therapy for acute MI.[244] At 6 months, the mortality rates were 6.2% for PCI and 8.2% for fibrinolysis



• **Fig. 29.6** Mortality rates for low-risk patients *(dashed lines)* and high-risk patients *(solid lines)* who were randomly assigned to receive fibrinolysis *(Fx) (blue lines)* or primary angioplasty *(PA) (red lines)* in the DANAMI-2 trial. Among 1134 patients who were classified as low risk by virtue of a TIMI risk score of 0 to 4, mortality after fibrinolysis and primary angioplasty was not significantly different. Among 393 patients with a TIMI risk score of 5 or higher, mortality was significantly lower after primary angioplasty compared with fibrinolysis. *DANAMI,* Danish Multicenter Randomized Study on Fibrinolytic Therapy versus Acute Coronary Angioplasty in Acute Myocardial Infarction; *Fx,* fibrinolytic therapy; *PA,* primary angioplasty; *PTCA,* percutaneous transluminal coronary angioplasty; *Rx,* treatment; *TIMI,* Thrombolysis in Myocardial Infarction study. (From Thune JJ, Hoefsten DE, Lindholm MG, et al. Simple risk stratification at admission to identify patients with reduced mortality from primary angioplasty. *Circulation.* 2005;112:2017–2021.)

(RR 0.73; CI 0.55–0.98; $P = 0.04$). A meta-analysis of 11 randomized trials that enrolled 4320 patients with STEMI found that long-term mortality (≥1 year) was 24% lower among patients treated with primary PCI compared with patients treated with fibrinolytic therapy.[209]

Analysis of patients enrolled in NRMI 2 showed that the in-hospital mortality was 28% lower among patients who underwent primary PCI at hospitals with the highest volume than among those who had PCI at hospitals with the lowest volume (adjusted RR 0.72; 95% CI 0.60–0.87; $P < 0.001$).[245] Among 463 hospitals that performed primary PCI for STEMI and participated in NRMI 4, the hospitals with the greatest relative utilization of primary PCI, versus fibrinolytic therapy, for reperfusion had shorter door-to-balloon times and lower in-hospital mortality rates.[246] These data may have provided some of the rationale for the ACC/AHA Practice Guidelines regarding the performance of PCI for STEMI.[20] PCI should be performed in a cardiac catheterization laboratory that performs more than 200 PCI procedures per year, including at least 36 cases of primary PCI for STEMI. The operator should perform more than 75 PCI procedures per year.

Door-to-Balloon Time. Both the extent of myocardial salvage[179,247] and the mortality benefit[150,248,249] of fibrinolytic therapy and primary PCI are inversely related to the time elapsed between symptom onset and treatment. Among a cohort of 1791 patients with STEMI treated with primary PCI, the RR of death at 1 year increased by 7.5% for each 30-minute delay.[250] Several studies have analyzed the relationship between mortality and the so-called door-to-balloon time, defined as the duration of time between arrival at the hospital and the first balloon inflation.[249,251–253] Although some studies found that in-hospital mortality was not related to the door-to-balloon time,[251] most studies have shown that both in-hospital and late mortality are higher when door-to-balloon time is longer.[249,252,253] Among 2082 patients with acute MI who were enrolled in the CADILLAC trial, door-to-balloon time was an independent predictor of 1-year mortality in patients who presented within 2 hours after the onset of symptoms (n = 965; HR 1.24; 95% CI 1.05–1.46; $P = 0.013$), but not in patients who presented later than 2 hours (n = 944; HR 0.88; 95% CI 0.67–1.15; $P = 0.33$).[254]

The ACC/AHA Practice Guidelines set a goal of balloon inflation within 90 minutes of presentation, and recent observational studies indicate that this goal is frequently achieved.[255] Among 96,738 patients with STEMI who underwent primary PCI between July 2005 and June 2009 at 515 hospitals that participated in the ACC's CathPCI Registry, the percentage of patients for whom the door-to-balloon time was 90 minutes or less increased from 59.7% in the first year to 83.1% in the last year ($P < 0.001$).[255] Krumholz and colleagues[256] analyzed the door-to-balloon times reported by hospitals to the Centers for Medicare & Medicaid Services from January 1, 2005 through September 30, 2010. Door-to-balloon time decreased from a median of 96 minutes in 2005 to a median of 64 minutes during the first three quarters of 2010.[256] The percentage of patients who had door-to-balloon times less than 90 minutes increased from 44.2% to 91.4%.[256]

The time of day and day of week had significant effects on door-to-balloon times among 33,647 patients with STEMI who underwent primary PCI between 1999 and 2002 and were enrolled in the NRMI 3 and NRMI 4 registries.[257] Fifty-four percent of patients who underwent primary PCI were treated during off-hours (weekdays 5 p.m.–7 a.m. and weekends). Door-to-balloon times exceeded 90 minutes in 74% of patients who underwent PCI during off-hours, compared with 53% of patients treated during regular hours (weekdays 7 a.m.–5 p.m.) ($P < 0.001$). Treatment delays are far greater among patients who are transferred to another hospital to undergo primary PCI.[255] Among 17,052 patients with STEMI who underwent interhospital transfer for primary PCI

between July 2008 and December 2012, the median door-to-balloon time was 118 minutes, and only 20% of patients had a first door-to-balloon time of 90 minutes or less.[258] Analysis of 23 randomized trials that compared primary PCI with fibrinolytic therapy for STEMI indicated that PCI affords a mortality advantage only if the door-to-balloon time exceeds the door-to-needle time by less than 1 hour.[259]

Several approaches have been suggested to reduce the delay between symptom onset and reperfusion in patients treated by primary PCI. One approach that has been tested is the performance of primary PCI at hospitals that have cardiac catheterization laboratories but lack on-site cardiac surgery.[260] One trial randomly assigned patients with STEMI to undergo primary PCI ($n = 225$) or receive accelerated t-PA ($n = 226$) at 11 community hospitals without on-site cardiac surgery.[260] The composite endpoint of death, recurrent MI, and stroke was significantly lower among patients treated with primary PCI than among those who received t-PA, both 6 weeks after MI (10.7% vs. 17.7%; $P = 0.03$) and 6 months after MI (12.4% vs. 19.9%; $P = 0.03$). A subsequent study by the NRMI investigators compared the outcomes of 58,821 patients with STEMI who presented to 214 hospitals with on-site cardiac surgery with the outcomes of patients who presented to 52 hospitals without on-site cardiac surgery.[261] The patients who presented to hospitals without on-site cardiac surgery were less likely to receive guideline-recommended medications within 24 hours and less likely to undergo acute reperfusion therapy, but there was no difference in mortality among patients who underwent primary PCI.[261] A meta-analysis of 11 studies that included 124,074 patients who underwent primary PCI for STEMI found that the in-hospital mortality for patients at hospitals without on-site cardiac surgery was not different from hospitals having on-site surgery (OR 0.96; 95% CI 0.88–1.05).[262] Another proposed strategy to reduce the delay between symptom onset and reperfusion is the diversion of patients with acute MI to a primary PCI hospital, instead of the current practice of transporting patients to the nearest emergency department. A survey of 365 hospitals identified six strategies that were significantly associated with a faster door-to-balloon time.[263] The use of prehospital ECGs to diagnose and triage patients with a suspected STEMI is associated with a greater use of reperfusion therapy and shorter door-to-needle and door-to-balloon times.[264]

Coronary Stents

Late reocclusion after successful primary angioplasty is associated with decreased long-term survival.[265] The CADILLAC trial randomly assigned 2082 patients with acute MI to undergo percutaneous transluminal coronary angioplasty (PTCA) or stenting.[266] Although stenting did not improve the myocardial blush score,[267] the angiographic rate of reocclusion of the IRA at 7 months was 5.7% after coronary stenting, compared with 11.3% after PTCA.[266]

At least 22 randomized clinical trials and at least 5 observational studies, plus numerous meta-analyses of those studies, have been performed to compare drug-eluting stents (DESs) with bare metal stents (BMSs) in patients with STEMI. A meta-analysis of five observational studies found that STEMI patients treated with first-generation DESs (paclitaxel-eluting or sirolimus-eluting stents) had a significantly lower mortality compared with patients who received BMS (OR 0.65; 95% CI 0.53–0.80; $P < 0.001$).[268] A meta-analysis of 15 randomized, controlled trials that enrolled a total of 7867 STEMI patients concluded that compared with a BMS, first-generation DES are associated with a reduction in target vessel revascularization and stent thrombosis during the first year after stent implantation, but an increased risk of very late stent thrombosis (>1 year after PCI).[269] The apparent increased risk of very late stent thrombosis is consistent with both postmortem and in vivo evidence of higher rates of incomplete stent apposition and uncovered stent struts among STEMI patients treated with DESs compared with BMSs.[270,271]

A network meta-analysis of 22 controlled trials that randomly assigned a total of 12,453 patients with STEMI concluded that second-generation cobalt-chromium everolimus-eluting stents were associated with significantly lower risk of 1-year cardiac death/MI, MI, and stent thrombosis compared with BMS, and significantly lower 1-year rates of stent thrombosis than paclitaxel-eluting stents.[272] A trial that randomly assigned 1498 patients with STEMI to PCI with either BMSs or everolimus-eluting stents provided encouraging results after follow-up for 5 years.[273] All-cause mortality was significantly lower for the group treated with drug-eluting stents (9% vs. 12%; HR 0.72; CI 0.52–0.10; $P = 0.047$).[273] The 2014 ESC/EACTS Guidelines on myocardial revascularization include a class I recommendation that new-generation DESs are recommended over BMSs in STEMI patients who undergo primary PCI.[274]

Rescue Percutaneous Coronary Intervention

Compared with TIMI grade 3 flow, TIMI grade 0 or 1 flow at 90 minutes after fibrinolytic therapy is associated with worse left ventricular function and increased mortality rates.[177,178] Compared with complete resolution of ST-segment elevation, incomplete resolution of ST-segment elevation after fibrinolytic therapy is associated with larger infarct size and greater short-term and long-term mortality.[42,44,275] Therefore various angiographic or electrocardiographic criteria have been used to define unsuccessful fibrinolysis and rescue PCI. A report from the TIMI 10B and TIMI 14 trials of fibrinolytic therapy defined rescue PCI as PCI performed between 90 and 150 minutes after the start of therapy for patients with TIMI 0 or 1 flow 90 minutes after the start of therapy.[276] The Middlesbrough Early Revascularization to Limit Infarction (MERLIN) trial defined failed fibrinolytic therapy as failure of the ST-segment elevation in the worst lead to have resolved by 50% 60 minutes after the onset of fibrinolytic therapy.[277] The Rescue Angioplasty versus Conservative Treatment or Repeat Thrombolysis (REACT) trial's definition of rescue PCI was PCI performed within 12 hours after failed fibrinolytic therapy, defined as an ECG obtained 90 minutes after the start of fibrinolytic therapy that showed less than 50% resolution of the ST-segment in the lead showing the greatest ST-segment elevation.[278] Thus many of the patients who underwent PCI in the REACT trial would meet the TIMI group's definition of either adjunctive PCI (defined as PCI for patients with TIMI grade 2 or 3 flow) or delayed PCI (defined as PCI longer than 150 minutes after fibrinolytic therapy), rather than rescue PCI as defined by the TIMI group and other investigators.[276] Among patients enrolled in the TIMI 10B and 14 trials, the rate of TIMI grade 3 flow was significantly greater after adjunctive PCI than after rescue PCI (89% vs. 78%; $P = 0.001$),[276] which might account for the REACT trial's 98% (106 of 108 patients) success rate for rescue PCI.[278]

There is conflicting information regarding the impact of rescue PCI on mortality. Among 150 patients who were enrolled in the TIMI 10B trial and had TIMI 0 or 1 flow 90 minutes after fibrinolytic therapy, 2-year mortality was significantly lower among the patients who underwent rescue PCI ($n = 120$) than among those who did not ($n = 30$) ($P = 0.03$).[279] The randomized trials that compared rescue PCI with conservative therapy were insufficiently powered to detect an effect on mortality. Although

differences in trial design and the definition of rescue PCI make it somewhat difficult to compare the results of various trials, at least two meta-analyses of the randomized trials have been published.[280,281] A pooled analysis of the short-term mortality (in-hospital or 30-day) among 942 patients who were enrolled in five randomized trials revealed that the risk of death was 36% lower among patients who were randomly assigned to PCI (RR 0.64; 95% CI 0.41–1.00; $P = 0.048$).[280] Another meta-analysis included six trials that randomly assigned 908 patients to rescue PCI or conservative therapy.[281] Rescue PCI was not associated with a reduction in all-cause mortality at 6 months (RR 0.69; 95% CI 0.46–01.05), but it was associated with significant reductions in the risk of HF and reinfarction and an increased risk of stroke and minor bleeding.[281]

The 2013 ACCF/AHA Guideline for the Management of ST-Elevation Myocardial Infarction included three indications for transfer for angiography after fibrinolytic therapy: class I—immediate transfer for cardiogenic shock or severe acute HF; class IIa—urgent transfer for failed reperfusion or reocclusion; and class IIa—as part of an invasive strategy in stable patients with PCI between 3 and 24 hours after successful fibrinolysis.[24]

Selection of Reperfusion Strategy

According to the 2013 ACCF/AHA Guideline for the Management of ST-Elevation Myocardial Infarction, there are three class I indications for primary PCI in patients with STEMI who present initially to a PCI-capable hospital:

1. Patients with ischemic symptoms of less than 12 hours' duration
2. Patients with ischemic symptoms of less than 12 hours' duration who have contraindications to fibrinolytic therapy, irrespective of the time delay from first medical contact
3. Patients with cardiogenic shock or acute severe HF, irrespective of time delay from MI onset[24]

Patients who are candidates for reperfusion therapy and present initially to a non–PCI-capable facility may be treated with fibrinolytic therapy or transferred to a PCI-capable facility for primary PCI.[24] Fibrinolytic therapy should be given to patients with STEMI and onset of ischemic symptoms within the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact.[24]

There are two class IIa indications for reperfusion therapy in patients with STEMI who present 12 or more hours after symptom onset. First: "Primary PCI is reasonable in patients with STEMI if there is clinical and/or ECG evidence of ongoing ischemia between 12 and 24 hours after symptom onset."[24] Second: "In the absence of contraindications and when PCI is not available, fibrinolytic therapy is reasonable for patients with STEMI if there is clinical and/or ECG evidence of ongoing ischemia within 12 to 24 hours of symptom onset and a large area of myocardium at risk or hemodynamic instability."[24]

The Occluded Artery Trial (OAT) randomly assigned 2166 stable patients with one- or two-vessel CAD and a total occlusion of the IRA 3 to 28 days after MI to medical therapy or PCI with stenting.[282] PCI did not reduce the occurrence of death, reinfarction, or HF. Consequently, the following class III recommendation was included in the 2013 ACCF/AHA Guideline for the Management of ST-Elevation Myocardial Infarction: "PCI of a totally occluded infarct artery greater than 24 hours after STEMI should not be performed in asymptomatic patients with one- or two-vessel disease if they are hemodynamically and electrically stable and do not have evidence of severe ischemia."[24]

Acute MI in patients who have undergone previous CABG surgery frequently is due to thrombotic occlusion of saphenous vein bypass grafts, rather than occlusion of native coronary arteries.[283,284] Among 1784 patient with previous CABG surgery who were enrolled in the GUSTO-1 trial, angiography after fibrinolytic therapy showed that 61.9% of the infarct vessels were native coronary arteries and 38.1% were occluded bypass grafts.[283] Among the patients with previous CABG surgery, angiography showed more infarct-related vessels with TIMI 0 or 1 flow (50%) and fewer infarct-related vessels with TIMI 3 flow (32%) compared with patients without previous CABG (29% and 49%, respectively).[283] Also, in patients with previous CABG surgery, native arteries and bypass grafts had nearly identical rates of TIMI 0 or 1 flow and TIMI 3 flow.[283] The APEX-AMI (Assessment of Pexelizumab in Acute Myocardial Infarction) study, a randomized trial of pexelizumab in STEMI patients undergoing primary PCI, enrolled 128 patients (2.2%) with previous CABG surgery.[284] The infarct-related vessel was a native coronary artery in 55 patients and a bypass graft in 63 patients.[284] Among the patients with previous CABG surgery who underwent PCI, post-PCI TIMI flow grade 3 was achieved in only 66.7% of bypass graft infarct-related vessels, compared with 88.0% of native artery infarct-related vessels.[284] The 90-day death rates were 19% for patients with a bypass graft infarct-related vessel, compared with 5.7% for patients with previous CABG surgery and a native artery infarct-related vessel, and 4.6% for patients without previous CABG surgery.[284]

According to an analysis of the National Cardiovascular Data Registry, the percentage of patients with STEMI who were eligible for reperfusion therapy and underwent reperfusion therapy increased from 78% in 2007 to 89% in 2013.[285] There is evidence, however, that reperfusion therapy may be underused in two high-risk groups: elderly patients and patients with chronic kidney disease. Although the utilization rate of PCI to treat STEMI patients aged 65 years and older old increased during the decade 2001–2010, among STEMI patients older than 80 years of age with similar number of comorbidities the utilization of PCI was lower.[286] Analysis of a cohort of 26,620 patients with end-stage renal disease and STEMI showed that only 30.4% underwent PCI, with an increase in the use of PCI for patients with end-stage renal disease and STEMI from 18.6% in 2003 to 37.8% in 2011.[287] The report did not state whether any patients with end-stage renal disease and STEMI were treated with fibrinolytic therapy.

Platelet Glycoprotein IIb/IIIa Receptor Antagonists

Numerous clinical trials have investigated the role of platelet GP IIb/IIIa inhibitors in patients with acute STEMI, either in conjunction with fibrinolytic agents or primary PCI.[288,289] One rationale of including a GP IIb/IIIa inhibitor in either pharmacologic or mechanical reperfusion strategies is that platelet inhibition may improve myocardial perfusion and enhance salvage of ischemic muscle by reducing distal embolization of platelet aggregates. Another proposed rationale is to achieve coronary artery patency using lower doses of fibrinolytic drugs. Although the addition of abciximab to either t-PA[290] or rPA[187] has been shown to improve angiographic indices of myocardial reperfusion, combination therapy with abciximab and a fibrinolytic drug has not been shown to reduce mortality compared with fibrinolytic therapy alone. A trial that randomly assigned 16,588 patients with acute STEMI to treatment with either standard-dose rPA or half-dose rPA plus full-dose abciximab showed no differences in either 30-day or 1-year mortality.[291] A meta-analysis of three fibrinolytic trials that included 23,166 patients who were randomized to receive either abciximab plus half-dose rPA or TNK versus full-dose rPA or TNK found that abciximab was associated with a significant reduction

in the 30-day rate of reinfarction (2.3% vs. 3.6%; $P < 0.001$), but 30-day mortality was 5.8% for both groups.[288] Therefore there are no class I or II indications for a combination of fibrinolytic agents with GP IIb/IIIa inhibitors in the ACC/AHA Practice Guidelines.[24]

Although at least 18 randomized trials have been performed to evaluate GP IIb/IIIa inhibitors in patients with acute STEMI who undergo primary PCI, it has been difficult to draw definitive conclusions for several reasons.[289] First, three different GP IIb/IIIa inhibitors have been studied, abciximab and the so-called small-molecule inhibitors eptifibatide and tirofiban. Second, the agents have been studied in conjunction with various other antiplatelet, anticoagulant, and fibrinolytic regimens, and periprocedural administration of a platelet $P2Y_{12}$ inhibitor was not mandated in many of the trials. Third, the timing of drug administration has varied from prehospital therapy to periprocedural treatment. Fourth, the trials have been underpowered to evaluate the effects on mortality.

The largest trial, HORIZONS-AMI, compared the combination of UFH and a GP IIb/IIIa inhibitor, either abciximab or eptifibatide, with bivalirudin in 3602 patients with STEMI who were treated with primary PCI.[137–139] Compared with UFH plus a GP IIb/IIIa inhibitor, treatment with bivalirudin was associated with a reduced rate of major bleeding and, among patients who were classified as high risk, a lower 1-year mortality rate.[138,139] A meta-analysis of 16 trials that enrolled a total of 10,085 patients with STEMI who underwent primary PCI concluded that GP IIb/IIIa inhibitors did not reduce the rates of mortality or reinfarction at 30 days.[289] A meta-analysis of five randomized trials ($n = 2138$ patients) that compared abciximab with the small-molecule GP IIb/IIIa inhibitors in STEMI patients undergoing primary PCI found no differences in outcome.[292]

A meta-analysis that included 1662 patients who were enrolled in 11 randomized trials that compared early versus late administration of GP IIb/IIIa inhibitors before primary PCI concluded that early administration of abciximab improved postprocedural TIMI 3 flow, myocardial blush grade, and survival compared with late administration.[293] A registry that enrolled 1086 patients who received abciximab also found that early administration of abciximab before transfer for PCI, compared with late administration, was associated with lower 1-year mortality among patients with a TIMI risk score of 3 or higher.[294] The 2013 ACCF/AHA Guideline for the Management of STEMI includes a class IIb recommendation that "It may be reasonable to administer intravenous GP IIb/IIIa receptor antagonist in the precatheterization laboratory setting (e.g., ambulance, emergency department) to patients with STEMI for whom primary PCI is intended."[24]

Numerous trials have investigated the utility of intracoronary administration of GP IIb/IIIa inhibitors during primary PCI for STEMI. A study that used MRI to measure infarct size in 795 patients with STEMI who underwent primary PCI found that there was no difference between intracoronary and intravenous administration of abciximab.[295] A meta-analysis of the individual data of 3158 patients who were enrolled in five randomized trials comparing intracoronary versus intravenous abciximab in STEMI patients undergoing primary PCI found no differences in the risk of death, reinfarction, or stent thrombosis at 30 days.[296] The 2013 ACCF/AHA Guideline for the Management of STEMI includes a class IIb recommendation that "It may be reasonable to administer intracoronary abciximab to patients with STEMI undergoing primary PCI."[24] The use of intravenous GP IIb/IIIa inhibitors as an adjunctive or "bailout" therapy in selected patients who are receiving UFH and undergo primary PCI received a class IIa recommendation in the ACCF/AHA Practice Guidelines for STEMI. There are no class I indications for GP IIb/IIIa inhibitors in patients with STEMI who are treated with either fibrinolytic therapy or primary PCI.

β-Blockers

β-Adrenergic blockers exert both antiarrhythmic and antiischemic effects. Numerous studies have investigated the effects of intravenous and/or oral β-blockers on arrhythmias, infarct size, and clinical outcomes in the acute and convalescent phases of MI. Randomized clinical trials have demonstrated that early administration of intravenous followed by oral metoprolol reduces the incidence of ventricular fibrillation (VF) in patients with acute STEMI.[297,298] Experimental studies have shown that β-blockers can limit the extent of MI during coronary occlusion because they reduce heart rate, systemic arterial pressure, and myocardial contractility, thereby decreasing myocardial oxygen demand. Clinical data are conflicting, however, regarding the effects of β-blockers on infarct size in patients. In the "prereperfusion era," several studies concluded that administration of intravenous timolol followed by oral timolol reduced the size of infarction measured by release of creatinine kinase and electrocardiographic assessment.[299,300]

More recent studies in patients with STEMI who were treated with intravenous metoprolol before primary PCI used cardiac MRI to assess infarct size and produced conflicting results.[301,302] The METOCARD-CNIC (Effect of Metoprolol in Cardioprotection During an Acute Myocardial Infarction) trial randomly assigned 270 patients with an anterior STEMI who were Killip class I or II to receiving intravenous metoprolol before primary PCI or no metoprolol before PCI.[301] All patients without contraindications received oral metoprolol within 24 hours.[301] The mean infarct size measured by MRI 5 to 7 days after STEMI was smaller in the group treated with intravenous metoprolol compared with the control group (21.2% of the left ventricle vs. 25.1% of the left ventricle; $P = 0.029$).[301] The EARLY-BAMI (Early-Beta Blocker Administration Before Reperfusion Primary PCI in Patients with ST-elevation Myocardial Infarction) trial was a larger, double-blind study that randomly assigned 683 Killip class I and II patients with either anterior or nonanterior STEMI to intravenous metoprolol or placebo before primary PCI.[302] The incidence of malignant ventricular arrhythmias in the acute phase was 3.6% in the metoprolol group versus 6.9% in the placebo group ($P = 0.05$).[302] Infarct size assessed by MRI 30 days after MI was 15.3% of the left ventricle for the metoprolol group compared with 14.9% for the placebo group ($P = 0.616$).[302]

Trials have been performed to examine the effects of early or delayed β-blockade on short-term and long-term clinical outcomes in patients with acute MI. Both atenolol[303] and metoprolol[304] administered by intravenous infusion followed by oral administration reduced mortality in patients who did not receive fibrinolytic therapy. A pooled analysis of 27 randomized trials indicated that early β-blockade reduced mortality by 13% in the first week, and the mortality reduction benefit was greatest in the first 2 days.[305]

Subsequent trials examined the impact of early intravenous β-blockade on the outcome of patients treated with fibrinolytic agents for acute STEMI.[306,307] In the TIMI II-B study, 1434 patients who received intravenous t-PA for acute STEMI were randomly assigned to receive immediate or deferred β-blockade.[306] The deferred blockade group received oral metoprolol beginning on day 6, whereas the immediate blockade group received intravenous metoprolol within 2 hours of initiation of t-PA, followed by oral

metoprolol. The incidence of reinfarction (2.7% vs. 5.1%, $P = 0.02$) and recurrent chest pain (18.8% vs. 24.1%, $P < 0.02$) at 6 days was lower in the immediate group. The GUSTO-I trial protocol recommended that patients without hypotension, bradycardia, or HF receive intravenous atenolol as soon as possible after enrollment, followed by oral atenolol daily.[307] Although adjusted 30-day mortality was significantly lower in patients who received atenolol, intravenous atenolol was associated with greater mortality compared with oral treatment alone (OR 1.3; 95% CI 1.0–1.5; $P = 0.02$). Also, administration of intravenous atenolol was associated with increased risks of HF, shock, recurrent ischemia, and need for a pacemaker. The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) randomly assigned patients with suspected acute MI to treatment with metoprolol (up to 15 mg intravenously, followed by 200 mg/day orally; $n = 22{,}929$) or placebo ($n = 22{,}923$).[298] Treatment was discontinued either at discharge from the hospital or on day 28 of the hospital stay; 93% of the patients had STEMI, and approximately 54% of the patients received a fibrinolytic agent. The risk of reinfarction during treatment was 18% lower among patients who received metoprolol (2% vs. 2.5%; $P = 0.001$). The overall in-hospital mortality rates were 7.7% in the metoprolol treatment group and 7.8% in the placebo group (OR 0.99; 95% CI 0.92–1.05; $P = 0.69$). Allocation to metoprolol was associated with a significant 22% reduction in death attributed to arrhythmia (1.7% vs. 2.2%; $P = 0.0002$), but there was a 29% increase in death attributed to cardiogenic shock among the metoprolol treatment group (2.2% vs. 1.7%; $P = 0.0002$).

At least 32 randomized trials including nearly 27,000 patients have been conducted to determine the effect of β-blockade on long-term survival after acute MI, and several meta-analyses have been published.[305,308] The Norwegian Multicenter Study Group randomly assigned 1884 patients to receive double-blind treatment with either oral timolol or placebo beginning 7 to 28 days after acute MI.[309] The cumulative mortality rate at 33 months was 39% lower in the timolol group than in the placebo group (10.6% vs. 17.5%; $P = 0.0005$), and the sudden-death rate at 33 months was reduced by 45% (7.7% vs. 13.9%; $P = 0.0001$). After continued follow-up for up to 6 years, a significant difference in mortality was maintained.[310] The Beta-Blocker Heart Attack Trial (BHAT) demonstrated that treatment with propranolol beginning 5 to 21 days after acute MI also reduced mortality during an average follow-up period of 25 months.[311] A pooled analysis of 31 long-term trials found that β-blocker therapy was associated with a 23% reduction in the odds of death (95% CI 15–31).[308] According to that analysis, the calculated number of patients needed to treat for 2 years with a β-blocker to avoid one death is 42, which is less than the calculated number needed to treat for antiplatelet therapy, which is 153.[308]

The Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) study is an important trial that was not available for inclusion in the pooled analyses discussed earlier.[312] The CAPRICORN study randomly assigned 1959 patients with an LVEF 40% or lower to carvedilol or placebo beginning 3 to 21 days after acute MI. Forty-six percent of the patients had received reperfusion therapy, and 97% had received an angiotensin-converting enzyme (ACE) inhibitor for at least 48 hours before randomization. After an average follow-up period of 1.3 years, a 23% reduction was found for all-cause mortality (12% vs. 15%; HR 0.77; 95% CI 0.60–0.98; $P = 0.031$), identical to that reported in a meta-analysis of previous randomized trials.[308] The CAPRICORN trial supports the conclusion that β-blockade reduces mortality after acute MI even among patients who receive reperfusion therapy and ACE inhibitors for left ventricular dysfunction.

The 2013 ACCF/AHA Guideline for the Management of ST-Elevation Myocardial Infarction contains three class I recommendations for beta blockers in patients with STEMI.[24] The three class I recommendations regarding oral β-blocker therapy are as follows:

1. Oral β-blocker therapy should be initiated in the first 24 hours for patients who do not have any of the following: (a) signs of HF, (b) evidence of a low output state, (c) increased risk for cardiogenic shock (age > 70 years, systolic blood pressure < 120 mm Hg, sinus tachycardia > 110 beats/min or heart rate < 60 beats/min, and increased time since onset of symptoms of STEMI), or (d) other relative contraindications to β-blockade (PR interval > 0.24 seconds, second- or third-degree heart block, active asthma, or reactive airway disease).
2. β-Blockers should be continued during and after hospitalization for all patients with STEMI and with no contraindications to their use.
3. Patients with initial contraindications to the use of beta blockers in the first 24 hours after STEMI should be reevaluated to determine their subsequent eligibility.

There is one class IIa recommendation regarding intravenous β-blockade in patients with STEMI: "It is reasonable to administer intravenous beta blockers at the time of presentation to patients with STEMI and no contraindications to their use who are hypertensive or have ongoing ischemia."[24]

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Acute MI triggers neurohormonal activation that is characterized by elevated plasma renin activity and aldosterone, and plasma renin activity was found to be an independent predictor of cardiovascular mortality among patients who were enrolled in the Survival and Ventricular Enlargement (SAVE) trial.[313] ACE inhibitors have been shown to attenuate left ventricular enlargement after acute MI.[314] Multiple clinical trials have demonstrated that ACE inhibitors reduce mortality after acute MI. The GISSI-3 trial randomly assigned 19,394 patients with acute MI, with or without ST-segment elevation, to an oral lisinopril treatment group or an open control group within 24 hours of symptom onset.[90] Seventy-one percent of the patients received fibrinolytic therapy. Six-week mortality was 11% lower among patients in the lisinopril treatment group than it was for those in the control group (6.3% vs. 7.1%; OR 0.88; 95% CI 0.79–0.99). The ISIS-4 trial randomly assigned 58,050 patients with acute MI to receive oral captopril or placebo within 24 hours of symptom onset.[91] Seventy-nine percent of the patients had ST-segment elevation on the initial ECG, and 70% of eligible patients received fibrinolytic therapy, predominantly with streptokinase. Five-week mortality was 7% lower among patients who received captopril than among those in the control group (7.19% vs. 7.69%; 95% CI 1–13; $P = 0.02$). The individual patient data from ISIS-4 and GISSI-3 were combined with the data from two other large trials, creating a database of 98,496 patients, who were randomly assigned to ACE inhibitor treatment or control groups during the acute phase (0–36 hours) of acute MI.[315] Thirty-day mortality was 7% lower among patients who received an ACE inhibitor (7.1% vs. 7.6%; 95% CI 2–11; $P = 0.004$). The absolute benefit of ACE inhibitor therapy was greater in patients with anterior MI.

Three additional trials have investigated the efficacy of ACE inhibitors in patients with acute MI and left ventricular dysfunction

or HF: the SAVE study,[316] the Acute Infarction Ramipril Efficacy (AIRE) study,[317] and the Trandolapril Cardiac Evaluation (TRACE) study.[318] The SAVE study enrolled 2231 patients with an acute MI, no overt HF, and an LVEF 40% or lower as measured by radionuclide ventriculography.[316] The patients were randomly assigned to double-blind treatment with captopril or placebo 3 to 16 days after acute MI. After an average follow-up period of 42 months, all-cause mortality was reduced by 19% (20% vs. 25%; 95% CI 3–32; $P = 0.019$). The risk reduction was 22% among patients treated with fibrinolytic therapy (33% of the patients) compared with 17% among patients who were not. Captopril reduced the risk of recurrent MI by 25% (95% CI 5–40; $P = 0.015$).[319] The AIRE study enrolled 2006 patients with an acute MI and clinical or radiologic evidence of HF.[317] The patients were randomly assigned to double-blind treatment with ramipril or placebo beginning 3 to 10 days after acute MI. After average follow-ups of 15 months, all-cause mortality was reduced by 27% (17% vs. 23%; 95% CI 11–40; $P = 0.002$). The TRACE study enrolled 1749 patients with an acute MI and LVEF 35% or lower as demonstrated by echocardiography.[318] The patients were randomly assigned to double-blind treatment with trandolapril or placebo beginning 3 to 7 days after acute MI. The RR of death from any cause in the trandolapril group, as compared with the control group, was 0.78 (95% CI 0.67–0.91; $P = 0.001$). After follow-up for a minimum of 6 years, the life expectancy of patients was 4.6 years for those who received placebo versus 6.2 years for those who were treated with trandolapril, a median increase of 15.3 months.[320] A pooled analysis of the data from individual patients enrolled in the SAVE, AIRE, and TRACE trials concluded that the mortality rate after a median treatment duration of 31 months was reduced from 29.1% in control patients to 23.4% in the ACE inhibitor group (OR 0.74; 95% CI 0.66–0.83; $P < 0.0001$).[321]

The Register of Information and Knowledge about Swedish Heart Intensive Care Admissions (RIKS-HIA) enrolled 105,225 patients with acute MI who were not treated with ACE inhibitors on admission.[322] The association between treatment with an ACE inhibitor at discharge from the hospital and the outcome at 1 year was evaluated using Cox regression analyses adjusted for medications at discharge and the propensity score. Among the entire cohort, treatment with an ACE inhibitor was associated with a 24% reduction in mortality (RR 0.76; 95% CI 0.73–0.80), but among patients without HF, a significant benefit was observed only in patients with renal dysfunction.

Two randomized clinical trials compared captopril with an angiotensin receptor blocker (ARB) in high-risk acute MI patients: the Optimal Trial in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL)[323] and the Valsartan in Acute Myocardial Infarction Trial (VALIANT).[324] The OPTIMAAL trial enrolled 5477 patients with acute STEMI who met any of the following entry criteria: symptoms or signs of HF, LVEF less than 35%, or new anterior Q waves. Fifty-four percent of the patients received fibrinolytic agents. The patients were randomly assigned to double-blind treatment with either losartan, titrated to a target dose of 50 mg daily, or captopril, titrated to a target dose of 50 mg three times daily, within 10 days of symptom onset. After an average follow-up period of 2.7 years, no significant difference in all-cause mortality was found between the losartan and the captopril treatment groups (18% vs. 16%; RR 1.13; 95% CI 0.99–1.28; $P = 0.07$). The prespecified criterion for noninferiority was not satisfied. The VALIANT trial enrolled 14,703 patients with acute MI complicated by clinical or radiographic signs of HF or reduced LVEF (≤35% by echocardiography or contrast ventriculography or ≤40% by radionuclide ventriculography), or both. Approximately 50% of the patients underwent reperfusion therapy; 35%, fibrinolytic therapy; and 15%, primary PCI. Within 10 days after the acute MI, the patients were randomly assigned to three treatment groups: valsartan monotherapy, captopril monotherapy, or the combination of valsartan and captopril. After an average follow-up period of 24.7 months, all-cause mortality was not significantly different for the three groups: valsartan 19.9%, captopril 19.5%, and the combination 19.3%. The investigators concluded that valsartan is at least as effective as captopril, because the criterion for noninferiority of valsartan relative to captopril was met.

Both aldosterone and angiotensin II, a potent stimulus of adrenal aldosterone production, are increased in patients with HF despite chronic treatment with an ACE inhibitor. Aldosterone exerts numerous adverse cardiovascular effects, including increased myocardial collagen deposition and fibrosis and cardiomyocyte apoptosis.[325] Eplerenone, a selective aldosterone blocker, was studied in a multicenter, international, randomized, double-blind, placebo-controlled trial called the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS).[326,327] The EPHESUS investigators enrolled 6632 patients with acute MI complicated by left ventricular dysfunction (ejection fraction <40%) plus either HF or diabetes.[326,327] The patients were randomly assigned to double-blind treatment with eplerenone or placebo beginning 3 to 14 days after acute MI. At the time of enrollment, 86% of the patients were taking an ACE inhibitor or ARB, and 75% were taking a β-blocker. During a mean follow-up period of 16 months, significantly fewer deaths occurred in the eplerenone group (478/3319 patients) than in the placebo group (554/3313 patients) (14.4% vs. 16.7%; RR 0.85; 95% CI 0.75–0.96; $P = 0.008$). A reduction in the rate of sudden death from cardiac causes (RR 0.79; 95% CI 0.64–0.97; $P = 0.03$) also was observed. Serious hyperkalemia, defined as a serum potassium of 6 mmol/L or more, occurred in 5.5% of patients in the eplerenone group versus 3.9% of those in the placebo group ($P = 0.002$).

The ACCF/AHA Practice Guidelines include three class I recommendations regarding inhibitors of the renin-angiotensin-aldosterone system. (1) An ACE inhibitor should be administered within the first 24 hours to all patients with STEMI with anterior location, HF, or EF of 0.40 or below, unless contraindicated. (2) An ARB should be given to patients with STEMI who have indications for but are intolerant of ACE inhibitors. (3) An aldosterone antagonist should be given to patients with STEMI and no contraindications who are already receiving an ACE inhibitor and β-blocker and who have an ejection fraction of 0.40 or lower and either symptomatic HF or diabetes mellitus.[24] There is one class IIa recommendation regarding ACE inhibitors in patients with STEMI: "ACE inhibitors are reasonable for all patients with STEMI and no contraindications to their use."[24]

Antiarrhythmic Drugs

Both atrial and ventricular arrhythmias are common in patients with acute MI. The incidence of atrial fibrillation (AF) was 10.4% among 40,891 patients who were enrolled in the GUSTO-I trial.[328] Patients in whom AF developed after admission were more likely to have a stroke or die within 30 days after acute MI. New-onset AF developed during hospitalization in 6.3% of the 5466 patients with STEMI who underwent primary PCI and were enrolled in the APEX-AMI trial.[329] New-onset AF was independently associated with 90-day mortality (HR 1.81; 95% CI 1.06–3.09; $P = 0.029$.[329] Intravenous β-adrenergic blockade is the preferred therapy for patients with sustained AF or atrial flutter that is not associated

with hemodynamic compromise, whereas sustained AF or flutter that is associated with hemodynamic compromise is an indication for synchronized cardioversion. Intravenous amiodarone is indicated for treatment of AF that does not respond to electrical cardioversion or recurs after cardioversion. Sustained AF should be treated with anticoagulants.

Primary VF, defined as VF occurring within 48 hours of the onset of symptoms in patients stable Killip class I, is an independent predictor of in-hospital mortality whether it occurs early (up to 4 hours) or late (after 4 to 48 hours) after the onset of acute MI.[330] Among 9720 patients with a first STEMI who were enrolled in the GISSI-2 fibrinolytic trial, 356 of the 7755 patients who were in Killip class I at entry developed primary VF.[330] Early primary VF occurred in 302 patients (3.7%) and late primary VF occurred in 54 patients (0.6%); 226 patients had VF within 1 hour of the onset of acute MI symptoms. In-hospital mortality rates were 13% among patients with late primary VF (RR 3.80; 95% CI 1.80–8.02) and 7% among patients with early primary VF (RR 2.00; 95% CI 1.29–3.12), compared with 4% among patients in Killip class I on admission in whom VF did not develop.

Among 11,712 patients enrolled in the GISSI–1 study, secondary VF, defined as VF in patients with acute MI complicated by HF or shock, occurred in 311 patients (2.7%).[331] The incidence of secondary VF within 24 hours of acute MI was similar among the patients treated with streptokinase and the control group, whereas streptokinase halved the frequency of secondary VF later than 24 hours after admission (27/5860 vs. 60/5852; RR 0.45; 95% CI 0.29–0.70). The protective effect of streptokinase was even greater among patients who were treated within 3 hours of symptom onset (9/3016 vs. 39/3078; RR 0.23; 95% CI 0.12–0.45). In-hospital mortality was higher among patients with secondary VF: 27.1% versus 17.3% for patients in Killip class II (RR 1.77; 95% CI 1.28–2.45) and 48.1% versus 35.3% for patients in Killip class III (RR 1.70; 95% CI 0.95 to 3.02). Secondary VF did not affect in-hospital mortality among the patients in Killip class IV (67.9% with secondary VF vs. 71.9% without secondary VF; RR 0.83; 95% CI 0.44–1.55).

Although primary and secondary VF are associated with an increased risk of in-hospital death, patients who survive to be discharged from the hospital after experiencing either type have a good prognosis. Among the patients who were enrolled in the GISSI-1 and GISSI-2 trials and had nonfatal primary VF, 6-month mortality after hospital discharge among patients with the primary type was not significantly different from that in patients who did not have this arrhythmia.[330,332] In GISSI-2, patients who survived the hospital phase of an acute MI complicated by secondary VF had a 1-year mortality of 10.4%, compared with 13.9% among patients who did not have secondary VF (20/193 vs. 322/2319; RR 0.72; 95% CI 0.44–1.15).[331]

The incidence of primary VF in the GISSI-1 trial was not significantly different in the streptokinase and control groups (2.73% vs. 2.93%; RR 0.93; 95% CI 0.75–1.15).[333] A meta-analysis of 15 randomized trials of fibrinolytic therapy for acute MI confirmed that the likelihood of this arrhythmia is not altered by fibrinolytic therapy, with an incidence of VF during the first hospital day of 2.99% for both the fibrinolytic treatment and placebo groups.[334] There is evidence, however, that fibrinolytic therapy exerts a protective effect against secondary VF.[331,334] Thus the meta-analysis of 15 fibrinolytic trials found that the OR for the development of VF at any time during hospitalization in the fibrinolytic treatment group was 0.83 (95% CI 0.76–0.90; $P < 0.0001$).[334]

Ventricular tachycardia (VT) or VF occurred in 329 of the 5745 patients (5.7%) with STEMI who underwent primary PCI in the APEX AMI trial.[335] Sixty-four percent of the arrhythmic events occurred before the end of the cardiac catheterization and 90% occurred within 48 hours of presentation to the hospital.[335] Ninety-day mortality was 17.2% (adjusted HR 2.34; 95% CI 1.44–3.80) among patients with early VT or VF—that is, during the cardiac catheterization—and 33.3% (adjusted HR 5.59; 95% CI 3.71–8.43) among patients who had late VT or VF—that is, after the catheterization, compared with 3.6% for patients without VT or VF.[335]

As discussed earlier, randomized clinical trials have demonstrated that early administration of intravenous followed by oral metoprolol reduces the incidence of VF in patients with acute STEMI.[297,298] The Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) randomly assigned patients with suspected acute MI to treatment with metoprolol (up to 15 mg intravenously, followed by 200 mg/day orally; $n = 22{,}929$) or placebo ($n = 22{,}923$).[298] Ninety-three percent of the patients had STEMI, and approximately 54% of the patients received a fibrinolytic agent. Allocation to metoprolol was associated with a significant 22% reduction in death attributed to arrhythmia (1.7% vs. 2.2%; $P = 0.0002$), but there was a 29% increase in death attributed to cardiogenic shock among the metoprolol treatment group (2.2% vs. 1.7%; $P = 0.0002$). The EARLY-BAMI investigators reported that the incidence of malignant ventricular arrhythmias during the acute phase was 3.6% among the patients who received intravenous metoprolol compared with 6.9% in the placebo group ($P = 0.05$).[302]

Although a small, double-blind, randomized study supported the routine prophylactic administration of lidocaine to all patient with acute MI to prevent primary VF,[336] subsequent studies of prophylactic lidocaine in acute MI, including more than 20 randomized trials and at least 4 meta-analyses, concluded that lidocaine reduces the incidence of VF but increases mortality.[337] Therefore according to the ACC/AHA Practice Guidelines published in 2004, prophylactic antiarrhythmic therapy is not recommended with use of fibrinolytic agents.[20] Also, the routine use of lidocaine is not indicated for suppression of isolated ventricular premature beats, couplets, runs of accelerated idioventricular rhythm, and nonsustained VT. The guidelines favor intravenous amiodarone for treatment of sustained monomorphic VT.

Although ventricular ectopy is a marker of an increased risk of sudden death in survivors of acute MI, trials of chronic, oral antiarrhythmic drugs have not shown beneficial effects. The Cardiac Arrhythmia Suppression Trial (CAST) I and CAST II found that treatment with the class IC drugs encainide and flecainide, or the class IA drug moricizine, increased mortality in survivors of acute MI.[338,339] *d*-Sotalol, a potassium channel blocker, also increased mortality among survivors of MI in the Survival with Oral *d*-Sotalol (SWORD) randomized trial.[340] Clinical trials of amiodarone, a class III antiarrhythmic drug, suggested that it may reduce the incidence of VF or arrhythmic death among survivors of acute MI.[341,342]

The implantable cardioverter-defibrillator (ICD) has become the standard of care for the prevention of sudden death in survivors of acute MI.[343] There is a class I indication for insertion of an ICD before discharge in patients who develop sustained VT/VF more than 48 hours after STEMI, provided the arrhythmia is not due to transient reversible ischemia, reinfarction, or metabolic abnormalities.[24] The indication for an ICD 40 days after STEMI are determined by the LVEF and New York Heart Association class of HF.[24] Implantation of an ICD is recommended for patients with an LVEF of 35% or less and class II or III HF symptoms, and patients with an LVEF of 30% or less regardless of HF symptoms.[24]

Calcium Antagonists

There are no class I or II indications for calcium channel blockers in patients with acute MI because neither individual clinical trials nor analyses of the pooled results of multiple trials showed a reduction in mortality after acute MI.[344,345] A randomized study that compared diltiazem with placebo starting 3 to 15 days after acute MI found that diltiazem therapy was associated with an increased risk of cardiac events in patients with radiographic evidence of pulmonary congestion.[346] The same trial concluded that diltiazem increases the risk of late-onset HF in patients with an LVEF less than 40%.[347] Nifedipine (immediate-release form) is contraindicated in the treatment of STEMI because of the reflex sympathetic activation, tachycardia, and hypotension associated with its use.[24]

Lipid-Lowering Agents

Numerous trials have evaluated the effects of statins on coronary events in patients with acute and chronic CAD, but none of the trials restricted enrollment to patients with STEMI or provided subgroup analyses of the outcomes among patients with STEMI before enrollment. The Scandinavian Simvastatin Survival Study (4S) was the first clinical trial to demonstrate significant reductions in total mortality and coronary heart disease mortality by treatment with lipid-lowering therapy.[348] Seventy-nine percent of the patients had a history of MI. After a median follow-up period of 5.4 years, total mortality was 12% in the placebo group versus 8% in the patients who were randomly assigned to receive simvastatin (RR 0.70; 95% CI 0.58–0.85; $P = 0.0003$). Also, there was a 37% reduction in the risk of undergoing a myocardial revascularization procedure. The beneficial effects of statin therapy in patients with a history of MI were confirmed by two studies that randomly assigned patients to receive pravastatin 40 mg daily or placebo: the Cholesterol and Recurrent Events (CARE) trial[349] and the Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID) trial.[350] All patients who were enrolled in the CARE trial had a history of MI between 3 and 20 months before enrollment, and 64% of the patients enrolled in the LIPID trial had a history of MI between 3 and 36 months before enrollment.

There is a class I indication for high-intensity statin therapy in all patients with STEMI and no contraindications.[24] A diagnosis of hyperlipidemia cannot be excluded during the first week after an acute MI because both total cholesterol and low-density lipoprotein (LDL) cholesterol decrease significantly during the first week after an acute MI.[351] There is a class IIa indication to obtain a fasting lipid profile in patients with STEMI, preferably within 24 hours of presentation.[24]

Intraaortic Balloon Counterpulsation

Two very small randomized trials and one large randomized trial evaluated the use of an IABP in patients with acute MI complicated by cardiogenic shock.[352] The IABP-SHOCK II (Investigators in the Intraaortic Balloon Pump in Cardiogenic Shock II) trial randomly assigned 600 patients with cardiogenic shock complicating acute MI to intraaortic balloon counterpulsation or no IABP.[353,354] Primary PCI was performed in 95% of the IABP patients and 96% of the control patients ($P = 0.55$).[353,354] Use of an IABP did not reduce all-cause mortality at either 30 days or 12 months.[353,354]

The Second Primary Angioplasty in Myocardial Infarction (PAMI-II) investigators randomly assigned 436 patients with a high-risk acute MI to insertion of an IABP or no IABP after primary PCI.[355] The rates of reocclusion of the IRA, reinfarction, and mortality were not significantly different, and there was a higher incidence of stroke among patients who received an IABP (2.4% vs. 0%; $P = 0.03$). Also, there was no enhancement of myocardial recovery at the time of hospital discharge or 6 weeks after discharge. The Counterpulsation to Reduce Infarct Size Pre-PCI Acute Myocardial Infarction (CRISP AMI) trial was a randomized trial to determine whether insertion of an IABP before primary PCI reduces infarct size in patients with an acute anterior STEMI without cardiogenic shock.[356] The mean infarct size, measured by cardiac MRI 3 to 5 days after PCI, was 42.1% of the left ventricle in the IABP group compared with 37.5% of the left ventricle in the control group ($P = 0.06$). Thus the IABP has not been shown to be beneficial in patients with high-risk or anterior acute MI who undergo primary PCI.

A meta-analysis by Ahmad et al.[352] identified 12 randomized, controlled trials comparing an IABP with a control group in patients with acute MI, 3 trials in patients with cardiogenic shock, and 9 in patients without shock. Fifteen observational studies were also analyzed separately.[352] The observational studies showed contradictory associations between IABP therapy and mortality that were mostly due to differences between studies in the balance of risk factors between the IABP and control groups.[352] There was no significant heterogeneity among the randomized trials, and analysis of the randomized trials did not show a statistically significant effect of IABP use on mortality (OR 0.96; 95% CI 0.74–1.24).[352] The use of the IABP in patients with cardiogenic shock is discussed in a subsequent section of this chapter and in the chapter on cardiogenic shock.

Coronary Artery Bypass Graft Surgery

Randomized trials have not been performed to compare surgical reperfusion for acute MI with either conservative medical therapy or reperfusion by means of fibrinolytic therapy or PCI. A nonrandomized study compared the outcomes in 200 patients managed conservatively with those in 187 patients who underwent surgical reperfusion between 1972 and 1976.[357] In-hospital mortality was 5.8% among patients who underwent CABG surgery, compared with 11.5% among patients who did not undergo myocardial reperfusion ($P < 0.08$). Among the patients who underwent coronary bypass grafting within 6 hours from the onset of symptoms of acute MI, in-hospital mortality was only 2% (2/100), compared with 10.3% (9/87) among the patients who underwent surgery more than 6 hours after the onset of symptoms.

Although registry data indicate that CABG surgery within 24 hours of an acute STEMI is associated with a marked increase of in-hospital mortality,[358] emergency surgical revascularization should be considered in certain subsets of patients. Emergency CABG surgery is a reasonable option in patients with cardiogenic shock and coronary anatomy poorly suited for PCI (e.g., severe stenosis of the left main coronary artery). Among patients enrolled in the Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock? (SHOCK) trial, survival rates were similar for CABG surgery and for PCI.[359]

The 2011 ACCF/AHA Guideline for Coronary Artery Bypass Graft (CABG) Surgery includes four class I, two class IIa, and two class III recommendations regarding CABG in patients with acute MI[360] (Box 29.6). The 2013 ACCF/AHA Guideline for the Management of STEMI, includes two class I indications for CABG: (1) urgent CABG is indicated in patients with STEM and coronary anatomy not amenable to PCI who have ongoing or recurrent ischemia, cardiogenic shock, severe HF, or other high-risk features; (2) CABG is recommended in patients with STEMI at time of operative repair of mechanical defects.[24]

• BOX 29.6 CABG in Patients With Acute MI

Class I

1. Emergency CABG is recommended in patients with acute MI in whom (1) primary PCI has failed or cannot be performed, (2) coronary anatomy is suitable for CABG, and (3) persistent ischemia of a significant area of myocardium at rest or hemodynamic instability refractory to nonsurgical therapy is present.
2. Emergency CABG is recommended in patients undergoing surgical repair of a postinfarction mechanical complication of MI, such as ventricular septal rupture, mitral valve insufficiency because of papillary muscle infarction or rupture, or free wall rupture.
3. Emergency CABG is recommended in patients with cardiogenic shock and who are suitable for CABG irrespective of the time interval from MI to onset of shock and time from MI to CABG.
4. Emergency CABG is recommended in patients with life-threatening ventricular arrhythmias (believed ischemic in origin) in the presence of left main stenosis greater than or equal to 50% or three-vessel CAD.

Class IIa

1. The use of CABG is reasonable as a revascularization strategy in patients with multivessel CAD with recurrent angina or MI within the first 48 hours of STEMI presentation as an alternative to a more delayed strategy.
2. Early revascularization with PCI or CABG is reasonable for selected patients older than 75 years of age with ST-segment elevation or left bundle branch block who are suitable for revascularization irrespective of the time interval from MI to onset of shock.

Class III

1. Emergency CABG should not be performed in patients with persistent angina and a small area of viable myocardium who are stable hemodynamically.
2. Emergency CABG should not be performed in patients with no reflow (successful epicardial reperfusion with unsuccessful microvascular reperfusion).

The timing of surgery in stable patients may influence the risk of bleeding in patients who have received a $P2Y_{12}$ inhibitor. Red blood cell transfusion of 4 units or more after CABG was an independent predictor of 1-year mortality among 1491 patients with ACS who underwent CABG.[361] There are conflicting data regarding the impact of $P2Y_{12}$ inhibitors on the risk of bleeding and transfusion after CABG. One retrospective analysis of 596 patients with ACS who underwent CABG found that exposure to clopidogrel within 5 days of surgery increased the risk of major bleeding and reoperation.[362] Among 1539 patients with ACS who were enrolled in the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial and underwent CABG before discharge, CABG within 5 days of the last clopidogrel dose was not associated with higher rates of transfusion or major bleeding compared with the rates among patients who did not receive any clopidogrel before CABG.[363] Administration of clopidogrel within 5 days before CABG was associated with a modestly increased risk of red blood cell transfusion but was not significantly associated with reoperation for bleeding among 332 patients who were enrolled in the Duke Databank between January 1999 and December 2003.[364]

According to the 2011 ACCF/AHA Guideline for CABG, clopidogrel and ticagrelor should be discontinued for at least 5 days before surgery and prasugrel for at least 7 days to limit blood transfusions, whereas clopidogrel and ticagrelor should be discontinued for at least 24 hours in patients referred for urgent CABG.[360] The 2013 ACCF/AHA Guideline for the Management of STEMI includes four class I recommendations for the timing of urgent CABG in patients with STEMI in relation to antiplatelet agents:

1. Aspirin should not be withheld before urgent CABG.
2. Clopidogrel or ticagrelor should be discontinued at least 24 hours before urgent on-pump CABG, if possible.
3. Short-acting intravenous GP IIb/IIIa receptor antagonists (eptifibatide, tirofiban) should be discontinued at least 2 to 4 hours before urgent CABG.
4. Abciximab should be discontinued at least 12 hours before urgent CABG.[24]

Management of Complications

Pericarditis and Pericardial Tamponade

Pericarditis, defined as the detection of a pericardial friction rub, was diagnosed in 20% (141/703) of patients who were enrolled in the Multicenter Investigation of the Limitation of Infarct Size (MILIS).[365] The frequency of pericarditis was higher in patients with Q-wave MI than in those with non–Q-wave MI (25% vs. 9%; $P < 0.001$). Pericarditis was associated with a lower admission LVEF (42% vs. 48%; $P < 0.001$) and a higher incidence of HF (47% vs. 26%; $P < 0.001$). Pericarditis was accompanied by pleuritic or positional chest pain in 70% of patients. Diagnostic electrocardiographic changes usually are absent in patients with infarction-associated pericarditis.[366] A prospective study of 423 patients with acute MI found that only 1 of the 31 patients with pericardial friction rubs had diagnostic ST-segment changes.[366]

There is evidence that reperfusion therapy reduces the risk of pericarditis after STEMI.[367,368] The GISSI investigators reported the frequency of pericardial involvement in patients who were enrolled in the GISSI-1 ($n = 11,806$) and GISSI-2 ($n = 12,381$) trials.[367] The incidence of pericardial involvement was lower among patients who received fibrinolytic therapy than among patients in the control groups (6.7% vs. 12%).[367] Earlier treatment with fibrinolytic therapy was associated with a lower risk of pericardial involvement. Although pericardial involvement was associated with a higher long-term mortality, it was not an independent prognostic factor because it was strongly associated with the extent of infarction as determined by ECG, peak creatine kinase, and echocardiography.[367] A relationship between the duration of symptoms before reperfusion and the incidence of post-MI pericarditis also was observed in a cohort of 743 consecutive patients with STEMI who were treated with primary PCI.[368] Early post-MI pericarditis was diagnosed in 31 patients (4.2%).[368] The prevalence was 1.7% among patients who underwent primary PCI less than 3 hours after the onset of symptoms, compared with 5.4% for presentation delays of 3 to 6 hours, and 13.6% for delays more than 6 hours.[368] Although early post-MI pericarditis was associated with larger infarct sizes, in-hospital and 1-year mortality were similar in the patients with and without pericarditis.[368]

The ACC/AHA Practice Guidelines recommend aspirin for treatment of pericarditis after STEMI.[24] Colchicine or acetaminophen is recommended for patients who do not respond to aspirin. Corticosteroids and NSAIDs are regarded as class III harmful therapies because of an increased risk of scar thinning and infarct

expansion. Finally, anticoagulation should be discontinued if a pericardial effusion is detected.

Although reperfusion therapy has decreased the occurrence of pericarditis in patients with STEMI, pericardial effusion remains relatively frequent. Among a total of 780 patients with STEMI who underwent primary PCI within 12 hours after symptom onset, a moderate to large pericardial effusion was detected by MRI in 183 patients (24%).[369] The incidence of a moderate to severe pericardial effusion was investigated in 4361 patients with STEMI who underwent an echocardiogram within 12 hours after hospitalization.[370] It varied from 12.0% in patients who did not receive reperfusion therapy, to 5.7% in patients who were treated with fibrinolytics, to 4.3% in patients who underwent primary PCI.[370] Among 228 patients with an echocardiographic pericardial effusion classified as moderate to severe, mortality was fivefold greater than those with a small or no pericardial effusion, and 80% of deaths were attributable to free wall rupture.[371]

Free wall rupture and hemorrhagic pericarditis are two potential mechanisms of cardiac tamponade after acute MI. Among 102,060 patients with STEMI who were enrolled in seven randomized clinical trials and received fibrinolytic therapy, cardiac tamponade developed in 1018 patients (1%).[372] Among the patients with tamponade, 153 also had a VSR or acute MR, and 865 had isolated cardiac tamponade. The adjusted 30-day mortality among 7-day survivors with tamponade was significantly increased (HR 7.9; 95% CI 4.7–13.5; $P < 0.0001$). Pericardial tamponade accounted for 1.4% of patients with cardiogenic shock among 1422 patients with acute MI who were enrolled in either the SHOCK registry or the randomized trial.[373]

Recurrent Ischemia or Infarction

Recurrent infarction (reinfarction) after an initial STEMI is relatively uncommon, but it often is an endpoint for clinical trials, because reinfarction is associated with increased morbidity and mortality.[374,375] Symptomatic recurrent MI during the index hospitalization occurred in 4.2% (836/20,101) of patients who were enrolled in four clinical trials of various fibrinolytic agents.[375] Recurrent MI occurred a median of 2.2 days after the initial MI and was associated with increased mortality rates at both 30 days (16.4% vs. 6.2%; $P < 0.001$) and 2 years (HR 2.11, $P < 0.001$). In-hospital reinfarction occurred in 4.3% of patients (2258/55,911) a median of 3.8 days after fibrinolytic therapy in the GUSTO I and GUSTO III trials.[374] The rates of reinfarction were 4.3% for alteplase, 4.5% for rPA, and 4.1% for streptokinase ($P = 0.55$). Patients with in-hospital reinfarction had higher mortality at 30 days (11.3% vs. 3.5%; OR 3.5; $P < 0.001$) and from 30 days to 1 year (4.7% vs. 3.2%; HR 1.5; $P < 0.001$).[374] Compared with patients who did not have reinfarction, patients with reinfarction had higher rates of HF (31.9% vs. 13.9%) and cardiogenic shock (15.9% vs. 2.4%).

The frequency of recurrent ischemia or reinfarction after an initial STEMI depends on the modality of reperfusion and the adjunctive therapy used. One of the purported advantages of primary PCI over fibrinolytic therapy is a decreased rate of reinfarction. The 30-day rates of reinfarction in the DANAMI-2 trial were 6.3% (49/782) among patients who were randomly assigned to fibrinolytic therapy compared with 1.6% (13/790) among patients who were assigned to the angioplasty group ($P < 0.001$).[214] In a meta-analysis of 13 randomized trials of primary angioplasty versus fibrin-specific agents, the frequency of nonfatal reinfarction was 3% (74/2753) among patients randomly assigned to angioplasty, compared with 6% (172/2757) among patients assigned to fibrinolytic therapy (OR 0.42; 95% CI 0.31–0.55).[209]

There is evidence that coronary revascularization reduces the risk of reinfarction after fibrinolytic therapy. Among patients who were enrolled in four clinical trials of various fibrinolytic drugs, PCI, or CABG surgery was performed during the index hospitalization in 26.1% (5238/20,039) of the patients and was associated with lower rates of both in-hospital recurrent MI (1.4% vs. 4.7%, $P < 0.001$) and 2-year mortality.[375]

A variety of antithrombotic and antiplatelet therapies have been shown to reduce the risk of reinfarction after STEMI. In a trial that randomly assigned 20,506 patients with STEMI to either enoxaparin or UFH as adjunctive treatment after fibrinolytic therapy, the rates of reinfarction at 30 days were 3% for the enoxaparin group (309/10,256) compared with 4.5% for the UFH group (458/10,223) (RR 0.67; 95% CI 0.58–0.77; $P < 0.001$).[131] A meta-analysis of 11 clinical trials found that administration of abciximab was associated with a reduction in the 30-day reinfarction rates among patients who underwent primary angioplasty (1% vs. 1.9%; OR 0.56; 95% CI 0.33–0.94; $P = 0.03$) and among patients who received fibrinolytic therapy (2.3% vs. 3.6%; OR 0.64; 95% CI 0.54–0.75; $P < 0.001$).[288]

Numerous clinical trials have investigated the effect of warfarin alone or in combination with aspirin on the risk of reinfarction and other events in patients with ACS, but most of the studies were not restricted to patients with STEMI, the target international normalized ratio (INR) has varied, and conflicting results have emerged.[376,377] The Warfarin Re-Infarction Study randomly assigned 1214 patients to receive placebo or warfarin (target INR 2.8–4.8) after an average interval between the index MI and enrollment of 27 days.[378] Approximately 70% of patients had Q waves on the baseline ECG, most patients did not receive reperfusion therapy, and all patients were advised not to take aspirin or other antiplatelet drugs. During an average treatment period of 37 months, the rate of reinfarction was significantly reduced by warfarin compared with placebo (82/607 vs. 124/607; RR 34%; 95% CI 19%–54%; $P = 0.0007$).

The Antithrombotics in the Secondary Prevention of Events in Coronary Thrombosis-2 (ASPECT-2) study randomly assigned 999 patients to receive one of three antithrombotic regimens: aspirin 80 mg daily, warfarin (target INR 3.0–4.0), or the combination of aspirin 80 mg daily and warfarin (target INR 2.0–2.5).[379] Patients were enrolled within 8 weeks of hospitalization for either UA (13%) or Q-wave or non–Q-wave MI. During a median follow-up period of 12 months, the primary composite endpoint of MI, stroke, or death was significantly less frequent for the two groups that received warfarin, but warfarin did not reduce the risk of MI, and it increased the risk of both major and minor bleeding.

The APRICOT-2 trial randomly assigned 308 patients with a patent IRA within 48 hours after fibrinolytic therapy to receive either aspirin alone (80 mg daily) or aspirin plus warfarin for 3 months (target INR 2.0–3.0).[380] The rate of reinfarction during 3 months of follow-up was 2% (3/135) for combination therapy, compared with 8% (11/139) for aspirin alone ($P < 0.05$). The Warfarin, Aspirin, Reinfarction Study (WARIS II) randomly assigned 3630 patients who were hospitalized for an acute MI to one of three treatment groups: warfarin alone (with a target INR of 2.8–4.2), aspirin alone (160 mg daily), or the combination of aspirin 75 mg daily and warfarin (target INR 2.0–2.5).[381] Fibrinolytic drugs were administered to 53% to 55% of the patients in each group. During a mean observation period of 4 years, the rates of reinfarction were significantly less in both groups of patients who received warfarin: 9.7% (117/1206) for aspirin alone, 7.4% (90/1216) for warfarin alone (RR 0.74; 95% CI 0.55–0.998; P

= 0.03), and 5.7% (69/1208) for aspirin plus warfarin (RR 0.56; 95% CI 0.41–0.78; $P < 0.001$). Another study that used a target INR of 1.5 to 2.5 found that the addition of warfarin to aspirin 81 mg daily did not reduce the rate of reinfarction compared with aspirin monotherapy (162 mg daily).[382] The combination of aspirin 80 mg daily with low, fixed-dose warfarin (1 mg or 3 mg) was not superior to aspirin 160 mg daily in patients with a recent STEMI or NSTEMI.[383] Thus the clinical trials suggest that warfarin is superior to placebo, that the combination of aspirin and warfarin is superior to aspirin alone if the target INR is sufficiently high, and that the risk of major bleeding is increased by adding warfarin to aspirin. Also, the published data should not be extrapolated to patients who receive dual antiplatelet therapy (aspirin plus a thienopyridine) after either fibrinolytic therapy or coronary artery stenting, because most of the patients who were enrolled in the warfarin trials did not receive reperfusion therapy or a thienopyridine.

In the ISIS-2 trial, aspirin reduced the rate of in-hospital reinfarction both in the patients who received streptokinase and in those who did not receive fibrinolytic therapy. In the CLARITY study, higher platelet counts were associated with an increased risk of reinfarction among patients with STEMI for whom treatment consisted of aspirin plus a fibrinolytic drug.[384] The addition of clopidogrel to aspirin abolishes the increased risk of reinfarction as the platelet count increases.[384] In the CLARITY study, the rate of recurrent MI after fibrinolytic therapy was 4.1% among patients treated with clopidogrel and aspirin, compared with 5.9% among patients who received placebo and aspirin (representing a 31% reduction in odds).[106]

Clinical trials have demonstrated that β-blockers, ACE inhibitors, and statins also reduce the risk of reinfarction after acute MI, although most of the trials enrolled patients with both STEMI and NSTEMI, and subgroup analyses of outcomes in patients with STEMI were not published. Compared with metoprolol started 6 days after t-PA for acute STEMI, metoprolol started within 2 hours of t-PA was associated with lower rates of reinfarction (5.1% vs. 2.7%; $P = 0.02$) and recurrent chest pain (24.1% vs. 18.8%; $P < 0.02$) at 6 days.[306] The Norwegian Multicenter Study Group randomly assigned 1884 patients to double-blind treatment groups, to receive either oral timolol or placebo, beginning 7 to 28 days after acute MI.[309] The cumulative reinfarction rate at 33 months was 28% lower in the timolol group than in the placebo group (14.4% vs. 20.1%; $P = 0.0006$). The CAPRICORN study randomly assigned 1959 patients with a LVEF of 40% or less to receive carvedilol or placebo beginning 3 to 21 days after acute MI.[312] Forty-six percent of the patients had received reperfusion therapy, and 97% had received an ACE inhibitor for at least 48 hours before beginning the study treatment.[312] After an average follow-up period of 1.3 years, the rate of nonfatal MI was significantly lower in the carvedilol group than in the placebo group (3% vs. 6%; HR 0.59; 95% CI 0.39–0.90; $P = 0.014$).[312]

The GISSI 3 trial did not show an effect of lisinopril on the rate of reinfarction after 6 weeks.[90] Although the AIRE[317] and TRACE[318] trials failed to show a significant effect of ramipril or trandolapril on the long-term risk of reinfarction, the SAVE study[316,319] did observe a significant decrease in the reinfarction rate among patients who were randomly selected to receive captopril 3 to 16 days after acute MI. After an average follow-up period of 42 months, captopril reduced the risk of recurrent MI by 25% (95% CI 5–40; $P = 0.015$).[319] Thus ACE inhibitors may not reduce the short-term risk of reinfarction after acute MI, but they may decrease the long-term risk of reinfarction.

Among a cohort of 2301 patients in whom reinfarction occurred after administration of fibrinolytic therapy in the GUSTO I and Assessment of Safety and Efficacy of a New Thrombolytic 2 (ASSENT 2) clinical trials, reinfarction was treated with repeat fibrinolysis ($n = 864$), with revascularization ($n = 525$), or conservatively ($n = 835$).[385] After adjustment for baseline characteristics, the 30-day mortality was significantly greater in the conservative group, 28%, compared with the repeat fibrinolysis group, 11% (OR 2.2; 95% CI 1.5–3.1; $P < 0.001$) or the revascularization group, 11% (OR 2.2; 95% CI 1.4–3.3; $P < 0.0001$). No significant difference was observed between the revascularization and repeat fibrinolysis groups.

One of the causes of reinfarction in patients with STEMI is stent thrombosis after primary PCI. A network meta-analysis of 22 controlled trials that randomly assigned a total of 12,453 patients with STEMI concluded that second-generation cobalt-chromium everolimus-eluting stents were associated with significantly lower risk of 1-year cardiac death/MI, MI, and stent thrombosis compared with BMS, and significantly lower 1-year rates of stent thrombosis than paclitaxel-eluting stents.[272] The 2014 ESC/EACTS Guidelines on myocardial revascularization include a class I recommendation that new-generation DESs are recommended over BMSs in STEMI patients who undergo primary PCI.[274]

The 2004 version of the ACC/AHA Guidelines for the Management of Patients with STEMI provided recommendations regarding the management of recurrent ischemia and reinfarction that were not included in the 2013 version of the guideline.[20,24] The 2004 version recommended escalation of medical therapy with nitrates, β-blockers, and intravenous anticoagulation, and consideration of an IABP in patients with hemodynamic instability, poor left ventricular function, or a large area of myocardium at risk. Coronary angiography and PCI or CABG surgery were recommended for patients who are considered candidates for revascularization and have recurrent ischemic-type chest discomfort. Also, there was a class IIa recommendation for readministration of fibrinolytic therapy to patients with ischemic-type chest discomfort and recurrent ST-segment elevation who are not considered candidates for revascularization or for whom coronary angiography and PCI cannot be implemented within 60 minutes of the onset of recurrent ischemia. A class III recommendation regarding streptokinase stated that it should not be readministered to patients who received a nonfibrin-specific fibrinolytic agent more than 5 days previously.

Congestive Heart Failure

An analysis of 2654 patients with acute MI who were enrolled in three primary angioplasty trials found that the Killip class on admission was a multivariate predictor of both in-hospital and 6-month mortality.[19] Hasdai and associates[386] combined the data from four large randomized trials of fibrinolytic therapy for STEMI to describe the incidence, timing, and consequences of mild to moderate HF in patients with STEMI. Excluding patients with cardiogenic shock, 17,949 of 61,041 (29.4%) patients had mild to moderate HF. Among the cohort with mild to moderate HF, 8.7% had HF only at baseline, 57.6% had HF only after admission, and 33.7% had HF at baseline and after admission. The incidence of death was similar for patients without HF and patients with HF at baseline that resolved after admission. Patients with HF that persisted from baseline or developed after admission had a four times greater risk of death at 30 days (8% vs. 2%).

There is evidence that patients with STEMI complicated by HF benefit from early revascularization. Analysis of an Israeli database compared the outcomes of 629 patients with STEMI who presented

in Killip class II or III HF.[387] Mortality at 6 months was lower among patients who underwent PTCA or CABG surgery within 30 days compared with patients who were managed noninvasively (11.6% vs. 27.4%; OR 0.40; 95% CI 0.24–0.64; $P < 0.0001$). According to the 2013 ACCF/AHA STEMI Guideline for the Management of STEMI, "the development of HF after STEMI is an indication for angiography with intent to proceed with revascularization if not previously performed."[24]

It is important to recognize that HF also is an important prognostic factor in patients with UA or NSTEMI.[388] Among a cohort of 13,707 patients with a confirmed diagnosis of ACS without prior HF or cardiogenic shock at the time of presentation to the hospital, HF (Killip class II or III) was present at hospital admission in 1778 patients (13%), and HF developed later during hospitalization in an additional 869 patients (6.3%).[388] The incidence of HF was similar in patients with STEMI (15.6%) or NSTEMI (15.7%) but less frequent in patients with UA (8.2%). HF at the time of admission was associated with a fourfold increase in crude in-hospital mortality rates across all three ACS subsets. The cumulative 6-month mortality rate was greater among patients in whom HF developed during hospitalization (25.3%) than among patients who had HF at admission (20.7%) or patients who did not have HF (5.9%).

ACE inhibitors, eplerenone, and β-adrenergic antagonists are believed to improve the long-term survival of patients with MI complicated by HF.[389] BHAT, a study that randomly assigned patients to receive propranolol or placebo 5 to 21 days after acute MI, included 710 patients who had a history of HF before enrollment.[390] After an average follow-up period of 25 months, propranolol reduced total mortality by 27% and sudden death by 47%. A retrospective analysis of the AIRE study was performed to determine the effects of β-blockade on the outcomes for patients with acute MI complicated by HF.[391] β-Blocker treatment was an independent predictor of reduced risk of total mortality (HR 0.66; 95% CI 0.48–0.90). The CAPRICORN study showed that carvedilol, started 3 to 21 days after MI, reduced all-cause mortality by 33% in patients with an LVEF of 40% or less.[312] Unfortunately, patients with acute MI complicated by HF are less likely to receive a β–blocker than are patients without HF.[392]

The AIRE study showed that ramipril, initiated 3 to 10 days after acute MI, reduced all-cause mortality by 27% in patients with either STEMI or NSTEMI and clinical or radiologic evidence of HF.[317] The EPHESUS study randomly assigned patients with either STEMI or NSTEMI and LVEF less than 40%, to eplerenone or placebo beginning 3 to 14 days after the acute MI.[326,327] Ninety percent of the patients had HF, documented by the presence of pulmonary rales, a third heart sound, or evidence of pulmonary venous congestion on the chest radiograph. Concomitant medications included β-blockers in 75% of patients and an ACE inhibitor or angiotensin receptor blocker in 86%. At 30 days after randomization, eplerenone reduced the risk of all-cause mortality by 31% (3.2% vs. 4.6%; RR 0.69; 95% CI 0.54–0.89; $P = 0.004$).[327] During a mean follow-up period of 16 months, the all-cause mortality rate was 14.4% in the eplerenone group and 16.7% in the placebo group (RR 0.85; 95% CI 0.75–0.96; $P = 0.008$).[326]

Although the 2013 ACCF/AHA Guideline for the Management of STEMI did not include specific recommendation for the treatment of patients with STEMI complicated by pulmonary congestion, on the basis of the foregoing evidence, the 2004 version of the STEMI guideline included eight class I recommendations for patients with STEMI complicated by pulmonary congestion[20]:

1. An arterial oxygen saturation greater than 90% should be maintained using supplemental oxygen.
2. Morphine sulfate should be given.
3. Patients with a systolic blood pressure 100 mm Hg or higher should receive an ACE inhibitor, beginning with titration of a low dose of a short-acting drug such as captopril.
4. Patients with a systolic blood pressure of 100 mm Hg or higher should receive nitrates.
5. A loop diuretic should be administered to patients with volume overload.
6. Although β-blockade should be initiated before hospital discharge, β-blockers should not be administered acutely to patients with "frank cardiac failure evidenced by pulmonary congestion or signs of a low-output state."
7. Patients already receiving an ACE inhibitor who have an LVEF less than 40% and either symptomatic HF or diabetes should receive long-term aldosterone blockade unless hyperkalemia (serum potassium >5 mEq/L) or significant renal dysfunction (serum creatinine >2.5 mg/dL in men or >2 mg/dL in women) is present.
8. Echocardiography should be performed urgently to evaluate left and right ventricular function and to exclude a mechanical complication.

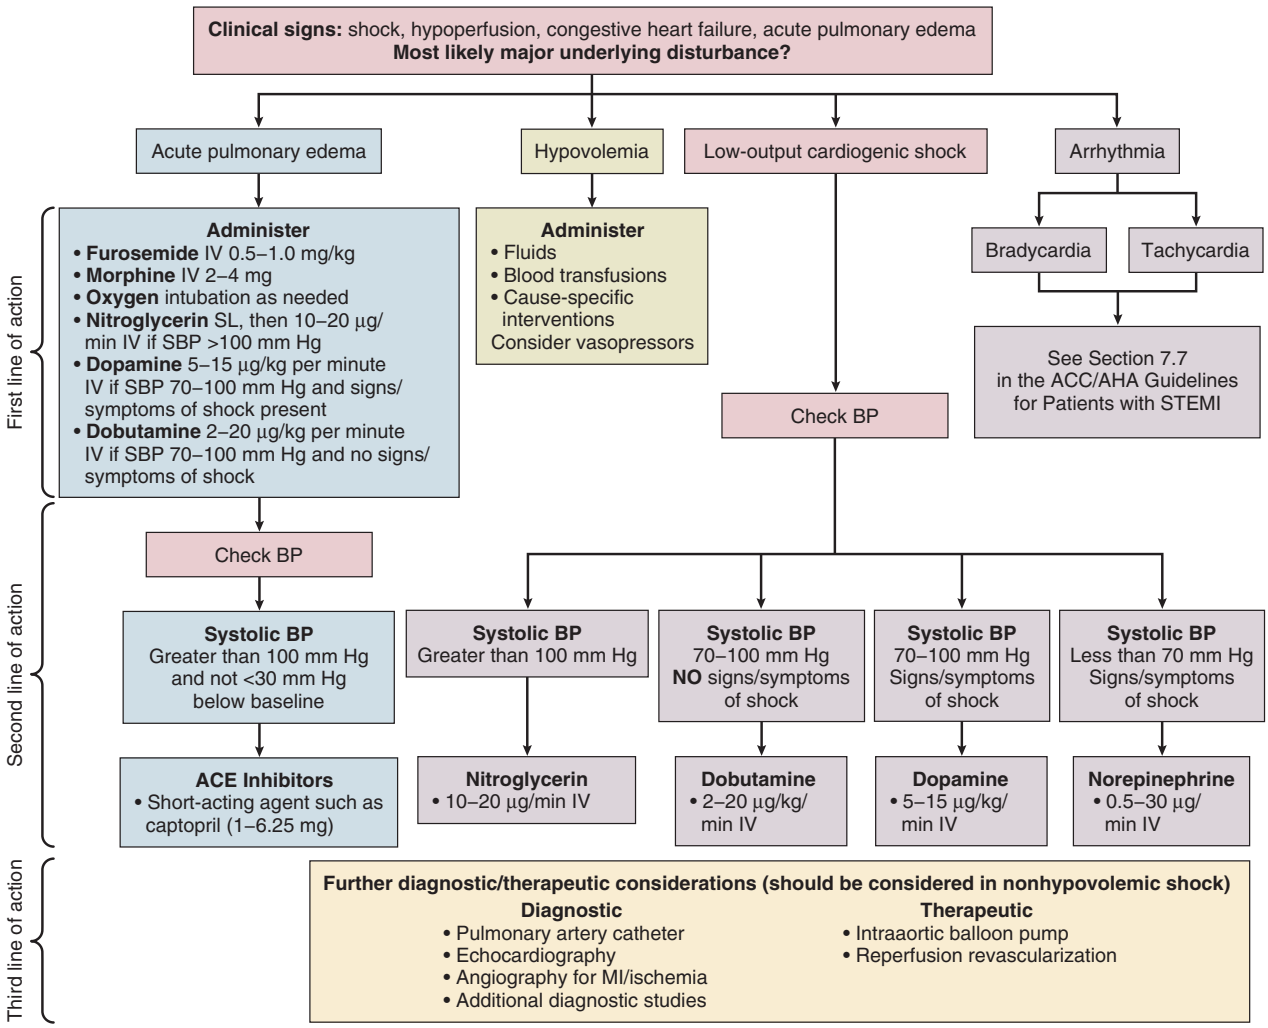
In view of the fact that the relevant clinical trials included patients with both STEMI and NSTEMI, it is logical that treatment of NSTEMI patients with HF should conform to the practice guidelines as discussed for STEMI patients with HF. Fig. 29.7 presents an algorithm for the emergency management of MI complicated by HF or hypotension.

Right Ventricular Dysfunction and Infarction

Among 416 patients with acute MI who were enrolled in an echocardiographic substudy of the SAVE trial, right ventricular function was an independent predictor of mortality and the development of HF.[393] The odds of cardiovascular mortality increased 16% for each 5% decrease in the percentage change in right ventricular cavity area from end diastole to end systole.

Occlusion of the right coronary artery (RCA) proximal to the acute marginal branches is the most frequent cause of right ventricular infarction, but occlusion of the LAD or a dominant left circumflex coronary artery also may result in right ventricular MI. Although autopsy studies have shown that anterior MI may be associated with a right ventricular infarction, right ventricular MI associated with hemodynamic compromise most commonly occurs in patients with an inferior MI because perfusion of the right ventricle occurs predominantly via the right ventricular branches of the RCA.[394,395] In a series of 125 patients with acute inferior MI who underwent emergency coronary angiography, echocardiography performed before coronary reperfusion demonstrated ischemic dysfunction of the right ventricle in 53 (42%) patients.[396] The RCA was the IRA in all patients with right ventricular MI, and depressed flow in the right ventricular branches was evident in each case. Right ventricular branch flow was preserved in patients without right ventricular MI.

Patients with inferior MI complicated by right ventricular infarction have an increased risk of major complications, including death, cardiogenic shock, and ventricular arrhythmias.[397] Cardiogenic shock during hospitalization occurred in 6.9% of a series of 491 patients with inferior MI complicated by right ventricular MI.[397] Patients with right ventricular infarction complicated by cardiogenic shock do not have a better prognosis than patients with cardiogenic shock associated with left ventricular failure.[398] Among a cohort of 1129 patients with acute inferior MI, there was no difference in left ventricular infarct size or function between patients with



• **Fig. 29.7** Algorithm for emergency management of complicated myocardial infarction *(MI). ACE,* Angiotensin-converting enzyme; *BP,* blood pressure; *IV,* intravenous; *SBP,* systolic BP; *SL,* sublingual; *STEMI,* ST-segment elevation myocardial infarction. (Data from Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care. Part 7, the era of reperfusion: section 1, acute coronary syndromes (acute myocardial infarction). The American Heart Association in collaboration with the International Liaison Committee on Resuscitation. *Circulation.* 2000;102(suppl I):I172–I1203.)

(n = 491) and patients without (n = 638) right ventricular MI, indicating that the increased risk of right ventricular MI is due to right ventricular dysfunction rather than greater left ventricular injury.[397] The impact of right ventricular MI on prognosis may depend on the patient's age.[399] Among a series of 798 consecutive patients with acute inferior MI, 296 (37%) satisfied electrocardiographic or echocardiographic criteria for right ventricular infarction.[399] Major complications (45% vs. 19%; $P < 0.0001$) and in-hospital death (22% vs. 6%; $P < 0.0001$) occurred more often in patients with than in those without right ventricular MI. The diagnosis of right ventricular MI increased the mortality risk in patients aged 65 or greater, but not among younger patients.

Although numerous electrocardiographic signs of right ventricular MI have been described, ST-segment elevation in lead V_4R is the most reliable electrocardiographic indicator of this form of MI.[400] Zehender and associates[401] studied the diagnostic and prognostic value of ST-segment elevation in V_4R in a series of 200 consecutive patients with acute inferior MI. ST-segment elevation in lead V_4R was present on the initial ECG in 107 patients (54%). Based on the results of autopsy, coronary angiography, right ventriculography, nuclear scan, or invasive hemodynamic data, ST-segment elevation in V_4R had 88% sensitivity, 78% specificity, and 83% diagnostic accuracy for right ventricular MI. ST-segment elevation in V_4R was associated with an in-hospital mortality of 31%, compared with 6% among patients without ST-segment elevation in V_4R ($P < 0.001$). Multivariate analysis of clinical data confirmed that 0.1 mV or greater of ST-segment elevation in V_4R was a strong independent predictor of in-hospital death (RR 7.7; 95% CI 2.6–23) and major complications (RR 4.7; 95% CI 2.4–9).

The triad of hypotension, clear lung fields, and elevated jugular venous pressure should raise suspicion of right ventricular MI in patients with inferior STEMI, but the triad has a sensitivity of less than 25%.[402] The hemodynamic criteria that have been used to diagnose right ventricular MI are right atrial pressure greater than 10 mm Hg and equal or nearly equal to the PCWP, or a noncompliant pattern in the right atrium.[403] Inferior STEMI with hemodynamic compromise is a class I indication for recording lead V_4R and an echocardiogram to screen for right ventricular

MI.[20] Echocardiographic signs of this disorder include right ventricular dilation, right ventricular asynergy, and abnormal interventricular septal motion.[403] Echocardiography also is valuable to exclude pericardial tamponade because both right ventricular MI and pericardial tamponade may manifest with hypotension and elevated jugular venous pressure.[404]

The ACC/AHA guidelines emphasize the importance of maintenance of right ventricular preload, reduction of right ventricular afterload, inotropic support of the right ventricle, maintenance of atrioventricular (AV) synchrony, and early reperfusion of the IRA.[24] Volume loading plus dobutamine, but not volume loading alone, has been shown to improve cardiac index in patients with acute right ventricular infarction.[405] Systemic vasodilators are poorly tolerated, and hypotension after administration of sublingual nitroglycerin is a common event in patients with right ventricular MI. Short-term inhalation of nitric oxide, a selective vasodilator of the pulmonary circulation, improved cardiac index by 24% in a series of 13 patients with right ventricular infarction and cardiogenic shock.[406] In patients with right ventricular MI complicated by cardiogenic shock and refractory low cardiac output and hypotension, insertion of a percutaneous right ventricular assist device should be considered as a therapeutic option.[407]

The status of right atrial function is an important determinant of the hemodynamic consequences of right ventricular MI.[408] Hemodynamic compromise may result if the atrial contribution to ventricular filling is lost in patients with right ventricular MI. Therefore high-grade AV block, other bradyarrhythmias, and AF are common causes of hypotension in patients with right ventricular MI. Ventricular pacing may not increase cardiac output in such patients, although atrial pacing and AV sequential pacing have been shown to improve cardiac output.[409,410] AF associated with hemodynamic compromise is an indication for electrical cardioversion.

The elevated right atrial pressure in patients with right ventricular MI may cause refractory hypoxemia as a result of increased right-to-left shunting in patients with an atrial septal defect or patent foramen ovale.[406,411] Inhalation of nitric oxide reduced right-to-left shunting by 56% in a series of three patients with right ventricular MI.[406] Right-to-left shunting in patients with right ventricular MI also can be treated by percutaneous closure of the patent foramen ovale.[411]

Some evidence indicates that reperfusion of the IRA improves right ventricular function and clinical outcome in patients with MI. Successful PCI of an occluded RCA in patients with right ventricular infarction has been associated with improved right ventricular wall motion within 1 hour[412] and a reduction in right atrial pressure within 8 hours.[413] Three to 5 days after successful PCI, right ventricular function was normal in 95% of patients.[412] In a study of the data for 49 patients with shock and right ventricular MI enrolled in the SHOCK trial registry, the in-hospital mortality rate was found to be 65.2% among patients who did not undergo revascularization, compared with 42.3% among patients who underwent PCI or CABG surgery.[398]

Mechanical Causes of Congestive Heart Failure or Low Cardiac Output

Mitral Regurgitation

Among 1976 patients with acute MI who were not in cardiogenic shock and underwent cardiac catheterization within 12 hours of symptom onset, left ventriculography demonstrated mild MR in 192 patients (9.7%) and moderate or severe MR in 58 patients (2.9%).[61] By multivariate analysis, mild MR and moderate or severe MR were the two strongest independent predictors of 1-year mortality. The HRs were 2.40 (95% CI 1.31–4.42; $P = 0.005$) for mild and 2.82 (95% CI 1.34–5.92; $P = 0.006$) for moderate or severe MR. The 1-year mortality rates were 2.9% for patients with no MR ($n = 1726$), 8.5% for patients with mild MR ($n = 192$), and 20.8% for patients with moderate or severe MR ($n = 58$).

Acute severe MR accounted for 6.9% of patients with cardiogenic shock among 1422 patients with acute MI who were enrolled in either the SHOCK registry or the randomized trial.[373] The median time from the onset of MI to shock was 12.8 hours.[414] In a postmortem series of 20 cases of papillary muscle rupture, the posteromedial papillary muscle was ruptured in 16 patients and the anterolateral papillary muscle was ruptured in 4 patients.[415] The greater tendency of the posteromedial papillary muscle to rupture is reflected by the distribution of the IRA in a series of 98 patients with acute MR and cardiogenic shock who were enrolled in the SHOCK studies. The location of the index MI was anterior in 34% of patients and nonanterior in 66%.[414]

The diagnosis of acute severe MR should be suspected in patients with acute onset of pulmonary edema or hypotension. The absence of a loud murmur does not exclude severe MR. The diagnosis can be confirmed by transthoracic or transesophageal echocardiography. The treatment of acute severe MR should include inotropic support, afterload reduction, an IABP, and emergency mitral valve surgery, but mortality is high despite surgical treatment. Among the patients with acute severe MR and cardiogenic shock who were enrolled in the SHOCK registry or the randomized trial, the in-hospital mortality rate was 40% among 43 patients who underwent valve surgery, compared with 71% among 51 patients who did not.[414]

Ventricular Septal Rupture

Among 41,021 patients with STEMI who were enrolled in the GUSTO-I trial, the incidence of VSR was only 0.2% (84/41,021 patients).[416] Acute VSR accounted for 3.9% of patients with cardiogenic shock among 1422 patients with acute MI who were enrolled in either the SHOCK registry or randomized trial.[373]

The clinical manifestations of VSR may include chest pain, dyspnea, and hypotension. A harsh holosystolic murmur may be audible. Cardiogenic shock occurred in 67% of patients in the GUSTO-I trial in whom VSR developed.[416] The diagnosis of VSR can be confirmed by Doppler echocardiography or right heart catheterization to measure the oxygen saturation in the right atrium, right ventricle, and PA. The median time from MI to diagnosis of VSR was 16 hours among a series of patients with VSR and cardiogenic shock.[417] The electrocardiographic location of the MI was inferior in 26 patients, anterior in 22, both anterior and inferior in 3, and apicolateral in 1 patient.[417] Only 35 of 55 patients underwent coronary angiography, and the IRA was identified in only 26 patients: the RCA in 12, the LAD in 11, and the left circumflex coronary artery in 3 cases.

The location of the IRA may be an important determinant of survival in patients with VSR.[416,418] Among a series of 25 patients with this diagnosis, mortality was greater among patients with inferior MI than among patients with anterior MI.[418] At least two factors may explain the differential outcome of patients with inferior and anterior MI complicated by VSR. First, the right ventricular volume overload caused by the left-to-right shunt may be less tolerated in the presence of ischemia or infarction of the right ventricle, both of which are more common with an inferior MI than an anterior MI. Second, histopathologic studies have shown that complex septal defects that are more difficult to repair surgically are more common in patients with an inferior MI.[419]

An IABP has been shown to decrease the shunt and increase systemic cardiac output in patients with VSR.[420] Therefore vasodilator therapy and an IABP often are used to stabilize patients before surgical repair of the rupture. The overall in-hospital survival rate among patients with VSR in the SHOCK registry was only 13% (7/55).[417] Although six of the seven survivors underwent surgical repair, mortality was 81% (25/31) in the group of patients who underwent surgery. In the GUSTO-I trial, patients whose rupture was repaired surgically had better 30-day mortality (47%) than patients who received medical treatment (94%).[416] Percutaneous closure of acute VSR may be an option in the future.

Left Ventricular Free Wall Rupture

Rupture of the left ventricular free wall may manifest in any of several ways: pericardial tamponade with acute hemodynamic collapse and immediate death, gradual onset of tamponade and hypotension, or subacute formation of a pseudoaneurysm.[421] Although a 6% rate of cardiac rupture among patients with acute MI often is quoted, reports suggest that the rate probably is lower, at least among patients who receive reperfusion therapy. A total of 65 (1.7%) cases of cardiac rupture occurred among 3759 patients with STEMI who received fibrinolytic therapy and were randomly assigned to receive either adjunctive heparin or hirudin.[422] The prevalence of cardiac rupture or pericardial tamponade was 2.3% (28/1190) among patients with cardiogenic shock in the SHOCK registry; 13 patients had both rupture and pericardial tamponade, 9 had tamponade alone, and 6 had rupture alone.[423]

It has been suggested that the incidence of cardiac rupture may be lower after primary PCI than after fibrinolytic therapy. The overall incidence of left ventricular free wall rupture was 2.5% (n = 34) among 1375 patients with STEMI who underwent primary PCI (55.4%) or fibrinolytic therapy (44.6%).[424] In a multivariate analysis, primary PCI was independently associated with a lower incidence of rupture, but no significant difference was observed in the incidence of rupture after primary PCI or fibrinolytic therapy (1.8% vs. 3.3%; $P = 0.686$).

The timing of reperfusion therapy may affect both the risk and the timing of free wall rupture. Death from cardiac rupture appears to occur earlier in patients given fibrinolytic therapy than among patients who do not undergo reperfusion therapy.[425] Honan and associates[426] analyzed the relationship between the risk of cardiac rupture and the timing of fibrinolytic therapy for 58 cases of cardiac rupture among 1638 patients enrolled in four randomized trials that compared intravenous streptokinase with no fibrinolytic therapy (in the control group). The OR of cardiac rupture increased significantly with increasing delay in the time to treatment. Regression analysis suggested that treatment within 7 hours after symptom onset reduces the risk of cardiac rupture, whereas treatment later than 17 hours after symptom onset increases the risk of cardiac rupture.[426] Thus it was hypothesized that early fibrinolytic therapy reduces the risk of rupture by reducing the extent of myocardial necrosis, whereas late fibrinolytic therapy increases the risk of rupture by promoting hemorrhagic infarction.

The antemortem diagnosis of free wall rupture, pericardial tamponade, and left ventricular pseudoaneurysm usually is confirmed by an echocardiogram. An echocardiogram was obtained in 20 of the 28 patients in the SHOCK registry who had rupture or pericardial tamponade. A pericardial effusion was observed in 15 (75%) and a myocardial tear was detected in 39%.[423] Six patients underwent pericardiocentesis alone, and 21 had surgical repair of the rupture. The in-hospital survival rate was 39.3%.

Cardiac Arrhythmias and Heart Block

Both atrial and ventricular arrhythmias are common in patients with acute MI. The incidence AF was 10.4% among 40,891 patients who were enrolled in the GUSTO-I trial.[328] Patients in whom AF developed after admission were more likely to have a stroke or die within 30 days after acute MI. New-onset AF developed during hospitalization in 6.3% of the 5466 patients with STEMI who underwent primary PCI and were enrolled in the APEX-AMI trial.[329] New-onset AF was independently associated with 90-day mortality (HR 1.81; 95% CI 1.06–3.09; $P = 0.029$.[329] Management of atrial arrhythmias is discussed in another chapter.

A meta-analysis of 15 randomized trials of fibrinolytic therapy for acute MI confirmed that the likelihood of primary VF is not altered by fibrinolytic therapy, with an incidence of VF during the first hospital day of 2.99% for both the fibrinolytic treatment and placebo groups.[334] Some evidence, however, suggests that fibrinolytic therapy exerts a protective effect against secondary VF (occurring in patients with acute MI complicated by HF or shock).[331,334] Management of ventricular arrhythmias is discussed in Chapter 32.

The incidence of second-degree or third-degree AV block was 6.9% among 75,993 patients with STEMI who received fibrinolytic therapy and were enrolled in a database that combined four randomized clinical trials.[427] Inferior MI was the strongest independent predictor of AV block (OR 3.3; 95% CI 3.1–3.5). In comparison with patients without AV block, adjusted mortality was greater at 30 days, 6 months, and 1 year among patients with AV block. The adjusted mortality ORs at 1 year were 2.4 (95% CI 2.2–2.6) for patients with AV block and inferior MI and 3.3 (95% CI 3.0–3.7) for patients with AV block and anterior MI.

Among 2073 patients with STEMI who underwent primary PCI at one Danish hospital during a 4-year period, second-degree or third-degree AV block occurred in 67 patients (3.2%) during the hospitalization, 91% within 48 hours after admission.[428] The incidence was 7% among patients with an RCA culprit, compared with 1% among patients with an LAD culprit.[428] Compared with patients without second-degree or third-degree AV block, patients with second-degree or third-degree AV block had higher mortality 30 days after STEMI (33% vs. 5%), but the landmark analysis of survival in patients who were alive 30 days after MI showed that the mortality rate was similar for the two groups.[428]

It is unclear whether reperfusion therapy has decreased the incidence of heart block in patients with STEMI. A total of 2,273,853 patients with STEMI were included in the U.S. National Inpatient Sample databases from 2003 to 2012.[429] Although the proportion of STEMI patients who did not undergo reperfusion decreased from 43.0% in 2003 to 20.1% in 2012, the incidence of complete heart block was relatively constant: 2.1% in 2003 and 2.3% in 2012.[429] In-hospital mortality was significantly higher among patients with complete heart block than among patients without complete heart block (20.4% vs. 8.7%; adjusted OR 2.47; 95% CI 2.41–2.53; $P < 0.001$).[429]

Unstable Angina and Non–ST-Segment Elevation Myocardial Infarction

Clinical Manifestations

Definition

In 2014 the American Heart Association and the ACC jointly issued a full revision of the clinical practice guideline for non–ST-elevation

acute coronary syndromes (NSTE-ACS).[1] As noted earlier, the distinction between UA and NSTEMI is determined by the detection of cardiac markers indicative of myocardial necrosis. Therefore as the sensitivity of troponin assays increases, patients with biomarker-negative ACS (i.e., UA) will be less common.[50]

Clinical History

The GRACE registry analyzed the presenting symptoms of 20,881 patients with STEMI, NSTEMI, or UA.[15] Among the patients with UA and NSTEMI, 5.7% and 12.3%, respectively, presented with symptoms other than chest pain. Patients with UA or NSTEMI who presented with atypical symptoms were less likely to undergo coronary angiography, PCI, or CABG surgery and were less likely to receive heparin, aspirin, or β-blockers. The absence of chest pain among patients with ACS was predictive of an increased risk of in-hospital death.

Several risk-stratification models have been developed to evaluate patients with suspected ACS. The TIMI risk score uses seven variables to calculate a score that is predictive of the risk of death and ischemic events in patients with suspected ACS.[430] Four of the seven variables are derived from the clinical history: age 65 years or older, at least three risk factors for CAD (family history of CAD, hypertension, hypercholesterolemia, diabetes, cigarette smoking), two or more anginal events within the previous 24 hours, and use of aspirin within the previous 7 days.[430] The GRACE risk score and a PURSUIT risk model also have been shown to have predictive power in patients with suspected ACS.[431,432]

Physical Examination

As in patients with STEMI, evidence of HF at the time of initial presentation has prognostic importance in patients with NSTE-ACS. In a database accrued from studies in 26,090 patients with UA or NSTEMI, heart rate, systolic blood pressure, and Killip class were independent predictors of mortality at 30 days and 6 months.[433] Patients in Killip class II, III, or IV constituted only 11% of the population but accounted for 30% of the deaths. Among a cohort of 13,707 patients with a confirmed diagnosis of ACS without prior HF or cardiogenic shock at the time of presentation to the hospital, HF (Killip class II or III) was present at hospital admission in 1778 patients (13%), and HF developed later during hospitalization in an additional 869 patients (6.3%).[388] The incidence of HF was similar in patients with STEMI (15.6%) or NSTEMI (15.7%) but less frequent in patients with UA (8.2%). HF at the time of admission was associated with a fourfold increase in crude in-hospital mortality rates across all three ACS subsets. The cumulative 6-month mortality rate was greater among patients in whom HF developed during hospitalization (25.3%) than among patients who had HF at admission (20.7%) or patients who did not have HF (5.9%).

A pooled patient-level analysis of seven large clinical trials included 46,519 patients with NSTE-ACS, and 4910 (10.6%) had HF at the time of presentation, whereas an additional 1194 (2.9%) developed HF during hospitalization.[434] The patients who presented with or developed HF during hospitalization had a higher risk of death at 30 days than patients without HF (adjusted OR 1.74; 95% CI 1.35–2.26).[434]

Diagnostic Approach

Electrocardiogram

The admission ECG has prognostic value in patients with ACS.[435,436] Although normal or nonspecific findings on the initial ECG confer a better prognosis than ST-segment depression or elevation seen on the ECG, such findings do not predict a benign outcome in patients with suspected ACS.[436] The risk of death or reinfarction at 30 days or 6 months is similar in patients with ST-segment elevation and in those with ST-segment depression; the risk is lower among patients with isolated T-wave inversion.[435] The GUSTO-IIb clinical trial enrolled 12,142 patients with symptoms of cardiac ischemia at rest and electrocardiographic signs of myocardial ischemia.[435] After adjustment for factors associated with an increased risk of death or reinfarction, the odds of death or reinfarction at 30 days were 1.68 (95% CI 1.36–2.08) in those with ST-segment elevation and 1.62 (95% CI 1.32–1.98) in those with ST-segment depression compared with those who had T-wave inversion only on the admission ECG.[435]

Among 1198 patients with isolated anterior (leads V_1-V_4) ST-segment depression who were enrolled in the TRITON-TIMI 38 trial, 314 (26.2%) had TIMI 0 or 1 flow and an elevated serum troponin.[437] The left circumflex coronary artery was the occluded culprit artery in 48.4% of the patients with an occluded artery, compared with the LAD coronary artery in 33.8% and the RCA in 17.8%.[437]

The impact of invasive management on outcome in patients with ACS is predicted by the presence or absence of ST-segment depression on the admission ECG. Among patients with ACS who were enrolled in the Fast Revascularization during InStability in Coronary Artery Disease (FRISC II) randomized trial comparing early invasive management and a noninvasive strategy, ST-segment depression was present at enrollment in 45.5% of patients.[438] Among the patients who presented with ST-segment depression, the invasive strategy reduced the risk of death or MI at 12 months from 18.2% to 12% (RR 0.66; 95% CI 0.50–0.88; $P = 0.004$). Mortality was reduced from 5.8% to 3.3% (RR 0.58; 95% CI 0.33–1.01; $P = 0.050$). Among the patients without ST-segment depression, the corresponding rates of death or MI were 10.4% and 8.9% ($P = 0.36$), and the mortality rates were 2% and 1.2% ($P = 0.26$). A similar dichotomy was found in the Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS)-TIMI 18 randomized trial of early invasive versus conservative strategies in patients with ACS.[439] Thus according to the ACA/AHA Practice Guidelines for the management of patients with UA and NSTEMI, new or presumably new ST-segment depression is a class I indication for use of an invasive strategy.[1]

The magnitude[440,441] and the location[442] of ST-segment depression also provide independent prognostic information in patients with UA and NSTEMI. Among 1846 patients who were enrolled in the TACTICS-TIMI 18 trial, the magnitude of ST-segment depression was a predictor of unsuccessful medical therapy in patients who were randomly assigned to the conservative strategy.[441] The magnitude of ST-segment depression was an independent predictor of the extent of CAD among patients who were randomly assigned to the early invasive strategy. After adjustment for baseline characteristics and the degree of troponin elevation, the benefit of an early invasive strategy was greater among patients with ST-segment depression of 0.10 mV or greater, compared with patients with 0.05 to 0.09 mV of ST-segment depression.

Among a cohort of 432 patients with a first NSTEMI, patients with ST-segment depression in two or more lateral leads (I, aVL, V_5, or V_6) had lower LVEFs, more frequent left main coronary artery or three-vessel CAD, and greater in-hospital mortality.[442] Although isolated T-wave inversion on the admission ECG is associated with a better prognosis than ST-segment depression or elevation, negative T waves in leads V_2 and V_3 are associated with

critical stenosis of the proximal LAD and stunning of the myocardium supplied by the LAD.[443,444]

Biochemical Markers

The distinction between NSTEMI and UA is based on the blood assays for biochemical markers of myocardial necrosis. As noted previously, a typical rise and gradual fall of troponin or more rapid rise and fall of CK-MB are required to diagnose an acute, evolving, or recent MI.[2] Although troponin has become the preferred biomarker for myocardial necrosis, the serum troponin is frequently elevated in patients with HF[10] or chronic kidney disease.[49] Numerous other causes of an elevated troponin have been recognized, and several may be associated with chest pain or ST-segment elevation.[50]

Symptoms consistent with ACS are a class I indication for measurement of cardiac-specific troponin (troponin I or T) at the time of presentation and 3 to 6 hours after symptom onset to identify a rising and/or falling pattern.[1] Another class I recommendation is that "additional troponin levels should be obtained beyond 6 hours after symptom onset in patients with normal troponin on serial examination when electrocardiographic changes and/or clinical presentation confer an intermediate or high index of suspicion for ACS."[1] Biochemical markers such as troponin or CK-MB provide both diagnostic and prognostic information, but CK-MB (and myoglobin) are now regarded as class III (no benefit) assays for the diagnosis of ACS.[1] Among 1404 patients with UA or NSTEMI who were enrolled in the TIMI IIIB trial, the mortality rate at 42 days was 3.7% (21/573) for patients with a baseline troponin I 0.4 ng/mL or greater, compared with 1% (8/831) for patients with a troponin I less than 0.4 ng/mL ($P < 0.001$).[445] There were significant increases in mortality with increasing levels of troponin I. An elevated troponin in patients with suspected ACS confers a greater risk of death or reinfarction even among patients without significant angiographic CAD.[446] Patients with ACS who have an elevated troponin level, even if the elevation is minor, derive greater benefit from platelet GP IIb/IIIa inhibitors[447,448] or invasive management[449] than do patients without an elevated troponin level.

Another biochemical marker that provides prognostic information is brain natriuretic peptide. An elevated brain natriuretic peptide at the time of presentation or after hospital discharge in patients with ACS is an independent predictor of death or new-onset HF during follow-up.[450,451]

Coronary CT Angiography

Several randomized trials have been performed to evaluate the utility of coronary CT angiography (CCTA) in "low-risk" patients with chest pain. Sixteen emergency departments enrolled 749 patients in a multicenter, randomized study called the Coronary Computed Tomographic Angiography for Systematic Triage of Acute Chest Pain Patients to Treatment (CT-STAT) trial.[452] The patients were randomly assigned to either CCTA ($n = 361$) or rest-stress myocardial perfusion imaging ($n = 338$). The time to diagnosis and costs of care were less in the patients who were randomly assigned to CCTA.[452] A larger study randomly assigned low- to intermediate-risk patients with possible ACS, in a 2:1 ratio, to undergo CCTA or traditional care.[453] None of the 640 patients with a negative CCTA died or had an MI within 30 days.[453] A multicenter trial that randomly assigned 1000 patients with suspected ACS but no ischemic electrocardiographic changes and a normal initial serum troponin found that patients evaluated by CCTA were discharged sooner than patients who underwent standard evaluation.[454] The patients who were randomly assigned to CCTA, however, underwent more downstream testing and had greater radiation exposure.[454] The 2014 AHA/ACC Guideline for the Management of Patients With Non-ST-Elevation Acute Coronary Syndromes includes a class IIa recommendation that "In patients with possible ACS and a normal ECG, normal cardiac troponins, and no history of CAD, it is reasonable to initially perform (without serial ECGs and troponins) coronary CT angiography to assess coronary artery anatomy or rest myocardial perfusion imaging with a technetium-99m radiopharmaceutical to exclude myocardial ischemia."[1]

Approach to Management

Fig. 29.8 presents an algorithm for the treatment of UA and non–ST-segment elevation myocardial infarction. Specific components of management are discussed next.

Antiischemic Therapy

Nitrates

The class I recommendations for antiischemic therapy in patients with NSTE-ACS include nitroglycerin administered initially as a sublingual tablet or spray, followed by intravenous infusion for patients with persistent ischemia, HF, or hypertension.[1] Although nitroglycerin often relieves chest pain in patients with ACS, nitrates have not been shown to reduce clinical events in patients with NSTE-ACS. Abrupt cessation of intravenous nitroglycerin may be associated with rebound myocardial ischemia in patients with ACS.[455] After intravenous infusion of nitroglycerin for longer than 24 hours the development of tolerance may require an increase in the dose to maintain efficacy, but 200 μg/min usually is considered the maximum dose.

β-Blockers

The class I recommendations for antiischemic therapy in patients with NSTE-ACS include the administration of a β-blocker within the first 24 hours for patients who do not have signs of HF, evidence of a low output state, increased risk for cardiogenic shock, or other relative contraindications to β-blockade.[1] Nevertheless, many patients who are eligible for β-blocker therapy do not receive it, possibly because there are limited data regarding the efficacy of β-blockers in patients with NSTE-ACS.[456] Clinical trials that evaluated β-blockers in patients with UA were not adequately powered to demonstrate reductions in mortality. A pooled analysis of randomized trials in patients with threatened or evolving MI concluded that β-blockers reduce the risk of MI by 13%.[457] A report from the GRACE registry analyzed the outcomes of 7106 patients with NSTEMI.[456] β-Blocker therapy was initiated within 24 hours of admission in 76% of patients without contraindications. After multivariable logistic regression analysis to adjust for presence of comorbidity, both in-hospital mortality (OR 0.58; 95% CI 0.42–0.81) and 6-month mortality (OR 0.75; 95% CI 0.56–0.997) were lower among patients who received β-blockers than among patients who did not.

Calcium Antagonists

The Holland Interuniversity Nifedipine/Metoprolol Trial (HINT) found that nifedipine alone increased the risk of MI or recurrent angina, relative to placebo, by 24% in patients with UA.[458] The 2014 AHA/ACC Guideline for the Management of Patients With Non-ST-Elevation Acute Coronary Syndromes includes a class III recommendation that "Immediate-release nifedipine should not be administered to patients with NSTE-ACS in the absence of beta-blocker therapy."[1]

(From Amsterdam EZ, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2014;64:e139–e228.)

The Multicenter Diltiazem Postinfarction Trial (MDPIT) randomly assigned 2466 patients to receive diltiazem or placebo 3 to 15 days after acute MI.[346] Approximately 70% of patients met ECG criteria for a Q-wave MI, and 25% had non–Q-wave MI. The percentage of patients with STEMI or NSTEMI was not reported. Total mortality rates for the two treatment groups were nearly identical, but treatment with diltiazem was associated with increased mortality in patients with either radiographic evidence of pulmonary congestion or an LVEF less than 40%. Also, diltiazem was associated with an increased risk of late-onset HF in patients with an LVEF less than 40%.[347]

Gibson and colleagues[459] performed a post hoc subset analysis of the 817 patients with non–Q-wave MI and no pulmonary congestion who were enrolled in two clinical trials: MDPIT and the second Danish Verapamil Infarction Trial (DAVIT-II).[459] The adjusted all-cause mortality was lower among patients who were given diltiazem or verapamil than among those who received placebo (RR 0.65; 95% CI 0.40–1.05). Nevertheless, calcium antagonists are not considered first-line therapeutic agents in patients with ACS and are reserved for patients with recurrent ischemia, but no severe left ventricular dysfunction, who have a contraindication to β-blockers.

Intraaortic Balloon Counterpulsation

Intraaortic balloon counterpulsation is believed to increase myocardial oxygen supply by increasing diastolic pressure and to reduce myocardial oxygen demand by afterload reduction of the left ventricle. The indications for an IABP in patients with NSTE-ACS include refractory ischemia, hypotension, and cardiogenic shock, although this modality should be considered an adjunct to definitive therapies such as percutaneous or surgical myocardial revascularization.

Antiplatelet Therapy

Aspirin

The 2014 AHA/ACC Guideline for the Management of Patients With Non-ST-Elevation Acute Coronary Syndromes includes a class I recommendation that "Non-enteric-coated, chewable aspirin (162 mg to 325 mg) should be given to all patients with NSTE-ACS without contraindications as soon as possible after presentation,

and a maintenance dose of aspirin (81 mg/day to 325 mg/day) should be continued indefinitely."[1] The recommendation is based on the results of four small randomized trials. A pooled analysis of the results concluded that aspirin reduces the risk of death or MI by 50% in patients with UA. The optimal dose of aspirin in patients with ACS is uncertain.[460] An aspirin dose of 75 mg/day reduced the risk of MI or death after 1 year in patients with UA or non–Q-wave MI who were enrolled in a prospective, randomized, double-blind, placebo-controlled multicenter trial (RR 0.52; 95% CI 0.37–0.72).[461] Among 20,521 patients with ACS who were enrolled in the GUSTO IIb and Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trials, an aspirin dose of 150 mg or greater was associated with a lower risk of MI at 6 months, compared with an aspirin dose less than 150 mg (HR 0.79; 95% CI 0.64–0.98; $P = 0.03$).[462] The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial randomly assigned 12,562 patients with ACS to aspirin plus clopidogrel 75 mg daily or aspirin plus placebo.[463] The study protocol recommended an aspirin dose of 75 to 325 mg and the dose was left to the discretion of the local investigator. In both arms of the study, higher doses of aspirin were associated with an increased risk of major bleeding but clinical event rates were not reduced by higher doses of aspirin. PCI-CURE was a substudy of the CURE trial that consisted of the 2658 patients who underwent PCI.[464,465] A post hoc analysis of the patients who were enrolled in PCI-CURE found that the moderate-dose (101 to 199 mg) and high-dose (≥200 mg) aspirin groups had similar rates of cardiovascular death, MI, or stroke compared with the low-dose (≤100 mg) aspirin group, but high-dose aspirin was associated with an increased risk of major bleeding.[464,465]

The Clopidogrel and Aspirin Optimal Dose Usage to Reduce Recurrent Events–Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS 7) Trial was the first randomized trial to compare two different doses of aspirin in patients with ACS.[466,467] The primary results have been published in two complementary articles in the September 2, 2010, issue of the *New England Journal of Medicine* and the October 9, 2010, issue of *Lancet*.[466,467] The *NEJM* article presents an analysis of the entire enrollment of 25,086 patients, including patients who did not undergo coronary angiography or PCI, whereas the *Lancet* article describes a prespecified analysis of the 17,263 patients who underwent PCI. Among the entire cohort of 25,086 patients there was no significant difference between the higher dose of aspirin (300–325 mg daily) and the lower dose of aspirin (75 to 100 mg daily) with respect to the primary composite end point of cardiovascular death, myocardial infarction, or stroke at 30 days. Although the rates of major bleeding were 2.3% for both doses of aspirin, there was significantly less minor bleeding among the patients who received the lower dose of aspirin (4.4% versus 5%; HR 1.13; $P = 0.04$).

Based on an analysis of the PLATO trial, the label for ticagrelor, a platelet $P2Y_{12}$ receptor inhibitor, includes a black box warning that maintenance doses of aspirin reduce the effectiveness of ticagrelor. The practice guidelines for PCI include a class IIa recommendation that it is reasonable to prescribe a maintenance aspirin dose of 81 mg daily in preference to higher doses.[468]

Inhibitors of the Platelet $P2Y_{12}$ Receptor

Inhibitors of the platelet $P2Y_{12}$ receptor have been shown to improve outcomes in patients with NSTE-ACS.[469,470] An open study that randomly assigned patients with UA to ticlopidine or conventional therapy (excluding aspirin) demonstrated a 46% reduction in the risk of vascular death and nonfatal MI.[469] Clopidogrel has a more rapid onset of action and a better safety profile than ticlopidine. The CURE trial demonstrated that the combination of clopidogrel and aspirin, compared with aspirin alone, improved outcomes among patients with ACS without ST-segment elevation.[470]

There is extensive evidence that platelet inhibition by clopidogrel is influenced by both drug interactions and certain genotypes that affect the metabolism of clopidogrel, a prodrug that is converted to an active metabolite by CYP 2C19 activity, a hepatic cytochrome P450 enzyme.[471,472] Coadministration of clopidogrel and drugs metabolized by CYP 2C19, such as some proton pump inhibitors, may inhibit the formation of clopidogrel's active metabolite, resulting in diminished platelet inhibition. On November 17, 2009, the U.S. FDA issued a public alert regarding updated labeling of clopidogrel that included that following statement: "New data show that when clopidogrel and omeprazole are taken together the effectiveness of clopidogrel is reduced." There is also evidence, however, that proton pump inhibitors may be associated with an increased risk of adverse cardiovascular events in the absence of clopidogrel.[473] Concomitant use of proton pump inhibitors and thienopyridines was discussed in detail in an expert consensus document published by the ACCF, the American College of Gastroenterology, and the AHA.[474]

Genetic polymorphisms that affect CYP 2C19 activity are common and are associated with variability in the bioavailability of clopidogrel's active metabolite, affecting platelet inhibition and clinical outcomes, including the risk of stent thrombosis. On March 12, 2010, the FDA approved a new label for clopidogrel that contained a boxed warning regarding the drug's decreased efficacy in patients with impaired capacity to convert clopidogrel to an active metabolite, prompting publication of a document by the ACCF/AHA.[475]

The drug interactions and genetic polymorphisms that affect clopidogrel's metabolism can be approached using several strategies. One potential strategy is to use genetic testing to identify patients who are heterozygous or homozygous for loss-of-function alleles that impair metabolism of clopidogrel, but genetic testing is expensive and has not gained widespread acceptance. Another approach is alternative dosing regimens of clopidogrel. Numerous studies have found that a 600-mg loading dose of clopidogrel, compared with a 300-mg loading dose, reduces the risk of major adverse cardiovascular events after PCI without increasing the risk of major bleeding.[476] Also, increased loading and maintenance doses of clopidogrel produces greater platelet inhibition in patients who are heterozygous for the CYP 2C19*2 loss-of-function allele.[477,478] High residual platelet activity during clopidogrel therapy is associated with an increased risk of ischemic events in patients with ACS who undergo PCI, but a randomized trial that compared standard- and high-dose clopidogrel regimens in patients with high residual platelet activity failed to show a reduction in the incidence of cardiovascular deaths, nonfatal MI, or stent thrombosis 6 months after PCI with drug-eluting stents.[479,480]

The CURRENT-OASIS 7 trial compared two regimens of clopidogrel in patients with ACS.[466,467] The double-dose patients received a clopidogrel loading dose of 600 mg and a daily maintenance dose of 150 mg on days 2 to 7, then 75 mg daily, whereas the standard-dose group received a loading dose of 300 mg followed by a daily maintenance dose of 75 mg. The frequency of major bleeding was greater among the patients who were randomly assigned to receive the higher dose of clopidogrel. Although the double-dose regimen was associated with a reduction in cardiovascular events and stent thrombosis in ACS patients

who underwent PCI, it is uncertain whether the higher maintenance dose that was administered for only 6 days provided any additional benefit beyond the documented benefit of the 600-mg loading dose.

A third approach is to prescribe other $P2Y_{12}$ inhibitors, such as prasugrel and ticagrelor. Cytochrome P450 genetic polymorphisms do not affect drug metabolite concentrations, inhibition of platelet aggregation, or clinical event rates in patients treated with prasugrel[481,482] or ticagrelor.[483] Also, compared with the combination of aspirin and clopidogrel, the combination of aspirin and ticagrelor reduced the risk of death in patients with ACS.[113]

Among the 11,080 patients with NSTE-ACS who were randomly assigned to receive ticagrelor or clopidogrel in the PLATO trial, 5366 patients were alive and had not undergone revascularization 10 days after randomization.[484] Whether the patient did or did not undergo revascularization during the first 10 days did not significantly affect the reduction by ticagrelor of the either the primary endpoint (HRs 0.86 for revascularization vs. 0.85 for no revascularization; interaction $P = 0.93$) or all-cause death (HRs 0.75 for revascularization vs. 0.73 for no revascularization; interaction; $P = 0.89$).[484] However, in the Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY-ACS) study, among 9326 patients with NSTE-ACS who were randomly assigned to received clopidogrel or prasugrel and managed medically without revascularization for the first 10 days, after a median follow-up of 17 months there was no significant difference in the rate of the primary endpoint, a composite of death from cardiovascular causes, nonfatal MI, or nonfatal stroke among patients younger than age 75 (HR in the prasugrel group 0.91; 95% CI 0.79–1.05; $P = 0.21$).[485] The combinations of clopidogrel, prasugrel, or ticagrelor with aspirin were included in the class I recommendations for dual antiplatelet therapy in the 2014 AHA/ACC Guideline for the Management of Patients With Non-ST-Elevation Acute Coronary Syndromes.[1] The guideline also added a class IIa recommendation that "it is reasonable to use ticagrelor in preference to clopidogrel for $P2Y_{12}$ treatment in patients with NSTE-ACS who undergo an early invasive or ischemia-guided strategy."[1] The ESC guidelines include several additional recommendations regarding selection of specific $P2Y_{12}$ inhibitors.[22] Ticagrelor is preferred in patients at moderate to high ischemic risk (class I recommendation), and the ESC guidelines recommend against treatment with prasugrel when the coronary anatomy is unknown.[22]

Whenever possible clopidogrel and ticagrelor should be discontinued at least 5 days before CABG surgery, and prasugrel should be stopped at least 7 days before CABG surgery, to attenuate the increased perioperative bleeding associated with inhibition of platelet $P2Y_{12}$ receptors.[1] Therefore some practitioners prefer to withhold platelet $P2Y_{12}$ receptor inhibitors until the results of diagnostic cardiac catheterization are known, but this approach ignores the proven benefit of pretreatment in patients with ACS who undergo PCI or CABG.[486,487] Also, CABG surgery can usually be deferred for 5 to 7 days, and percutaneous revascularization is more frequent than surgical revascularization in patients with ACS.[486] The CURE investigators concluded that the increased bleeding risk in patients who may require CABG surgery is outweighed by the overall reduction in ischemic events among all patients.[486] Also, among patients who were enrolled in the TRITON-TIMI 38 trial and underwent CABG, patients who were randomly assigned to receive prasugrel had a lower rate of death after CABG, compared with the rate among patients who were randomly assigned to receive clopidogrel, despite an increase in bleeding, platelet transfusion, and surgical reexploration for bleeding.[487] Thus a policy of withholding $P2Y_{12}$ antagonists until after coronary angiography may harm more patients than a policy of starting a $P2Y_{12}$ antagonist upon admission to the hospital. If an intravenous $P2Y_{12}$ antagonist with a short half-life, such as cangrelor, is used instead of one of the oral $P2Y_{12}$ antagonists before the coronary anatomy is known, patients who need CABG would be able to undergo surgery sooner, whereas patients who are treated with PCI can be switched to an oral agent.[488] The 2014 AHA/ACC NSTE-ACS guideline did not include any recommendations regarding cangrelor, but the 2015 ESC Guidelines for the management of ACS in patients presenting without persistent ST-segment elevation included a IIb recommendation for cangrelor: cangrelor may be considered in $P2Y_{12}$ inhibitor–naive patients undergoing PCI[1,22]

Platelet Glycoprotein IIb/IIIa Receptor Antagonists

Discontinuation of either UFH or LMWH in patients with UA is associated with a rebound increase in thrombin generation,[489] which may underlie the increase in death and MI that has been observed during the 12 hours after heparin is stopped in patients with ACS.[490,491] Compared with patients who were randomly assigned to a placebo group, patients who were randomly assigned to treatment with a GP IIb/IIIa antagonist, eptifibatide, experienced significantly fewer deaths and MIs during the 12 hours after heparin was terminated.[491]

A retrospective analysis of the PURSUIT trial found that treatment with eptifibatide was associated with improved outcome among patients in whom cardiogenic shock developed during hospitalization for ACS without persistent ST-segment elevation.[492] Although randomization to eptifibatide treatment did not affect the occurrence of shock, patients with shock who received eptifibatide had significantly reduced adjusted odds of death at 30 days (OR 0.51; 95% CI 0.28–0.94; $P = 0.03$). It is unlikely that improved outcome after PCI was responsible for the beneficial effect of eptifibatide because only 25% of the patients with shock in PURSUIT underwent PCI.

Boersma and colleagues[493] performed a meta-analysis of the individual patient data from six trials that randomly assigned 31,402 patients with ACS without persistent ST-segment elevation to a GP IIb/IIIa inhibitor treatment group (abciximab, eptifibatide, lamifiban, or tirofiban) or to a control group. Overall, there was a 9% reduction in the odds of death or MI at 30 days (10.8% vs. 11.8%; OR 0.91; 95% CI 0.84–0.98; $P = 0.015$).[493] The baseline troponin value was available in a subset of 11,059 patients (35% of the entire cohort). Among the 45% of patients with a troponin T or I level 0.1 ng/mL or greater, there was a 15% reduction in the odds of death or MI at 30 days compared with that for the control group (10.3% vs. 12%; OR 0.85; 95% CI 0.71–1.03). No risk reduction was observed among patients with negative troponin levels (GP IIb/IIIa inhibitor 7% vs. control 6.2%; OR 1.17; 95% CI 0.94–1.44). Another meta-analysis of the same six trials found that the impact of GP IIb/IIIa antagonists on outcome varied with the revascularization strategy.[494] The reduction of ischemic events was greater among patients who underwent PCI during the index hospitalization (OR 0.82; $P = 0.01$) than among patients who were managed medically (OR 0.95; $P = 0.27$).[494] The corresponding number of events (death or MI at 30 days) prevented per 1000 patients treated was 20 for patients who underwent PCI compared with 4 for patients treated medically.[494] The GUSTO IV ACS trial failed to show a benefit of abciximab among patients with ACS who did not undergo early coronary revascularization.[495]

The Early Glycoprotein IIb/IIIa Inhibition in Non-ST-Segment Elevation Acute Coronary Syndrome (EARLY ACS) trial compared two strategies of GP IIb/IIIa administration in 9492 patients with ACS without ST-segment elevation who were assigned to an invasive strategy.[496] The patients were randomly assigned to either early eptifibatide beginning ≥12 hours before coronary angiography, or a matching placebo infusion with provisional, delayed use of eptifibatide after angiography. At 30 days the rate of death or MI was 11.2% in the early-eptifibatide group compared with 12.3% in the delayed-eptifibatide group (OR 0.89; 95% CI 0.79–1.01; $P = 0.08$). The rates of bleeding and red blood cell transfusion, but not severe bleeding, were significantly higher in the early-eptifibatide group. A meta-analysis that included 12 clinical trials that evaluated a strategy of so-called upstream administration of GP IIb/IIIa inhibitors concluded that upstream use was associated with an 11% reduction in the combined endpoint of death or myocardial infarction (OR 0.89; 95% CI 0.83–0.95), no significant mortality effect (OR 0.93; 95% CI 0.83–1.05), and a 23% higher risk of major bleeding (OR 1.23; 95% CI 1.02–1.48).[497]

The 2014 AHA/ACC NSTE-ACS Guideline contains several recommendations regarding the use of platelet GP IIb/IIIa inhibitors.[1] The class I recommendation states "In patients with NSTE-ACS and high-risk features (e.g., elevated troponin) who are not adequately pretreated with clopidogrel or ticagrelor, it is useful to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-dose bolus tirofiban) at the time of PCI."[1] The class IIa recommendation states "In patients with NSTSE-ACS and high-risk features (e.g., elevated troponin) treated with UFH and adequately pretreated with clopidogrel, it is reasonable to administer a GP IIb/IIIa inhibitor (abciximab, double-bolus eptifibatide, or high-dose bolus tirofiban) at the time of PCI."[1] The class IIb recommendation states "In patients with NSTE-ACS treated with an early invasive strategy and dual antiplatelet therapy (DAPT) with intermediate/high-risk features (e.g., positive troponin), a GP IIb/IIIa inhibitor may be considered as part of initial antiplatelet therapy. Preferred options are eptifibatide or tirofiban."[1]

GP IIb/IIIa antagonists increase the risk of bleeding, frequently involving the access site used for cardiac catheterization, but the risk of intracranial hemorrhage is not increased.[493] The meta-analysis performed by Boersma and colleagues[493] found that the risk of major bleeding was 2.4% among patients who were randomly assigned to receive a GP IIb/IIIa antagonist compared with 1.4% among control patients (OR 1.62; 95% CI 1.36–1.94; $P < 0.0001$). One preventable cause of bleeding is excess dosing of a GP IIb/IIIa antagonist, which occurred in 26.8% of patients with NSTE-ACS who were enrolled in the CRUSADE registry by 387 hospitals in 2004.[498]

A complete blood cell count including platelet count should be included in monitoring during administration of GP IIb/IIIa antagonists. A review of eight large placebo-controlled, randomized trials, however, concluded that abciximab, but not eptifibatide or tirofiban, increases the incidence of thrombocytopenia.[499]

Antithrombin Therapy

Unfractionated Heparin

At least seven randomized, placebo-controlled trials have compared UFH plus aspirin with aspirin alone in patients with UA, but none of them was adequately powered to detect a reduction in the rate of death or MI during hospitalization. A meta-analysis of six of the trials concluded that the addition of UFH to aspirin reduced the risk of death or MI during treatment by 33% (RR 0.67; 95% CI 0.44–1.02; $P = 0.06$).[500] Therefore the ACC/AHA Practice Guidelines include intravenous UFH in the list of class I recommendations for patients NSTE-ACS.[1] During treatment with UFH the platelet count and the hemoglobin or hematocrit should be measured daily because of the increased risks of bleeding and thrombocytopenia. An analysis of patients who were enrolled in the CRUSADE registry in 2004 found that bleeding was related to excess dosing of UFH, which occurred in 32.8% of patients who received UFH.[498]

As discussed earlier, a rebound increase in thrombin generation with reactivation of UA has been observed after the discontinuation of UFH. One clinical trial observed an eightfold increase in death and a twofold increase in MI during the 12 hours after heparin was discontinued.[491] The rate of events during the 12 hours after heparin was terminated was significantly lower among patients who were randomly assigned to treatment with eptifibatide than among patients in the placebo group.[491]

Low-Molecular-Weight Heparin

The FRISC study randomly assigned 1506 patients with UA or non–Q-wave MI to receive placebo or dalteparin, an LMWH, twice daily for 6 days, followed by once daily for 35 to 45 days.[501] A 63% reduction in the risk of death or MI occurred during the first 6 days (4.8% vs. 1.8%; $P = 0.001$). Subsequently, 21,946 patients with non-ST-segment elevation ACS were enrolled in six randomized trials that compared enoxaparin, another LMWH, with UFH. A meta-analysis of the trials found no significant difference in death at 30 days for enoxaparin versus UFH (3% vs. 3%; OR 1.00; 95% CI 0.85–1.17).[502] A statistically significant reduction was observed in the combined endpoints of death and nonfatal MI at 30 days for enoxaparin versus UFH (10.1% vs. 11%; OR 0.91; 95% CI 0.83–0.99).

Although it had been hypothesized that the risk of bleeding would be less during treatment with LMWH than during treatment with UFH, the meta-analysis performed by Petersen and colleagues[502] found no significant difference between enoxaparin and UFH in the rates of blood transfusion or major bleeding at 7 days after initiation of the study treatment. The risk of bleeding during treatment with LWMH may be increased by excess dosing, which occurred in 13.8% of patients who were enrolled in the CRUSADE registry in 2004 and received LMWH.[498]

The current ACC/AHA guideline for NSTE-ACS states that "In patients with NSTE-ACS, anticoagulation, in addition to antiplatelet therapy, is recommended for all patients irrespective of initial treatment strategy."[1] The options include intravenous UFH for 48 hours or until PCI is performed, and enoxaparin for the duration of hospitalization or until PCI is performed.[1]

Direct Thrombin Inhibitors

Direct thrombin inhibitors, such as hirudin and bivalirudin, have been evaluated in patients with NSTE-ACS. The ACUITY trial was an open-label, randomized, multicenter trial that compared heparin plus a GP IIb/IIIa antagonist, bivalirudin plus a GP IIb/IIIa antagonist, and bivalirudin alone in patients with moderate-risk or high-risk NSTE-ACS who were undergoing an early invasive strategy.[503–505] NSTEMI was present in 59% of patients, and 41% had UA. Compared with patients who received a GP IIb/IIIa antagonist plus UFH or enoxaparin, patients who received bivalirudin alone experienced significantly less non–CABG-related major bleeding (3% vs. 5.7%; RR 0.53; 95% CI 0.43–0.65). Compared with heparin plus a GP IIb/IIIa antagonist, bivalirudin alone resulted

in a noninferior rate of the composite ischemia endpoint (7.3% vs. 7.8%, respectively; RR 1.08; 95% CI 93–1.24; $P = 0.32$). Administration of bivalirudin plus a GP IIb/IIIa antagonist, as compared with heparin plus a GP IIb/IIIa antagonist, resulted in noninferior 30-day rates of the composite ischemia endpoint (7.7% vs. 7.3%, respectively; RR 1.07; 95% CI 0.92–1.23; $P = 0.39$) and major bleeding (5.3% vs. 5.7%, respectively; RR 0.93; 95% CI 0.78–1.10; $P = 0.38$). Bivalirudin is a class I anticoagulant in patients with NSTE-ACS only in patients who are selected for an early invasive strategy.[1]

In addition, the 2014 AHA/ACC guideline for NSTE-ACS includes a class IIa recommendation that "In patients with NSTSE-ACS undergoing PCI who are at high risk of bleeding, it is reasonable to use bivalirudin monotherapy in preference to the combination of UFH and a GP IIb/IIIa receptor antagonist."[1]

Factor Xa Inhibitors

Several factor Xa inhibitors, fondaparinux,[506] apixaban,[507,508] and rivaroxaban,[509] have been studied in patients with NSTE-ACS. The OASIS-5 trial compared fondaparinux with enoxaparin for a mean of 6 days in 20,078 patients with ACS.[506] The rate of major bleeding at 9 days was lower with fondaparinux than with enoxaparin (2.2% vs. 4.1%; HR 0.52; $P < 0.001$). Also, the number of deaths at 30 days was significantly reduced by fondaparinux compared with enoxaparin (295 vs. 352; $P = 0.02$). Because of the risk of catheter thrombosis, fondaparinux should not be used as the sole anticoagulant during PCI, and an additional anticoagulant with antifactor IIa activity should be administered.[1]

In patients with a recent ACS, treatment with rivaroxaban, compared with placebo, significantly reduced the primary efficacy endpoint of death from cardiovascular causes, MI, or stroke (8.9% vs. 10.7%, respectively; HR in the rivaroxaban group 0.84; 95% CI 0.74–0.96; $P = 0.008$), but rivaroxaban increased the risk of major bleeding and intracranial hemorrhage.[509] Treatment with apixaban also increased bleeding in high-risk ACS patients, but it did not reduce recurrent ischemic events, regardless of whether concomitant antiplatelet therapy consisted of aspirin alone or aspirin plus clopidogrel.[507,508]

Angiotensin-Converting Enzyme Inhibitors

Little information is available regarding the administration of ACE inhibitors to patients with NSTEMI because most of the ACE inhibitor trials did not report subgroup analyses of patients with STEMI or NSTEMI. The Survival of Myocardial Infarction Long-Term Evaluation (SMILE) study enrolled 1556 patients with acute anterior MI who were not eligible for fibrinolytic therapy.[510] The patients were randomly assigned to receive 6-week courses of placebo or zofenopril, an ACE inhibitor. Among the 526 patients with ECG criteria for NSTEMI, death or severe HF occurred in 10.3% (28/273) of placebo patients and 3.6% (9/253) of zofenopril patients (RR reduction 65%; 95% CI 20–80; $P = 0.003$).[511] The 1-year mortality rate also was significantly reduced by zofenopril (7.9% vs. 15.8%; RR reduction 43%; 95% CI 14–57; $P = 0.036$).

Lipid-Lowering Therapy

Numerous randomized trials have investigated the effects of statins on outcomes in patients with ACS. Compared with placebo, treatment with atorvastatin 80 mg daily beginning 24 to 96 hours after hospital admission for UA or non-Q-wave MI reduced the rate of recurrent ischemic events at 16 weeks.[512] As discussed earlier, the 4S,[348] CARE,[349] and LIPID[350] trials have established the long-term benefits of starting statin therapy 3 months or later after hospitalization for an MI or UA. Analysis of the LIPID trial showed that initiation of pravastatin 40 mg daily 3 to 36 months after hospitalization for UA significantly reduced the risk of several endpoints, including death (RR 0.74; 95% CI 0.50–0.91; $P = 0.004$) and nonfatal MI (RR 0.67; 95% CI 0.51–0.88; $P = 0.004$).[513]

The Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction 22 (PROVE IT-TIMI 22) study compared atorvastatin 80 mg daily with pravastatin 40 mg daily started within 10 days of hospitalization for an ACS.[514,515] The median LDL cholesterol during treatment was 95 mg/dL in the pravastatin group and 62 mg/dL in the atorvastatin group ($P < 0.001$). The primary endpoint was a composite of death, MI, UA, revascularization, and stroke. For the entire study population of 4162 patients, the rates for the primary endpoint at 2 years were 22.4% in the atorvastatin group and 26.3% in the pravastatin group, representing a 16% reduction in the HR in favor of atorvastatin (95% CI 5–26; $P = 0.005$). For the patients with unstable angina the rates for the primary endpoint at 2 years were 26.5% for the atorvastatin group and 31.4% for the pravastatin group. For the patients with NSTEMI the rates for the primary endpoint were 19.0% for the atorvastatin group and 24.1% for the pravastatin group. For the entire study population of 4162 patients, during a median follow-up of 24 months, hospitalization for HF more than 30 days after randomization was significantly less frequent among patients who were treated with atorvastatin than among patients who were treated with pravastatin (1.6% vs. 3.1%; HR 0.55; 95% CI 0.35–0.85; $P = 0.008$).[515]

It appears that patients who are treated with statins may be adversely affected if statin therapy is discontinued after hospitalization for an ACS.[516,517] A retrospective analysis of the outcomes in 1616 patients with ACS concluded that statin pretreatment is associated with improved clinical outcome, whereas the discontinuation of statins after symptom onset is associated with an increased risk of death and nonfatal MI within 30 days.[516] Similarly, multivariate analysis of the 13,871 patients in the NRMI 4 database who were receiving statin therapy before hospitalization for a NSTEMI found that withdrawal of statin therapy in the first 24 hours of hospitalization was associated with a statistically significant increased risk of hospital death compared with those who continued statin therapy.[517]

At least two meta-analyses of relevant randomized controlled trials have been performed to estimate the effects of early treatment with statins on short-term outcomes in patients with ACS.[518,519] One analysis of 12 randomized trials concluded that statin therapy initiated within 14 days of hospital admission does not reduce the risk of death, MI, or stroke during the first 4 months after ACS.[518] Another meta-analysis of 13 randomized trials concluded that early statin therapy reduces the rates of death and cardiovascular events after 4 months of treatment.[519]

The Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) randomly assigned 18,144 patients who were hospitalized for an ACS within the preceding 10 days to either simvastatin 40 mg/day or simvastatin 40 mg/day and 10 mg/day of ezetimibe, a nonstatin that reduces intestinal absorption of cholesterol.[520] The index event was a NSTE-ACS in the majority of patients: NSTEMI in 47%, STEMI in 29%, and UA in 24%. The median time-weighted average LDL cholesterol during the study was 53.7 mg/dL in the simvastatin-ezetimibe group compared with 69.5 mg/dL in the simvastatin monotherapy group ($P < 0.001$). At 7 years, the event rate for the primary endpoint—a composite of cardiovascular death, nonfatal MI,

rehospitalization for UA, coronary revascularization within 30 days of randomization, or nonfatal stroke—was 2.0 percentage points lower for the combination group (32.7% vs. 34.7%; HR 0.936; 95% CI 0.89–0.99; $P = 0.016$).[520]

Invasive versus Conservative Management

At least eight randomized trials have compared early invasive and early conservative management strategies for patients with NSTE-ACS. Patients who are managed by an early conservative strategy undergo coronary angiography if evidence points to spontaneous recurrent ischemia or if results of stress testing are strongly positive despite medical therapy. Patients who are managed using an early invasive strategy undergo routine coronary angiography and coronary revascularization as indicated. Three relatively large trials demonstrated better short-term and long-term outcomes among patients randomly assigned to the early invasive strategy compared with the early conservative strategy: FRISC II,[521–523] TACTICS-TIMI 18,[439] and the Randomized Intervention Trial of Unstable Angina-3 (RITA-3).[524–526] The FRISC II[521–523] and TACTICS-TIMI 18[439] trials randomly assigned 2457 and 2220 patients, respectively, with UA or NSTEMI to either an early conservative or an early invasive strategy. Both trials found that the early invasive strategy was associated with a lower risk of death or MI at 6 months compared with the early conservative strategy: 9.4% versus 12.1% (RR 0.78; 95% CI 0.62–0.98; $P = 0.031$) for FRISC II and 7.3% versus 9.5% (OR 0.74; 95% CI 0.54–1.00; $P < 0.05$) for TIMI 18. The early invasive strategy also was associated with a reduced rate of rehospitalization for ACS in both trials. After follow-up for 5 years in the FRISC II trial, patients who were randomly assigned to the early invasive arm experienced a lower rate of MI (12.9% vs. 17.7%; RR 0.73; 95% CI 0.60–0.89; $P = 0.002$) but not overall mortality (9.7% vs. 10.1%; RR 0.95; 95% CI 0.75–1.21; $P = 0.693$).[523] The RITA-3 study randomly assigned 1810 patients with NSTE-ACS to early invasive or early conservative treatment.[524–526] After a median follow-up period of 5 years, 142 (16.6%) patients randomly assigned to the early intervention group and 178 (20%) patients assigned to the early conservative group died or had a nonfatal MI (OR 0.78; 95% CI 0.61–0.99; $P = 0.044$). The death rates were 12% for the interventional group versus 15% for the conservative group (OR 0.76; 95% CI 0.58–1.00; $P = 0.054$). The advantage of the routine early invasive strategy that was observed at 5 years was not sustained, and after follow-up for 10 years there were no differences between the routine invasive and selective invasive groups in either all-cause mortality (25.1% vs. 25.4%; $P = 0.94$) or cardiovascular mortality (15.1% vs. 16.1%; $P = 0.65$).[526] An editorial that was co-published with the 10-year results of the RITA-3 Trial speculated that a possible explanation for the attenuation of benefit is that the advantage of the routine invasive strategy observed at 5 years probably influenced the management decisions that were made when the patients who were enrolled in the study experienced ischemic events between 5 and 10 years after enrollment.[527]

A meta-analysis of the 5-year outcomes of three large trials found that cardiovascular death or MI occurred in 14.7% (389/2721) of patients randomly assigned to a routine invasive strategy versus 17.9% (475/2746) of patients who were randomly assigned to a selective invasive strategy (HR 0.81; 95% CI 0.71 to 0.93; $P = 0.002$).[528] The absolute risk reductions for the combined endpoint of cardiovascular death or MI were 2%, 3.8%, and 11.1% for the low-, moderate-, and high-risk patients.

The early invasive strategy confers the greatest benefit in patients who are characterized by high-risk indicators such as ST-segment depression[438,439] or elevated troponin levels.[449] Therefore elevated troponin T or I levels and new or presumably new ST-segment depression are included in a list of 15 high-risk indicators that warrant an early invasive strategy in patients with UA or NSTEMI (Box 29.7).[1] A meta-analysis of nine randomized trials that compared an invasive versus a conservative strategy in patients with NSTE-ACS included 1789 patients with diabetes mellitus.[529] Compared with the conservative strategy, the invasive strategy was associated with a 3.7% absolute risk reduction of nonfatal MI and a 5.1% absolute risk reduction of death, MI, or rehospitalization with ACS among patients with diabetes.[529] Consequently, diabetes is included in the list of 15 high-risk indicators that warrant an early invasive strategy in patients with NSTE-ACS.[1]

Both women and men with NSTE-ACS benefited from an early invasive strategy in the TACTICS-TIMI 18 trial.[530] The adjusted OR for the primary composite endpoint of death, MI, or rehospitalization for ACS at 6 months was 0.72 (95% CI 0.47–1.11) for women and 0.64 (95% CI 0.47–0.88) for men who were randomly assigned to the invasive strategy.[530] The benefit of invasive therapy was magnified in women with elevated troponin T levels.[530] A meta-analysis of 8 trials included 3075 women and 7075 men

• BOX 29.7 Factors Associated With Appropriate Selection of Early Invasive Strategy or Ischemia-Guided Strategy in Patients With NSTE-ACS

Immediate Invasive (Within 2 h)

Refractory angina
Signs or symptoms of heart failure or new or worsening mitral regurgitation
Hemodynamic instability
Recurrent angina or ischemia at rest or with low-level activities despite intensive medical therapy
Sustained VT or VF

Early Invasive (Within 24 h)

None of the above, but GRACE risk score >140
Temporal change in troponin (evidence for a serial increase or decrease ≥20% is required if the initial value is above the 99th percentile of the upper reference level)
New or presumably new ST-segment depression

Delayed Invasive (Within 25–72 h)

None of the above but diabetes mellitus
Renal insufficiency (GFR <60 mL/min per 1.73 m^2)
Reduced LVEF (≤40%)
Early postinfarction angina
PCI within 6 months
Prior CABG surgery
GRACE risk score 109–140; TIMI score ≥2

Ischemia-Guided Strategy

Low-risk score (e.g., TIMI 0 or 1, GRACE <109)
Low-risk troponin-negative female patients
Patient or clinician preference in the absence of high-risk features

CABG, *Coronary artery bypass graft;* GFR, *glomerular filtration rate;* GRACE, *Global Registry of Acute Coronary Events;* LVEF, *left ventricular ejection fraction;* PCI, *percutaneous coronary intervention;* TIMI, *thrombolysis in myocardial infarction;* VF, *ventricular fibrillation;* VT, *ventricular tachycardia. From Amsterdam EZ, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines.* J Am Coll Cardiol. *2014;64:e139–e228.*

with NSTE-ACS who were randomly assigned to an invasive or a conservative strategy.[531] The OR for the composite of death, MI, or ACS for the invasive versus the conservative strategy was 0.81 (95% CI 0.65–1.01; 21.1% vs. 25.0%) in women and 0.73 (95% CI 0.55–0.98; 21.2% vs. 26.3%) in men.[531] Among biomarker-positive women an invasive strategy was associated with a 33% lower odds of death, MI, or ACS (OR 0.67; 95% CI 0.50–0.88), but an invasive strategy was not associated with a significant reduction in the triple composite endpoint in biomarker-negative women (OR 0.94; 95% CI 0.61–1.44).[531]

There are limited data regarding the impact that age should have on the decision whether to recommend an early invasive or early conservative strategy in patients with NSTE-ACS. Among patients with NSTE-ACS who were randomly assigned to an invasive strategy or a conservative strategy in the TACTICS-TIMI 18 trial benefit of the invasive strategy was observed only in patients 65 years of age or older.[532] The absolute reduction of death or MI at 6 months was 4.8 percentage points (8.8% vs. 13.6%; $P = 0.018$) among patients 65 years or older, but among patients younger than 65 years the rates of death or MI at 6 months were 6.1% for the invasive strategy compared with 6.5% for the conservative strategy ($P > 0.2$). Among patients older than 75 years the early invasive strategy was associated with a 56% relative reduction in death or MI at 6 months and an absolute reduction of 10.8 percentage points (10.8% vs. 21.6%; $P = 0.016$). A meta-analysis of patient-pooled data from the FRISC II, ICTUS, and RITA-3 trials found that a routine invasive strategy was associated with a lower hazard of the 5-year composite of cardiovascular death or MI in patients aged 65 to 74 years (HR 0.72; 95% CI 0.58–0.90) and in patients 75 years or older (HR 0.71; 95% CI 0.55–0.91), but not in those younger than 65 years (HR 1.11; 95% CI 0.90–1.38).[533] The After Eighty study was conducted at 16 hospitals in Norway and randomly assigned 457 patients 80 years or older with NSTE-ACS to an invasive strategy or a conservative strategy.[534] During a median follow-up of 1.5 years, the primary outcome—a composite of MI, need for urgent revascularization, stroke, and death—occurred in 93 (40.6%) of 229 patients assigned to the invasive group and 140 (61.4%) of 228 patients assigned to the conservative group (HR 0.53; 95% CI 0.41–0.69; $P = 0.0001$).[534]

Several studies have attempted to determine the optimal timing of revascularization with PCI among patients with NSTE-ACS who are selected for early invasive management. The Timing of Intervention in Acute Coronary Syndrome (TIMACS) trial randomly assigned 3031 patients with NSTE-ACS to two groups: routine early intervention (coronary angiography ≤24 hours after randomization) or delayed intervention (coronary angiography ≥36 hours after randomization).[535] The median time to coronary angiography was 14 hours for the early intervention group and 50 hours for the delayed-intervention group. Early intervention improved the primary composite endpoint of death, MI, or stroke at 6 months in the one-third of patients who were at highest risk (HR 0.65; 95% CI 0.48–0.89), but not in the two-thirds of patients at low or intermediate risk (HR 1.12; 95% CI 0.81–1.56). PCI was performed in 7749 patients with NSTE-ACS who were enrolled in the ACUITY randomized trial.[536] Delay to PCI more than 24 hours after presentation was associated with a significant increase in the mortality and MI rates at 30 days. A delay to PCI more than 24 hours after presentation was an independent predictor of both 30-day and 1-year mortality.

The outcome in invasively managed patients with ACS is affected by numerous factors, including the access route. Two reviewers identified 17 randomized trials that compared radial versus femoral access in invasively managed patients with ACS.[537] The pooled data from four trials that were judged to be high-quality, multicenter trials included patients with either STEMI or NSTE-ACS; all of the trials included patients with STEMI, whereas only two of the trials included patients with NSTE-ACS.[537] For the total population of 17,133 patients with STEMI or NSTE-ACS, radial access was associated with reduced mortality (RR 0.73; 95% CI, 0.59–0.90; $P = 0.003$), major adverse cardiovascular events (RR 0.86; 95% CI 0.75–0.98; $P = 0.025$), and major bleeding (RR 0.57; 95% CI 0.37–0.88; $P = 0.011$). There is evidence that radial access, compared with femoral access, is associated with less major bleeding and reduced mortality in patients with STEMI.[538,539] A subgroup analysis of the Radial Vs femorAL access for coronary intervention trial (RIVAL) trial did not show a mortality benefit of radial access in patients with NSTE-ACS.[538] An observational cohort study of 10,095 patients with NSTEMI concluded that a 1-year mortality benefit of radial access, compared with femoral access, was demonstrated in high-volume radial centers (HR 0.70; 95% CI 0.51–0.97; $P = 0.031$) but not in the low-volume centers (HR 0.80; 95% CI 0.47–1.38; $P = 0.428$).[540] Finally, a meta-analysis of eight randomized trials that compared bivalirudin to heparin in patients with ACS concluded that radial access reduces bleeding risk in patients treated with heparin (OR 0.57; 95% CI 0.43–0.77; $P < 0.001$) but not in patients treated with bivalirudin (OR 0.96; 95% CI 0.65–1.41; $P = 0.83$).[541] The 2014 AHA/ACC NSTE-ACS guideline did not include any recommendations regarding vascular access, but the 2015 ESC Guidelines for the management of ACS in patients presenting without persistent ST-segment elevation included a class I recommendation: "In centres experienced with radial access, a radial approach is recommended for coronary angiography and PCI."[1,22]

A pooled cohort analysis of the individual data from 37,555 participants with NSTE-ACS who were enrolled in four trials found that sudden cardiac death accounted for approximately one-third of the cardiovascular deaths, and the risk of sudden death was reduced in patients who underwent revascularization with either PCI or CABG surgery (HR 0.75; 95% CI 0.58–0.98; $P = 0.03$).[542] According to the 2014 AHA/ACC NSTE-ACS Guideline, the following factors should influence the choice of PCI or CABG surgery for revascularization in patients with NSTE-ACS: the extent and complexity of CAD, the short-term risk and long-term durability of PCI, operative mortality, diabetes mellitus, chronic kidney disease, completeness of revascularization, left ventricular systolic dysfunction, previous CABG, and the ability of the patient to tolerate and comply with dual antiplatelet therapy.[1] Although the guidelines do not specify a preference for PCI or CABG surgery in patients with a non–Q-wave MI, periprocedural mortality was greater after CABG surgery than after PCI in the Veterans Affairs Non–Q-Wave Infarction Strategies in Hospital (VANQWISH) trial.[543] Thirty-day mortality was 11.6% after CABG surgery (11/95 patients) compared with 0% after PCI (0/98 patients).[543]

Long-Term Medical Therapy

Prescription of evidence-based medical therapy at the time of hospital discharge has a major impact on outcome in patients with ACS. Mukherjee and coworkers[544] calculated an appropriateness score based on the use of antiplatelet agents, β-blockers, ACE inhibitors, and lipid-lowering agents in patients with an indication for each class of drugs. The use of combination evidence-based medical therapies was independently associated with lower 6-month

mortality among a cohort of 1358 patients with ACS (55% NSTEMI, 30% UA, and 15% STEMI). The OR for death for prescription of all indicated medications versus none of the indicated medications was 0.10 (95% CI 0.03–0.42; $P < 0.0001$).

A comparison of the 2014 AHA/ACC and 2015 ESC guidelines for NSTE-ACS determined that the AHA/ACC document included a total of 168 recommendations, 100 class I, 35 class IIa, 17 class IIb, and 16 class III, whereas the ESC document included fewer total recommendations (95) and fewer class I recommendations (75).[545] The 2014 AHA/ACC and 2015 ESC guidelines for NSTE-ACS include multiple class I recommendations for long-term medical therapy (Box 29.8).[1,22] High-intensity statin therapy—that is, statin regimens that reduce LDL cholesterol by approximately 50%—should be initiated as early as possible and continued indefinitely in all patients with NSTE-ACS and no contraindications to its use. According to the ESC guideline, in patients with LDL cholesterol of 70 mg/dL or higher despite a maximally tolerated statin dose, further reduction in LDL cholesterol with ezetimibe should be considered (class IIa recommendation).[22]

An ACE inhibitor should be continued indefinitely for all patients with a, LVEF of 40% or less, or HF, hypertension, diabetes, or stable chronic kidney disease unless contraindicated. An ARB is an alternative for patients who do not tolerate ACE inhibitors. A mineralocorticoid receptor antagonist, preferably eplerenone, is recommended in patients with an LVEF or 35% or less and either HF or diabetes but no significant renal dysfunction or hyperkalemia (serum potassium <5.0 mmol/L; serum creatinine <2.5 mg/dL for men and <2.0 mg/dL for women).[22]

As discussed earlier, the class I recommendations for antiischemic therapy in patients with NSTE-ACS include the administration of a β-blocker within the first 24 hours for patients who do not have signs of HF, evidence of a low output state, increased risk for cardiogenic shock, or other relative contraindications to β-blockade.[1] In patients with concomitant NSTE-ACS, stabilized HF, and reduced left ventricular systolic function, treatment should include one of the three drugs proven to reduce mortality in HF: sustained-release metoprolol succinate, carvedilol, or bisoprolol. The ESC guideline recommends long-term β-blocker therapy in patients with an LVEF or 40% or less, but neither the 2014 AHA/ACC nor the 2015 ESC guidelines for NSTE-ACS provide a recommendation regarding the duration of treatment in patients without HF or impaired left ventricular systolic function.[1,22]

Aspirin should be continued indefinitely.[1] The maintenance dose should be 81 mg in patients treated with ticagrelor and 81 mg to 325 mg daily in all other patients. A $P2Y_{12}$ inhibitor should be continued for up to 12 months in all patients with NSTE-ACS without contraindications. The options include clopidogrel 75 mg daily or ticagrelor 90 mg twice daily in patients who are managed with an ischemia-guided strategy, and clopidogrel 75 mg daily, ticagrelor 90 mg twice daily, or prasugrel 10 mg daily in patients who receive a stent (either bare metal or drug-eluting).

The optimal duration of DAPT is an area of active investigation and has been the subject of a systematic review and a guideline focused update by the ACC/AHA Task Force on Clinical Practice Guidelines.[546,547] The addition of clopidogrel to aspirin decreased the risk of the primary endpoint of cardiovascular death, MI, or stroke in patients with a history of MI who were enrolled in the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial (6.6% vs. 8.3%; HR 0.774; 95% CI 0.61–0.98; $P = 0.031$).[548] The DAPT study, a double-blind, placebo-controlled randomized trial, compared 30 months with 12 months of dual antiplatelet therapy (aspirin plus clopidogrel or prasugrel) after coronary stenting.[549] The study population included 3576 patients who had an MI at the time of enrollment (47% STEMI, 53% NSTEMI) and were randomly assigned 12 months after MI to receive aspirin plus placebo or aspirin plus continued thienopyridine. The rates of stent thrombosis and MI were lower among the patients randomly assigned to extended DAPT than among the patients assigned to aspirin alone. Long-term use of ticagrelor in patients with a prior MI was investigated in the Prevention of Cardiovascular Events in Patients with Prior Heart Attack Using Ticagrelor Compared to Placebo on a Background of Aspirin-Thrombolysis in Myocardial Infarction 54 (PEGASUS-TIMI 54) trial.[550] Ticagrelor, administered

• BOX 29.8 Class I Recommendations for Long-Term Medical Therapy for Patients With NSTE-ACS

1. All patients should be given sublingual or spray nitroglycerin.
2. Aspirin should be continued indefinitely. The maintenance dose should be 81 mg daily in patients treated with ticagrelor and 81–325 mg daily in all other patients.
3. Unless contraindicated, patients should be treated with a $P2Y1_{12}$ inhibitor as follows:
   For patients treated with an ischemia-guided strategy, clopidogrel 75 mg daily or ticagrelor 90 mg twice daily for up to 12 months
   For patients receiving a stent, clopidogrel 75 mg daily, ticagrelor 90 mg twice daily, or prasugrel 10 mg daily for at least 12 months
4. β-Blockers are indicated for all patients recovering from UA/NSTEMI unless contraindicated. Treatment should begin within a few days of the event, if not initiated acutely, and should be continued indefinitely. Patients recovering from NSTE-ACS with moderate or severe LV failure should receive β-blocker therapy with a gradual titration scheme.
5. ACE inhibitors should be given and continued indefinitely for patients recovering from NSTE-ACS with heart failure, LV dysfunction (LVEF < 0.4), hypertension, or diabetes mellitus, unless contraindicated.
6. An angiotensin receptor blocker should be prescribed at discharge to those NSTE-ACS patients who are intolerant of an ACE inhibitor and who have either clinical or radiologic signs of heart failure and LVEF <0.4.
7. Long-term aldosterone receptor blockade should be prescribed for NSTE-ACS patients without significant renal dysfunction (estimated creatinine clearance should be >30 mL/min) or hyperkalemia (potassium should be ≤5 mEq/L) who are already receiving therapeutic doses of an ACE inhibitor and a β-blocker, have an LVEF ≤0.4, and have either diabetes mellitus or symptomatic heart failure.
8. The following lipid recommendations are beneficial:
   Lipid management should include assessment of a fasting lipid profile for all patients, within 24 hours of hospitalization.
   High-intensity statin therapy, in the absence of contraindications, regardless of baseline LDL-C and diet modification, should be given to post-NSTE-ACS patients, including postrevascularization patients.
   For hospitalized patients, lipid-lowering medications should be initiated before discharge.

ACE, *Angiotensin-converting enzyme;* ACS, *acute coronary syndrome;* LDL-C, *low-density lipoprotein cholesterol;* LV, *left ventricular;* LVEF, *left ventricular ejection fraction;* NSTE-ACS, *non–ST-segment elevation acute coronary syndrome;* NSTEMI, *non–ST-segment elevation myocardial infarction;* UA, *unstable angina;*

Modified slightly from Amsterdam EZ, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol. *2014; 64:e139–e228.*

in a dose of either 60 mg twice daily or 90 mg twice daily, reduced the composite of cardiovascular death, MI, or stroke in patients who had a STEMI or NSTEMI 1 to 3 years earlier.[550] A meta-analysis that included the CHARISMA and PEGASUS-TIMI 54 data and four additional trials was performed to compare long-term DAPT with aspirin alone in patients with a history of prior MI.[551] A total of 33,435 patients were followed for a mean of 31 months during treatment with aspirin alone or DAPT with aspirin plus clopidogrel, prasugrel, or ticagrelor. Extended DAPT for more than 1 year after an MI resulted in a 22% RR reduction and 1.1% absolute risk reduction in major adverse cardiovascular events, and significant reductions of cardiovascular death (2.3% vs. 2.6%; RR 0.85; 95% CI 0.74–0.98; $P = 0.03$), MI, stroke, and stent thrombosis. Although there was an increased risk of major bleeding (1.85% vs. 1.09%; RR 1.73; 95% CI 1.19–2.50; $P = 0.004$), intracranial hemorrhage and fatal bleeding events were infrequent and were not significantly different between extended DAPT and aspirin alone. According to the 2016 ACC/AHA Guideline Focused Update on Duration of Dual Antiplatelet Therapy in Patients with Coronary Artery Disease, in patients with ACS who are treated with either medical therapy alone or PCI, continuation of DAPT for longer than 12 months may be reasonable if DAPT has been tolerated without bleeding complications and there is not a high bleeding risk (class IIb recommendation).[547] In patients with ACS who are treated with DAPT after DES implantation, discontinuation of $P2Y_{12}$ therapy after 6 months may be reasonable in patients who develop a high risk of bleeding, are at high risk of severe bleeding, or develop significant overt bleeding (class IIb recommendation).[547]

Key Points

- Patients with suspected STEMI should have an ECG performed and interpreted within 10 minutes of presentation, and serial ECGs should be performed at intervals of 5 to 10 minutes in patients with a nondiagnostic initial ECG and clinical findings strongly suggestive of STEMI. Right-sided lead tracings should be obtained to screen for right ventricular MI in patients with inferior STEMI.
- Fibrinolytic therapy should be given to patients with STEMI and onset of ischemic symptoms within the previous 12 hours when it is anticipated that primary PCI cannot be performed within 120 minutes of first medical contact.
- Fibrinolytic therapy should be initiated within 30 minutes of presentation.
- Intracranial hemorrhage should be ruled out in any patient with a change in neurologic status during or after fibrinolytic therapy.
- Nitrates are indicated for relief of ischemic discomfort in patients with STEMI, but large clinical trials did not demonstrate a reduction in mortality among patients who received nitroglycerin over prolonged periods after acute MI.
- Aspirin has been shown to reduce mortality in patients with acute MI or UA. Patients with STEMI should receive 162 to 325 mg of non–enteric-coated aspirin, and the aspirin tablets should be chewed.
- The addition of clopidogrel to aspirin has been shown to improve angiographic and clinical outcomes in patients with STEMI or ACS without ST-segment elevation.
- A meta-analysis of 23 randomized trials concluded that the rates of death over the short-term, nonfatal reinfarction, stroke, and the combined endpoint of all three were lower for primary coronary intervention than for fibrinolytic therapy in patients with STEMI.
- Balloon inflation should occur within 90 minutes of presentation in patients with STEMI who undergo primary coronary intervention.
- There are three class I indications for primary PCI in patients with STEMI who present initially to a PCI-capable hospital: (1) patients with ischemic symptoms of less than 12 hours' duration; (2) patients with ischemic symptoms of less than 12 hours' duration who have contraindications to fibrinolytic therapy, irrespective of the time delay from first medical contact; (3) patients with cardiogenic shock or acute severe HF, irrespective of time delay from MI onset.
- In patients with acute MI, the early administration of β-blockers reduces the rate of reinfarction and chronic administration improves long-term survival.
- An ACE inhibitor should be administered orally within the first 24 hours of STEMI to patients with anterior infarction, pulmonary congestion, or LVEF less than 40% in the absence of hypotension.
- An angiotensin receptor blocker should be administered to patients with STEMI who are intolerant of ACE inhibitors and have either HF or an LVEF less than 40%.
- Long-term aldosterone blockade should be prescribed for post-STEMI patients without significant renal dysfunction or hyperkalemia who are already receiving therapeutic doses of an ACE inhibitor, have an LVEF of 40% or less, and have either diabetes or symptomatic HF.
- Diltiazem and verapamil are contraindicated in patients with STEMI and associated systolic left ventricular dysfunction and HF.
- High-intensity statin therapy is indicated at the time of hospital discharge in all patients with ACS.
- Patients with NSTE-ACS should be treated with both an anticoagulant (UFH, enoxaparin, or fondaparinux) and at least dual antiplatelet therapy with aspirin and an antagonist of the platelet $P2Y_{12}$ receptor (clopidogrel, prasugrel, or ticagrelor).
- An early invasive strategy is favored in patients with NSTE-ACS who have any of the following high-risk indicators: recurrent angina or ischemia at rest or with low-level activities despite intensive medical therapy; early postinfarction angina; refractory angina; signs or symptoms of HF or new or worsening MR; hemodynamic instability; temporal change in troponin; new or presumably new ST-segment depression; LVEF less than 40%; sustained ventricular tachycardia; ventricular fibrillation; diabetes mellitus; renal insufficiency (glomerular filtration rate <60 mL/min per 1.73 meters squared); PCI within the past 6 months; prior CABG surgery; or a high risk score (TIMI ≥2, GRACE ≥109).

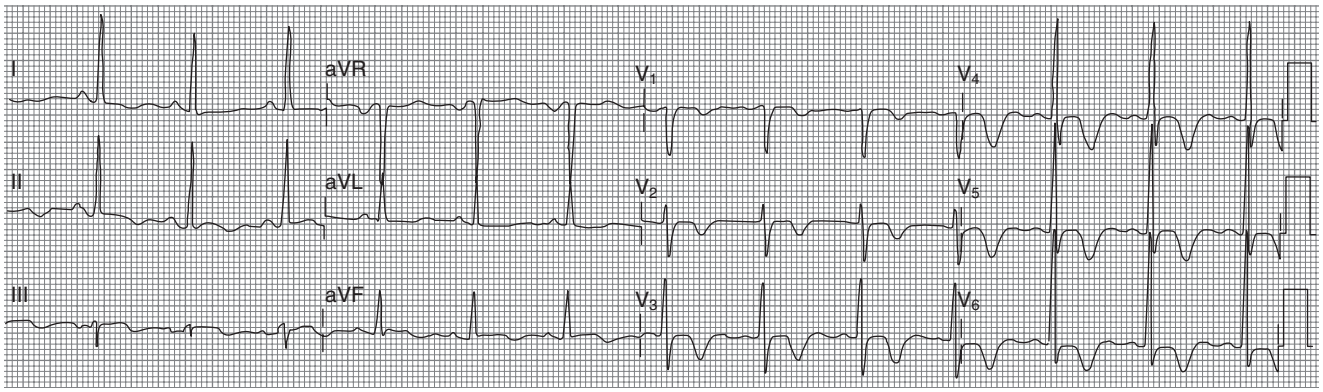
Review Questions

1. A 56-year-old woman presents to the emergency department (ED) 3 hours after the onset of severe dyspnea. The following electrocardiogram (ECG) was obtained at 1:55:

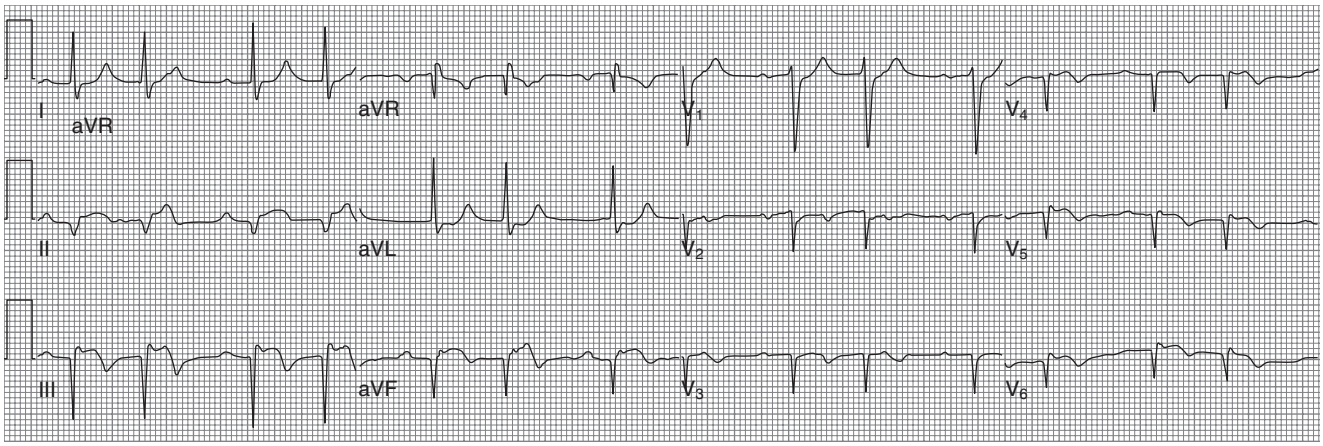


Which of the following should be recommended?

a. Repeat the ECG in 15 to 30 minutes
b. Order an immediate echocardiogram
c. Schedule an exercise echocardiogram
d. Schedule a dipyridamole nuclear stress test
e. Order an immediate computed tomography (CT) scan of the chest

Answer: a. Although the ECG is not diagnostic of an ST-segment elevation myocardial infarction (STEMI), it shows deep T-wave inversions in the precordial leads consistent with myocardial ischemia. It is common for patients to develop ST-segment elevation on subsequent ECGs. Therefore the American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend repeating an ECG within 15 to 30 minutes in patients with an acute coronary syndrome if the initial ECG is nondiagnostic.[21]

2. A 75-year-old man with a history of a coronary artery stent and exertional angina has been admitted to the intensive care unit (ICU) after undergoing an open surgical repair of an abdominal aortic aneurysm. His aspirin and clopidogrel were discontinued 10 days before surgery. On the second postoperative day he complains of chest pain, his serum troponin is elevated, and the following ECG is obtained:

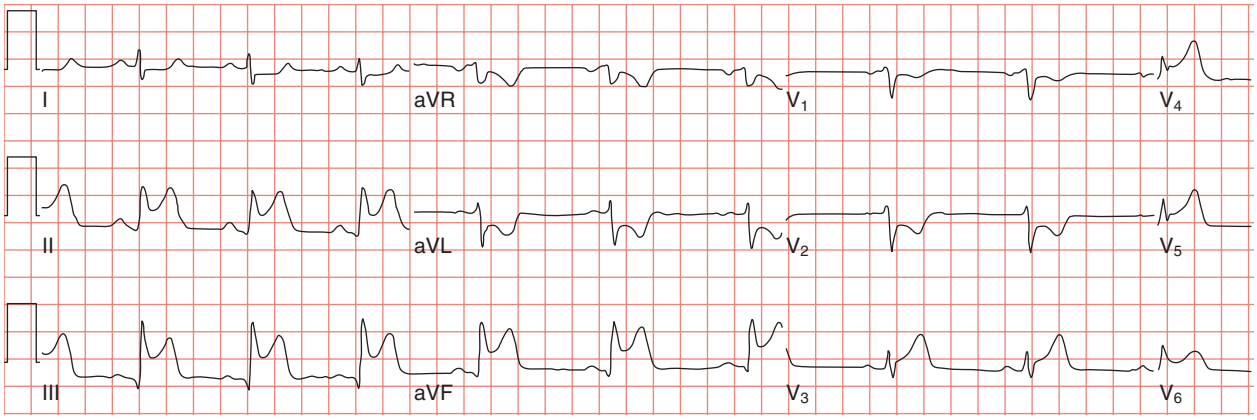


Which of the following management strategies is most appropriate?

a. His age is a contraindication to reperfusion therapy.
b. The Q waves are a contraindication to reperfusion therapy.
c. A fibrinolytic drug should be administered because his aortic aneurysm repair is a contraindication to cardiac catheterization.
d. Cardiac catheterization should be performed because his aortic aneurysm repair is a contraindication to fibrinolytic therapy.

Answer: d. The patient's age is not a contraindication to reperfusion therapy. Q waves are present on the initial ECG in approximately 50% of patients with an acute STEMI, and Q waves are not a contraindication to reperfusion therapy. The patient's recent surgery is a contraindication to fibrinolytic therapy, but it is not a contraindication to cardiac catheterization, which can be performed via the radial artery.

3. A 60-year-old man presents to the ED within 1 hour of the onset of chest pain. The following ECG was obtained:



Which of the following treatments is most appropriate?

a. A glycoprotein IIb/IIIa inhibitor while awaiting the serum troponin result
b. Sublingual nifedipine for treatment of coronary artery spasm
c. Aspirin, clopidogrel, and an intravenous fibrinolytic drug (tissue plasminogen activator, reteplase, or tenecteplase)
d. Transfer of the patient to a hospital 2 hours away for cardiac catheterization

Answer: c. Reperfusion therapy is indicated because the ECG shows an acute inferior STEMI. Transfer to another hospital for cardiac catheterization would be appropriate if percutaneous coronary intervention can be performed within 2 hours of arrival at the initial ED or if the patient has a contraindication to fibrinolytic therapy. According to the 2013 ACC/AHA STEMI Guideline, a fibrinolytic agent should be administered when the anticipated first medical contact to device time exceeds 120 minutes (see O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2013;127:e362–e425). Therefore if this patient does not have a contraindication to fibrinolytic therapy, he should be treated with a fibrinolytic agent along with aspirin and clopidogrel. Treatment should not be delayed to obtain a serum troponin result. Sublingual nifedipine is contraindicated in a patient with a STEMI because of hypotension and reflex sympathetic activation with tachycardia.

4. In the Second International Study of Infarct Survival, after follow-up for 5 weeks, vascular death occurred in 804 of the 8587 (9.2%) patients who were randomly assigned to receive aspirin compared with 1016 of the 8600 patients who were randomly assigned to receive placebo (11.8%). Therefore how many patients with suspected myocardial infarction (MI) would need to be treated with aspirin to prevent one vascular death after 5 weeks?

a. 10
b. 20
c. 38
d. 50
e. 100

Answer: c. The number needed to treat = 1/(absolute risk reduction) = 1/(11.8% − 9.2%) = 1/2.6% = 1/0.026 = 38.46.

5. A 65-year-old woman is transferred to the ICU after having chest pain during hemodialysis. She has long-standing hypertension and chronic kidney disease, and she started hemodialysis recently. Her antihypertensive medications are clonidine, diltiazem, and hydralazine. Her blood pressure is 180/100 mm Hg. She has bibasilar rales and an S_3 gallop. Her serum troponin is mildly elevated. Her chest radiograph shows pulmonary congestion. The patient does not want to undergo invasive diagnostic studies. Which of the following medications is most appropriate?

a. Unfractionated heparin
b. Enoxaparin
c. Fondaparinux
d. Eptifibatide

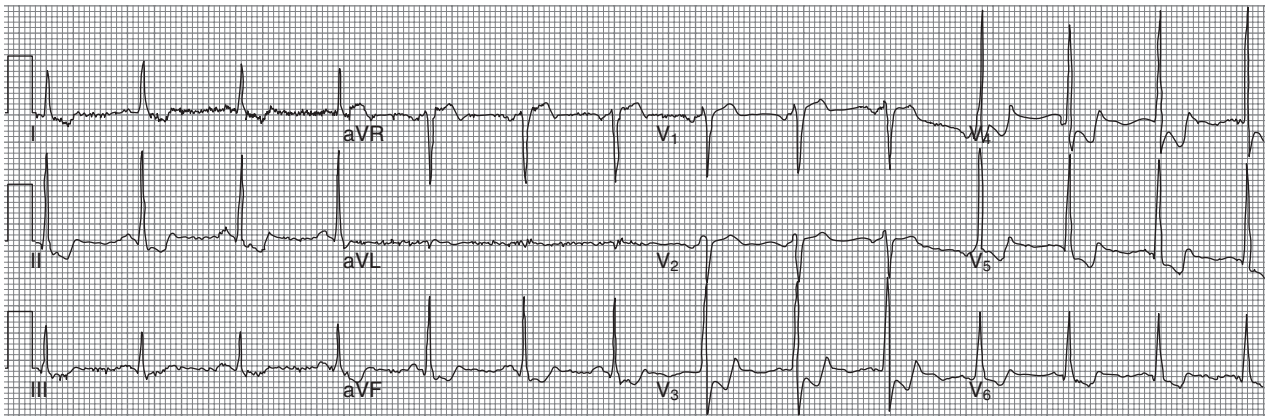
Answer: a. Enoxaparin, fondaparinux, and eptifibatide are contraindicated in patients treated with hemodialysis.

6. A 65-year-old woman is transferred to the ICU after having chest pain during hemodialysis. She has long-standing hypertension and chronic kidney disease, and she started hemodialysis recently. Her antihypertensive medications are clonidine, diltiazem, and hydralazine. Her blood pressure is 180/100 mm Hg. She has bibasilar rales and an S_3 gallop. Her serum troponin is mildly elevated. The patient does not want to undergo invasive diagnostic studies. Which of the following orders is most appropriate:

a. Aspirin 325 mg daily
b. Aspirin 325 mg daily and prasugrel 10 mg daily
c. Aspirin 325 mg daily and clopidogrel 75 mg daily
d. Aspirin 325 mg daily and ticagrelor 90 mg twice daily

Answer: c. Dual antiplatelet therapy with aspirin 325 mg daily and clopidogrel 75 mg daily is the correct therapy. Aspirin monotherapy is incorrect. Prasugrel is indicated only in patients who undergo PCI. Patients treated with ticagrelor should receive an aspirin dose <100 mg daily.

7. An 80-year-old man with diabetes presented to the ED with chest pain. He had a transient ischemic attack 1 year ago, and 6 months ago he was treated for upper gastrointestinal bleeding owing to gastritis. Results of his physical examination are normal. This ECG was obtained during chest pain:



Which of the following would you recommend:
a. A resting sestamibi scan
b. A nuclear stress test
c. An intravenous fibrinolytic drug
d. Cardiac catheterization
Answer: d. The patient's ECG shows diffuse ST-segment depressions consistent with myocardial ischemia. Therefore a cardiac catheterization is indicated. A fibrinolytic drug is not indicated because the patient's ECG does not show a STEMI or left bundle branch block. A stress test is contraindicated. A resting sestamibi scan would not be useful.

8. An 80-year-old man presented to the ED with chest pain. He had a transient ischemic attack (TIA) 1 year ago, and 6 months ago he was treated for upper gastrointestinal bleeding owing to gastritis. Coronary angiography showed a 90% stenosis of the left anterior descending coronary artery that was treated with a drug-eluting stent. Which of the following medication orders is most appropriate for this patient?
a. Aspirin 81 mg daily and omeprazole 40 mg daily
b. Aspirin 81 mg daily, prasugrel 10 mg daily, and omeprazole 40 mg daily
c. Aspirin 81 mg daily, ticagrelor 90 mg twice daily, and omeprazole 40 mg daily
d. Aspirin 325 mg daily, ticagrelor 90 mg twice daily, and omeprazole 40 mg daily
Answer: c. The patient received a drug-eluting stent and should be treated with dual antiplatelet therapy. He should also receive a proton-pump inhibitor because of his history of gastrointestinal bleeding. Prasugrel is contraindicated because of the patient's age and history of a TIA. Patients treated with ticagrelor should receive an aspirin dose less than 100 mg daily.

Hypertrophic Obstructive Cardiomyopathy
- Pathophysiology
- Diagnosis
- Therapy

Mitral Valve Stenosis
- Pathophysiology
- Diagnosis
- Therapy

Prosthetic Heart Valves
- Pathophysiology
- Diagnosis
- Therapy

The profile of valvular heart disease (VHD) in the critical care setting has evolved substantially over the past several decades.[1] Aortic stenosis (AS), mitral regurgitation (MR), and aortic insufficiency (AI) are the most common and significant valve diseases seen in the intensive care unit, but hypertrophic cardiomyopathy (HCM) and mitral stenosis (MS) remain important entities as well, as are prosthetic valve dysfunction and paravalvular leak (PVL). Patients with VHD in critical care units typically fall into one of two categories: (1) those who are critically ill because of valvular dysfunction or (2) those in whom VHD represents an important comorbidity. Many patients present without prior diagnosis of VHD,[2] either because the progression has been insidious and the disease not previously diagnosed or because the onset has been acute. Improvements in technology and the ubiquitous availability of echocardiography have improved diagnosis, whereas clinician skills at integrating physical examination and other data have generally atrophied during this time frame.[3]

Diagnosis of VHD in critical care units is challenging, with lack of a quiet environment for auscultation; comorbidities that affect physical findings; and stress, infection, or metabolic abnormalities that result in tachycardia and shorter intervals for evaluation of heart sounds. The progression of VHD was redefined by the 2014 American College of Cardiology/American Heart Association (AHA/ACC) guidelines,[4] which abandoned the previous "mild," "moderate," and "severe" categories for a classification that describes four stages (A to D) that represent a progression from early anatomic findings (A) through progressive physiologic abnormalities (B) and then severe, clinically and physiologically important disease that is either asymptomatic (C) or symptomatic (D). In most cases, intervention is reserved primarily for patients with severe VHD Table 30.1.

Aortic Stenosis

With the aging of the population, AS has moved to the forefront in frequency of VHD encountered in the elderly. The prevalence is surprisingly high; in patients 85 years of age, more than 8% of a random general population survey had Doppler-derived aortic valve area estimates of 1 cm^2 or less (Fig. 30.1).[5] Thus AS should be considered in the differential diagnosis of every older critical care patient with hemodynamic instability. The possibility of AS should be dismissed only after considering physical examination and electrocardiographic and, when applicable, echocardiographic and invasive findings, all of which have potential limitations in achieving accurate diagnosis as discussed subsequently.[6]

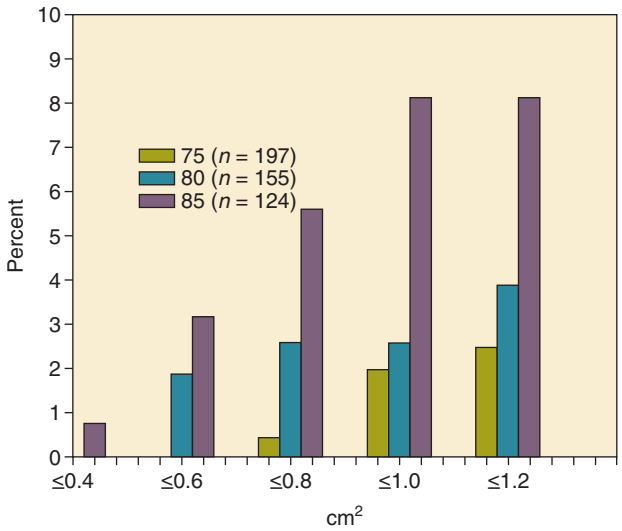
Pathophysiology

AS represents a continuum, from hemodynamically insignificant congenital and atherosclerotic disease to end-stage decompensation secondary to severe valvular obstruction. The congenital pathway is typically secondary to a bicuspid aortic valve, the most common congenital cardiac anomaly if mitral valve prolapse is excluded, occurring in approximately 1.5% of the population.[7] Bicuspid aortic valve disease is part of a larger aortopathy[8] syndrome with significant implications for the natural course of aortic valve disease.[9] The most common acquired anomaly is typically referred to as *degenerative disease,* an atherosclerotic process that represents a continuum from aortic valve sclerosis, which is not associated with a hemodynamically significant gradient, to a densely calcified aortic

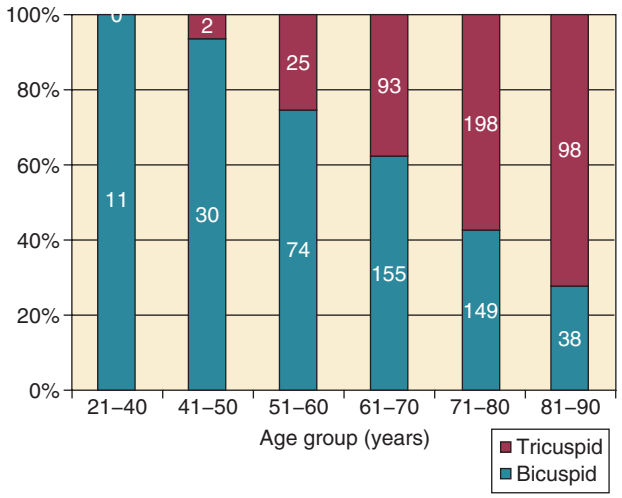
TABLE 30.1 Stages of Progression of Valvular Heart Disease

Stage	Definition	Description
A	At risk	Patients with risk factors for the development of VHD
B	Progressive	Patients with progressive VHD (mild to moderate severity and asymptomatic)
C	Asymptomatic severe	Asymptomatic patients who reached the criteria for severe VHD C1: Asymptomatic patients with severe VHD in whom the left or right ventricle remains compensated C2: Asymptomatic patients who have severe VHD with decompensation of the left or right ventricle
D	Symptomatic severe	Patients who have developed symptoms as a result of VHD

VHD, Valvular heart disease.
From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014;129:2440–2492.



• **Fig. 30.1** Doppler-derived estimates of aortic valve area at ages 75, 80, and 85 years from a randomized sampling of individuals in the general population. Bars represent percentages of individuals with valve areas at or below the thresholds on the abscissa (in square centimeters). (Data from Lindroos M, Kupari M, Heikkila J, et al. Prevalence of aortic valve abnormalities in the elderly: an echocardiographic study of a random population sample. *J Am Coll Cardiol.* 1993;21:1220–1225.)



• **Fig. 30.2** Distribution by age group of bicuspid versus tricuspid aortic valves in patients undergoing aortic valve replacement for aortic stenosis. (Modified from Roberts WC, Ko JM. Frequency by decades of unicuspid, bicuspid, and tricuspid aortic valves in adults having isolated aortic valve replacement for aortic stenosis, with or without associated aortic regurgitation. *Circulation.* 2005;111:920–925.)

valve with severe outflow obstruction. Although the etiology of aortic valve stenosis in patients undergoing aortic valve replacement (AVR) has shifted to calcific tricuspid aortic valve disease from bicuspid and rheumatic disease, this remains an age-related phenomenon, with a predominance of bicuspid aortic valve disease in patients younger than 70 years of age (Fig. 30.2).[10]

Aortic Valve Sclerosis

Aortic valve *sclerosis* is an important disease entity, although usually not because of hemodynamic considerations. Defined as calcification and thickening of the aortic valve without significant outflow obstruction (gradient <20–25 mm Hg), it is present in nearly 30% of the population older than age 65 and nearly 50% by age 85[11] and is associated with a 50% increase in 5-year cardiovascular mortality rate.[12] Its incidence is as high as 15-fold greater than aortic valve stenosis; the two diagnoses can be differentiated from one another by hemodynamics and physical examination findings discussed subsequently. In keeping with the primary atherosclerotic nature of aortic sclerosis, it is associated with increasing age, male gender, hypertension, smoking, elevated low-density lipoprotein and lipoprotein(a) levels, and diabetes.[11] The primary importance of aortic valve sclerosis is that it provides a window on the overall presence of vascular disease, in particular coronary artery disease (CAD).[13] Thus there should be a high index of suspicion of vascular disease in any patient with aortic valve sclerosis managed in the critical care setting.

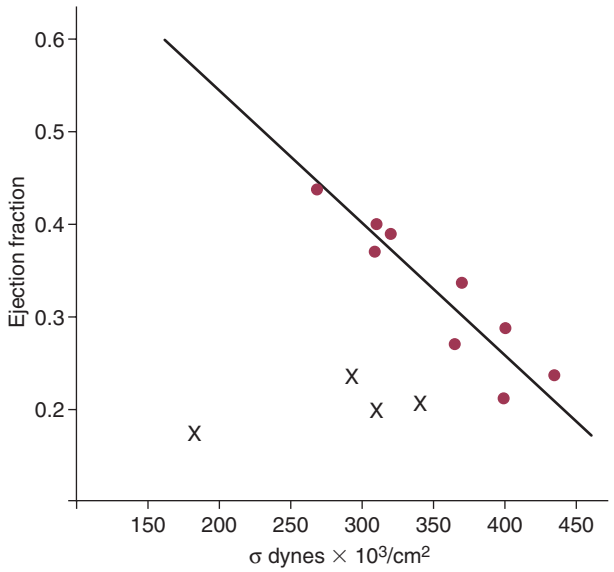
Patients with aortic sclerosis do progress to aortic valve stenosis; a study of more than 2000 patients with valve thickening showed progression to severe AS in 2.5% over an average time interval of 7 years,[14] with a more recent meta-analysis of 22 studies showing a nearly 2% annual rate of progression to severe AS and a 69% increased risk of cardiovascular mortality.[15] The fact that so-called degenerative disease of the aortic valve is absent in nearly half of octogenarians is also important to consider because it implies that

it is not only aging but other factors that result in leaflet thickening, calcification, and stenosis. In the Helsinki Aging Study from which data are reflected in Fig. 30.1, additional analysis demonstrated that not only age but also hypertension and low body mass index independently predicted calcification of the aortic valve, and age and serum ionized calcium were independently associated with valvular stenosis.[16] In general, the process of sclerosis and then stenosis of the aortic valve appears, like atherosclerosis in general, to be an active inflammatory process, with deposition of lipoproteins, local inflammation with T-lymphocyte and macrophage infiltration, fibroblast proliferation, and eventually osteoblast and bone formation.[17] Similar to other vascular disease, endothelial disruption likely leads to the initial lipid deposition in the leaflet tissues. The areas of early focal plaque formation appear at the loci of greatest stress: on the aortic side of the leaflets at the flexion points. Because bicuspid valves have greater mechanical stress, the average age at presentation of patients with bicuspid aortic valve stenosis is significantly lower than in the tricuspid aortic valve stenosis that is typically seen in an elderly population.[18]

An important element in understanding calcific AS is the relatively lower contribution of commissural fusion to the overall obstruction; unlike rheumatic mitral valve stenosis, in which fusion of the commissures is the primary cause of obstructive disease, lack of mobility of the aortic valve leaflets is the primary cause of obstruction in AS. Rheumatic AS is associated with commissural fusion but is now a rare finding, even in countries where rheumatic heart disease is prevalent, and is usually associated with mitral valve involvement and typically AI as well. More obscure causes, such as unicuspid and quadricuspid aortic valve disease, are uncommon, although presentation can be delayed to adulthood. In the case of unicuspid aortic valves there is a strong association with AS,[19] whereas with quadricuspid aortic valves there is a high incidence of significant aortic insufficiency.[20]

Normal aortic valve area ranges from 3 to 4 cm^2. Significant resistance to outflow does not occur until the valve orifice is reduced more than 50%. Based on the simple hydraulic principle of Poiseuille's law, a 50% reduction in valve diameter results in approximately a 16-fold increase in resistance. In practice, as the resistance to outflow rises, the left ventricle is subject to pressure overload, resulting in compensatory hypertrophy. This in turn normalizes wall stress because the latter is proportional to chamber diameter times pressure divided by wall thickness (the LaPlace principle). The degree of wall thickness is variable: In patients with inadequate hypertrophic response, wall stress is inordinately high and there is early dilation and dysfunction.[21] In patients with a profound hypertrophic response disproportionate to valvular resistance, wall stress actually falls below normal and ejection fraction (EF) becomes supranormal,[22] a phenomenon that appears to be more common in women with AS. The EF for any degree of wall stress is predictable,[21] and patients who have disproportionately poor ejection phase indices (afterload mismatch) typically manifest left ventricular (LV) dysfunction beyond the depression that would be associated with high wall stress (Fig. 30.3),[23] a phenomenon described under low-gradient, low-output AS that follows.

LV hypertrophy, although it reduces wall stress, has several features that may be deleterious. With progressive hypertrophy, diastolic pressures may rise as LV compliance decreases, resulting in increased LV filling pressures. In addition, the myocardial supply-demand relationship is deleteriously affected by hypertrophy in this setting. With increased wall stress and increased wall mass, myocardial oxygen demand is increased; at the same time coronary flow reserve is decreased in AS,[24] and in later stages of the disease

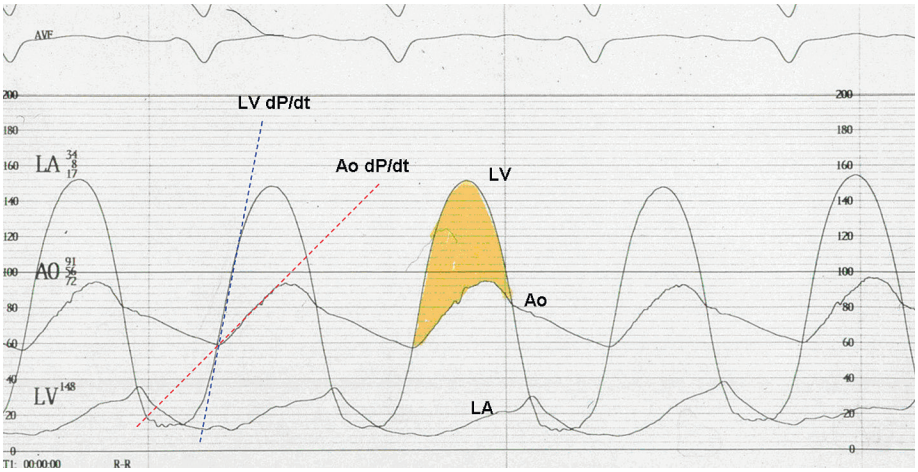


• **Fig. 30.3** The relationship between ejection fraction and wall stress in patients with aortic stenosis. The patients (each represented by an "X") whose ejection fraction was disproportionately lower than the regression line had a poor overall outcome. In these patients ejection phase indices were depressed despite a low transvalvular gradient, a phenomenon suggesting intrinsic contractile dysfunction. (From Carabello BA, Green LH, Grossman W, et al. Hemodynamic determinants of prognosis of aortic valve replacement in critical aortic stenosis and advanced congestive heart failure. *Circulation.* 1980;62:42–48.)

diastolic perfusion pressure is lowered. Because of abnormal flow reserve, conventional testing for ischemia in the setting of significant aortic valve stenosis (fractional flow reserve) has less specificity to identify the presence or absence of hemodynamically significant concomitant CAD.[25]

Other features associated with AS that are important in the critical care setting include abnormal platelet function and decreased levels of von Willebrand factor,[26] with associated bleeding risk that improves with AVR. Another associated cause of bleeding is gastrointestinal angiodysplasia (Heyde syndrome) associated with aortic valve stenosis,[27] possibly exacerbated by the concomitant presence of von Willebrand syndrome.

The progression of AS is highly variable, but with the onset of moderately severe disease, the estimated mean decrease in valve area is on the order of 0.1 cm^2/yr.[28] It is important to note that the rate of progression is quite variable in individual patients, with some demonstrating accelerating progression while others remain stable for years. Certain demographics and noninvasive findings appear to predict more rapid progression, including age and severity of valve calcification.[29] The issue of progression is particularly important in patients who are asymptomatic of the disease, because AVR before it is necessary is undesirable but must be weighed against the risk of sudden death. The latter has been investigated in a number of longitudinal studies and is rare if patients' conditions are followed prospectively. The patients who are most likely to require early intervention are those with peak Doppler systolic velocities greater than 4 m/s or who have a rapid increase in serial transvalvular Doppler velocity measurements.[28,29] This threshold has been confirmed by other series.[30] Once patients become symptomatic, with a classic triad of heart failure, angina, or syncope, hemodynamic deterioration can be rapid with significant associated mortality risk.[31]



• **Fig. 30.4** Left ventricular *(LV)*, aortic *(Ao),* and left atrial *(LA)* pressure on 200-mm Hg scale, 100-mm/s paper speed. The aortic valve gradient is filled in *yellow.* The dramatic difference in the slope of left ventricular (*LV dP/dt, dashed blue line*) and aortic pressure upstroke *(Ao dP/dt, dashed red line*) and the low pulse pressure (≈30 mm Hg) in this patient with classic severe aortic valve stenosis is demonstrated.

An important consideration relates to patients with moderate AS (AVA 1.0–1.5 cm^2) and LV systolic dysfunction (LV ejection fraction [LVEF] <50%) who are symptomatic (New York Heart Association [NYHA] class III or IV); these patients appear to be at high risk of all-cause death and hospitalization for heart failure.[32] Whether AVR in this group improves clinical outcomes is the subject of the ongoing Transcatheter Aortic Valve Replacement to Unload the Left Ventricle in Patients With Advanced Heart Failure trial (TAVR UNLOAD) comparing transcatheter aortic valve replacement (TAVR) to optimal heart failure therapy.

Diagnosis

Physical Examination

The hallmarks of the physical examination relate to the contour of the aortic pressure upstroke, with a low volume and delayed carotid upstroke (pulsus parvus et tardus), a late peaking systolic ejection murmur, and a diminished or absent aortic second sound. Fig. 30.4 demonstrates the hemodynamics that manifest in an abnormal carotid pulse contour; unlike the brisk upstroke of LV pressure over time (dP/dt), the aortic pressure is slow to rise and of significantly lower volume. An ejection click may be present in young patients with congenital AS, but with increasing calcification of the valve, mobility decreases to a point at which an ejection click becomes unlikely. The aortic component of the second heart sound, reflecting deceleration and closure of the aortic valve, is diminished or absent in severe AS where the thickened aortic valve leaflets are poorly mobile, have little deceleration, and drift rather than snap shut. In contrast, if pulmonary hypertension is present, the P2 component may be exaggerated and can potentially mask the diminished A2. The murmur of AS is characteristically a crescendo-decrescendo murmur that is late peaking, consistent with the timing of the peak gradient as seen in Fig. 30.4, and is typically best heard over the right upper sternum and clavicle. It reflects the high-velocity systolic jet directed into the ascending aorta. In the critical care setting, where patients have a low output state and end-stage AS, the murmur may be relatively quiet or absent altogether. A second component, described by Gallavardin as a musical component, is best heard at the left lower sternal border. The latter confounds diagnosis because the murmur is suggestive of mitral regurgitation (MR), but in its true form it is purely secondary to aortic valve stenosis. Because handgrip raises resistance to LV ejection, the murmur should decrease if it is a true Gallavardin phenomenon, whereas when it is secondary to MR, it should increase.[33]

Unfortunately, none of these findings has sufficiently high sensitivity or specificity for AS or for differentiating moderate from severe disease.[3] Many patients with AS, particularly the elderly with stiff noncompliant vessels, have a wide pulse pressure even with declining cardiac output (CO) and may have systolic hypertension. Hypotension may not be seen until late stages of the disease. The loudness of the murmur, which correlates to some degree with severity, is also not specific because body habitus and a variety of other factors affect the acoustics transmitted across the chest. Most importantly, in severe AS, as the CO drops, the gradient generated decreases as well. In this setting the murmur may be quite soft, although sometimes still high-pitched because of the high velocity across a tight constriction. A useful means of differentiating aortic sclerosis from stenosis is that in the former the systolic ejection murmur heard over the right sternum is typically mid-peaking and mild to moderate in intensity, and it features a well-preserved aortic second heart sound. Although the physical findings described are variable, the presence of a preserved aortic second heart sound tends to exclude severe calcific AS.[34]

Noninvasive Evaluation

In contrast to the physical examination, echocardiographic techniques have progressively improved over the past several decades and availability in the critical care setting in industrialized nations is ubiquitous. The characteristic echocardiographic features of AS are decreased valve leaflet mobility, calcification in all except congenital AS in adolescents and young adults, and an augmented Doppler velocity that generally allows accurate estimation of the gradient. In congenital bicuspid AS in young adults, when commissural fusion is dominant, a characteristic doming pattern is seen, but this disappears with progressive valve calcification. The severity of calcification correlates with extent of obstruction by middle age, and typically Doppler signal velocity with peak and mean pressure gradient and valve area by continuity equation provide an accurate overall assessment. However, the gradient is

TABLE 30.2 Stages of Valvular Aortic Stenosis

Stage	Definition	Valve Anatomy	Valve Hemodynamics	Hemodynamic Consequences	Symptoms
C: Asymptomatic Severe AS					
C1	• Asymptomatic severe AS	• Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	• Aortic V_{max} ≥4 m/s or mean ΔP ≥40 mm Hg • AVA typically is ≤1 cm^2 (or AVAi ≤0.6 cm^2/m^2) • Very severe AS is an aortic V_{max} ≥5 m/s, or mean ≤P ≥60 mm Hg	• LV diastolic dysfunction • Mild LV hypertrophy • Normal LVEF	• None—exercise testing is reasonable to confirm symptom status
C2	• Asymptomatic severe AS with LV dysfunction	• Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	• Aortic V_{max} ≥4 m/s or mean ΔP ≥40 mm Hg • AVA typically is ≤1 cm^2 (or AVAi ≤0.6 cm^2/m^2)	• LVEF <50%	• None
D: Symptomatic Severe AS					
D1	• Symptomatic severe high-gradient AS	• Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	• Aortic V_{max} ≥4 m/s, or mean ΔP ≥40 mm Hg • AVA typically is ≤1 cm^2 (or AVAi ≤0.6 cm^2/m^2), but may be larger with mixed AS/AR	• LV diastolic dysfunction • LV hypertrophy • Pulmonary hypertension may be present	• Exertional dyspnea or decreased exercise tolerance • Exertional angina • Exertional syncope or presyncope
D2	• Symptomatic severe low-flow, low-gradient AS with reduced LVEF	• Severe leaflet calcification with severely reduced leaflet motion	• AVA ≤1 cm^2 with resting aortic V_{max} <4 m/s or mean ΔP <40 mm Hg • Dobutamine stress echo shows AVA ≤1 cm^2 with V_{max} ≥4 m/s at any flow rate	• LV diastolic dysfunction • LV hypertrophy • LVEF <50%	• HF • Angina • Syncope or presyncope
D3	• Symptomatic severe low-gradient AS with normal LVEF or paradoxical low-flow severe AS	• Severe leaflet calcification with severely reduced leaflet motion	• AVA ≤1 cm^2 with aortic V_{max} <4 m/s, or mean ΔP <40 mm Hg • Indexed AVA ≤0.6 cm^2/m_2 and stroke volume index <35 mL/m^2 • Measured when the patient is normotensive (systolic BP <140 mm Hg)	• Increased LV relative wall thickness • Small LV chamber with low stroke volume • Restrictive diastolic filling • LVEF ≥50%	• HF • Angina • Syncope or presyncope

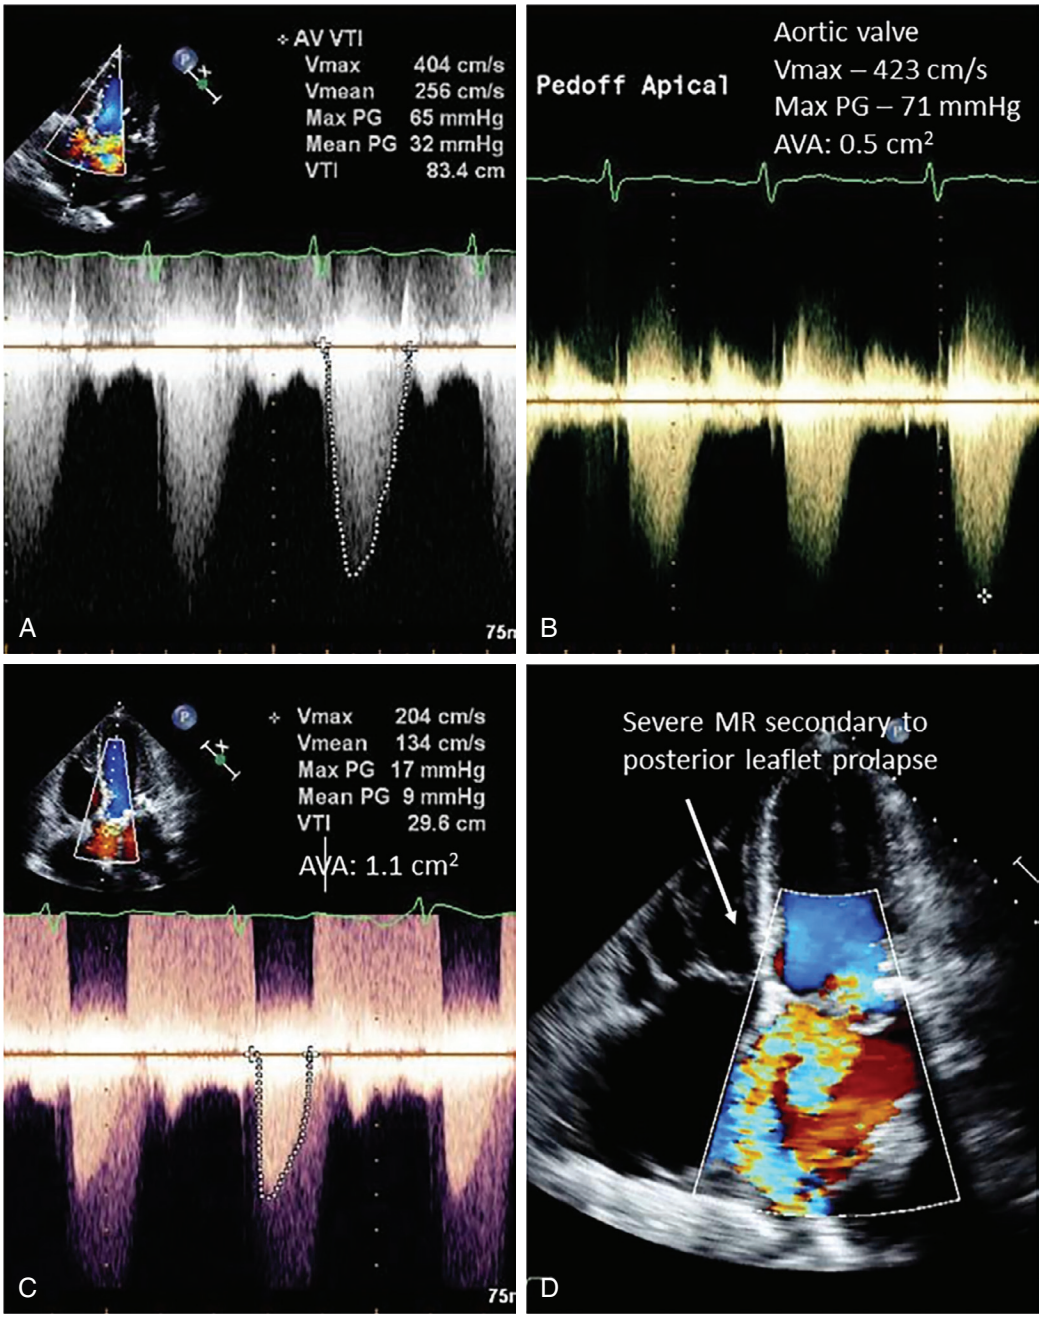
From Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guideline for the Management of Patients With Valvular Heart Disease: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2014;129:2440–2492.

highly dependent on flow across the valve, and in low-output states the gradient may result in underestimation of severity of disease; in high-output states such as in patients with augmented CO caused by inotropic stimulation, endogenous high catecholamine states, and sepsis, the gradient may be disproportionately higher than the severity of stenosis would suggest. The latest AHA/ACC guidelines[4] describe the threshold for severe AS as antegrade jet velocity greater than 4 m/s, mean gradient greater than 40 mm Hg, and aortic valve area less than 1 cm^2 (valve area index less than 0.6 cm^2) with the caveat that the gradient and jet velocity depend on the overall transvalvular flow (Table 30.2). Importantly, antegrade flow across the aortic valve does not equal CO in patients with confounding conditions, including aortic insufficiency; thus, for example, a patient with mild to moderate AS and moderate AI may have a transvalvular gradient suggestive of severe AS. Finally, although many practitioners do not index the valve area, it is important to appreciate that in a patient with a large body surface area (BSA), disease that might be considered moderate in smaller patients may be functionally severe.

Several caveats need to be considered before acceptance of noninvasive data in the critical care setting. Inadequate acoustic windows in some patients and difficulty in positioning patients supported by respirators and with multiple lines in place do limit echocardiographic imaging. Technical errors in recording and interpretation result in significant misdiagnosis; errors in recording angle, inadvertent imaging of MR jets instead of aortic outflow (Fig. 30.5), assessing proximal velocity instead of the transvalvular signal, and selecting signals in the setting of arrhythmias that are not representative of mean heartbeats can all lead to skewed assessment of valve disease severity.[35] Further, a number of other potential



• **Fig. 30.5** Noninvasive findings in a symptomatic patient who was referred for aortic valve intervention. A, Continuous Doppler across the aortic valve showed a peak velocity of 4.0 m/s, suggesting severe aortic stenosis. B, Pedoff apical Doppler confirmed peak velocity above 4.0 m/s. C, However, a repeat continuous Doppler with care to avoid mitral regurgitant flow showed the true aortic velocity of 2.0 m/s. D, Color Doppler showed severe mitral regurgitation in the same patient. Therapy was directed to correcting mitral regurgitation instead. *AV,* Aortic valve; *AVA,* aortic valve area; *MR,* mitral regurgitation; *PG,* gradient; *Vmax,* peak aortic jet velocity; *VTI,* time-velocity integral.

confounding variables can lead to overestimation or underestimation of the severity of AS,[6,36] and valve area calculations by the continuity equation in a low-flow setting may be inaccurate.[37] Because the continuity equation depends on measurement of the LV outflow tract (LVOT) dimension, which is prone to inaccuracy, another measure of AS severity—the dimensionless index (the ratio of blood flow velocity across the LVOT to that across the aortic valve)—has been widely adopted.[38] A number of other techniques for determining the severity of AS supplement the most commonly used noninvasive tools, including three-dimensional echocardiography, computed tomography (CT),[39] and magnetic resonance imaging (MRI).[40] Overall, there has been a major a shift in the gold standard from catheter-derived to noninvasive-derived determination of AS severity, and cardiac catheterization is no longer indicated for hemodynamic assessment of aortic valve disease severity when noninvasive findings are unequivocal.[4]

The echocardiogram provides important additional information including severity of LV hypertrophy, LV function and size, and concomitant disease of other heart valves. The presence of regional wall motion abnormalities, in the absence of a conduction disturbance, suggests concomitant CAD. The electrocardiogram (ECG) in AS is typically abnormal and frequently features LV hypertrophy, with ST-segment abnormalities in the lateral leads typically described as a strain pattern.[41] Although occasionally mistaken for anterior ischemia or infarction, with loss of R voltage across the precordium and occasionally with narrow QS complexes, the ECG is not specific for severity of AS. With increasing calcification of the perivalvular tissues, heart block and other conduction disturbances are seen, representing a significant issue in the management of patients after surgical AVR (SAVR) or TAVR.

Cardiac Catheterization

Cardiac catheterization *is* indicated in patients in whom the noninvasive data are equivocal (Box 30.1). In addition, coronary angiography before heart surgery is indicated in patients with an increased likelihood of CAD and those with functional MR; coronary CT angiography (CTA) is a potential alternative.[4] The hemodynamics of AS are best recorded with a catheter or catheters placed simultaneously on either side of the aortic valve.[6,42] Unfortunately, most laboratories record femoral artery pressure in lieu of central aortic pressure or do a catheter pullback in lieu of simultaneous pressure tracings; both techniques can result in significant misinterpretation of the severity of aortic valve disease.[43] A variety of other errors in catheterization laboratory pressure measurements makes the catheter-derived valve area generally more variable than desirable in all except a few laboratories; such errors include inherent errors in estimating rather than measuring oxygen consumption and in assuming that the Gorlin constant (originally established for a limited subset of patients[44]) and the valve area itself remain constant under varying loading conditions.[37] In the catheterization laboratory as well, transvalvular flow may be underestimated if there is concomitant AI, resulting in overestimation of the severity of aortic valve disease.

In addition to echocardiography, high-resolution CTA is an increasingly used tool to assess VHD. Planimetry on CTA has been shown to agree well with valve area derived from transesophageal echocardiography (TEE) in high-risk subjects.[45] Valve area (Fig. 30.6) can be traced and calcium scoring can be useful in determining the need for intervention in certain subsets of patients with AS.

Low-Gradient Aortic Stenosis

The critical care unit patient with a low to moderate gradient across the aortic valve, especially in the setting of low CO, represents an important conundrum (and should be differentiated from the patient with aortic *sclerosis*). There are at least three types of low-gradient severe AS that need to be considered[46] (Fig. 30.7): type D2 ("classical" low-flow, low-gradient AS), which incorporates patients with depressed EF and requires differentiation between

• BOX 30.1 Indications for Cardiac Catheterization in Patients With Valvular Heart Disease

General Indications

1. When noninvasive findings are inconclusive or discordant with clinical findings or inadequate imaging is obtained. Class I
2. Exercise hemodynamics in symptomatic patients with chronic primary MR when there is a discrepancy between symptoms and severity of MR at rest (alternatively Doppler echocardiography may be used). Class IIa
3. Right-sided heart catheterization when clinical decision making will be influenced by hemodynamics not otherwise obtainable. (Not in guidelines)

Specific Indications for Coronary Angiography

Class I

1. Before valve intervention in patients with symptoms of angina, objective evidence of ischemia, decreased LV systolic function, history of CAD, or coronary risk factors (including men older than 40 years of age and postmenopausal women).
2. Coronary arteriography is useful to establish etiology of chronic secondary MR and/or to assess myocardial viability.

Class IIa

1. Surgery without coronary angiography is reasonable for patients requiring emergency valve surgery for acute valve regurgitation, disease of the aortic sinuses or ascending aorta, or infective endocarditis.
2. CT coronary angiography is reasonable to exclude the presence of significant obstructive CAD in selected patients with a low/intermediate pretest probability of CAD. A positive coronary CT angiogram can be confirmed with invasive coronary angiography.

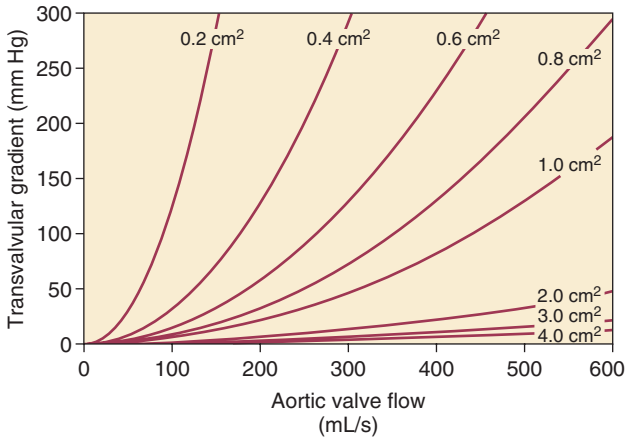
true severe AS and so called pseudo-severe AS; type D3 ("paradoxical" low-flow, low-gradient AS), where LV function is preserved, but the gradient is low because of a typically small left ventricle with very low stroke volume; and normal-flow low-gradient AS (proposed classification type D4). The approaches to these types of low-gradient AS are substantially different, including evaluation, management, and prognosis.

Patients with type D2 with true AS and depressed LV function generate a substantial rise in gradient with dobutamine infusion as long as they have contractile reserve. Because the rules of hydraulics demonstrate that valve area is proportional to flow divided by the square root of the gradient,[44] when the valve area is fixed, as in true severe AS, increased flow is associated with an exponential rise in gradient when valve areas are less than 1 cm^2 (Fig. 30.8). In these patients, the depressed LV function is related to high wall stress (see Fig. 30.3). In contrast, patients with pseudo-severe AS, where the left ventricle is depressed because of a cardiomyopathy and the stenosis is less than severe, inotropic increase in myocardial function results in an improvement in EF as well as an improvement in valve opening and valve area and minimal increase in gradient. The differentiation can be made with dobutamine infusion (typical peak dose 20 μg/kg per minute).[47] In addition to increasing flow across the valve in these patients,[48] the echocardiogram can be useful in several other ways[49]; valve calcification is suggestive of fixed outflow obstruction and, if severe, suggests that the underlying disease is severe AS rather than LV dysfunction. The stenosis is considered severe when the mean gradient with dobutamine rises to 40 mm Hg or higher with little to no change in aortic valve area (AVA). Preserved LV contractile reserve, with significant rise in stroke volume (>20%), peak velocity (>0.6 m/s), or mean transvalvular gradient (>10 mm Hg) at the time of dobutamine infusion is an additional useful marker. Patients with lack of contractile reserve, and hence no significant increase in contractility despite dobutamine, may have true severe AS despite lack of increase in gradient; this has been associated with lower operative survival rate[50] (68% vs. 95% in one study), although it should not be the sole parameter for the decision on whether or not to perform AVR, Patients who survive may manifest significant



• **Fig. 30.8** The relationship between transvalvular flow and transvalvular gradient for given valve areas. An exponential rise in gradient occurs when flow is increased with valve areas in the severe stenosis range (<1 cm^2). The curve demonstrates that change in gradient is proportional to the square of change in flow; thus doubling the flow rate results in a fourfold increase in gradient. (From Gorlin R, Gorlin SG. Hydraulic formula for calculation of the area of the stenotic mitral valve, other cardiac valves, and central circulatory shunts. *Am Heart J.* 1951;41:1–29.)

recovery in LV function postoperatively.[51] Low contractile reserve should not always preclude AVR in patients who do have severe fixed obstruction because their prognosis without surgery is abysmal.[52] Aortic valve calcium scoring (calculated on multidetector computed tomography [MDCT]) may help in distinguishing true from pseudo-AS as well.[53]

Patients with type D3 AS (paradoxical low-flow, low-gradient AS with preserved EF) are characterized by low-flow (stroke volume index <35 mL/m^2), small hypertrophied ventricles with impaired LV filling, and calcification with small valve areas. Dobutamine echocardiography is somewhat controversial in this setting, but MDCT calcium scoring can be useful, and dimensionless index by echocardiography can also provide adjunctive evidence. Although a burgeoning evidence base does show improved results with AVR compared with medical therapy,[54] the overall outcome for these patients has been inferior to patients with classic severe AS, and at best comparable to those seen with AVR in low-flow, low-gradient depressed EF (type D2) AS.[55] Finally, patients with normal-flow low-gradient AS have an AVA less than 1.0 cm^2 (indexed AVA <0.6 cm^2) with mean gradient less than 40 mm Hg, LVEF of 50% or higher but normal flow (stroke volume index >35 mL/m^2). In these patients, a true severe AS may be masked by decreased gradient owing to reduced aortic compliance with high aortic systolic pressure. Reassessment of these patients after controlling hypertension should be performed as a significant proportion of these patients may have true severe AS. Calcium scoring on MDCT is preferred over dobutamine stress echo in these patients to distinguish true severe AS.[56]

Therapy

Medical Management

Medical management is aimed solely at patient stabilization because pharmacologic intervention has never been shown to prolong life and can achieve modest hemodynamic improvement at best. In the critical care setting the approach to the patient with AS normally parallels treatment of corresponding degrees of heart failure, albeit with caution, because the normal therapeutic approach to heart failure can be deleterious or fatal in the setting of severe AS. The traditional heart failure therapies—particularly, diuretics and vasodilators—need to be used with care because reduction in preload can cause hypotension, decreased CO, and a downward spiral into refractory shock. In patients with small-volume hypertrophic left ventricles, CO is particularly preload dependent.

Atrial arrhythmias—particularly atrial fibrillation (AF)—can lead to abrupt and severe decompensation because of loss of the atrial contraction component of LV filling. Cardioversion in the critical care setting is particularly helpful in severely decompensated patients, and maintenance of sinus rhythm in patients who are otherwise suitable (e.g., left atrium <6 cm, recent onset of AF, and absence of clot in the left atrium by TEE) should be a priority.

Despite the caveats, vasodilator therapy, including nitroprusside, has been used in the critical care setting in patients with severe LV dysfunction and severe AS.[57] In a select group of patients not dependent on inotropes, CO rose significantly and there was overall hemodynamic improvement. Similarly, intraaortic balloon pumping (IABP) has been used, although there are only small series with modest demonstration of hemodynamic benefit.[58] As would be expected, both nitroprusside and IABP result in afterload reduction and some increase in transvalvular flow along with some increase in aortic valve gradient.

Hemodynamic monitoring is essential for the pharmacologic management of decompensated patients with severe AS in the critical care setting. Because of the dependence on preload, a fine threshold exists between optimal filling pressures and pulmonary edema. Vasodilator therapy as described earlier results in peripheral vasodilation, but because of the fixed obstruction to outflow it may not provide sufficient increase in stroke volume and CO to maintain systemic blood pressure. Inotropic agents are frequently required, and patients with inadequate contractile reserve may show limited improvement. β-Blockers are relatively dangerous, although tachycardia is hemodynamically unfavorable, even in sinus rhythm. β-Blockade, if used, should be used with great caution. β-Blockers decrease contractility and, in addition, an increase in heart rate (HR) may be the only remaining compensatory mechanism for low stroke volume because of the fixed resistance to outflow. Patients with severe AS can enter a "death spiral" in which hemodynamic recovery becomes impossible.

Lipid-lowering therapy and converting enzyme inhibitors have been the subject of substantial investigation, although their role is in the chronic setting rather than during critical care. Two prospective randomized trials failed to show clear benefits of a statin[59,60] in slowing disease progression; overall the evidence base has not been compelling.[61] Some preliminary evidence suggests potential benefits of angiotensin-converting enzyme (ACE) inhibitors in decreasing progression of aortic valve calcification,[62,63] but the available clinical data do not show slowing of AS progression. Both lipid-lowering and converting enzyme inhibitors need to be tested in larger populations earlier in the course of aortic valve disease.

Percutaneous Interventions

Balloon Valvuloplasty

Balloon aortic valvuloplasty (BAV) is a temporizing measure for patients who are hemodynamically unstable and are at high risk for AVR. Although the procedure is therapeutic and indicated in congenital AS in children and young adults, the risk/benefit ratio as a stand-alone procedure in patients older than their 20s is usually unfavorable. Because calcific AS is associated with open commissures

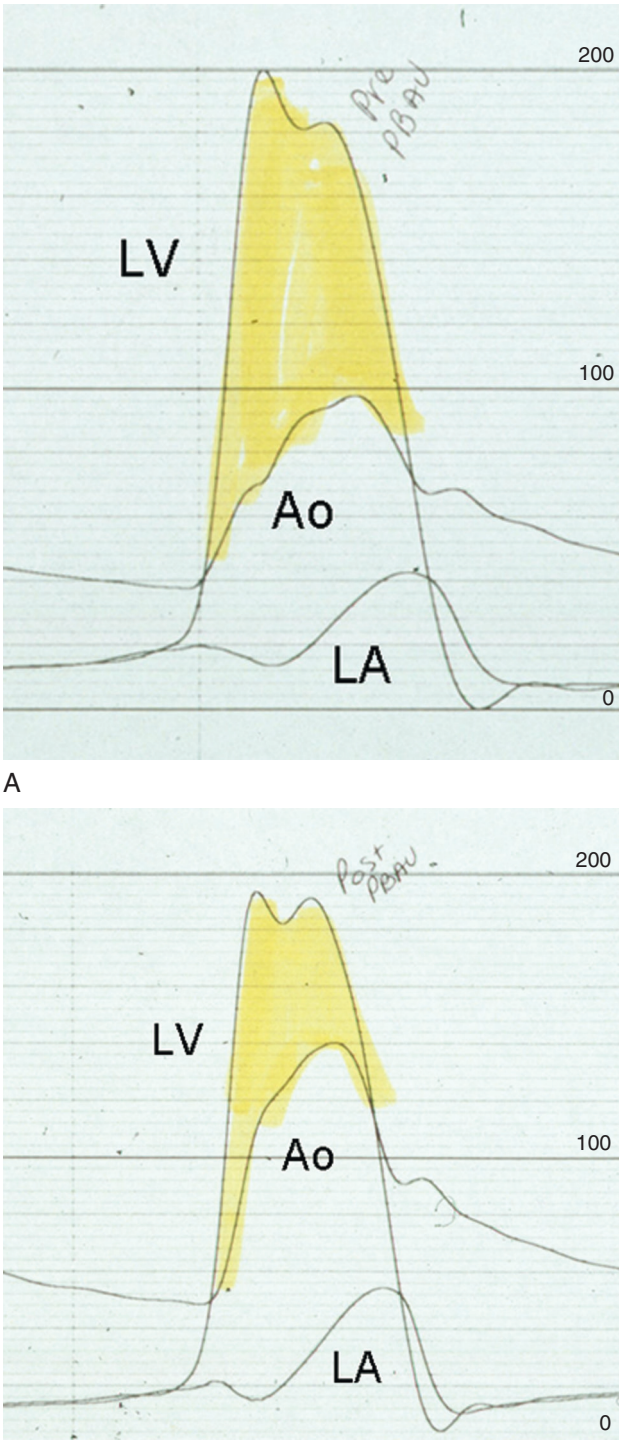
and ossified leaflets, abrupt balloon inflation exerts its effect by improving leaflet compliance through the formation of multiple, usually microscopic, fracture lines in the calcified tissues. Stretching of the commissures is temporary, and any hemodynamic benefit of the latter resolves within hours. The leaflets lose their improved compliance within weeks to months, and the AVA typically returns to baseline.

The acute hemodynamic results (Fig. 30.9) are poor compared with those of AVR, with a 50% reduction in gradient and an increase in AVA of only 0.2 to 0.3 cm^2.[64] The in-hospital mortality rate was close to 10% in the National Heart, Lung and Blood Institute registry[65] and is substantially higher in patients with hemodynamic decompensation and multiorgan failure. Most valves have restenosed within a few months, and the overall outcomes if no additional intervention is performed are very poor; one series reported an 87% mortality rate after a median period of less than 7 months.[66] No benefit for long-term outcomes has been shown. Indeed, the overall clinical course is not influenced by BAV alone.[67] Nevertheless, it can serve as a bridge to TAVR or SAVR in select patients with multiple comorbid conditions and is an alternative but low efficacy measure for patients who are not candidates for TAVR or AVR. It is not an alternative to TAVR or surgery for patients who can undergo valve replacement, even for most patients at relatively high risk for the latter.

Several settings in which BAV was previously considered to have a role are no longer included as indications in the 2014 AHA/ACC guidelines.[4] These include preoperative balloon dilation in patients undergoing noncardiac surgery[68]; in general all but decompensated patients can withstand general anesthesia as long as careful hemodynamic monitoring and anesthesia management are performed.[69] Patients who require urgent noncardiac surgery in the setting of severe symptomatic AS do have a significant perioperative risk,[70] and preoperative TAVR or AVR should be considered if at all possible. In severely hemodynamically compromised patients, BAV has been performed successfully with a variety of hemodynamic support devices, including IABP as well as the Impella device (Abiomed, Danvers, MA).[71,72] BAV has also been proposed as a tool to differentiate less than severe AS with severe myocardial dysfunction from severe AS combined with secondary LV dysfunction in low-gradient, low-output AS.[73] The latter patients typically demonstrate substantial improvement in stroke volume and EF after balloon dilation, but dobutamine stress testing is usually a safer, less morbid screening tool. With the growth of TAVR, the use of BAV as a therapeutic test has gained traction.[74] The 2014 guidelines[4] describe only one (class IIb) indication for BAV: as a bridge to TAVR or AVR. Nevertheless, because of the widespread availability of TAVR and resultant exponential rise in percutaneous AS interventions that include BAV, BAV techniques have improved[75] and the proper role of BAV remains under active debate.[76]

Transcatheter Aortic Valve Replacement

TAVR, a technology developed in the past 2 decades, has revolutionized the treatment of AS. The procedure is of increasing importance in the critical care setting. Tissue valves are sewn to either balloon expandable or self-expanding stents, which are crimped onto a catheter and advanced across the stenotic native valve. Both balloon expandable and self-expanding technologies are widely available (Fig. 30.10A and B). The landmark PARTNER (Placement of AoRtic TraNscathetER valves) study had two cohorts: PARTNER A enrolled high-risk but operable patients, whereas PARTNER B enrolled patients deemed inoperable. PARTNER A randomly



• **Fig. 30.9** Hemodynamic response to percutaneous balloon aortic valvuloplasty *(PBAV)*. Tracings show before (A) and after (B) balloon dilation on a 200-mm Hg scale. A successful 50% reduction in gradient occurs, but residual gradient remains at 50 mm Hg, still in the severe category. The pulse pressure has increased from 60 to 90 mm Hg, the peak aortic systolic pressure has increased to 140 mm Hg from 100 mm Hg, and the aortic pressure upslope can be seen to have improved dramatically. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.

assigned patients to SAVR versus two approaches to TAVR: transfemoral if the iliac and femoral vasculature was suitable for accommodating the large catheter shafts or transapical if not.[77] The results of TAVR compared with SAVR were similar, with published follow-up through 2 years; however, vascular complications and stroke were higher with TAVR and major bleeding and AF were higher with SAVR (see Fig. 30.10C). PARTNER B randomly assigned patients with suitable vasculature to transfemoral TAVR versus medical therapy.[78] Patients who received only medical therapy (with or without balloon valvuloplasty) had a 51% 1-year mortality rate compared with those inoperable patients randomly assigned to TAVR, who had a 31% 1-year mortality rate, an approximately 40% relative reduction (see Fig. 30.10D). Thus TAVR appears to be among the most dramatically successful of all modern cardiac interventions. It is noteworthy that the residual mortality rate in inoperable patients, whether treated with TAVR or medical therapy, remained very high (the 5 year mortality was 93.6% vs 71.8%),[79] reflecting the severe comorbidities in patients who met inoperability criteria. There was an initially higher stroke risk in TAVR patients,[78] but because of the greater ongoing stroke rate in patients treated only with medical therapy, the disparity resolved by 24 months. In general, the risk of stroke appeared to be largely related to patient comorbid conditions that increase stroke risk, rather than the type of valve replacement.[80] Indeed, the risk of stroke in subsequent TAVR trials has been the same or lower than with surgery.[81] The U.S. Food and Drug Administration (FDA) initially approved TAVR for inoperable patients based on the results of PARTNER B and subsequently approved the high-risk population treated in PARTNER A. Thereafter two randomized controlled trials comparing TAVR versus SAVR in intermediate-risk patients with severe AS showed that TAVR was noninferior to SAVR[82,83]; the AHA/ACC 2017 Guidelines Update has given TAVR a class IIa recommendation for patients with intermediate surgical risk, and class I for patients with high surgical risk and those who are inoperable.[84] In addition, there have been excellent results with valve-in-valve (ViV) TAVR for patients with bioprosthetic valve dysfunction (owing to either stenosis or insufficiency).[85,86] The likelihood that transcatheter ViV replacement will eventually supplant reoperation is changing the algorithm for choice of tissue versus mechanical AVR during heart surgery, with a lowering of the recommended age when tissue valves should be considered (rather than mechanical ones) from 60 to 50 years of age.[87] In addition, percutaneous ViV replacement rather than reoperation is now a class IIa indication for both bioprosthetic AS and AR.

The management of TAVR patients after valve replacement initially took place in a critical care unit or open heart recovery area; in the current era of "minimalist" TAVR, there is a shift toward performing TAVR procedures under monitored anesthesia care (MAC) instead of general anesthesia with recovery in step-down units. Nevertheless, critical care physicians and staff remain involved in the immediate postprocedure management and early mobilization and discharge of TAVR patients even as length of stay declines.[88] The persistent but now single-digit rate of major vascular complications[89] associated with TAVR requires careful monitoring for limb ischemia, retroperitoneal hemorrhage, and a variety of other vascular complications. Conduction disturbances, particularly after use of a self-expanding TAVR platform, and especially in patients with existing conduction disturbances, particularly right bundle branch block, continue to occur in a significant percentage of cases, requiring permanent pacemaker placement.[90] Pericardial tamponade can occur infrequently late after TAVR (owing to trauma secondary to wire and catheter manipulation) and should be suspected in patients with hemodynamic compromise. Most operators have treated TAVR patients with lifelong aspirin 75 mg to 100 mg daily plus clopidogrel for periods ranging from 1 to 6 months (class IIb per the 2017 Guidelines[84]). Evidence that thrombus formation takes place after TAVR[91] (and SAVR with bioprosthetic valves) has led to a class IIb indication for anticoagulation after TAVR

for at least 3 months and class IIa indication for 3 to 6 months anticoagulation after SAVR in patients at low risk of bleeding.[84] A number of issues, such as the use of dual antiplatelet therapy plus anticoagulation after TAVR in patients with AF, remain to be fully investigated, but these are associated with high bleeding risk; as such, non-AF patients treated with anticoagulation typically receive concomitant aspirin only.[92]

Surgical Aortic Valve Replacement

AVR remains the treatment of choice for severe AS in patients who are considered to have low operative risk. Class I indications are severe AS (valve area <1 cm^2) with symptoms or, regardless of symptoms, if patients have severe AS and are undergoing coronary artery bypass, are undergoing surgery of the aorta or other heart valves, or have LV dysfunction. A long list of class II indications generally focuses on patients who do not meet class I criteria but are thought to be at increased risk because of rapid disease progression, abnormal stress test results, or "very severe" AS (as defined by a maximum velocity ≥5 m/s or mean gradient threshold ≥60 mm Hg). In addition, patients with moderate AS who undergo other cardiac surgery generally have simultaneous AVR. Survival after AVR is excellent if LV function is preserved, with an operative mortality rate in ideal candidates as low as 1%. In these patients, age-matched survival is not significantly different from patients without AS.[93] In the setting of LV dysfunction, however, postoperative life expectancy is relatively poor.[94] Nevertheless, conservative therapy for severe AS remains an undesirable alternative. A review of 453 patients treated without intervention despite severe AS had 1-year, 5-year, and 10-year survival rates of only 62%, 32%, and 18%, respectively,[95] with the worst survival in patients with renal failure, pulmonary hypertension, age older than 75 years, diminished EF, and congestive heart failure.

A number of technological advances in the SAVR arena have decreased the morbidity of AVR along with shorter length of stay. These include minimally invasive surgery and the use of sutureless valve replacement,[96,97] both of which need formal high-level comparison to TAVR. The postoperative management of AVR patients includes antiplatelet and anticoagulation therapy as discussed earlier and in the 2017 guidelines; an important caveat is that anti-Xa anticoagulants are contraindicated for mechanical valves (class III harm). The level of anticoagulation after surgery is specific to prosthetic valve type and location.[84]

Aortic Insufficiency

The overall prevalence of moderate or severe AI in the United States, as shown in the Framingham Offspring Study, ranged from 0.3% in the fifth decade of life to 2.2% for patients aged 70 to 83.[98] The frequency is age and male gender related. The diagnosis of AI is more difficult and the treatment issues in many ways more complex than for AS, with a less clear dichotomy in the decision tree for valve replacement. AI needs to be considered in light of its acuity: Acute AI is usually associated with life-threatening comorbidities and the resultant acute regurgitation places great stress on the left ventricle and may itself be fatal. In contrast, it may take decades for chronic AI to evolve from clinically insignificant to requiring surgery. Unlike AS, it is not primarily a disease of the aging process (although it does occur more frequently with increasing age) and is typically secondary to one of an extensive list of systemic or structural pathologies that result in insufficiency of the aortic valve. Acute AI frequently requires urgent surgery, whereas chronic AI may be managed by watchful waiting and some limited options for medical therapy, although the trend is for operating earlier than in prior decades.

• BOX 30.2 Etiology of Acute and Chronic Aortic Insufficiency

Acute
- Infective endocarditis
- Aortic dissection
- Trauma

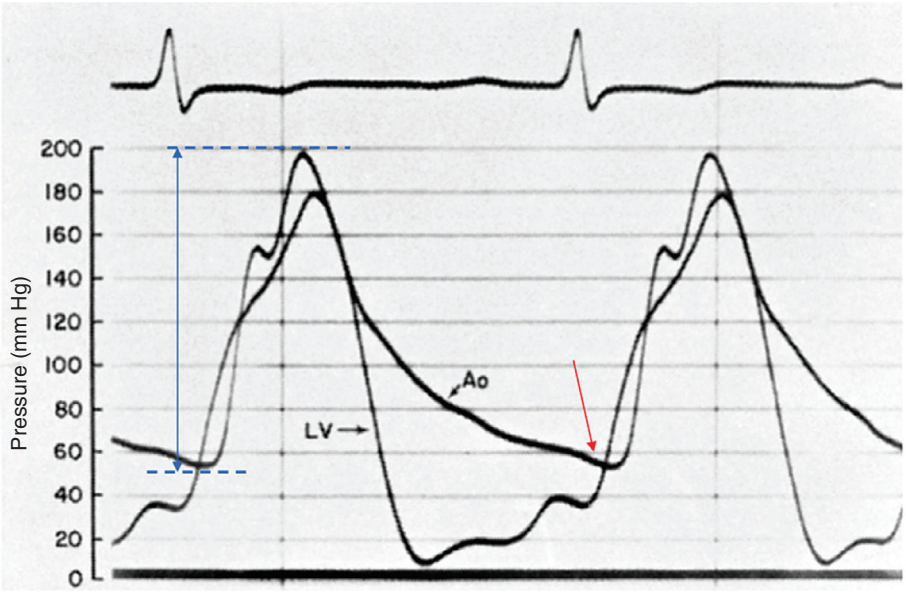
Chronic
- Dilation of the aorta
  - Systemic hypertension
  - Bicuspid aortic valve
  - Calcific degenerated aortic valve disease
  - Aortic dissection
  - Marfan syndrome
  - Trauma
  - Ankylosing spondylitis
  - Syphilis
  - Rheumatoid arthritis
  - Osteogenesis imperfecta
  - Giant cell aortitis
  - Ehlers-Danlos syndrome
- Rheumatic aortic valve disease
- Infective endocarditis
- Myxomatous degeneration
- Ventricular assist device use
- Subaortic stenosis
- Ventricular septal defect with cusp prolapse
- Anorectic drug reaction
- Prosthetic paravalvular leak

Pathophysiology

Acute AI is generally associated with leaflet involvement by endocarditis or disruption of the aortic valve's annular structure by dissection or trauma. Chronic AI, by contrast, is caused by congenital valve abnormalities, most importantly bicuspid aortic valve disease, or by the degenerative process described earlier associated with AS. Conditions that distort the annulus and aortic root including systemic hypertension have been considered as important causes of secondary AI, although the association between chronic AI and systemic hypertension remains to be confirmed.[99] Rheumatic AI, almost invariably associated with mitral valve involvement as well, remains prevalent in developing countries.

In general, causes of AI (Box 30.2) have been divided into those that affect the leaflets primarily and those that affect the root and annulus. The former group includes bicuspid and other aortic valve abnormalities, endocarditis, rheumatic aortic valve disease, the atherosclerotic process described earlier, connective tissue disorders, antiphospholipid syndrome (Libman-Sacks endocarditis), and toxicity from anorectic drugs.[100] The aortic root and annulus are affected by a variety of comorbidities that dilate the aortic root; Marfan and Ehlers-Danlos syndromes; osteogenesis imperfecta; chronic aortic dissection; syphilitic aortitis; connective tissue disorders; and, along with the valve leaflets, ankylosing spondylitis. AI is commonly seen in patients with long-term implantation of ventricular assist devices, with moderate or severe AI occurring in perhaps a third of these patients (see Chapter 7).[101]

In isolated acute AI, the sudden onset of regurgitation imposes a large-volume load on the left ventricle in diastole before an adaptive process is in place. The abrupt rise in pressure is reflected by parallel development of left atrial and pulmonary vascular hypertension, frequently resulting in pulmonary edema. Because the compliance of a previously unaffected left ventricle is not sufficient to allow adequate dilation to absorb the regurgitant volume, the ventricle operates on the steep portion of its pressure-volume curve, with inadequate stroke volume to accommodate the high regurgitant flow. The effective (net) forward stroke volume (antegrade flow minus retrograde filling) is therefore low,



• **Fig. 30.11** The hemodynamics of acute aortic insufficiency. The wide pulse pressure (150 mm Hg) difference between peak and minimum aortic pressure *(blue arrow)* and near diastasis of left ventricular and aortic pressure late in diastole *(red arrow)* are demonstrated. *Ao,* Aorta; *LV,* left ventricle. (Modified from Grossman W. Profiles in valvular heart disease. In Baim DS, ed. *Grossman's Cardiac Catheterization, Angiography and Intervention.* 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:654.)

compensated to some degree by tachycardia, but frequently insufficient to maintain normal CO. This phenomenon is exaggerated in patients with preexistent LV hypertrophy in whom the ventricle is already operating on the steep portion of its pressure-volume curve, and particularly severe decompensation is seen when the left ventricle is small and hypertrophic. Critical care settings for the latter unfortunately include many of the common scenarios for acute AI, including endocarditis in the setting of AS, and aortic dissection in patients with hypertension and a dilated aortic root.[4]

Acute severe AI results in near approximation of aortic and LV pressures at end diastole, with consequent deleterious effects on coronary perfusion of the subendocardium (Fig. 30.11). Because coronary perfusion pressure is the difference between diastolic pressure in the aortic root and subendocardial pressure in the LV cavity, the decrease in aortic diastolic pressure and rise in subendocardial pressure that are hallmarks of acute AI can result in profound subendocardial ischemia, especially in patients with preexistent hypertrophy or patients with underlying CAD. In addition, because afterload and wall stress in this setting are increased, there is a rise in myocardial oxygen demand simultaneous with a fall in supply, occasionally leading to cardiogenic shock and death. Acute AI also results in early closure of the mitral valve as LV diastolic pressure rises above left atrial pressure, a phenomenon that has potential protective benefits for the pulmonary circulation.

In contrast, chronic AI features a host of adaptive processes by the left ventricle, including progressive dilation, increased compliance, and hypertrophy. As with AS, hypertrophy results in lower wall stress, but AI features an increase in afterload combined with progressive LV dilation and somewhat less hypertrophy, resulting in significantly higher wall stress than seen in compensated AS.[102] End-diastolic dilation of the left ventricle allows for larger stroke volumes to compensate for regurgitant fractions, which may be in the range of 50% or greater. With combined pressure and volume overload, unique among the valve disorders discussed in this chapter, LV adaptations allow for maintenance of normal overall function until ventricular remodeling and hypertrophy are no longer sufficient to maintain forward stroke volume and EF. With increasing wall stress and LV dilation, LV contractility is eventually impaired, at which point filling pressures begin to rise (or rise further) and patients become symptomatic. Coronary flow reserve in AI, as with AS, is impaired and, combined with increased demand and the need for additional perfusion for a hypertrophic myocardium, may result in significant ischemia. The onset of symptoms may be abrupt, especially with new onset of atrial tachyarrhythmias or sudden increase in CO demand such as with exertion or infection.

Although acute AI represents a relative or absolute medical emergency, chronic AI may have an insidious course over decades. In a review of nine admittedly heterogeneous studies incorporating nearly 600 primarily asymptomatic or mildly symptomatic patients with AI, average progression to symptoms with or without LV systolic dysfunction was 4.3% annually, and sudden death occurred in 0.2% per year.[103] Although this rate of progression is modest, patients do not necessarily develop symptoms before developing LV dysfunction or sudden death.[104] Age, end-systolic dimensions,[105] and rate of deterioration of end-systolic dimension and EF[106] are more sensitive tools for predicting outcome in chronic AI.

In contrast, in the setting of *symptomatic* AI that does not fall in the acute severe category, an annual mortality rate of 6% to 25% has been described, depending on severity of symptoms. By the 10-year follow-up, 75% had undergone AVR or died.[107]

Diagnosis

Physical Examination

The hallmarks of *acute* severe AI include features consistent with congestive heart failure and low CO, including tachycardia, dyspnea,

and signs of impaired CO such as peripheral vasoconstriction. The wide pulse pressure that is a hallmark of AI may or may not be seen, in part because it is dependent on LV compliance. The classic AI murmur may not be heard because of the limited gradient between the aorta and left ventricle during diastole when LV diastolic pressures in some cases approach systemic diastolic pressures. Tachycardia and diminished effective forward flow in acute AI may offset the augmented systolic and wide pulse pressure seen in later stages of the disease, and these patients may have normal or occasionally diminished pulses, although more moderate acute AI may feature the more classic findings. Early closure of the mitral valve may result in a soft first heart sound, and distortions of leaflet anatomy may result in lack of a distinct aortic second heart sound. In some cases absence of a second heart sound in a patient presenting with cardiogenic shock may be the most prominent physical finding.[100]

The dramatic physical findings in *chronic* AI are among the most familiar to physicians and trainees. A wide pulse pressure results primarily because of increased stroke volume, which augments systolic pressure[108] and low aortic diastolic pressures because of volume runoff into the left ventricle. This in turn results in a large variety of associated eponymous physical findings, including bounding carotid and peripheral pulses (Corrigan and water-hammer pulses, respectively); Hill's sign (dramatically higher systolic pressure in the legs than the arms because of the exaggerated effect of harmonics on systolic pressure waveforms, variously described as having a 20 or 40 mm Hg threshold); Duroziez's sign (to-and-fro murmur over the femoral arteries); and Traube's sign ("pistol shot" sound over the femoral artery during simultaneous compression). With LV dilation, the apical impulse is displaced laterally.

The intensity and duration of the classic diastolic decrescendo murmur heard over the left midsternal border generally correlates well with the severity of AI,[109] although in later stages of decompensation (or in acute AI), when the gradient between the aorta and the left ventricle disappears in later stages of diastole, the murmur typically shortens. When the murmur is better heard over the right (rather than left) sternal border, the cause of the AI may be secondary to a dilated aortic root rather than a primary leaflet abnormality.[110] Two other murmurs are frequently heard with moderate to severe AI: a systolic ejection murmur consistent with increased transvalvular flow and on occasion an Austin Flint murmur. The latter is the apical diastolic rumble occasionally confused with MS and thought to originate from vibration of the anterior mitral leaflet caused by the diastolic regurgitant jet originating at the aortic valve; it has been described only in the setting of severe AI.[110] In rheumatic AI, if a diastolic rumble is heard, MS should be excluded. An S_3 gallop is most likely to be present when severe AI occurs in a setting of depressed LV function[111] but may merely reflect substantial volume loading; the finding is not specific.

Noninvasive Evaluation

As with AS, noninvasive assessment has replaced cardiac catheterization for determining severity of AI. It provides both structural and physiologic information, including visualization of the leaflets, annulus, and aortic root; semiquantitative assessment of the severity of AI; and characterization of LV size, hypertrophy, and function, as well as other structural heart disease. TEE has superior diagnostic sensitivity to transthoracic echocardiography for certain parameters, in particular for detection of valvular vegetations.[112] A wide range of techniques for measurement of AI severity, including width of the color Doppler jet compared to the size of the LVOT, width of the vena contracta, regurgitant volume, regurgitant fraction, pressure half-time, and regurgitant orifice area, are described in Chapter 8. Additional findings of importance are the rate of jet velocity deceleration as diastasis is achieved between aortic and LV diastolic pressures and duration of diastolic flow reversal in the aorta.[113] In addition to echocardiography, cine MRI can assess severity of AI, size of chamber volumes, LV mass, wall thickness, and systolic function[114] as well as regurgitant volume, with good reproducibility[115] and is indicated[4] (class I) when echocardiography data are equivocal. LV size and function have also been followed serially by radionuclide ventriculography.[116]

The size and function of the left ventricle have been used to set thresholds at which AVR should be considered. The AHA/ACC guidelines[4] and the European Society of Cardiology guidelines[117] largely correlate but have set slightly different values for class I and II recommendations.[118] The echocardiogram-based recommendations for AVR for severe asymptomatic AR include LV end-diastolic dimension thresholds of 65 mm or 70 mm and end-systolic dimension greater than 50 mm along with variable consideration of whether the LVEF is greater than 50%. An additional consideration relates to patients with aortic root dilatation (aortic root dimension >45 to 55 mm with the thresholds varying for patients with bicuspid valves or Marfan syndrome).[117] As the observational data have grown, these numbers have shifted slightly from the familiar "rule of 55s," which recommended surgery for asymptomatic patients with EF less than 55% or LV end-systolic dimension greater than 55 mm. An important consideration is that the end-systolic and end-diastolic dimensions should be adjusted downward for patients with small BSA. The rate of dilatation of the left ventricle and rate of deterioration in LV function are also important parameters. It is important to keep in mind that these threshold values can be confounded by comorbid conditions that affect chamber size and function, including ischemic and other forms of cardiomyopathy, as well as multivalvular disease.

The ECG was once an important tool in the serial assessment of patients with AI. Similar to AS, features of LV hypertrophy may be present. Progression of LV dilation and dysfunction were thought to correlate with development of an LV strain pattern on ECG, a phenomenon that has been confirmed.[119] As a result, because the use of digitalis glycosides (which has decreased substantially in general) can cause a similar strain pattern, it was discouraged to maintain relative specificity of the ECG finding. Conduction disturbances remain an important feature, particularly heart block in the setting of endocarditis, discussed subsequently.

Cardiac Catheterization

As with the other valvular diseases discussed in this chapter, cardiac catheterization (other than coronary angiography) is indicated only for patients with inconclusive noninvasive findings or when noninvasive findings are discordant with the rest of the clinical picture. Typical findings include a wide aortic pulse pressure and an exaggerated rise in LV diastolic pressure, reflecting continuous retrograde filling during diastole (see Fig. 30.11). Cardiac catheterization in this setting normally includes aortic root angiography, although the latter requires a significant dye load (typically ≥30 mL/s for up to 2 seconds) to be diagnostically accurate. The hallmark of severe AI is greater opacification of the left ventricle than the aorta. The indications for coronary angiography in this setting are listed in Box 30.1.

Therapy

Medical Management

In acute AI, medical therapy is targeted to stabilization pending urgent or emergent AVR. Nitroprusside has been the standard for

reducing peripheral vascular resistance and improving net forward flow across the aortic valve since the 1970s.[120] The use of arterial vasodilators is more complex when the patient is already hypotensive, and a combination of inotropes and afterload reduction should be considered. Although afterload reduction in this setting is highly beneficial, the otherwise optimal combination of afterload reduction and augmented diastolic pressure normally provided by IABP in cardiogenic shock (see Chapter 7) is normally not a viable choice in AI. Counterpulsation during diastole increases the severity of AI with potentially catastrophic consequences; it typically represents an absolute contraindication to the intraaortic balloon pump.

Besides vasodilator therapy, maneuvers to raise the HR may be helpful, especially in patients who are bradycardic or have a normal HR. Tachycardia disproportionately decreases the diastolic filling period, thereby decreasing the duration of regurgitation across the aortic valve. Both isoproterenol and electrical pacing to raise the HR have been used with therapeutic benefit.

In *chronic* AI, the evidence base is incomplete and somewhat controversial. The general consensus is that asymptomatic patients with mild to at most moderate AI with normal LV function who are not hypertensive do not require or benefit from vasodilator therapy.[104,106] Hypertension (systolic blood pressure > 140 mm Hg) should be treated with a dihydropyridine calcium channel blocker or an ACE inhibitor or angiotensin receptor blocker (class I indication), and if a patient is not a surgical candidate, vasodilators can be used in the setting of symptomatic heart failure and/or LV dysfunction (class IIa indication).[4] Class II indications are short-term treatment to optimize the patient's hemodynamic status before AVR and, more controversially, long-term therapy for asymptomatic patients with severe AI but preserved LV function. Two important studies with divergent results were performed. One study, using nifedipine, appeared to demonstrate some slowing of progression to need for AVR compared with patients using digoxin.[121] The second study, a placebo-controlled trial failed to demonstrate clear benefits of vasodilator therapy with either nifedipine or an ACE inhibitor,[122] but there are concerns regarding the size of the study, dose of drug used, and modest severity of disease at baseline.

Oral vasodilators that have been described as having potential therapeutic benefit include several dihydropyridine calcium channel blockers (nifedipine and felodipine), as well as hydralazine. The appropriateness of vasodilator therapy regardless of severity of disease is clearer in patients with systemic hypertension, in whom reduction of afterload has dual benefits. The dose of drug should be sufficient to show at least some reduction in systolic pressure. There is no evidence base to recommend other forms of medical therapy, such as nitrates or drugs commonly used to treat congestive heart failure, to prevent progression of disease in chronic asymptomatic AI. Nevertheless, there is a general consensus that ACE inhibitors or ARBs as well as β-blockers are reasonable in patients with severe symptomatic AI and/or those who have LV dysfunction[123]; β-blockers in general should be used with caution because of potential deleterious effects of negative chronotropy. In the critical care setting, inotropes and vasodilators are appropriate if patients have congestive heart failure, a low output state, or both.

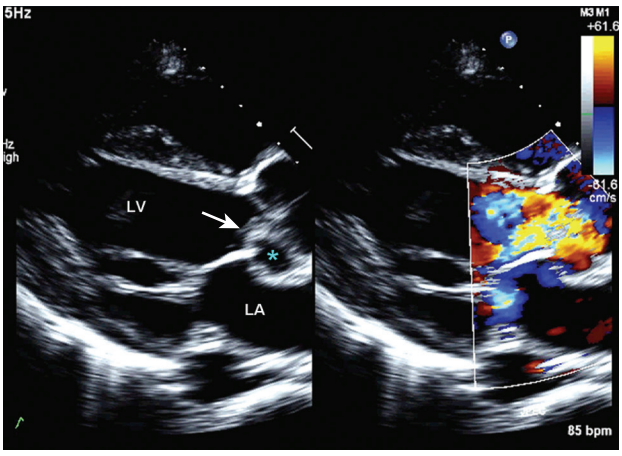
Aortic Valve Replacement

Two factors primarily determine when a patient should be referred for valve replacement for aortic insufficiency: the presence of symptoms and findings of LV systolic dysfunction.[4] Surgery results in superior long-term survival compared with medical therapy alone for symptomatic patients.[107,124] Similarly, patients with LV dysfunction have an inverse correlation between EF and mortality risk.[125] Three AHA/ACC class I indications for surgery, all for patients with severe AI, exist: (1) patients with symptoms regardless of LV function; (2) patients with LV systolic dysfunction (EF ≤ 50%) regardless of symptoms; and (3) patients undergoing coronary bypass surgery or surgery on other heart valves or the aorta. Several devices are being developed for TAVR for native aortic valve insufficiency; these typically attach by clipping onto the existing leaflets rather than attaching to leaflet calcification. The JenaValve (JenaValve Technology, Inc., Irvine, CA) is CE (European Conformity) marked for this indication.

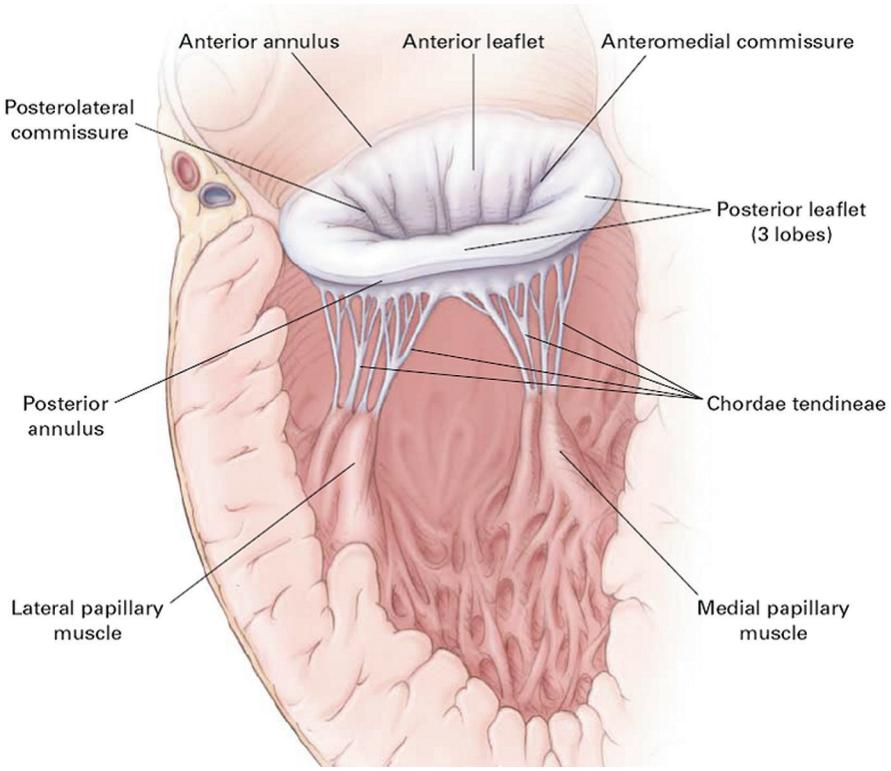
The AHA/ACC guidelines lowered the thresholds for AVR in 2014[4] for patients with chronic severe AI. For asymptomatic patients with preserved LVEF (≥50%) who show signs of LV dilatation, the threshold is set at 50 mm as the end-systolic threshold (class IIa) and 65 mm as the end-diastolic threshold (class IIb and assumes the patient is low surgical risk). Patients with only moderate (progressive) AI who are undergoing other cardiac surgery are also considered to have class II indications.

The question of whether it is ever too late to perform AVR in patients with AI has been raised.[108] Because the disease involves high afterload and wall stress, there is postoperative improvement in EF[126] even in patients with severe baseline LV dysfunction. In general, there is substantial reversal of the physiologic adaptations required by chronic severe AI in the postoperative state.[127] Nevertheless, delay in referring patients for surgery is deleterious, with significant negative impact on outcomes[128]; the prognosis is adversely affected both by the severity and duration of LV dysfunction.[129] This includes a fourfold increase in the operative mortality rate for patients with EF less than 35% (14%) compared with those with EF greater than 50% (3.7%). Thus the trend has been for earlier referral of symptomatic patients and more aggressive noninvasive monitoring for early detection of deterioration in LV function or dimensions.

Special consideration should be given to patients with acute aortic valve endocarditis. Deteriorating hemodynamics mandate early surgery,[84] as do the following conditions: extension of infection, as manifest by progressive heart block and ring abscess formation on echocardiography (Fig. 30.12); recurrent emboli and persistent vegetations despite antibiotics or mobile vegetations greater than 10 mm in length; infection with *Staphylococcus aureus* organisms,



• **Fig. 30.12** Vegetation *(arrow).* On the right is wide-open aortic insufficiency; the jet fills the outflow tract. The asterisk on the left refers to a walled-off echolucent abscess cavity. *LA,* Left atrium; *LV,* left ventricle.



• **Fig. 30.13** Structure of the mitral valve, its surrounding apparatus, and relationship to the left ventricle. Each component can contribute to the presence and extent of mitral regurgitation. (From Otto CM. Evaluation and management of chronic mitral regurgitation. *N Engl J Med*. 2001;345:740–746.)

fungi, or other highly resistant organisms[4]; or the occurrence of stroke without intracranial bleeding or extensive neurologic damage.[130,131] Despite the semielective nature of the operation (with an operative mortality rate close to 10%) and the theoretical risk of an infected prosthesis, the long-term outcomes have been satisfactory, with 75% 10-year survival rate after hospital discharge.[132]

Mixed Aortic Valve Disease

Mixed aortic valve disease (MAVD) denotes the presence of both AS and AI. This combination results in both pressure and volume overload that appears to have an additive effect on severity of symptoms as well as on outcomes. As such, the 2014 Guidelines[84] incorporate a higher valve area threshold (≥1.0 cm^2) for the class D1 category of severe AS (see Table 30.2). The prognosis and management of MAVD are less well studied than isolated aortic valve disease, but in general the available literature suggests an adverse effect on overall prognosis.[133] In a study from the Mayo Clinic,[134] patients with moderate MAVD demonstrated adverse event rates similar to those of patients with severe AS, and higher than in patients with either isolated moderate AS or AI. In addition, in a subset of MAVD patients with concentric hypertrophy, patients tended to become symptomatic, requiring AVR even in the absence of any progression of the severity of aortic valve disease. The recommendation is for closer echocardiographic and clinical follow-up in patients with MAVD.[84] In a multicenter registry of patients undergoing TAVR,[135] the incidence of MAVD was approximately 40% and MAVD was associated with lower device success and higher postprocedural AI; the latter was associated with increased cardiovascular mortality. TAVR is currently not FDA approved for treatment of predominant AI.

Mitral Regurgitation

Anatomically and physiologically, the mitral valve is the most complex of the heart valves, dependent for function on the interaction among leaflets, annulus, commissures, and the supporting apparatus consisting of chordae tendineae tethered to the papillary muscles (Fig. 30.13). Distortion or dysfunction of any of the elements and changes in function and geometry of the left ventricle and left atrium can all have a significant impact on flow across the mitral valve. In addition, unlike other valvulopathies, the mitral valve is highly dependent on the myocardial circulation. In contrast with the relatively passive nature of opening and closing of the aortic valve, mitral valve motion is an active process reflecting not only cyclical pressure variations but also tethering and dynamic interaction with the supporting apparatus. As with AI, MR has acute and chronic manifestations and chronic (rather than acute) insufficiency is more common. However, acute MR has a much larger variety of causes than acute AI and the overall incidence is higher. Data from the Framingham Offspring Study revealed a prevalence of moderate or greater MR from 0.9% of women in the fifth decade of life to 11.2% of men between ages 70 and 83, which was correlated with age, low body mass, and systemic hypertension.[98] As with AI, ventricular function predicts overall outcomes. Chronic MR can both cause and be the result of LV remodeling and heart failure and, when secondary to LV dysfunction, is associated with a significantly poorer overall prognosis than LV dysfunction without secondary MR.[136]

Pathophysiology

Fundamental understanding of the pathophysiology of MR has expanded substantially in the past two decades. In particular, awareness of the role of the subvalvular apparatus in preserving LV function and data demonstrating the need for earlier referral to surgery have resulted in significant changes in clinical and surgical practice, leading to substantial improvement in outcomes.[137]

As with AI, MR results in volume overloading of the LV. Unlike AI, the afterload is not increased and overall LV ejection is enhanced rather than impaired by loading conditions, although in significant MR half or more of the ejection is retrograde into the left atrium. The incompetent mitral valve acts as a second pathway for blood ejection, which reduces afterload in a setting in which preload is increased, thus potentiating ejection via the Frank-Starling mechanism. The combination ultimately may raise EF to supranormal early in the course of the disease. As a result, patients with "normal" EF may already have significant impairment in LV function.[138] Adaptations to the volume loading include lengthening of the myocytes, which increases LV volume. Progressive MR eventually results in contractile dysfunction. Relatively early in the course of the disease, the sympathetic nervous system is activated as a compensatory mechanism to volume loading and decreased forward ejection.[139] Chronic high sympathetic tone results in secondary myocardial damage[140] and has been postulated as the rationale for potential benefit from β-blockade in chronic MR.[141] Over time, although some hypertrophy develops, the predominant response to volume overload without pressure overload is enlargement of chamber size. Extrapolating the LaPlace relationship, which is manifestly protective of wall stress in AS, the progressive expansion of LV dimensions in MR without similar compensatory hypertrophy results in increasing wall stress, which in turn results in increasing MR. In a similar manner, a second vicious circle is caused by the effect of MR on LV chamber size, which, as it enlarges, results in stretching of the annulus, further exacerbating MR.[142] Thus chronic MR can both cause and be the result of LV remodeling and heart failure.

The causes of MR vary by geography, with mitral valve prolapse the most common cause in industrialized nations. Rheumatic MR remains common in developing countries. The causes of acute MR include ischemic MR, endocarditis, chordal rupture, papillary muscle dysfunction, and a variety of pathologies affecting prosthetic valves (Box 30.3). The most likely causes of acute MR in the critical care setting are ischemia, including acute myocardial

• BOX 30.3 Etiology of Acute and Chronic Mitral Insufficiency

Acute

Mitral Annular Disorders
Infective endocarditis (with abscess)
Trauma (e.g., valve surgery)
Paravalvular leak
- Surgical—suture interruption
- Infection

Mitral Leaflet Disorders
Infective endocarditis (with perforation or vegetation interfering with coaptation)
Trauma
Atrial myxoma
Myxomatous degeneration
Systemic lupus erythematosus (Libman-Sacks lesions)

Chordal Rupture
Spontaneous
Myxomatous degeneration
- Mitral valve prolapse
- Marfan syndrome
- Ehlers-Danlos syndrome

Infective endocarditis
Acute rheumatic fever
Trauma

Papillary Muscle Disorders
Coronary artery disease
Acute global left ventricular dysfunction
Infiltrative diseases (amyloidosis, sarcoidosis)
Trauma

Primary Mitral Valve Prosthetic Disorders
Bioprosthetic cusp perforation
Bioprosthetic cusp degeneration
Mechanical failure (e.g., strut fracture)
- Immobilized disk or ball

Chronic Disorders

Inflammatory
Rheumatic heart disease
Systemic lupus erythematosus
Scleroderma

Degenerative
Myxomatous degeneration (mitral valve prolapse)
Marfan syndrome
Ehlers-Danlos syndrome
Pseudoxanthoma elasticum
Calcification of mitral valve annulus

Infective
Endocarditis

Structural
Ruptured chordae tendineae
Spontaneous secondary to:
- Myocardial infarction
- Trauma
- Mitral valve prolapse
- Endocarditis
- Rupture or dysfunction of papillary muscle (ischemia or infarction)

Dilation of mitral valve annulus and left ventricular cavity
- Congestive cardiomyopathies
- Aneurysmal dilation of the left ventricle

Hypertrophic cardiomyopathy
Prosthetic paravalvular leak

Congenital Disorders
Mitral valve clefts or fenestrations
Parachute mitral valve abnormality in association with other congenital disorders

From Otto CM, Bonow RO. Valvular heart disease. In: Mann DL, Zipes DP, Libby P, et al., eds. Braunwald's Heart Disease; A Textbook of Cardiovascular Medicine. *10th ed. Philadelphia: Elsevier; 2015:1446–1523.*

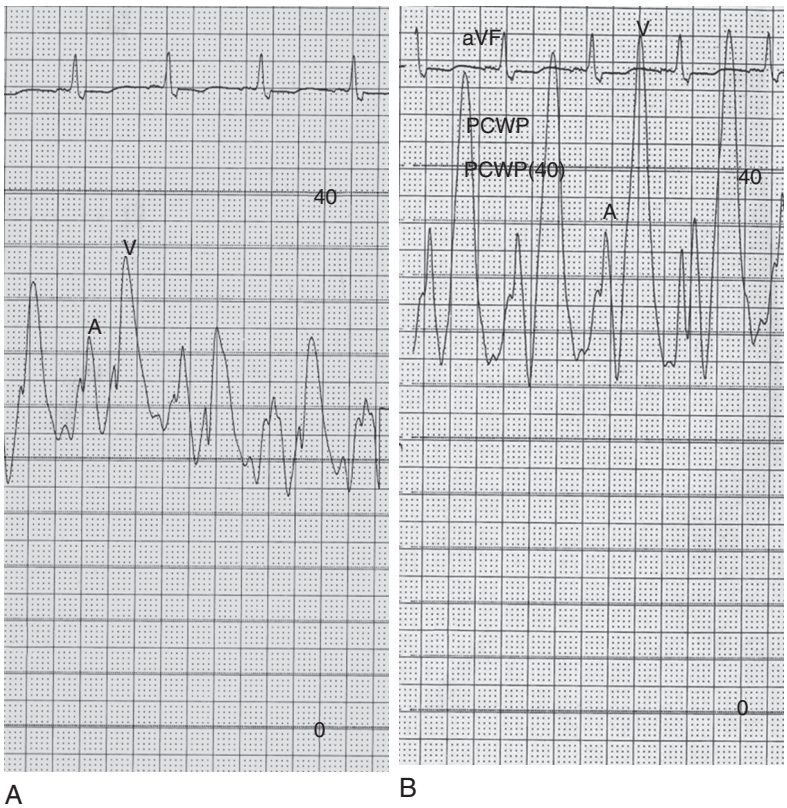
infarction (AMI), and infectious endocarditis, and should be considered in any patient who develops sudden hemodynamic decompensation in the peri-infarction period or who has known endocarditis. Chronic MR is secondary to a variety of structural, degenerative, connective tissue, inflammatory, and ischemic disorders, as well as congenital abnormalities outlined in Box 30.3.

The classic teaching has been that acute MR secondary to ischemia was caused by papillary muscle dysfunction, most likely secondary to ischemia of the posteromedial papillary muscle, which is dependent on a single blood supply from the right coronary artery. The anterolateral papillary muscle typically has dual circulation from the left anterior descending and circumflex coronary arteries, specifically from a diagonal branch and a circumflex marginal branch. The source of papillary muscle circulation is in fact variable, and on occasion the anterior papillary muscle also has a single blood supply.[143] The role of impaired circulation to the papillary muscle as the cause of ischemic MR has been revisited,[144] and evidence to date suggests that ischemic MR is secondary to alterations in ventricular geometry and leaflet tethering rather than dysfunction caused solely by impaired circulation to the papillary muscle during ischemia,[145] although alterations in papillary muscle geometry can be seen in chronic ischemic MR.[146] The hemodynamics of dynamic, ischemic MR are shown in Fig. 30.14.

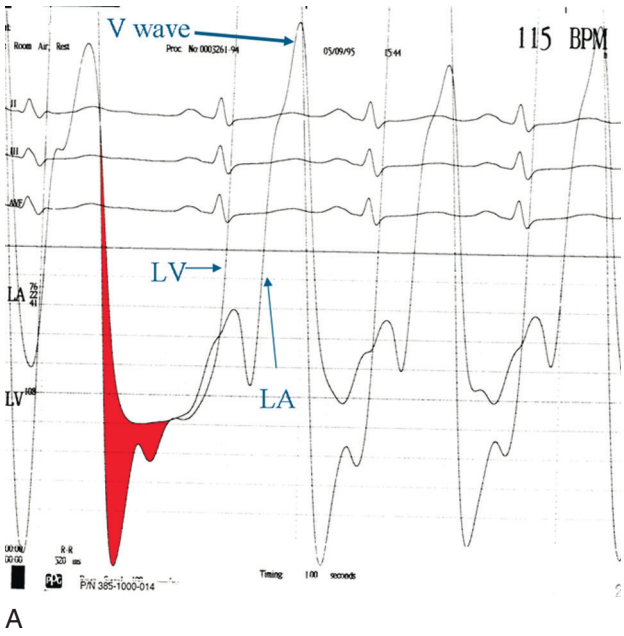
Analysis of thrombolysis in myocardial infarction (MI) data showed a 27% incidence of MR (most commonly in the setting of anterior rather than inferior MI), although these values vary widely by criteria and techniques used for screening, with the incidence ranging from 11% to 59%.[147] A Mayo Clinic review of more than 1300 patients with AMI found moderate to severe MR in 12% and found it to be an independent predictor of both heart failure and survival.[148] It is associated with multivessel CAD, as well as prior infarction.[149]

Papillary muscle rupture is a rare but potentially catastrophic cause of flail leaflets and represents a surgical emergency.[150] In addition to the typical AMI setting, it may be secondary to trauma and isolated other causes such as postpartum Ehlers-Danlos syndrome.[151] Other causes of acute MR to consider (see Box 30.3) include spontaneous chordal rupture, infectious endocarditis with distortion of the valve leaflets or chordal rupture, and prosthetic valve dysfunction including paravalvular prosthetic valve leak. In patients with sudden onset of acute MR, retrograde flow is typically into a normal-sized and relatively noncompliant left atrium unless preexisting atrial hypertension has been present. The sudden volume loading immediately places the left atrium on the steep portion of its pressure-volume curve, which commonly causes acute pulmonary edema. As is the case with acute AI, the left ventricle is unable to adapt acutely and effective forward stroke volume is decreased. In the setting of MI in particular, patients with acute MR may develop cardiogenic shock.

The classic hemodynamic response, a giant V wave, is shown in Fig. 30.15. Differentiating a giant V wave from a prominent pulmonary artery pressure waveform can be difficult in the critical



• **Fig. 30.14** Dynamic mitral insufficiency in a patient with transient left ventricular dysfunction after recent acute myocardial infarction. The panel on the left (A) demonstrates hemodynamics on a 40-mm Hg scale at baseline. Note elevated filling pressures at a mean of 24 mm Hg with V waves at average height of 32 mm Hg. The panel on the right (B) shows tracings recorded a few minutes later. Mean pulmonary capillary wedge pressure rose to 33 mm Hg with V waves to 48 mm Hg. *A,* A wave; *PCWP,* pulmonary capillary wedge pressure; *V,* V wave.



• **Fig. 30.15** Hemodynamics (A) of severe MR (40-mm Hg scale) with giant V wave (to 70 mm Hg) late in systole. As left atrium *(LA)* pressure rises in acute severe mitral regurgitation, the gradient between the left ventricle *(LV)* and LA pressure tracing is reduced and may result in a decrease in intensity of the murmur in late systole. The markedly thickened mitral valve (B) was excised from this patient after being torn *(arrow)* during balloon mitral commissurotomy. Elimination of mitral stenosis gradient *(area in A, filled in red)* is demonstrated. *BPM,* Beats/min.

care setting, and repeated attempts to obtain a wedge pressure when the catheter is already in the wedge position may result in iatrogenic pulmonary artery hemorrhage.

Diagnosis

Physical Examination

In acute MR the abrupt rise of left atrial pressure results from torrential retrograde flow, although the gradient between the left atrium and left ventricle may narrow substantially near the end of systole because of the substantial rise in left atrial pressure as shown in Fig. 30.15. Thus the systolic murmur may decrease in intensity before the onset of the aortic second heart sound. A systolic thrill may be noted. The sudden and severe left atrial hypertension typically results in pulmonary edema with accompanying physical findings, as well as an increase in the pulmonic second sound and paradoxical splitting of the second heart sound. Because the adaptive mechanisms are not yet in place, features of LV volume overload are not seen, although a prominent precordial impulse, reflecting increased (albeit retrograde) ejection, may be noted. Unlike AI, the pulse pressure is not increased and may be reduced to reflect the lower forward stroke volume.

In chronic MR, precordial features of volume overload include a displaced point of maximal impulse and prominent precordial pulsation. An S_3 gallop is heard, especially with marked dilation of the left ventricle,[110] and a diastolic flow murmur representing increased transvalvular flow (rather than MS) may be present. The first heart sound may be soft, reflecting lack of brisk apposition of the mitral valve leaflets. The murmur of MR commences immediately after the first heart sound, reflecting the observation that a significant amount of regurgitation takes place during what would otherwise be isovolumic systole (which normally commences immediately after mitral valve closure). The murmur of chronic MR is characteristically blowing; may be medium or high pitched; is best heard at the apex; radiates to the axilla and left scapula (when severe); and extends throughout systole, reflecting the presence of a relatively high gradient throughout LV ejection.

The location of radiation can provide a clue to the affected leaflet; anteriorly directed jets result from posterior leaflet dysfunction, and conversely, anterior leaflet prolapse results in a murmur best heard toward the patient's back. Because the Gallavardin phenomenon in AS mimics an MR murmur, it is important to differentiate these two when possible (AS and MR frequently occur concurrently, given the high LV systolic pressure with the former). The murmur of MR differs because it is holosystolic and increases rather than decreases with handgrip.

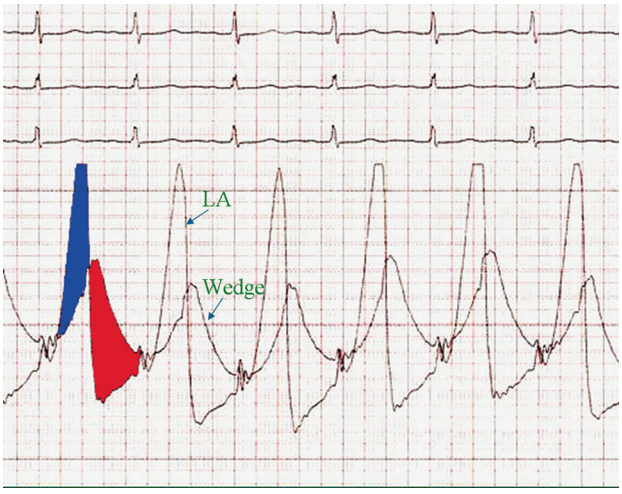
The intensity of the MR murmur reflects a number of phenomena relating to the size of the gradient, compliance of the left ventricle and left atrium, and contractility of the left ventricle but does not correlate well with extent of MR; thus the murmur may be difficult to hear or inaudible, especially in the critical care setting.[152]

Noninvasive Evaluation

Echocardiography provides visualization of the multiple structures responsible for causing MR, including the valve leaflets, annulus, chordae tendineae papillary muscles, and left ventricle (see Fig. 30.13). TEE provides superior imaging of the valve, including assessment for vegetations if endocarditis is suspected and better visualization of flail leaflets; it is particularly useful when the transthoracic views are incomplete or inadequate. In general, TEE is superior for fully assessing characteristics of the mitral regurgitant jet[153] and provides additional information in evaluating mitral valve morphology and motion. As with AI, Doppler methods allow assessment of the width of the regurgitant jet and size of the vena contracta, and semiquantitative measures of the regurgitant volume, regurgitant jet, and effective orifice area; these are discussed in detail in Chapter 8. In patients presenting with acute heart failure and a hyperdynamic left ventricle, acute MR should always be considered. Where TEE does not provide adequate information to assess severity of MR, cardiac MRI is indicated (class I).[154]

Cardiac Catheterization

Although the indications for cardiac catheterization (see Box 30.1) are similar to those for AS and AI, an additional consideration is included as a class I indication: to assess pulmonary artery pressures



• **Fig. 30.16** Underestimation of the left atrial V wave by pulmonary wedge pressure recording in the setting of severe mitral insufficiency (mitral regurgitation [MR]). The tracings show simultaneous left atrial and pulmonary artery wedge pressures in a patient with chronic severe MR because of paravalvular leak (40-mm Hg scale). The V wave on the wedge tracings is approximately 28 mm Hg, but on direct left atrial pressure the measurement obtained by transseptal puncture is 44 mm Hg. The gradients between the wedge pressure and left atrial pressure during systole *(area filled in blue)* and during diastole *(area filled in red)* represent artifact because of damping and phase delay of pressure waveforms reflected across the pulmonary vascular bed. The effect of this damping is gross underestimation of the severity of the V wave and overestimation of any gradient between the left atrium *(LA)* and left ventricle; these in turn result in underestimation of severity of MR and overestimation of the severity of mitral stenosis when pulmonary wedge pressures are used. The mean of the two pressures is exactly the same.

at rest and if necessary with exercise to evaluate appropriateness for surgery (see valve replacement indications later). The size of the V wave is not an accurate indicator of MR severity and is not used as a decision-making criterion for surgery because it may be unremarkable even in severe MR when there is high left atrial compliance. In addition, the size of the V wave is typically recorded by wedge rather than direct left atrial pressure, which can result in significant underestimation of the severity of MR (Fig. 30.16). Right heart catheterization and oxygen saturation sampling allow differentiation between two of the most common causes of abrupt mechanical deterioration in AMI: severe MR and ventricular septal defect. Both conditions can feature a large V wave because of sudden volume loading of a noncompliant left atrium—secondary to retrograde flow across the mitral valve in the case of acute MR and antegrade flow of shunted blood from the LV across the pulmonary circulation in the case of a ventricular septal defect.

Therapy

Medical Management

For acute, severe, symptomatic MR, the primary medical therapy consists of aggressive vasodilation with nitroprusside or nicardipine.[4] It provides improved aortic flow, diminishes MR, and decreases left-sided filling pressures. In the setting of acute MR with shock, nitroprusside alone is usually considered undesirable because of poor end-organ perfusion if further hypotension is caused by the drug. IABP is highly effective in this setting[155] (see Chapter 7) because it lowers aortic impedance, improves CO, and decreases regurgitant fraction at the same time as it restores blood pressure. A combination of an inotrope (typically dobutamine; a vasoconstrictor should be avoided) and nitroprusside can have similar salutary effects. When the acute MR is dynamic (i.e., occurs and resolves abruptly), the cause is frequently acute ischemia, and consideration should be given to evaluating the coronary circulation. In a small number of cases, acute coronary intervention has been documented to alleviate MR in the setting of acute ischemia.[156]

Medical therapy for chronic MR is more controversial. Because afterload is typically not increased, the benefits of afterload reduction are without clear physiologic foundation in normotensive patients with preserved LV function. As such, ACE inhibitors have consistently been shown not to be effective for chronic MR in this setting.[157–159] When concomitant systemic hypertension exists, physiologic benefits appear more convincing.[160] If patients have LV dysfunction superimposed on chronic MR, medical therapy with ACE inhibitors, ARBs, β-blockers, and aldosterone antagonists may be beneficial, and several studies have observed functional improvement with resynchronization.[161,162] As with other valvular disorders, new-onset AF can result in abrupt hemodynamic deterioration and cardioversion should be considered with adjunctive pharmacotherapy to maintain sinus rhythm and rate control. Because of the sympathetic activation previously discussed, β-blockers appear to be beneficial[163,164] and may have additive benefit when used in combination with ACE inhibitors.[165] Both classes of drugs appear to be therapeutic when used after mitral valve repair.[166]

Mitral Valve Surgery

Three types of surgery are performed on the mitral valve: repair, replacement with preservation of the subvalvular apparatus and attachments, and replacement with transection of the chordae. In the setting of nonischemic MR, mitral valve repair has been consistently shown to improve outcomes compared with mitral valve replacement, both acutely and long term, with a fourfold lower operative mortality rate and a 30% improvement in 10-year survival rate.[167] With mitral valve replacement, patients who nevertheless have the chordal apparatus preserved have superior long-term outcomes compared with those who have the chords transected.[168] An additional benefit of repair is the potential avoidance of anticoagulation if patients are in sinus rhythm compared with replacement with a mechanical valve where anticoagulation is required.

In contrast, outcomes in the setting of ischemic MR have been much more muted. In a randomized trial of repair versus replacement, repair provided no survival or LV remodeling benefits at 2 years follow-up,[169] but there was a higher rate of recurrence of moderate or severe MR, with an associated increase in heart failure–related events. Similarly, random assignment of patients undergoing coronary artery bypass grafting (CABG) who had moderate ischemic MR to CABG alone or CABG plus mitral valve replacement did not demonstrate improvement in survival or LV remodeling in the latter group but was associated with more early neurologic events and supraventricular arrhythmias.[170]

In general, the timing of surgery for chronic MR should be before the onset of LV dysfunction. The most commonly used markers are symptoms and echocardiographic parameters, including LVEF less than 60%.[4] Patients who develop class III or IV symptoms, even transiently, have a nearly 10-fold increase in annual mortality rate,[171] with evidence that early surgery in the setting of severe MR improves overall survival. The 60% LVEF threshold for surgery has been shown to correlate with postoperative LV function[172] as well as survival.[173] The effective regurgitant orifice

has been shown to be strongly predictive of 5-year mortality risk; patients with an orifice size of 40 mm^2 or greater have an odds ratio of death greater than 5:1 compared with patients with orifice size of 20 mm^2 or less.[174] Preoperative end-systolic diameter of 40 mm or less has also been associated with superior outcomes. Patients with AF in general have a worse prognosis,[175] although in large part because of embolic events rather than LV dysfunction, as do patients with pulmonary hypertension or right-sided heart failure, or both.[176] Conventional wisdom has been that mitral valve surgery may result in postoperative return to normal function in patients with depressed EF.[177] However, patients with severe MR who reach the 60% EF threshold (or LV end-diastolic dimension ≥40 mm) have in fact already developed LV systolic function. As a result, the 2017 AHA/CCC Guidelines[84] have added a class IIa indication for mitral valve surgery for asymptomatic patients with severe primary MR and preserved LV function who have progressive increase in LV size or decreasing EF; this is based on evidence that waiting for patients to reach the thresholds described earlier, when the LV is dilating and systolic function is deteriorating, may result in irreversible LV dysfunction.[178] Comparison of long-term outcomes between operated and medically treated patients with asymptomatic MR has invariably favored the former,[174] although much of the data depend on nonrandomized registry data. The key to improved function and outcomes has generally included preserving the integrity of the submitral apparatus,[179] and comparison of successful repair versus replacement has indicated that high-volume institutions (>140 mitral operations/year) have the best results with nearly twice the rate of successful repair as low-volume institutions.[180]

A common teaching has been that repair or replacement of the mitral valve eliminates the "pop-off valve" represented by incompetent leaflets, resulting in dramatically increased afterload postoperatively. This has in turn led to concern that if significant preoperative LV dysfunction is present, the left ventricle will fail, with hemodynamic deterioration and subsequent death. In fact, careful investigation has demonstrated that when postoperative deterioration of LV function occurs, it has been secondary to disruption of chordal integrity[181] and elimination of the favorable effects of the submitral apparatus on valvular-ventricular interaction rather than the elimination of a low-pressure decompression pathway. Afterload following mitral valve surgery with chordal transection does in fact increase, whereas patients who undergo mitral valve surgery with preservation of the chordal apparatus have decreased LV chamber volume and, in keeping with the LaPlace equation, reduced afterload.[182] Thus the recommendations regarding LVEF for surgery have changed dramatically, and successful repair of mitral valves in a series of patients with EF less than 25% has been reported with operative risk of less than or equal to 5%.[183] The operative risk is in the 1% to 2% range for symptomatic patients with LV dysfunction but higher EF.[184] Similarly, the Society of Thoracic Surgeons database has reported mortality rates of approximately 5% with EF less than or equal to 30% but 3% with EF greater than 30%.[185] Propensity analysis of patients eligible for mitral valve repair who did or did not undergo the procedure has not shown a survival advantage in patients with mean EF less than 25%,[166] although a randomized trial has not been reported. Similarly, concomitant mitral valve surgery in patients with moderate or greater MR undergoing CABG procedures did not clearly improve short-term survival,[186] similar to the subsequent randomized trial of moderate ischemic MR already described.[170]

In symptomatic acute severe MR, mitral valve surgery is the primary treatment regardless of level of LV function.[4] With both infective endocarditis[131] and papillary muscle or chordal rupture, surgery is mandated to be performed with as little delay as possible.[187] However, the overall risk of mortality when MR accompanies AMI is substantially increased,[188] a phenomenon noted in patients undergoing emergent percutaneous intervention as well.[189] The management for chronic severe MR is complex as outlined in Fig. 30.17.

Percutaneous Mitral Valve Repair and Replacement

A number of innovative technologies are being developed for percutaneous treatment of MR (Fig. 30.18). The most extensively studied is based on catheter-based edge-to-edge repair of the mitral leaflets designed to mimic the surgical procedure developed by Alfieri and colleagues.[190] The EVEREST (Endovascular Valve Edge-to-edge REpair STudy) II trial[191] compared 184 patients randomly assigned to percutaneous repair (MitraClip; Abbott Vascular, Santa Clara, CA) versus 95 patients randomly assigned to surgical mitral valve repair and had promising though somewhat nuanced results. Although there was good safety profile and similar quality-of-life improvement, grade 2 or greater MR was present in nearly half the percutaneous repair patients at 1 year compared with only 17% of the surgical repair patients. The surgical patients did have more adverse events, primarily blood transfusions. The surgical approach appeared clearly superior for patients with degenerative (or primary) MR, with relative parity in outcomes in functional (or secondary) MR patients (those with structurally normal mitral valves, but typically dilatation of the mitral annulus). Although the difference between surgery and MitraClip persisted at 5-year follow-up, the majority of events that favored surgery were noted early. Follow-up after 6 months showed that the rates of worsening MR and surgery for mitral dysfunction were comparable; these findings point to durability of clip repair.[192] MitraClip is currently approved in the United States for severe primary MR in patients who are severely symptomatic (NYHA class III/IV) and are at prohibitive risk for surgery (a class IIB indication).[4] There is an ongoing Cardiovascular Outcomes Assessment of the MitraClip Percutaneous Therapy for Heart Failure Patients with Functional Mitral Regurgitation (COAPT) trial comparing MitraClip for functional MR versus guideline-directed medical therapy in patients who are very high risk to inoperable.

Transcatheter mitral valve replacement is being performed via a variety of access routes including transapical, transjugular, and transseptal. Most commonly the Sapien 3 valve (Edwards Lifesciences, Irvine, CA) is being placed in three settings when there is a suitable anchor: ViV replacement for prosthetic degenerative MR or MS (FDA approved), valve-in-ring when there is sufficient support from a previously placed annular prosthesis, and valve-in-calcium when there is severe mitral annular calcification (MAC). There are ongoing registries and moderate success, albeit with some important limitations, perhaps most importantly impingement on the LVOT, which requires careful preprocedure assessment and planning.[193]

Future Directions

The Alfieri procedure is an uncommonly performed type of surgical mitral valve repair, and as with most repair procedures typically involves placement of a prosthetic ring, an option not available with the percutaneous approach; this is a potential limitation of its long-term (>5-year) applicability as an isolated intervention.[194] In this context, it is worth noting that several other percutaneous technologies are under development[195] (see Fig. 30.18). They are broadly based on a few principles and techniques: (1) direct annuloplasty annular repair, (2) indirect annuloplasty by coronary

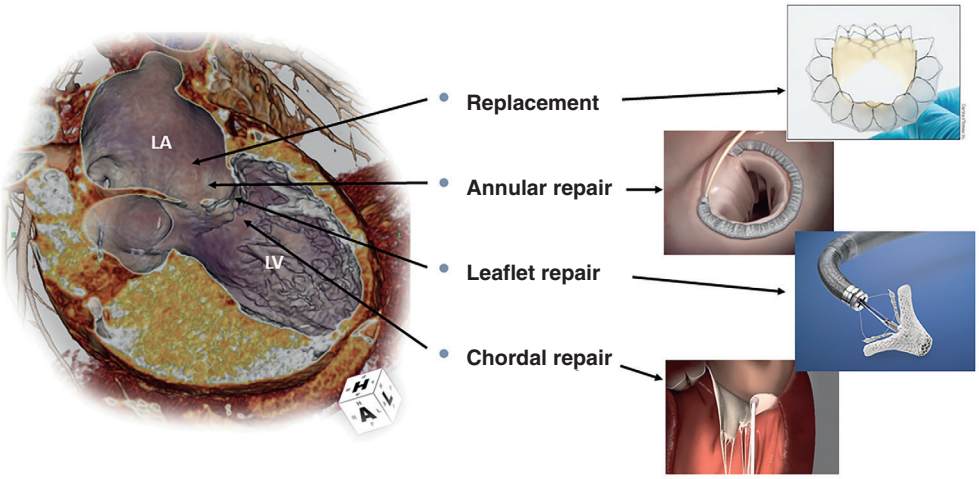
Hypertrophic Obstructive Cardiomyopathy

Although a disease of the heart muscle rather than a primary valvular disorder, HCM has important features of LV outflow obstruction and concomitant MR. The clinical presentation, physical examination, noninvasive and invasive findings, and overall management differ in general from AS or MR, and HCM represents an important consideration for patients in critical care units,[196] where patients with a systolic murmur and hypotension, syncope, or exercise-induced cardiac arrest in particular should have HCM included in the differential diagnosis. The disease has a wide variety of manifestations, including diastolic dysfunction and LV outflow obstruction, and may include coronary flow abnormalities resulting in ischemia, atrial and ventricular rhythm disorders, and LV systolic dysfunction. There is an associated risk of sudden death, heart failure, and cerebral and systemic embolism.[197] Approximately one-third of patients with HCM have a nonobstructive form of the disease, which in a minority of cases, predisposes patients to severe, sometimes refractory, heart failure.[198]

Pathophysiology

The hallmark of the obstructive form of HCM is dynamic obstruction of the LOVT with eccentric hypertrophy; many variations exist, and obstruction is not always at the subvalvular level. Only approximately one-fourth to one-third of patients with HCM have a resting gradient of 30 mm Hg or greater.[199] HCM is found in approximately 0.2% of the population[200] and is defined as hypertrophy of the left ventricle that is not secondary to hypertrophic stimuli such as systemic hypertension or AS. LV hypertrophy usually



• **Fig. 30.18** Novel therapeutic interventions for mitral insufficiency. All except the mitral valve clip used for leaflet repair are experimental in the United States. *LA,* Left atrium; *LV,* left ventricle.

develops during adolescence, although it can occur late.[201] Contrary to conventional wisdom, the majority of patients with HCM were found to have provocable gradients with exercise in a single large-volume center[202] (likely with some skewing owing to the nature of its referral population). The genetics of HCM have been studied extensively, and although complex, there is a familial association in a majority of patients. The degree of hypertrophy may be related to the underlying genetic abnormality. In familial HCM, autosomal dominant loci that encode one of the myocardial contractile proteins of the cardiac sarcomere are frequently present.[203] Cardiac myosin-binding protein C gene and cardiac β-myosin heavy chain gene mutations are most commonly noted. Although the clinical course may be generally benign in patients without risk factors for adverse events,[204] it is the most common cardiac cause of sudden death in young adults,[205] is associated with cardiac arrest in athletes,[206] and leads to heart failure, rhythm disturbances, and occasional sudden death in older patients. The patients at high risk for sudden death, comprising only about 10% to 20% of those within the HCM population, include those with prior cardiac arrest or sustained ventricular tachycardia, those with a family history of HCM and sudden death, hypotensive response to exercise, and severe LVH with wall thickness of 30 mm or greater.[201] A resting gradient across the outflow tract of more than 30 mm Hg alone predicts an increased risk of sudden death or development of moderate to severe congestive heart failure,[199] and there may be higher risk with very high gradients.[207] Because of impaired coronary flow reserve[208] and severe hypertrophy, myocardial ischemia is a potentially important factor in acute patient management; there is also an association between HCM and myocardial coronary bridging.[209]

Diagnosis

Physical Examination

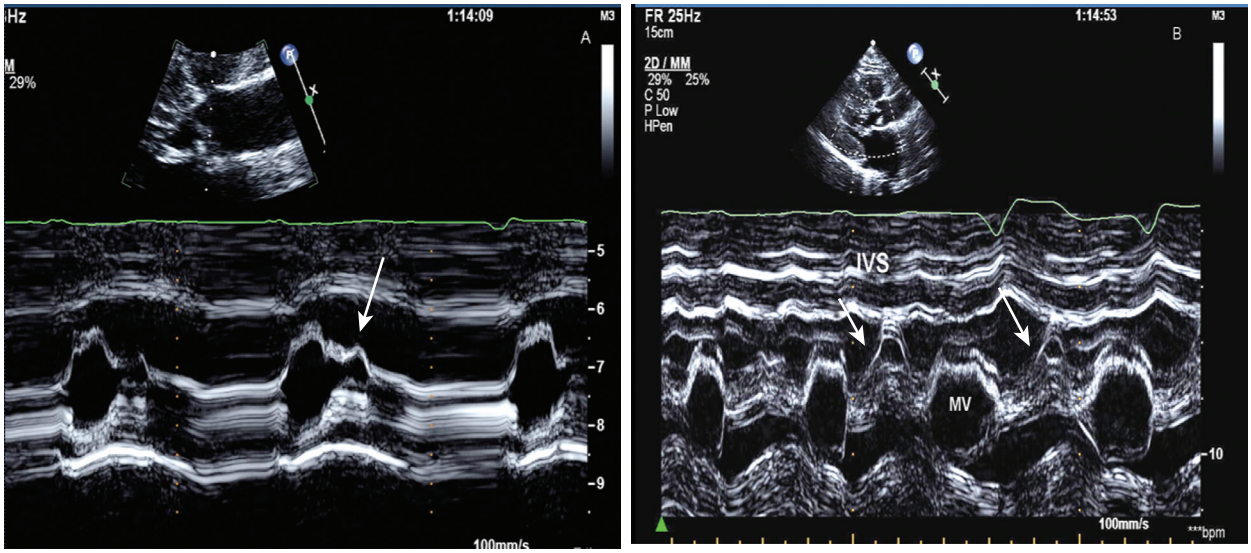
The physical examination in HCM features an abrupt early rise in systolic pressure followed by obstruction to LV outflow, resulting in a blunted pressure rise later in systole. This translates to the spike and dome pattern characteristic of obstructive HCM on palpation of the carotid pulse. The typically hypertrophic septum (1.3 to 1.5 times the thickness of the posterior wall and typically ≥18 mm in clinically significant HCM) obstructs the outflow tract after initial ejection as LV volume decreases. Physiologic maneuvers or clinical states that lower LV volume abruptly, such as standing, dehydration, or use of diuretics, can substantially exacerbate the gradient and increase the intensity of the systolic ejection murmur characteristic of HCM. Because the obstruction begins after the initial brisk ejection of blood from the ventricle, the onset of murmur is late after the first heart sound. It is best heard over the left base of the heart. In contrast to AS, the murmur typically does not radiate to the carotids, does not extend throughout systole, and decreases with squatting. The blunting of the carotid upstroke, so characteristic of AS, is not seen because of the vigorous early ejection.

Noninvasive Evaluation

Abnormalities of mitral valve function are common. Systolic anterior motion of the mitral valve is associated with further obstruction[210]; in addition, MR is a typical secondary finding in HCM. The ECG features LV hypertrophy, strain, and prominent Q waves in the inferior and precordial leads, with narrow QRS complexes being common. The echocardiogram is diagnostic for HCM, providing both an anatomic basis and physiologic evidence of the degree of obstruction (Fig. 30.19). Cardiac MRI is particularly valuable in assessing HCM, providing enhanced visualization of hypertrophied areas, the mitral valve leaflets, aberrant LV muscle bundles, and a variety of other features essential to understanding the many forms of the disease, and helpful in planning intervention.[211]

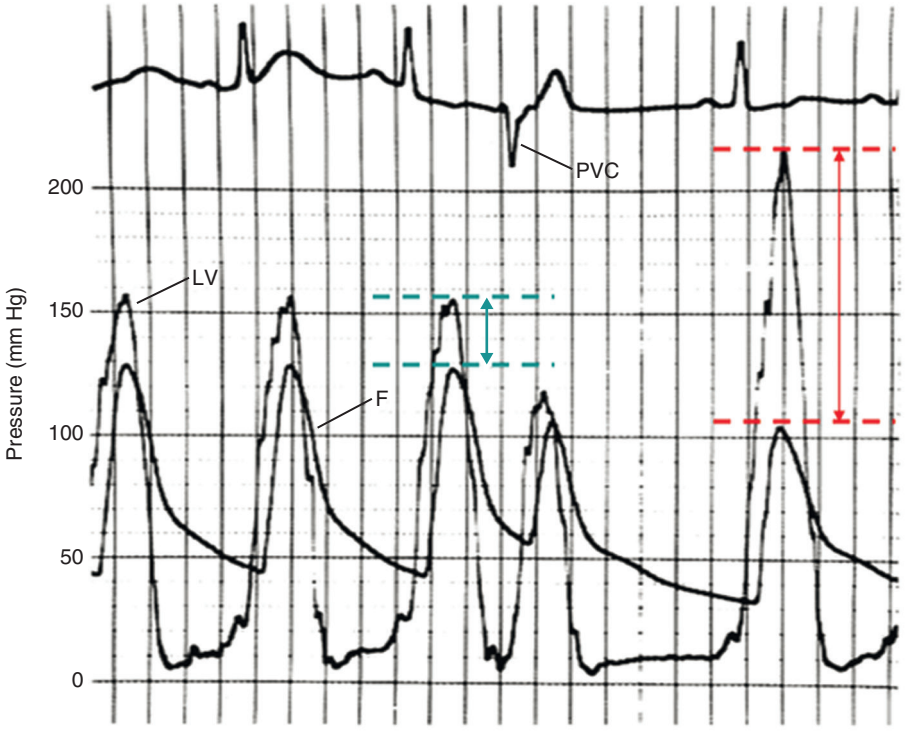
Cardiac Catheterization

Cardiac catheterization in HCM may reveal the standard triad of the Brockenbrough-Braunwald-Morrow sign in the postextrasystolic heartbeat: increase in the gradient between the left ventricle and the aorta, decrease in systemic blood pressure, and narrowing of the pulse pressure (Fig. 30.20). Access to the LV via transseptal puncture, although rarely necessary, affords the opportunity to record pressure gradients without the confounding issues of midcavitary obstruction or catheter entrapment.[212] Other stimuli that increase outflow obstruction and increase gradient are the Valsalva maneuver and amyl nitrite inhalation, in addition to postextrasystolic potentiation.



A B

• **Fig. 30.19** A, M-mode of hypertrophic obstructive cardiomyopathy with aortic valve opening showing the effect of midsystolic outflow obstruction; after initial normal opening, the aortic valve leaflets remain only partially separated because of diminished transvalvular flow *(arrow)*. B, Systolic anterior motion of the anterior mitral leaflet with apposition against outflow tract *(arrows)*. The severely hypertrophied septum on the two-dimensional view is shown at the top of each panel. *IVS,* interventricular septum; *MV,* mitral valve.



• **Fig. 30.20** The Brockenbrough-Braunwald-Morrow sign. Dramatic exaggeration of the resting gradient in the postextrasystolic beat, with lower systemic pressure, and narrowed pulse pressure (difference between femoral systolic and diastolic pressure) are demonstrated—all hallmarks of dynamic outflow obstruction. The *dashed lines* represent left ventricle *(LV)* and femoral *(F)* systolic pressures at rest *(green)* and after a premature ventricular contraction *(PVC) (red);* the gradient rises from a basal 30 mm Hg *(double-headed green arrow)* to approximately 130 mm Hg *(double-headed red arrow)*. Therapy

Medical Management

The management of critically ill patients with HCM focuses on several core principles: optimizing LV volumes, specifically increasing preload while not decreasing afterload; decreasing contractility; and maintaining the patient in sinus rhythm. Thus the typical regimen of diuretics, vasodilators, and inotropes used in most patients presenting with congestive heart failure who do not have HCM can severely exacerbate the outflow gradient and lead to further decompensation or death[213] (as can IABP); somewhat counterintuitively in this setting, negative inotropes, particularly β-blockers, combined with volume loading can stabilize patients.[214,215] Other negative inotropes including verapamil and disopyramide appear to have favorable hemodynamic effects and may represent an alternative to β-blockade.[216] In the patient in shock, if vasopressors are required, agents such as phenylephrine that are primarily peripheral vasoconstrictors should be used rather than inotropic agents. Verapamil has negative inotropic benefits and some utility as an antiarrhythmic agent, as well as diastolic relaxation properties, and has been used successfully in both chronic therapy and acutely decompensated patients with HCM.[217] Verapamil does have some potentially undesirable vasodilator properties and can cause synergistic depression of conduction and contractility in combination with β-blockade; the effects of combined therapy, if used, should be monitored closely.[218] In HCM patients with ongoing chest pain despite medical therapy, ranolazine has been used as an alternative agent.[219]

Patients with hypertrophic heart disease are highly dependent on the atrial contribution to CO,[220] and patients with obstruction in particular depend on the additional LV filling from atrial contraction. AF is a cause of acute decompensation in HCM patients, and cardioversion should be considered acutely. AF occurred in approximately one-fourth of patients with HCM at 9-year follow-up and is predictive of heart failure–related death and stroke.[221] In terms of the latter, patients with HCM and AF appear particularly predisposed to thromboembolic events[222]; anticoagulation has been shown to reduce the incidence significantly.[223] Left atrial size and function predict the onset of AF.[224] The Maze procedure and catheter ablation of left atrial pathways have been used successfully to prevent recurrent AF.[225,226] Amiodarone has been particularly effective for the maintenance of sinus rhythm in the population with AF and HCM[227] and may also have additional efficacy in preventing sudden death in patients with episodes of nonsustained ventricular tachycardia.[228,229] Ventricular fibrillation appears to be the primary cause of sudden death and can be prevented with implantable defibrillators for either primary or secondary prevention, with activation of the devices in 5% to 11% of patients annually depending on indications for placement[230]; episodes of sustained ventricular tachycardia and a history of prior sudden death place patients in the highest risk category.

Percutaneous Intervention or Surgery

Once patients develop refractory symptoms despite pharmacologic management and have significant obstruction to LV outflow (outflow gradient >50 mm Hg at rest or with physiologic provocation), surgical myomectomy or alcohol septal ablation must be considered. The choice is controversial, but in general surgical septal myectomy achieves sustained relief of LVOT obstruction with lower incidence of need for permanent pacemaker and without the potential adverse consequences of the iatrogenic infarction caused by alcohol.[231] Ultimately, the decision depends on LV and coronary anatomy, comorbid conditions, severity of coexistent mitral valve or other potentially surgical heart disease, and a variety of other clinical issues; equivalence of outcomes with the less invasive percutaneous approach has not been demonstrated.[232] Although alcohol ablation does reduce the outflow gradient, it creates a septal infarct and intramyocardial scarring, but it represents an alternative for older patients and those with major comorbidities who are reluctant to have surgery or are poor candidates for surgery.[233] Complications of alcohol septal ablation include the need for permanent pacemaker implantation in 10% to 20% of cases, risk of ventricular tachyarrhythmias, periprocedural mortality (2%), and sudden death. Typical thresholds for intervention are a resting peak instantaneous gradient of 50 mm Hg or more, although depending on degree of symptoms and provocability, a variety of other thresholds have been applied.[201] Mitral valve replacement can frequently be avoided, especially in patients without intrinsic mitral disease in whom MR is largely abolished by myomectomy and relief of the outflow gradient.[234] In patients with intrinsic mitral valve disease or for a variety of other anatomic considerations, mitral valve surgery including use of low-profile prostheses is used.[201] Dual-chamber pacing, once considered therapeutically effective,[235] with theoretical benefit from asynchronous septal contraction and secondary reduction in outflow tract gradient, has not been shown to have clear therapeutic benefit in randomized clinical trials, with functional benefits occurring in a limited subset of elderly patients.[236]

Mitral Valve Stenosis

Mitral valve stenosis (MS) is primarily a rheumatic disorder and, as such, has become increasingly uncommon in industrialized nations. Nevertheless, the disease remains prevalent in developing countries and a small but significant number of patients continue to present in the critical care setting throughout the world. Rheumatic MS involves disease of both the valve leaflets and submitral apparatus and may involve the valve ring as well (Fig. 30.21). Although MS is primarily caused by rheumatic deformity and scarring of the valve leaflets and subvalve with fusion of the commissures, a variety of disorders result in leaflet and annular calcification that also create obstruction between the left atrium and left ventricle. Most notably, MAC, present in 6% of patients undergoing routine echocardiography,[237] is more prevalent in the elderly, women, smokers, and patients receiving dialysis (who have high parathyroid hormone levels). It may present with severe nonrheumatic MS, although MR is a more common association.[238,239] A variety of uncommon other causes account for less than 1% of cases of MS.[240]

Pathophysiology

The physiologic hallmark of MS is obstruction to left atrial outflow resulting in rising left atrial and pulmonary pressures (the extent of the latter depends to a significant degree on left atrial compliance). The normal mitral valve is in the range of 4 to 6 cm^2, and patients typically do not become symptomatic until valve areas decrease significantly below 2 cm^2. As valve area decreases, an additional pressure gradient is required to maintain transvalvular flow (see Fig. 30.8). Because antegrade flow occurs entirely during diastole, and the diastolic filling period shortens or lengthens disproportionately with increase or decrease in HR, respectively, the gradient is highly flow dependent. In MS, as with virtually all valvulopathies, CO is potentially highly dependent on maintenance of sinus rhythm; because the influence on CO is exaggerated by the need for active

• **Fig. 30.21** Long-axis view during diastole of the mitral apparatus, left atrium, and left ventricle in a normal patient (A) and a patient with mitral stenosis (B). Cross-sectional views of the left atrial surface of the valve are shown in the inset. With mitral stenosis, the valve opening is restricted with a characteristic doming appearance, the commissures are fused, the leaflets are thickened, the subvalvular apparatus is deformed, and some calcification is noted. The left atrium is enlarged. (From Turi ZG. Cardiology patient page. Mitral valve disease. *Circulation.* 2004;109:e38–e41.)

left atrial pumping across a stenotic orifice, atrial contraction is particularly important in MS. A frequent mode of presentation is acute congestive heart failure in a patient with MS who suddenly develops AF; the concomitant loss of atrial contraction and high ventricular rate with short diastolic filling period frequently results in pulmonary edema.

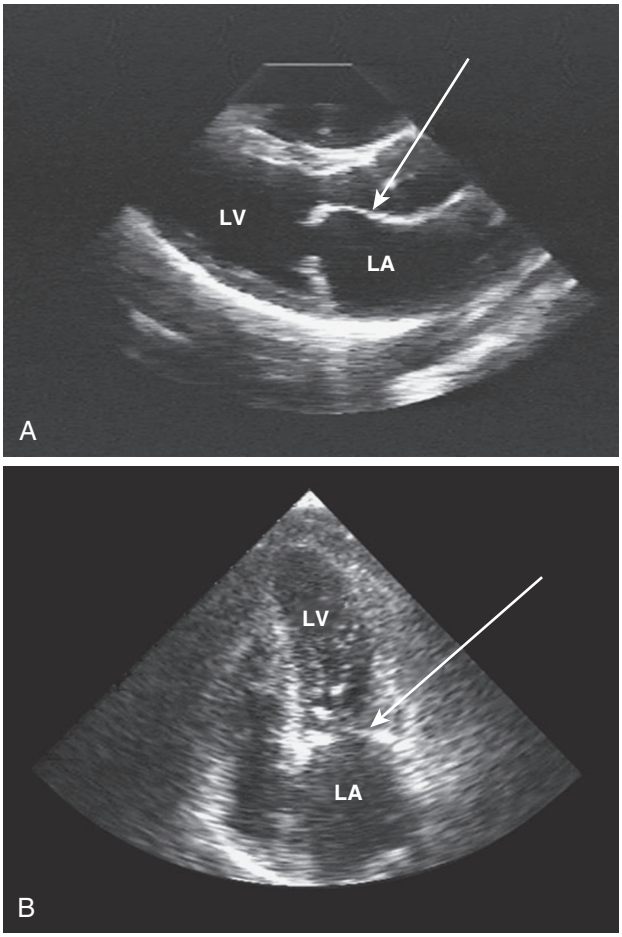
Diagnosis

Physical Examination

The diagnosis of MS on physical examination is frequently missed, in part because it is uncommonly seen by most practitioners outside developing countries. Besides findings suggestive of congestive heart failure with a low output in the critical care setting, several findings correlate strongly with MS. A right ventricular lift may occur in patients with advanced and chronic pulmonary hypertension, and occasionally a palpable pulmonic second sound is felt. Both S1 and P2 are increased early in the course of the disease; with progressive deformity of the subvalvular apparatus, S1 may become quite soft as mitral valve closure velocity decreases. The opening snap is preserved until the end stages of MS, and the severity of the disease correlates inversely with the length of time between S2 and the opening snap. The diastolic rumble may not be heard if the patient is not placed in the lateral decubitus position and is difficult to hear in the critical care setting. Presystolic accentuation is the result of increased flow in late diastole caused by atrial contraction in patients in sinus rhythm. The diagnosis is often elusive in both the outpatient and critical care settings,[224] and patients are sometimes treated for years for bronchitis, pneumonia, or asthma when in fact the presentation is congestive heart failure with the underlying disease process being MS.

Noninvasive Evaluation

The echocardiogram is the primary tool for diagnosis of MS. The typical hockey-stick appearance of the rheumatic anterior mitral leaflet is caused by partial restriction of mobility (Fig. 30.22). Other important characteristics of the mitral leaflets are degree of thickening, mobility, and calcification, all of which, along with extent of subvalvular disease, help to address suitability for balloon dilation or commissurotomy rather than valve replacement.[241] It is important to differentiate rheumatic MS from severe nonrheumatic MS, as shown in Fig. 30.22. TEE provides the requisite sensitivity to detect left atrial thrombus before balloon commissurotomy or cardioversion. Severity of MS is graded by physiologic and anatomic criteria: The former depends on Doppler interrogation of transvalvular flow, with peak velocity used to estimate the gradient; the rate of decompression of the left atrial pressure, or pressure half-time, correlates inversely with valve area. The valve area is frequently directly measured using planimetry of a cross-sectional view. Because these methods have potential for error, a number of alternative methodologies have been proposed,[242–244] although there is no agreement on a gold standard.[245] As with AS, a dramatic increase in gradient accompanies increased flow related to exercise or dobutamine infusion[246] (Figs. 30.23 and 30.24). Cardiac catheterization may be required if the noninvasive data are inconclusive; there is a tendency for the pulmonary wedge pressure/LV gradient to overestimate the severity of MS compared with left atrial/LV gradient measurement[247] (Fig. 30.25). Cardiac catheterization can also be used to assess pulmonary artery pressures and response to exercise if the clinical and noninvasive pictures are discordant.[4]



• **Fig. 30.22** Two appearances of stenotic mitral valves. A, The parasternal long-axis view shows typical rheumatic deformity with a hockey-stick appearance of the anterior mitral leaflet *(arrow)*. B, The four-chamber view is from a patient with a significant gradient across the mitral orifice; this patient was treated with dialysis, did not have rheumatic heart disease, and demonstrated significant calcification of the mitral leaflets and annulus *(arrow)*. *LA,* Left atrium; *LV,* left ventricle.

Therapy

Medical Therapy

Medical therapy specifically aimed at improving hemodynamics and preventing stroke in MS is basically twofold: slowing the HR and anticoagulation. In sinus rhythm, β-blockade is the preferred therapy; patients with significant bronchospasm or with coexistent, usually secondary, severe pulmonary hypertension with or without right-sided heart failure may not tolerate β-blockers. Diltiazem or low doses of β-blocker combined with diltiazem or verapamil are sometimes used in this setting. With combined therapy, care should be exercised that severe HR slowing or atrioventricular block does not occur, and verapamil may not be tolerated in right-sided heart failure. For the acutely decompensated patient with MS, diuretics, nitrates, inotropes (preferably agents that do not raise HR) and, to a lesser degree, arterial vasodilator therapy may all be beneficial.

Approximately 30% of patients with MS are thought to develop AF, with the risk increased by progressive left atrial dilatation. The risk of embolic events, especially stroke, is substantially higher than in AF patients without MS[248] (up to 15% in unanticoagulated patients), possibly in part because of a hypercoagulopathy and increased platelet activation associated with MS,[249] making the use of anticoagulation essential. It is not uncommon for the presenting finding to be an embolic event in a patient with previously undiagnosed MS. Even in the setting of sinus rhythm,[4] if spontaneous echocardiographic contrast is seen in the MS patient or left atrial size is greater than 55 mm, anticoagulation may decrease the risk of stroke[249] and it should also be used in the sinus rhythm patient with prior embolic event or with left atrial thrombus detected by TEE.

In the setting of new-onset AF and acute decompensation, cardioversion should be considered. Regardless of chronicity, HR slowing is essential; digoxin, β-blockers, diltiazem, or verapamil alone or in combination may be beneficial. Rate control only at rest is inadequate; many patients with low resting HRs become tachycardic with minimal exercise. This is a vicious circle because the tachycardia may be a response to inadequate stroke volume; the tachycardia then lowers the diastolic filling period and further exacerbates the gradient. Control of tachycardia is important beyond its hemodynamic benefit; it also helps avoid tachycardia-induced cardiomyopathy.[250]

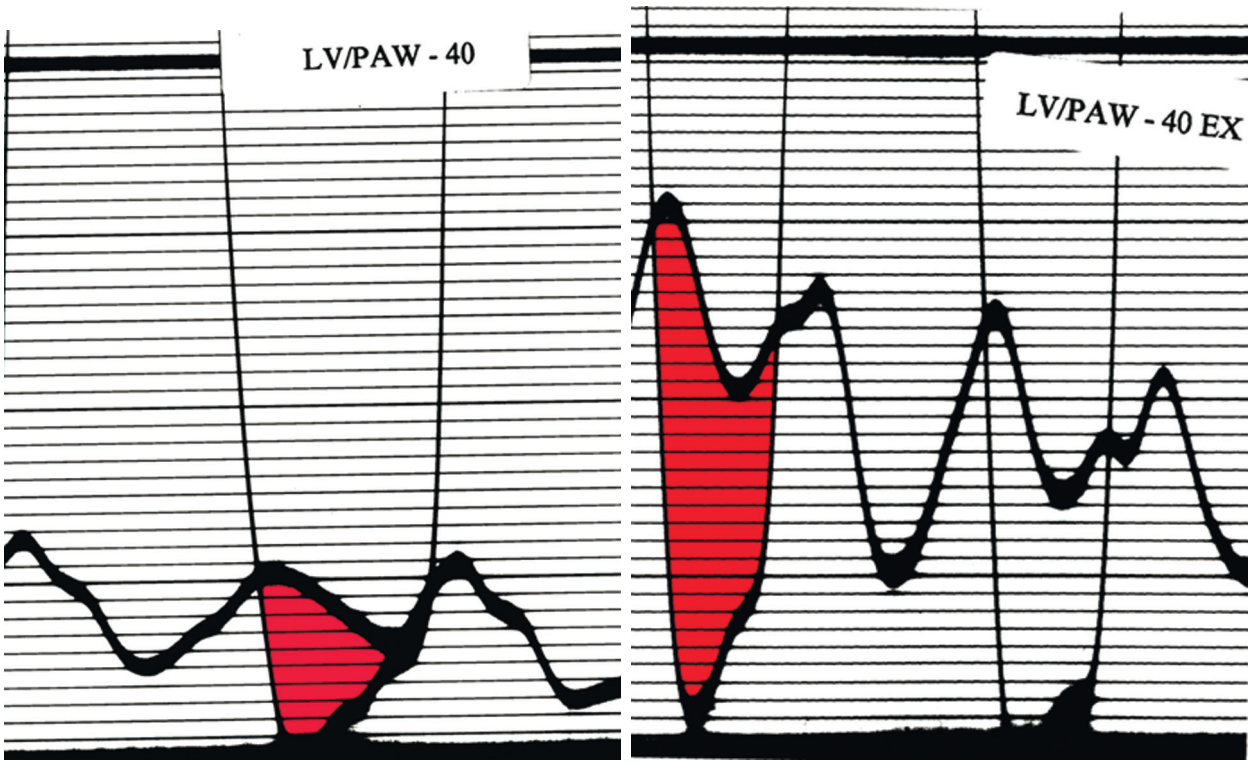
Percutaneous Intervention or Surgery

Percutaneous balloon mitral valvuloplasty (PBMV) is equivalent or superior to surgery in patients with favorable valve anatomy,[251,252] characterized by mild to moderate impairment of leaflet mobility, valve thickness, valve calcification, and subvalvular disease, the components of the Wilkins-Weyman echocardiography score.[253] The scoring system has been shown to correlate with long-term outcomes.[254] Surgery should be reserved for patients with unfavorable anatomy, more than mild MR, or persistent thrombus in the left atrium despite anticoagulation.[4] The threshold for percutaneous or surgical intervention is a mitral valve area of 1.5 cm^2 or less. If patients are symptomatic and have favorable anatomy or if they are asymptomatic but have very severe MS (valve area ≤1.0 cm^2) or new-onset AF, PBMV is indicated. Patients who have unfavorable anatomy and are functional class III or IV are considered to have a class IIb indication for PBMV if they are poor candidates for surgery. Symptomatic patients with progressive but less than severe MS (valve area >1.5 cm^2) who have wedge pressure greater than 25 mm Hg with exercise are also considered class IIb candidates.[4]

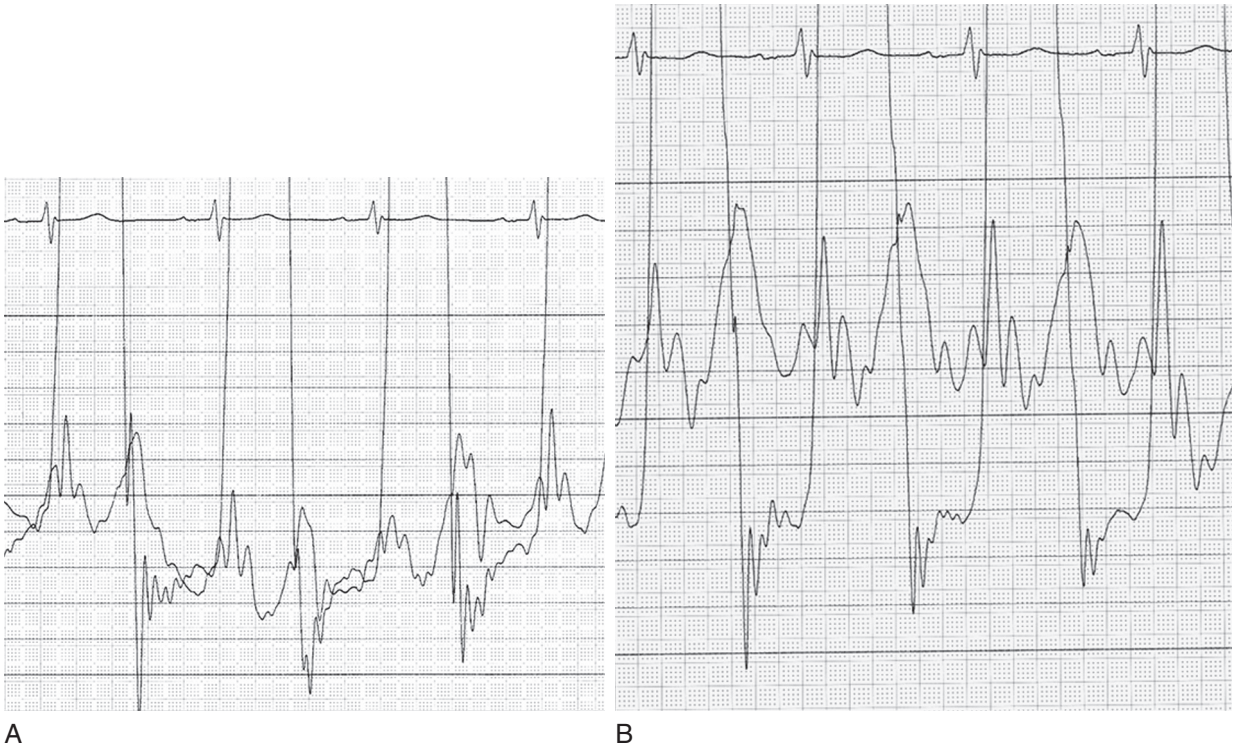
For severely symptomatic patients with severe MAC who are not candidates for surgery, an increasing number of percutaneous balloon expanding TAVR valves have been placed on a compassionate use basis.[255] However, 30-day postprocedure mortality has been as high as 30%. LV obstruction with the newly implanted valve can be catastrophic; hence, imaging algorithms for preprocedure assessment are important. If the patient is at high risk of LVOT obstruction, an alcohol septal ablation or percutaneous laceration of the anterior mitral leaflet has been performed in a limited number of cases to expand the outflow tract.

Prosthetic Heart Valves

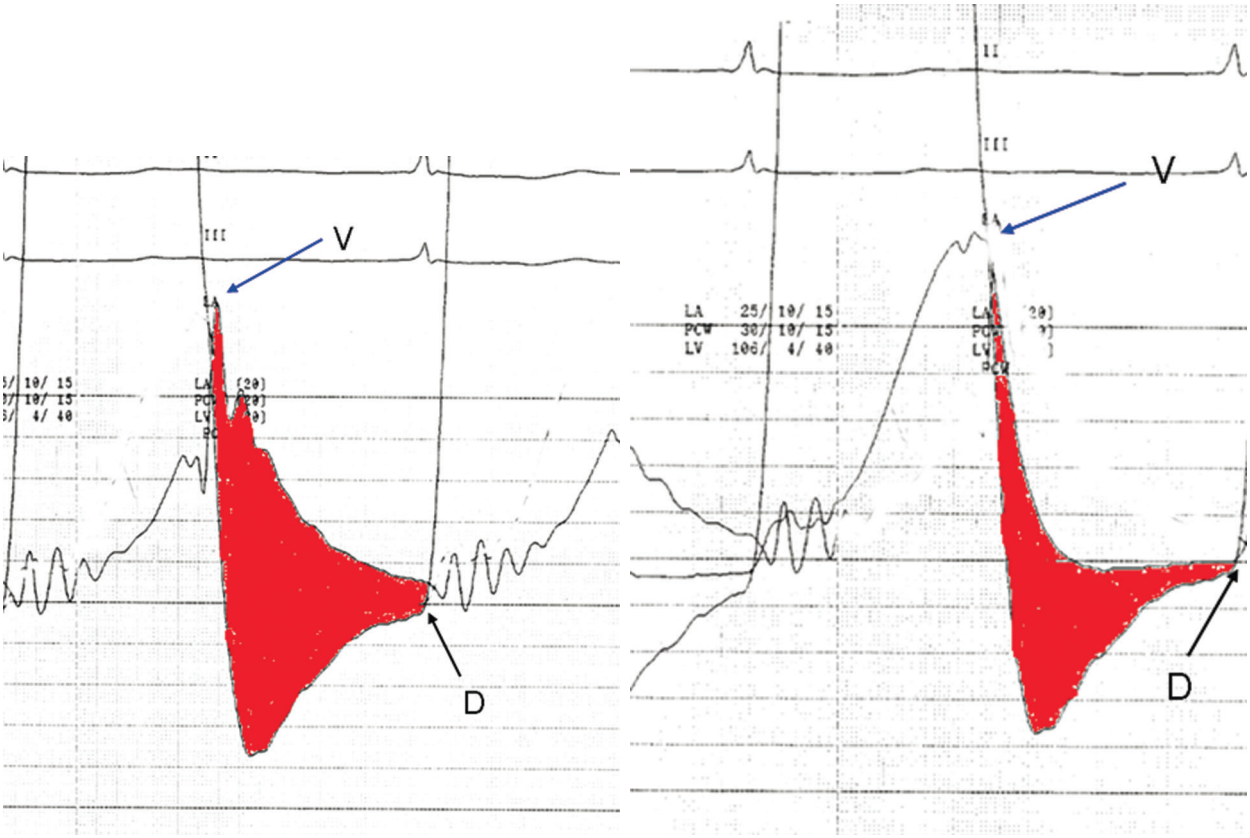
With the increasing number of patients undergoing valve replacement, prosthetic valves are of increasing importance in critical care management. Prosthetic heart valves (PHVs) are broadly categorized into biologic (stented, stentless, and more recently percutaneous) and mechanical (almost exclusively bileaflet in the modern era) valves. The management of normally functioning prosthetic valves (particularly anticoagulation) can add to the complexity of critical



• **Fig. 30.23** Effect of exercise and increased heart rate on mitral valve gradient *(red)* in a patient with mitral valve stenosis (40-mm Hg scale). The left tracing (A) shows a mean gradient of approximately 5 mm Hg with diastasis late in diastole; with increased heart rate and cardiac output (B), the gradient rose to a mean of approximately 20 mm Hg, a fourfold increase. *LV,* Left ventricle; *PAW,* pulmonary artery wedge.



• **Fig. 30.24** Effect of dobutamine infusion on transmitral valve gradient (40-mm Hg scale). Effect in a patient whose gradient was nearly abolished at rest (A) and was augmented dramatically with infusion of dobutamine (B).



• **Fig. 30.25** Effect of using pulmonary wedge pressure (A) or direct left atrial pressure (B) to assess gradient *(in red)* between the left atrium and left ventricle in mitral stenosis (40-mm Hg scale). Using the wedge pressure, the gradient appears to be approximately twice as great as when left atrial pressure is used. Rapid decompression of left atrial pressure is shown in the tracing on the right. The findings are consistent with mixed mitral stenosis and regurgitation, with the dominant physiology secondary to mitral insufficiency. In both tracings, diastasis *(D)* is noted by end diastole, a feature not consistent with severe mitral stenosis except in marked bradycardia. The V-wave height is similar in both tracings, unlike in Fig. 30.16. The two tracings shown here were recorded a few seconds apart.

care, and dysfunctional valves lead to a variety of symptoms, including dyspnea and precordial pain, as well as syncope, stroke, systemic embolism, and infection including endocarditis. Management of anticoagulation and antiplatelet therapy in patients with PHVs is complex and can result in a variety of hemorrhagic and thrombotic complications. The incidences of various complications related to PHVs[256–259] are noted in Table 30.3.

Pathophysiology

Thrombus formation occurs most commonly in mechanical valves. The mitral valve is more likely to be affected, in part because of lower pressure, slower flow, and more stagnation of blood in the left atrium, particularly in the setting of AF.[260] With aortic PHVs, the rate of thromboembolic events is highest in the first 3 months after AVR.[261] Although mechanical valves have a higher incidence of thromboembolic events without anticoagulation, the rates become comparable to bioprosthetic valves when patients are anticoagulated. Recently subclinical leaflet thrombosis has been described in both TAVR as well as surgical bioprosthetic PHV, resulting in reduced motion of one or more leaflets; this is mainly noted on four-dimensional (4D) volume-rendered cardiac CTA scans.[91] Clinical

TABLE 30.3 Incidence of Complications Associated With Prosthetic Heart Valves

Complications of Prosthetic Heart Valves	Incidence/Prevalence
Bioprosthetic valve failure	25%–40% at 15 years (porcine valves)
Prosthetic valve thrombosis	0.01%–6% per year
Thromboembolic complications	2.5%–3.7% per year (mechanical valve)
Mechanical valve obstruction	0.5%–0.6% per year
Pannus formation	0.2%–4.5% per patient-year
Severe prosthesis-patient mismatch	2%–11%
Severe hemolysis	3%
Paravalvular leak	5%–18%
Infective endocarditis	1%–6%

presentation can include stroke as well as hemodynamic abnormalities, but overall clinical implications of this finding require further investigation.

Prosthetic valve obstruction as reflected by elevated velocities/gradient across the prosthetic valve can be the cause of congestive heart failure and hemodynamic decompensation. The obstruction can be caused by thrombus or pannus formation, prosthesis-patient mismatch (P-PM), or degeneration of the bioprosthesis including calcification and valve leaflet fibrosis. Abrupt mechanical obstruction of the leaflets is more likely due to thrombus than pannus. P-PM is present when the effective orifice area (EOA) of the implanted prosthetic valve is too small in relation to the patient's size (BSA).[262] Typically the valve itself functions normally, but high transvalvular gradients are noted, caused by the small orifice of the implanted PHV. P-PM is now recognized to be an independent predictor of both congestive heart failure as well as mortality. It is best prevented by careful choice of valve size at time of AVR as well as expansion of the aortic root at the time of surgery when needed.[263]

Prosthetic valve regurgitation can occur secondary to leaflet degeneration, calcification, thrombus or pannus formation, and endocarditis. Mechanical prosthetic valves usually have small regurgitant jets called "washing jets" that help prevent thrombus formation. Structural failure of a mechanical prosthesis is rare (although it was a major concern with mechanical PHVs placed before the mid-1980s). Bioprosthetic valves may have severe regurgitation owing to a tear or rupture of one or more of the valve cusps that have become rigid and calcified, chronic degeneration of the leaflets, or in the setting of endocarditis where a variety of mechanisms for severe regurgitation include leaflet perforation.

Besides valvular regurgitation, PVL is a significant and highly morbid clinical entity. The risk factors for PVL include severe calcification of the annulus to which the valve is sewn, surgical technique (continuous sutures have higher risk), multiple valve replacements, inflammation, endocarditis, or steroid use.[258] Implantation of TAVR valves either too shallow or too deep can cause severe PVL. The cardinal hallmarks of significant PVL are heart failure owing to the volume loading caused by regurgitation and hemolytic anemia owing to the high velocity of regurgitant blood flow through the typically narrow PVL orifice, which results in high shear forces and hemolysis of red blood cells.[258] There is occasional hemolysis associated primarily with older-generation mechanical valves.[264]

Infective endocarditis is caused by contamination at the time of surgery or by direct contact of organisms to the prosthetic valve and surrounding structures early after implantation. After endothelialization of the prosthetic valve, as with native valve endocarditis, pathogenic mechanisms include adherence of bacteria to injured or inflamed valve structure, persistence of bacteria and proliferation, and dissemination into the blood stream.[265] Highly virulent organisms such as *S. aureus* can affect adjacent structures and cause perivalvular abscess, fistula, and valve dehiscence.

Diagnosis

Physical Examination

Patients can present with signs of heart failure, stroke, or endocarditis; diagnostic clues may not be apparent. The presence of a new murmur should raise suspicion of prosthetic valve dysfunction. In the case of mechanical valves, the absence or blunting of opening and closing sounds suggests thrombus or pannus formation. The normal auscultatory findings of prosthetic valves and abnormal findings have been described[266]; it is important to appreciate the significance of a variety of murmurs as well as diminished prosthetic valve closing sounds in particular.

Noninvasive Evaluation

Transthoracic echocardiography remains the first-line modality for evaluating prosthetic valve structure and function. TEE has substantially higher sensitivity to assess for endocarditis and regurgitation, especially with mitral valves. PHV evaluation should include stability of the PHV, leaflet morphology and mobility, thrombus or pannus formation of the prosthesis on two-dimensional (2D) and 3D echocardiography, flow dynamics by color Doppler, valve hemodynamics and quantification by Doppler, size and function of cardiac chambers, assessment for any vegetations, as well as pulmonary artery pressure. Apart from transprosthetic velocity and gradients, the key parameters used are EOA, Doppler velocity index, acceleration time, and pressure half-time in the case of mitral prosthetic valves. Doppler flow parameters like vena contracta, jet width, circumferential extent, regurgitant fraction, and volume can be calculated to assess valvular and paravalvular regurgitation.[257,267] Higher than expected gradients from baseline echocardiography (recommended at 6 weeks to 3 months after surgery) may be present owing to high-output states, P-PM, or PVL and should be differentiated from true prosthetic valve obstruction (Fig. 30.26). An indexed EOA less than 0.65 cm^2/m^2 (in obese patients with body mass index ≥30 kg/m^2; cutoff <0.60) is the criterion to determine the presence of P-PM. Peak velocity greater than 4 m/s, mean gradient greater than 35 mm Hg, Doppler velocity index less than 0.25, EOA less than 0.8 cm^2, rounded, symmetric contour of the jet velocity, and acceleration time longer than 100 msec suggest significant aortic prosthetic stenosis. Similarly, peak velocity of 2.5 m/s or higher, mean gradient greater than 10 mm Hg, EOA less than 1 cm^2, and pressure half-time greater than 200 msec is consistent with severe mitral prosthetic stenosis.[267] Often restricted valve leaflet mobility, thrombus, calcification, or pannus formation is seen in prosthetic stenosis.

Other imaging modalities can be used for specific purposes. In addition to echocardiography (bioprosthetic PVL seen in Fig. 30.27A), cinefluoroscopy or multiphase CT can be used to evaluate leaflet mobility in mechanical valves; these can be excellent tools for assessing PVL (Fig. 30.27B and C). CT offers excellent spatial imaging and is highly sensitive to detect calcification. 4D CT can be used to assess prosthetic valve mobility in addition to the detection of leaflet thrombosis on bioprosthetic valves.[91] Cardiac MRI, especially with steady-state free precession sequences (discriminates blood from tissue) and phase-contrast velocity mapping, can detect turbulent flow, velocity, and regurgitant volume through the regurgitant orifice.[268,269] Radiolabeled white blood cell single-photon emission CT (WBC SPECT/CT) and ^{18}F-fluorodeoxyglucose positron emission tomography/CT (F-FDG PET/CT) are showing promise in diagnosing prosthetic valve endocarditis.[270]

Therapy

Medical Therapy

The AHA and ACC recommend antithrombotic therapy with vitamin K antagonists (VKAs) for mechanical valves with an international normalized ratio (INR) range of 2.5 to 3.0. Additionally, aspirin 75 to 100 mg daily is recommended for mechanical valves.[4,84] Anticoagulation with VKA (INR target 2.5) for surgical bioprosthetic valves for 3 to 6 months is recommended (class IIa) as there is an increased risk of stroke early after surgery.[271] Temporary interruption of VKA without a bridging agent (heparin) can be carried out with bileaflet mechanical aortic valves if no other risk

A delivery catheter *(asterisk)* is seen going through the PVL beside a previously placed Amplatzer Duct Occluder *(ADO)* device (St. Jude Medical/Abbott, St. Paul, MN). Two Amplatzer Vascular Plug II devices were placed through the catheter, eliminating PVL. B, The patient from figure A underwent valve-in-valve transcatheter aortic valve replacement (TAVR). The fluoroscopic image shows Hancock II bioprosthetic valve *(white arrow)* in which an Evolut R (Medtronic, Inc., Minneapolis, MN) TAVR valve *(black arrow)* was placed. There was no residual regurgitation noted after the procedure and the patient's condition improved significantly.

factors for thrombosis are present. Otherwise, bridging should be considered, keeping in mind the enhanced risk of bleeding for patients with mechanical AVRs and thromboembolic risk (including older-generation valves) and patients with mechanical mitral valves.[84,272] Administration of fresh frozen plasma is reasonable with mechanical valves for patients receiving VKAs who require emergency noncardiac surgery or invasive procedures.[4] In patients presenting with left-sided mechanical valve obstruction caused by thrombosis, urgent initial treatment with either slow-infusion low-dose fibrinolytic therapy (echocardiography-guided) or surgery is recommended. A large clot (>0.8 cm^2), recurrent thrombosis, readily available surgical expertise, and low surgical risk should sway the treatment toward surgery rather than thrombolysis. In bioprosthetic valves with suspected or confirmed thrombosis in patients who are hemodynamically stable with no contraindications for anticoagulation, initial treatment with VKAs is reasonable and repeat imaging is usually performed to document resolution. Unfortunately, there is as yet no evidence-based medical therapy to prevent or treat bioprosthetic degeneration.

Prosthetic valve endocarditis (PVE) requires aggressive management and often early surgery, with management guided by identification of the causative organism and infectious disease consultation. Revised guidelines for the management of infective endocarditis can be found in a 2015 Scientific Statement from the AHA.[112]

Percutaneous Intervention or Surgery

Redo surgery remains the mainstay of treatment in operable patients with prosthetic stenosis, dysfunction, prosthetic or paravalvular regurgitation, dehiscence, and PVE; however, it is associated with significant morbidity and mortality. Surgery should be considered early (during initial hospitalization before completion of a full therapeutic course of antibiotics) for PVE in patients with valve dysfunction resulting in heart failure; left-sided PVE caused by *S. aureus*, fungal or highly resistant organisms; PVE complicated by heart block or abscess; or persistent infection lasting longer than 7 days.[4,84] Redo surgery with aortic root enlargement is an option for P-PM, whereas balloon rupture of the PHV followed by ViV TAVR has been performed successfully in a small series of patients with bioprosthetic P-PM.[273]

With the advent of catheter-based therapies, percutaneous ViV replacement for stenotic or regurgitant bioprosthetic valves with TAVR valves has become FDA approved. Examples of PVL closure and ViV replacement in a patient at high risk for reoperation are seen in Fig. 30.28. Transcatheter ViV procedures are being performed off-label in other prosthetic valves as well. The current indications for percutaneous PVL closure (still off-label in the United States) are PVL-related heart failure or hemolysis in patients who are at high risk for surgery and have anatomic features suitable for catheter-based therapy.[258]

Key Points

- Valvular heart disease in the critical care setting ranges from the primary cause of acute decompensation to a comorbidity of varying degrees of clinical significance.
- Valvulopathy affects not only valve anatomy but also cardiac structure and function and overall hemodynamics; it is essential to consider all four elements in diagnosis and management.
- AS in the critical care setting requires careful titration of need to maintain cardiac output, avoid hypotension, and replace the aortic valve early if AS is the primary cause of symptoms.
- Low-gradient, low-output AS requires increasing cardiac contractility or transvalvular flow, or both, to differentiate severe AS from primary myocardial dysfunction.

- Acute aortic and mitral insufficiency in the decompensated patient benefit from vasodilator therapy with or without inotropic support; routine vasodilator treatment of chronic aortic and mitral insufficiency in asymptomatic patients does not have the benefit of a compelling evidence base.
- Intraaortic balloon counterpulsation is useful in hemodynamically decompensated patients with MR, of some benefit in severely ill patients with AS, but contraindicated in those with HCM and especially in patients with AI.
- AF exacerbates hemodynamic deterioration in valvulopathies; if left atrial size is less than 6 cm and thrombus is not present, cardioversion and maintenance of sinus rhythm may be highly beneficial.
- Prosthetic valves are a source of significant pathology, including prosthesis-patient mismatch, thrombosis, degeneration, endocarditis, and paravalvular leak among others.

Review Questions

1. An 80-year-old male is hospitalized with congestive heart failure. The patient does not have coronary artery disease. The aortic valve is severely calcified. Aortic valve intervention might be recommended in which (one or more) of the following patient scenarios?

a. Maximum aortic velocity (V_{max}) is 3.2 m/s, mean gradient 25 mm Hg, ejection fraction (EF) 30%, aortic valve area (AVA) 0.8 cm^2. Dobutamine infusion results in a mean gradient rising to 32 mm Hg, EF to 40%, and valve area increasing to 1.1 cm^2.

b. V_{max} is 3.2 m/s, mean gradient 25 mm Hg, EF 55%, AVA 0.8 cm^2, stroke volume index (SVI) 45 mL/min per m^2.

c. V_{max} is 3.2 m/s, mean gradient 25 mm Hg, EF 30%, AVA 0.8 cm^2. Dobutamine infusion results in a mean gradient of 45 mm Hg, EF to 40%, and valve area remaining at 0.8 cm^2.

d. V_{max} is 3.2 m/s, mean gradient 25 mm Hg, EF 55%, aortic valve area 0.8 cm^2, SVI 30 mL/min per m^2.

Answer: c and d. In low-gradient aortic stenosis (AS) where mean gradient is less than 40 mm Hg, it is important to ensure that patients have true severe AS as the cause of heart failure. The patient in scenario a. has pseudo-severe AS, where the low EF is secondary to left ventricular (LV) dysfunction rather than severe AS. Thus with dobutamine infusion, LV function improves, and although there is a slight rise in gradient, the valve opens better, resulting in a higher valve area. The patient in scenario b. has preserved EF with a low gradient; this is a possible presentation of severe AS for patients with small hypertrophic ventricles who simply cannot generate enough flow across the aortic valve to generate a gradient of 40 mm Hg. However, this patient has normal stroke volume (SV). The patient in scenario c. has a "classical" low-gradient, low-flow stage D2-type AS. As such, dobutamine infusion results in an increase in cardiac output and gradient, but the valve area remains the same or rises only slightly, implying a true fixed obstruction of the valve orifice. The patient in scenario d. has classic stage D3-type aortic stenosis with preserved LV function and low gradient owing to low SV volume, typically defined as less than 35 mL/min per m^2.

2. A 68-year-old male patient with symptomatic chronic severe mitral insufficiency and mitral valve prolapse is referred for percutaneous mitral valve repair. His LV ejection fraction is 40%. He is a diabetic receiving dialysis with prior bypass surgery who had mantle radiation for lymphoma 25 years ago. You perform a workup for possible transcatheter mitral clip placement, note him to be suitable on an anatomic basis, and explain to him that which of the following applies to him?

a. He does not meet ACC/AHA criteria for mitral valve repair at present.

b. He does meet American College of Cardiology/American Heart Association (ACC/AHA) criteria but should have surgical mitral valve repair instead.

c. Based on a randomized trial of patients like him, percutaneous mitral valve repair is a suitable alternative to surgery.

d. The likelihood of moderate or greater mitral insufficiency after percutaneous mitral valve repair will be slightly worse than if he were to undergo surgery.

e. When compared with surgical mitral valve repair, the overall outcomes for percutaneous repair of functional mitral regurgitation (MR) have been similar, whereas the outcomes for degenerative MR (like he has) have been inferior to surgery.

Answer: e. By ACC/AHA criteria, patients with symptomatic chronic severe MR and EF greater than 30% meet class I criteria for mitral valve repair; this recommendation is unchanged in the 2017 amended guidelines. As a diabetic patient receiving dialysis with a likely hostile chest (prior coronary artery bypass grafting plus mantle radiation), he would make a prohibitive risk for surgical repair of the mitral valve. The EVEREST II Trial compared patients with well-preserved EF and low risk for surgery; the high-risk study was not a randomized trial. Both studies enrolled patients with preserved EF. The evidence base therefore does not warrant answer c. Moderate or greater mitral insufficiency in EVEREST II was almost 3 times as likely at 1 year (46% vs. 17%) with percutaneous rather than surgical mitral valve repair. In subgroup analyses, outcomes after mitral valve clip were similar for functional MR compared to surgery, whereas surgery was superior to clipping for degenerative MR. This patient is a potential candidate for U.S. Food and Drug Administration (FDA)-approved mitral clip implantation in patients with degenerative MR.

3. A 50-year-old female presents to the emergency department with dyspnea on exertion with NYHA class III-IV symptoms. Her past medical history includes known hypertrophic cardiomyopathy and coronary artery disease with a stent to the left anterior descending artery (LAD) a year ago. She is currently taking Toprol XL 50 mg daily. Her blood pressure is 140/80 and her heart rate is 65 beats/min. Her echocardiogram shows normal LV function and septal hypertrophy with a septal width of 2.2 cm. The left ventricular outflow tract (LVOT) gradient at rest was 55 mm Hg. There is systolic anterior movement of the anterior mitral valve leaflet. The mitral valve leaflet is abnormally long, and moderate to severe MR is seen. She underwent coronary angiography that shows a patent LAD stent and nonobstructive disease in the rest of the vessels. Which of the following is the best management strategy?

a. Increase Toprol XL to 100 mg daily to decrease the heart rate even further.

b. Refer to an interventional cardiologist for alcohol septal ablation and reassess the mitral regurgitation later.

c. Perform stress echocardiogram to determine if the LVOT gradient increases with exercise.

d. Refer to cardiac surgery for myomectomy and mitral valve repair.

Answer: d. Patients who have an LVOT gradient greater than 50 mm Hg at rest or with physiologic provocation despite reasonable pharmacologic management can be considered for intervention with surgical myomectomy or alcohol septal ablation. Generally speaking, the latter should be reserved for patients who have major comorbidities and are poor candidates for surgery. Surgical myomectomy with mitral valve repair in patients with coexisting mitral valve pathology is a better option for sustained relief of LVOT obstruction and has a lower incidence of permanent pacemaker placement, avoids myocardial necrosis with its attendant risks, and addresses the mitral valve pathology. Performing a stress echocardiogram is not necessary as this patient already qualifies for intervention based on her resting LVOT gradient.

- Electrical Shocks
- Electrolyte, Endocrine, and Metabolic Abnormalities
- Acquired QT Prolongation

Metabolic Derangements

Conclusions

Cardiac arrhythmias occur in up to 30% of patients admitted to the intensive care unit (ICU).[1] Arrhythmias are associated with an increased morbidity and prolongation of the hospital stay. Management of serious cardiac arrhythmias is the shared responsibility of emergency specialists: critical care physicians, cardiologists, and electrophysiologists. Antiarrhythmic drugs are the mainstay of acute therapy for supraventricular arrhythmias and hemodynamically stable ventricular tachycardia (VT), but we also have the option of catheter ablation for refractory supraventricular arrhythmias and VT. Temporary pacing remains the "gold standard" for urgent/emergent therapy of symptomatic bradyarrhythmias. Permanent pacing is the only option for treatment of chronic bradycardias. Patients with structural heart disease at risk for sudden cardiac death (SCD), and those resuscitated from hemodynamically unstable ventricular tachyarrhythmias are usually managed with implantable defibrillators that can have adjunctive biventricular pacing for treatment of congestive heart failure (CHF) in patients with native conduction disturbances.

Critical care physicians deal with a plethora of medical and surgical problems in their patients. Arrhythmias may be the primary abnormality or may be secondary to myocardial ischemia, electrolyte imbalance, or toxic/metabolic disturbances. Optimal management of arrhythmias requires expertise in electrocardiography and clinical pharmacology as well as knowledge of arrhythmia precipitants, including proarrhythmia caused by antiarrhythmic medication or other drugs.[2] The responsibility of the critical care physician is to facilitate the transition from acute to chronic care by referring the patient with an arrhythmia to a cardiologist or an electrophysiologist.

Therefore the major emphasis of this chapter is on acute care of the patients with arrhythmias.

Bradycardias

Bradyarrhythmias usually present as either sinus node dysfunction or atrioventricular blockade (AV block). Bradyarrhythmias and indications and techniques for temporary cardiac pacing are reviewed extensively in Chapter 5. A brief overview is included here to highlight important issues for the intensivist.

Sinus Bradycardia and Sinus Node Dysfunction

Sinus bradycardia is defined as periods when the impulse from the sinoatrial (SA) node is less than 60 beats/min. Normal resting heart rates vary with age and physical conditioning and are affected by multiple factors, including medications, emotions, fever, and the interplay between the parasympathetic and sympathetic nervous systems. In the absence of symptoms, sinus bradycardia is usually benign and requires no treatment. In healthy adults sinus bradycardia is a frequent finding, especially during sleep when rates of 30 beats/min and pauses up to 2 seconds are not uncommon and are usually benign.[3–6]

Without overt heart disease physiologic bradycardia can be due to enhanced vagal tone as is seen in well-conditioned athletes.[7–10] In the elderly, sinus bradycardia may be a prelude to the development of sick sinus syndrome, a condition in which the sinus node is no longer functioning appropriately.[11] Finally, bradycardia in a normal heart can be due to a rare familial disorder in which asymptomatic sinus bradycardia results from a mutation in the *HCN4* and *SCN5A* ion channel genes.

Vasovagal episodes may be associated with severe bradycardia owing to heightened parasympathetic activity and sympathetic withdrawal.[12] Stimuli that cause vagal activation, include carotid sinus stimulation, vomiting, the Valsalva maneuver, as well as many other external events that can precipitate activation of the neurohormonal axis, causing heightened parasympathetic activity and sympathetic withdrawal and resulting syncope.

Pathologic Conditions Causing Sinus Bradycardia

Sinus bradycardia may be the first manifestation of sinus node dysfunction and sick sinus syndrome, which is a condition in which the sinus node can no longer provide adequate heart rates for normal physical activities. This results in patient complaints of fatigue and exercise intolerance.[13] Sinus bradycardia is a complication of acute myocardial infarction (AMI) in 10% to 15% of cases, particularly those involving the right coronary artery, as it supplies the SA node in approximately 60% of people. Patients with obstructive sleep apnea frequently have sinus bradycardia, which can be severe, with rates less than 30 beats/min during apneic episodes.[14] Sinus bradycardia can be caused by increased intracranial pressure, which should be suspected when bradycardia occurs in patients with neurologic disorders. Other neurologic conditions that can cause sinus bradycardia include stroke or trauma to the cervical or thoracic spine that causes sympathetic denervation of the heart leaving unopposed parasympathetic tone.[15] Infectious agents that cause bradycardia include Lyme disease, Chagas disease, *Legionella,* psittacosis, Q fever, typhoid fever, typhus, babesiosis, malaria, leptospirosis, yellow fever, dengue fever, viral hemorrhagic fevers, trichinosis, Rocky Mountain spotted fever, and gram-negative sepsis.[11,16] Miscellaneous pathologic causes of bradycardia include hypothyroidism, anorexia nervosa, hypothermia, and severe hypoxia.

Several medications are associated with sinus bradycardia either as an expected response or associated with toxicity.

- Nondihydropyridine calcium channel blockers: verapamil and diltiazem
- Opioids and sedatives
- Cimetidine
- Ivabradine
- Amiodarone and other antiarrhythmic medications
- Hepatitis C drugs sofosbuvir and daclatasvir in patients receiving amiodarone
- Chemotherapeutic agents including thalidomide, lenalidomide, paclitaxel
- Organophosphate compounds

Of note, digoxin, in therapeutic doses, does not significantly affect the sinus node.[13]

Types of SA Nodal Dysfunction

Sinus pause or arrest is defined as the absence of sinus P waves on the ECG that can last from 2 seconds to several minutes. This is caused by a failure of discharge from the sinus node and thus has no arithmetic relationship to the basic sinus rate (Fig. 31.1).

SA nodal exit block occurs as a result of interference with the delivery of impulses from the SA node to the neighboring atrial tissue. First-degree SA exit block results from intra–SA node conduction delay and is not manifest on the surface ECG. Second-degree SA exit block has two types. Type I second-degree SA exit block is characterized by progressive PP interval shortening before a pause caused by a dropped P wave. This is analogous to the Wenckebach phenomenon that occurs in the AV node. The pause has a duration that is less than two PP cycles in duration. In type II second-degree SA exit block, pauses are exact multiples of the basic PP interval, analogous to second-degree type 2 block that occurs in the AV node (Fig. 31.2). Third-degree SA nodal exit block prevents sinus node impulse to reach the right atrium. It cannot be distinguished from sinus arrest.

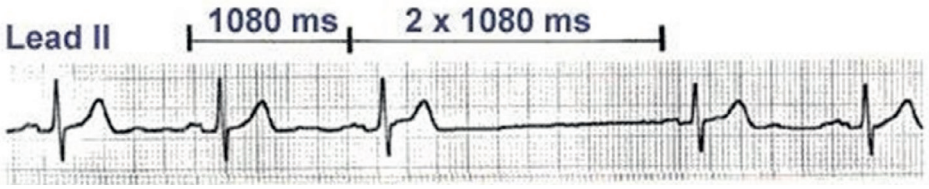
Sinus arrhythmia (Fig. 31.3) is a normal variant in which there are respirophasic changes in the PP intervals on ECG (usually prolongation of PP intervals during expiration). Rarely sinus arrhythmia can be seen secondary to digoxin toxicity. Sinus arrhythmia, except when caused by digoxin toxicity, is not considered abnormal, rarely causes symptoms, and requires no treatment.

Wandering atrial pacemaker is present when there are three or more ectopic atrial foci within the atrial myocardium that serve as the dominant pacemaker for atrial rhythm (Fig. 31.4). Because the location of the pacemaker changes, the PR interval can change as well. This can be seen in young, healthy individuals, especially in athletes; symptoms are rare and no treatment is required.

Treatment of Sinus Bradycardia

When severe symptomatic sinus bradycardia occurs, the patient should be treated per the standard Advanced Cardiovascular Life

• **Fig. 31.1** Sinus pause.



• **Fig. 31.2** Sinoatrial exit block (type II).

• **Fig. 31.3** Sinus arrhythmia, a normal variant of sinus rhythm. Here there are respirophasic changes in the RR interval on electrocardiogram (gradual prolongation of RR intervals during expiration).

• **Fig. 31.4** Wandering atrial pacemaker.

Support (ACLS) guidelines[17] (Fig. 31.5). Atropine is the initial treatment: 0.5 mg intravenous (IV) push to repeat every 3 to 5 minutes, if needed, up to a dose of 3 mg IV. If atropine is not effective, IV dopamine or IV epinephrine can be used. If the patient does not respond to atropine, dopamine, or epinephrine, transcutaneous pacing can be effective in the acute management of these patients. In large patients, high transcutaneous pacing outputs are required to achieve capture and this can cause significant discomfort to the patient. It is important to assess either the radial or femoral pulse during transcutaneous pacing to confirm capture, as telemetry readings often give a false indication of capture owing to the large pacing artifact seen on the monitor; 30% to 40% of patients have either no or inconsistent capture with transcutaneous pacing. Any patient with symptomatic sinus node dysfunction that is not acutely reversible with medications or transcutaneous pacing requires placement of a temporary transvenous pacemaker. If no reversible cause of the bradycardia is found, permanent pacing is required.

AV Block

AV block is the delay or interruption of conduction between the atrium and ventricle because of anatomic or functional impairment. AV block can be intermittent or permanent. We describe the various types of AV block in the following text.

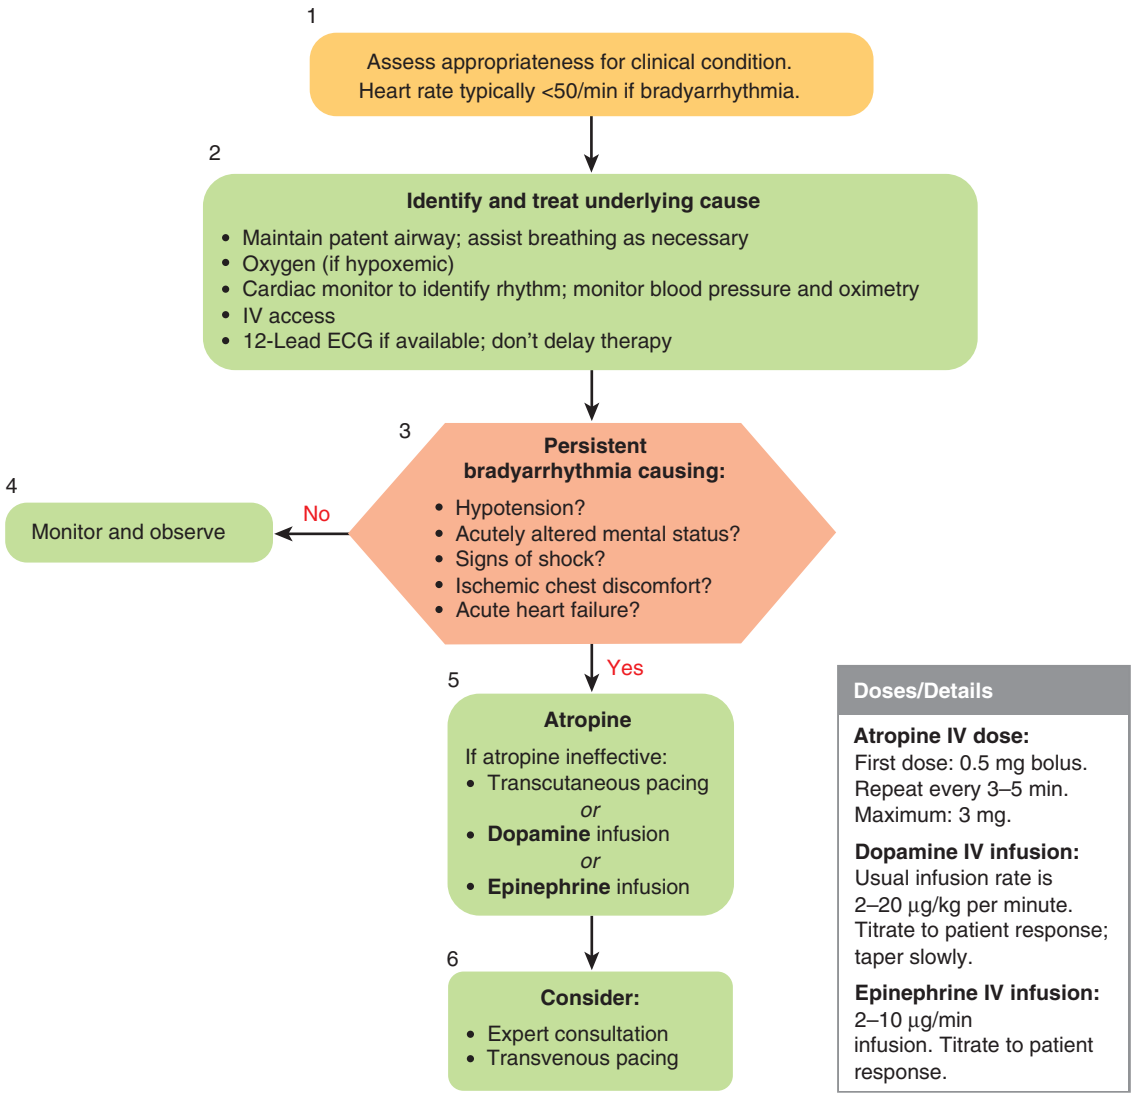
First-degree AV block is simply delayed conduction from the atria to the ventricles. Every atrial impulse is conducted to the ventricles in a delayed fashion such that the PR interval is greater than 200 msec. If the QRS complex on the surface ECG is narrow, the delay is almost always in the AV node. In the presence of a wide QRS complex, the delay may be in either the AV node or the His-Purkinje system.

Second-degree AV block occurs when not every atrial impulse is conducted to the ventricles. Second-degree AV block is classified as Mobitz type I (Wenckebach); Mobitz type II is 2:1 AV block or high-degree AV block. In *Mobitz I (Wenckebach) block,* PP intervals are constant, with gradual PR prolongation before failure of impulse conduction to the ventricle (nonconducted P wave) (Fig. 31.6). Although classic Wenckebach block involves simultaneous shortening of successive RR intervals before AV block, variable RR intervals are actually more common. In younger people, Mobitz I AV block with narrow QRS complexes is benign and does not progress to more advanced AV conduction disturbances. In older patients, however, the prognosis may be worse and similar to that of Mobitz II block (see following text). Mobitz type I AV block with a narrow QRS complex almost always occurs at the AV node. Rarely, Mobitz I second-degree AV block may have an intra-His location. Mobitz I AV block with wide QRS complexes may occur in either the AV node or the His-Purkinje system. Mobitz I second-degree AV block may accompany an inferior myocardial infarction (MI). That condition is benign, with a favorable prognosis in the absence of hemodynamic compromise. The conduction disturbance usually is transient, and permanent pacing is not required.

Mobitz II AV block is characterized by sudden failure of atrial impulse conduction to the ventricle without prior PR prolongation (Fig. 31.7). This form of AV block can herald development of complete AV block and possible syncope. Mobitz II AV block usually occurs in the setting of wide QRS complexes, and usually is a sign of infranodal, His-Purkinje system conduction system disease. Escape rhythms are unreliable below the AV node; therefore Mobitz II second-degree AV block is often an indication for permanent pacing. Mobitz II second-degree AV block in the setting of anterior infarction is associated with pump failure and high mortality rates. Survivors should receive permanent pacemakers.

Complete AV block is diagnosed by the presence of independent atrial and ventricular activity on the ECG, with the atrial rate being faster than the ventricular rate. The PP interval is constant and the RR intervals are constant. The PR interval is variable in a random, nonrecurring pattern (Fig. 31.8). Complete AV block can also be present during all varieties of atrial tachycardias (ATs) including atrial fibrillation (AF).

Complete AV block proximal to the His bundle results in a narrow QRS complex escape rhythm with rates of 50 to 60 beats/min. Complete intra-His block may also result in a narrow QRS escape rhythm with ventricular rates less than or equal to 45 beats/min. Complete AV block below the His bundle results in a wide



• **Fig. 31.5** Management of adult bradycardia. *ECG,* Electrocardiogram. (From Link MS, Berkow LC, Kudenchuk PJ, et al. Part 7: adult advanced cardiovascular life support: 2015 American Heart Association guidelines update for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation.* 2015;132(18 suppl 2):S444–S464.)

• **Fig. 31.6** Second-degree atrioventricular block, Mobitz type I (Wenckebach). The PR interval progressively lengthens until a P wave is not conducted. The intervals may be fixed or variable. In this example, there are four P waves for every three QRS complexes.

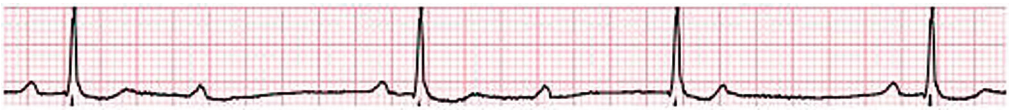
QRS complex escape, usually less than 40 beats/min, and is an indication for immediate pacing because the escape rhythm in this case is very unreliable and could terminate at any time.

In the setting of inferior infarction, complete (narrow QRS) AV nodal block can occur and is expected to recover in more than 90% of patients (time to recovery 30 minutes to 16 days).[18] In general, atropine improves AV nodal conduction and carotid massage worsens it. These interventions have the opposite effect when the AV block is in the His-Purkinje system. Exercise, by increasing endogenous catecholamines, may reduce the extent of block at the AV node but may worsen block below the AV node. Precipitation of second-degree, high-grade, or complete AV block during exercise strongly suggests an infranodal site of block and is an indication for permanent pacing.[19]

The surface ECG allows the clinician to localize the site of AV block without the use of invasive electrophysiologic testing. It is important to remember a few general rules to avoid common ECG misinterpretations of second-degree AV block. First, 2:1 AV block

• **Fig. 31.7** Second-degree atrioventricular block, Mobitz type II. There is a constant PR interval until a P wave is suddenly not conducted. Note the QRS is prolonged to approximately 120 msec.

• **Fig. 31.8** Complete heart block. The P waves and QRS complexes are regular, but they are not associated with one another.



• **Fig. 31.9** 2:1 Atrioventricular (AV) block. In the setting of AV block with a 2:1 interval, it is not possible to determine by surface electrocardiogram if the block is Mobitz type I or Mobitz type II. Narrow QRS complexes generally result from AV nodal block. Wide QRS complexes are compatible with block in either the AV node or His-Purkinje system.

• **Fig. 31.10** High-grade atrioventricular (AV) block. Two or more P waves are not followed by a QRS complex. In this example, there are three P waves for each QRS complex, an example of 3:1 high-grade AV block.

can be nodal or infranodal and, second, 2:1 block associated with narrow QRS complexes generally results from AV nodal block (Fig. 31.9). Wide QRS complexes are consistent with block in either the AV node or His-Purkinje system. If more than one P wave is not conducted to the ventricle, the term *high-grade AV block* is used (Fig. 31.10).

Pathophysiologic Causes of AV Block

- *Idiopathic cause.* This is the most common cause of AV block; it accounts for 50% of cases and is caused by progressive impairment of the conduction system over decades. Lev disease refers to progressive fibrotic infiltration of the conduction system in patients younger than 60 years. Lenegre disease occurs in older patients (>70 years) and is caused by fibrosis or calcification extending from any of the fibrous structures adjacent to the conduction system into the conduction system.[20,21]
- *Causes associated with other cardiac disease.* Ischemic heart disease accounts for approximately 40% of cases of AV block.[22] AV block is seen with either chronic ischemic heart disease or during AMIs. Up to 20% of patients with AMIs develop some form of AV block.[23,24] The larger the infarct, the more likely and more severe the heart block is. Restoring perfusion in the setting of an AMI often improves AV conduction. Myocarditis can cause AV block from a variety of causes, including rheumatic fever, Lyme disease, diphtheria, viruses, toxoplasmosis, and syphilis.[25–34] Infiltrative cardiomyopathies such as amyloidosis and sarcoidosis can also lead to AV block
- *Cardiac procedures.* Transient AV block can occur from catheter manipulations in the right heart across the tricuspid valve—for example, Swan-Ganz catheter placement or pacing wires of any type. This "traumatic" AV block usually recovers within several minutes to hours. AV conduction abnormalities may also result from other cardiac procedures, including coronary artery bypass grafting, valve replacement surgery, transcatheter aortic valve implantation, catheter ablation of arrhythmias, transcatheter closure of ventricular septal defect, and alcohol (ethanol) septal ablation.[35–37]
- *Congenital causes.* AV block can be seen in a variety of congenital heart defects that result in structural abnormalities, such as congenitally corrected transposition of the great arteries, large primum atrial septal defects, and large AV septal defects. Congenital AV block can also be seen without structural heart disease, most commonly in neonatal lupus where anti-Ro/SSA or anti-LA/SSB antibodies pass via the placental from the mother

to the baby.[38,39] The mortality rate in this condition is highest in neonates, diminishes during childhood and adolescence, and then increases later in life. Persistent ventricular rates less than 50 beats/min correlate with the development of symptoms and syncope. Symptomatic patients and those patients with left ventricular (LV) dilatation should receive permanent pacemakers.

Medications Causing AV Block

Multiple medications can impair AV conduction. The most common are β-blockers, nondihydropyridine calcium channel blockers (verapamil and cardizem), digoxin, adenosine, amiodarone, and other antiarrhythmic medications. Most patients with drug-induced AV block have preexisting underlying conduction disease. In a study of 169 patients with second- or third-degree AV block not related to digitalis toxicity, AMI, or vasovagal syncope, 54% were receiving β-blockers, verapamil, or diltiazem.[40] Drug discontinuation resulted in resolution of AV block in 32 of 79 cases, but AV block later recurred without medication in 18 of these patients.

Miscellaneous Causes of AV Block

Hyperkalemia with plasma potassium concentrations above 6.3 mmol/L, hyperthyroidism, hypothyroidism, myxedema, and thyrotoxic periodic paralysis can all cause degrees of AV block.[41–43]

Treatment of AV Block

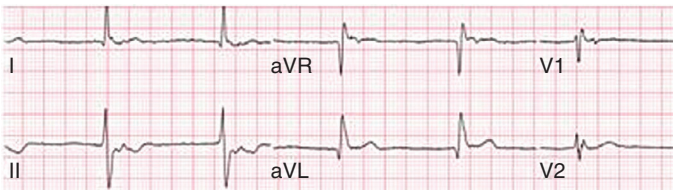
Often there are medications that can be withdrawn to improve AV conduction, but there are no medications that can be administered to permanently improve AV conduction. Transient AV nodal block may be managed with atropine. Infranodal block may be managed with (carefully titrated) isoproterenol until temporary or permanent pacing is established.

Junctional Rhythm

When the sinus node does not depolarize the atrium for any reason (high vagal tone, sinus node dysfunction), the cells near the AV junction (AV node, His bundle) may take over as the active pacemaker. Retrograde activation of the atrium, manifest as negative P waves in the inferior leads (II, III, aVF), may be seen (Fig. 31.11). If the junctional rhythm goes faster than 60 beats/min, it is termed an *accelerated junctional rhythm*. This is a common manifestation of digitalis toxicity or can be seen with any type of cardiac injury (myocarditis, after coronary artery bypass grafting, and after valve replacement surgery).[44]

Vagally Mediated Sinus Arrest, Bradycardia, and Heart Block

The most common cause of nonconducted P waves on telemetry or Holter recordings is bradycardia-associated AV block caused by increased vagal tone. This manifests as sudden (usually nocturnal) block of one or more P waves with or without antecedent PR prolongation. This phenomenon is characterized by PP prolongation before AV block. Vagally mediated sinus arrest, bradycardia, and heart block often occur in the ICU setting as a result of suctioning, gagging, femoral vessel compression (for hemostasis), and a variety of other triggers (Box 31.1). Vagal stimulation may lower blood pressure with or without significant bradycardia. Bradyarrhythmias and hypotension usually resolve when vagal stimulation ceases. Persistent bradycardia or hypotension mediated by vagal tone may require placing the patient in the Trendelenburg position, temporary saline solution infusion, or IV administration of atropine to fully resolve the transient episode.



• **Fig. 31.11** Junctional rhythm with retrograde P waves that are negative in the inferior leads.

• BOX 31.1 Triggers for Vagally Mediated Heart Block

Gagging reflexes such as with intubation or placement of a nasogastric tube
Endotracheal suctioning and irrigation of the carina
Distention of a visceral organ such as during colonoscopy or bladder irrigation
Increased intrathoracic pressure as may occur with coughing or excessive tidal volumes on the ventilator
Direct stimulation of the carotid body, which may occur with vascular surgery in this area
Increased intracranial pressure and certain neurologic procedures
Manual compression during femoral artery line removal
Seizure-related
Neurocardiogenic syncope or simple fainting in patients undergoing painful procedures or possibly in visitors to the intensive care unit

Supraventricular Tachycardia

Overview

Supraventricular tachyarrhythmias occur frequently in critically ill patients. Conditions such as hypoxemia, electrolyte imbalance, catecholamine excess (endogenous and exogenous), and other metabolic disturbances predispose ill patients (with or without preexisting arrhythmic substrates) to tachyarrhythmias. Intensivists must be prepared for acute management of supraventricular tachycardia (SVT). Knowledge of arrhythmia mechanisms, appropriate choices for acute pharmacotherapy, and indications for urgent or emergent direct current cardioversion are requisite.[45] We discuss the mechanisms of SVTs, provide an ECG-guided approach to their diagnosis, and cover specific treatments for these dysrhythmias. The substrate for some SVTs is present before ICU admission, but the most common SVTs—AF (and flutter) and multifocal AT (which may be transient, requiring no chronic therapy)—do not necessarily have a prior substrate.

Premature Atrial Contractions, Junctional Premature Contractions

Premature atrial, junctional, or ventricular beats are common in patients with or without structural heart disease and rarely result in significant alteration of cardiac output. They may occur as a result of enhanced sympathetic tone, metabolic stress, pericarditis, or direct mechanical irritation (as occurs with intracardiac catheters). They can also be due to the stimulant effects of caffeine, alcohol, intravenous inotropic support, or illicit drugs (such as cocaine).

Atrial premature beats may be conducted aberrantly to the ventricle and can be confused with premature ventricular beats, or they may block in the AV node, creating a pause that may be confused with sinus arrest or SA exit block. Atrial premature beats may initiate reentrant SVTs or AF. Premature atrial contractions rarely require treatment, unless they trigger sustained SVTs. β-Blockers or calcium blockers would be the first-line therapy for premature beats if treatment is required.

Paroxysmal Supraventricular Tachycardia

The prevalence of paroxysmal SVT (PSVT) in the general population is 2.25 per 1000 persons.[45] Compared with patients with PSVT and other cardiovascular diseases, patients with PSVT and structurally normal hearts are younger (37 years vs. 69 years, $P = 0.0002$) and have faster PSVT (186 beats/min vs. 155 beats/min, $P = 0.0006$). Women have twice the risk of men of developing PSVT.[45] Individuals older than 65 years have more than 5 times the risk of younger persons of developing PSVT.[46]

Among women with SVT and no other cardiovascular disease, the onset of symptoms begins during childbearing years (e.g., 15–50 years) in 58%.[46] The first onset of SVT can occur during pregnancy (in 3.9% of women), but among women with an established history of SVT, pregnancy exacerbates arrhythmia occurrences and makes them more difficult to treat because of the potential side effects of treatments (medications or catheter ablation) to the fetus.[47]

It is important to record a 12-lead ECG of any SVT to differentiate tachycardia mechanisms. If the AV node is *not* an obligate component, treatment that targets the AV node does not reliably terminate those arrhythmias. Also, if the QRS duration is longer than 120 msec, it is crucial to distinguish VT from SVT with aberrant conduction, preexisting bundle branch block, or preexcitation. The presence of AV dissociation (with ventricular rate faster than atrial rate) most commonly means VT is present but it could also mean junctional tachycardia, especially if the QRS is narrow.

Types of PSVT reviewed in the following text are: AV nodal reentry tachycardia (AVNRT), AV reentrant tachycardia (AVRT), Wolff-Parkinson-White (WPW) syndrome, AT, atrial fibrillation, and atrial flutter.

AV Nodal Reentrant Tachycardia

AVNRT is the most common reentrant SVT. It is usually seen in young adults without structural heart disease, and more than 60% of cases are observed in women.[48] The ventricular rate is usually 160 beats/min to 200 beats/min but can range from 110 beats/min to more than 250 beats/min (in rare cases, the rate can be <100 beats/min).[49] Symptoms caused by AVNRT include palpitations, lightheadedness, and near-syncope; rarely patients may be asymptomatic. True syncope is unusual. Atrial contraction on a closed AV valve may produce neck pounding.[50]

The anatomic substrate of AVNRT is dual AV nodal physiology. In 76% to 90% of cases, antegrade conduction proceeds along the posterior (slow) AV nodal pathway and retrograde conduction along the anterior (fast) AV nodal pathway[51,52]; this is typical slow-fast AVNRT. Because retrograde conduction is so rapid, atrial and ventricular activation are virtually simultaneous. P waves are usually not visible on the surface ECG or may appear in the terminal portion of the QRS complex (pseudo R′ in lead V1 or pseudo-S waves in the inferior leads) (see Fig. 31.12). Less common (so-called atypical) variants (fast-slow, slow-slow, and slow–sort of slow) of AV nodal reentry also exist, and all are easily amenable to catheter ablation.[52] In the less common types, the inverted retrograde P waves may be seen on the 12-lead ECG anywhere in the ST segment. Medical treatment of AVNRT is discussed later, and if medications fail, this arrhythmia is easily amenable to catheter ablation.

AV Reentrant Tachycardia and Wolff-Parkinson-White Syndrome

APs directly connect the atrium and ventricle, bypassing the normal conduction through the AV node and the His-Purkinje system. APs have conduction properties similar to those of myocardium and are therefore capable of very rapid conduction. The pathways are considered "manifest" if they conduct in the anterograde direction, demonstrating preexcitation with a delta wave on the ECG. The ECG pattern of preexcitation is a short PR interval with a slurred, wide upstroke (delta wave) of the QRS complex. Manifest pathways occur in 0.1% to 0.3% of the population, are more common in men than women, and can conduct in both the anterograde and retrograde directions or, less commonly, only in the anterograde direction.[53] Anterograde pathways that are capable of conducting very rapidly place patients at risk of SCD when AF occurs leading to very rapid sequential activation of the ventricles, causing the ventricles to fibrillate. "Concealed" pathways conduct only in the retrograde direction and therefore do not cause preexcitation on the 12-lead ECG and do not place patients at risk of SCD.

AVRT is a reentrant arrhythmia that uses the AP as one limb of the tachycardia circuit and the AV node as the other limb. Orthodromic AVRT uses the AV node as the antegrade limb and the AP as the retrograde limb; usually a narrow QRS is seen on the surface ECG with a retrograde P wave seen in the ST segment (Fig. 31.13).

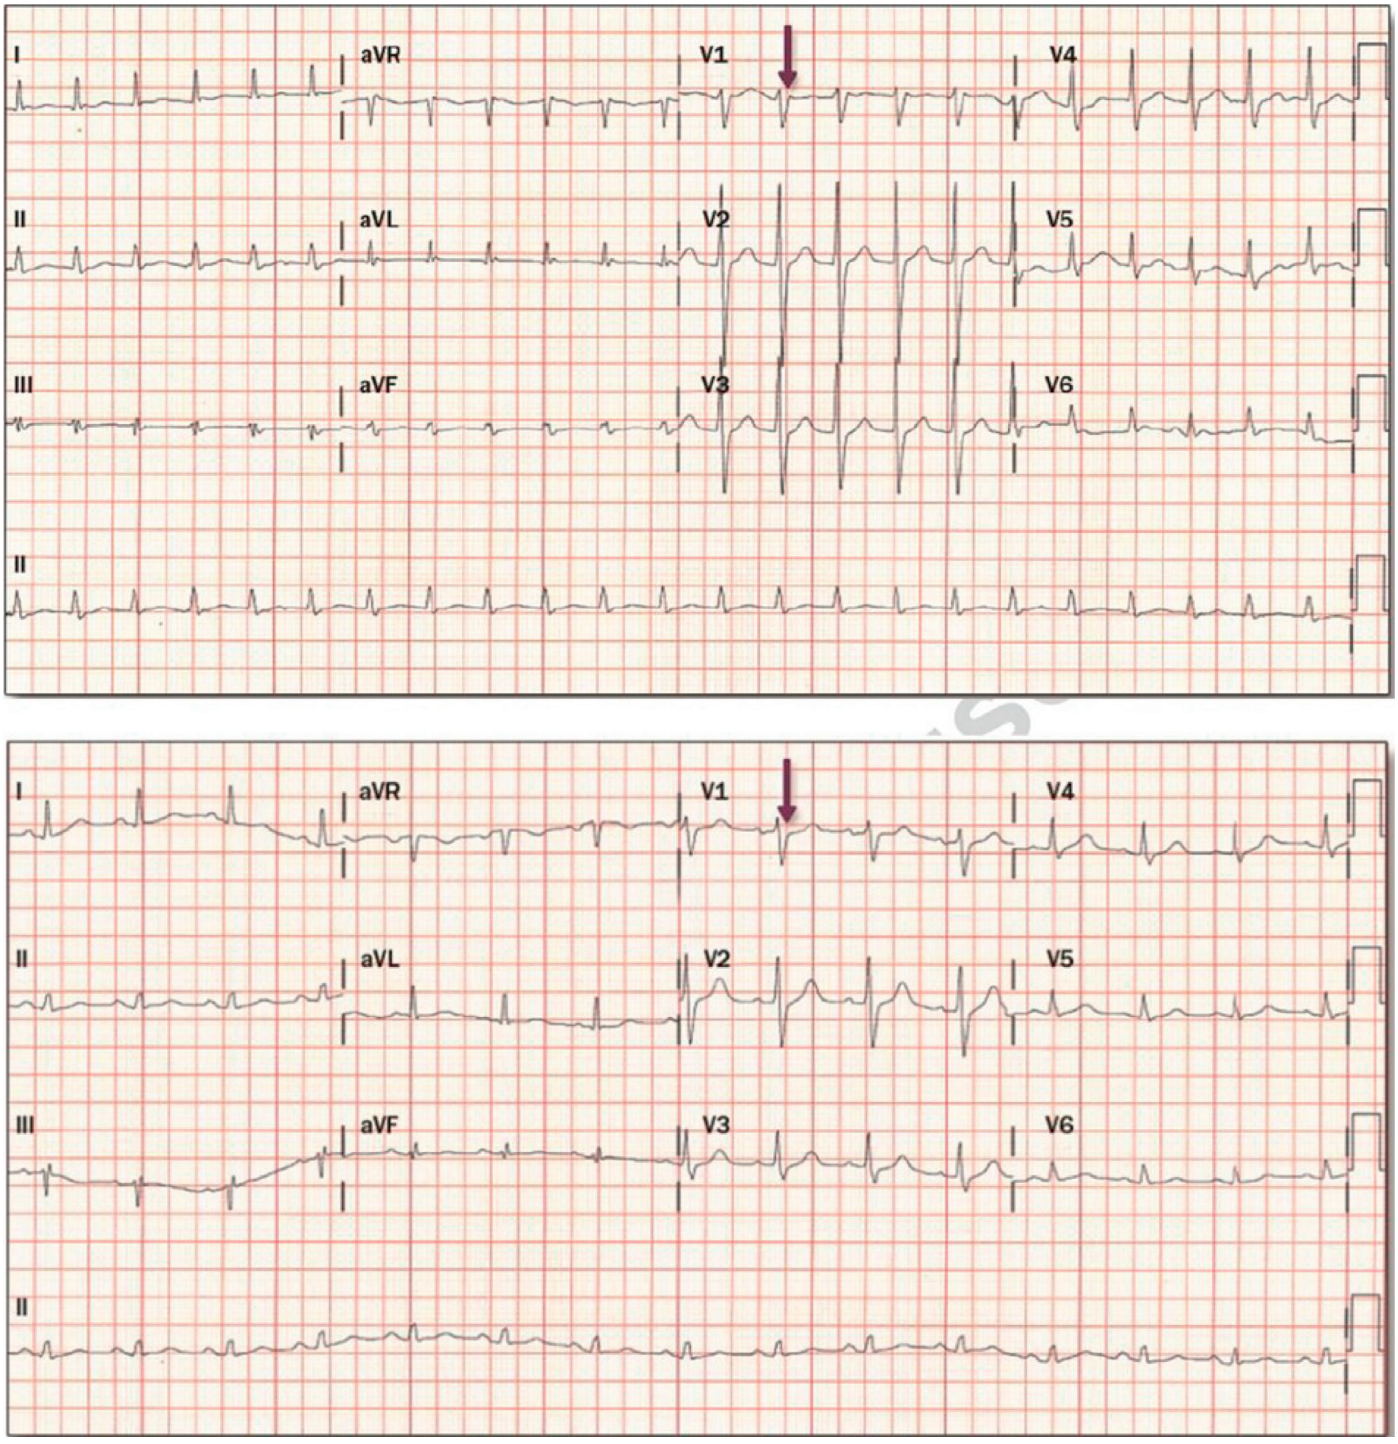
Antidromic AVRT uses the AP as the antegrade limb and the AV node as the retrograde limb; this tachycardia almost always has a wide QRS morphology. The resulting maximally preexcited wide QRS rhythm of antidromic AVRT may be difficult to distinguish from VT on an ECG (Fig. 31.14).

AVRT has a longer RP interval during tachycardia compared with that seen in AVNRT. In both AVNRT and AVRT P waves (if visible on surface ECG) will be negative in the inferior leads because the atria are activated in the retrograde direction. AV block is unusual during AVNRT and *excludes* the diagnosis of AVRT (which requires both atrial and ventricular participation).

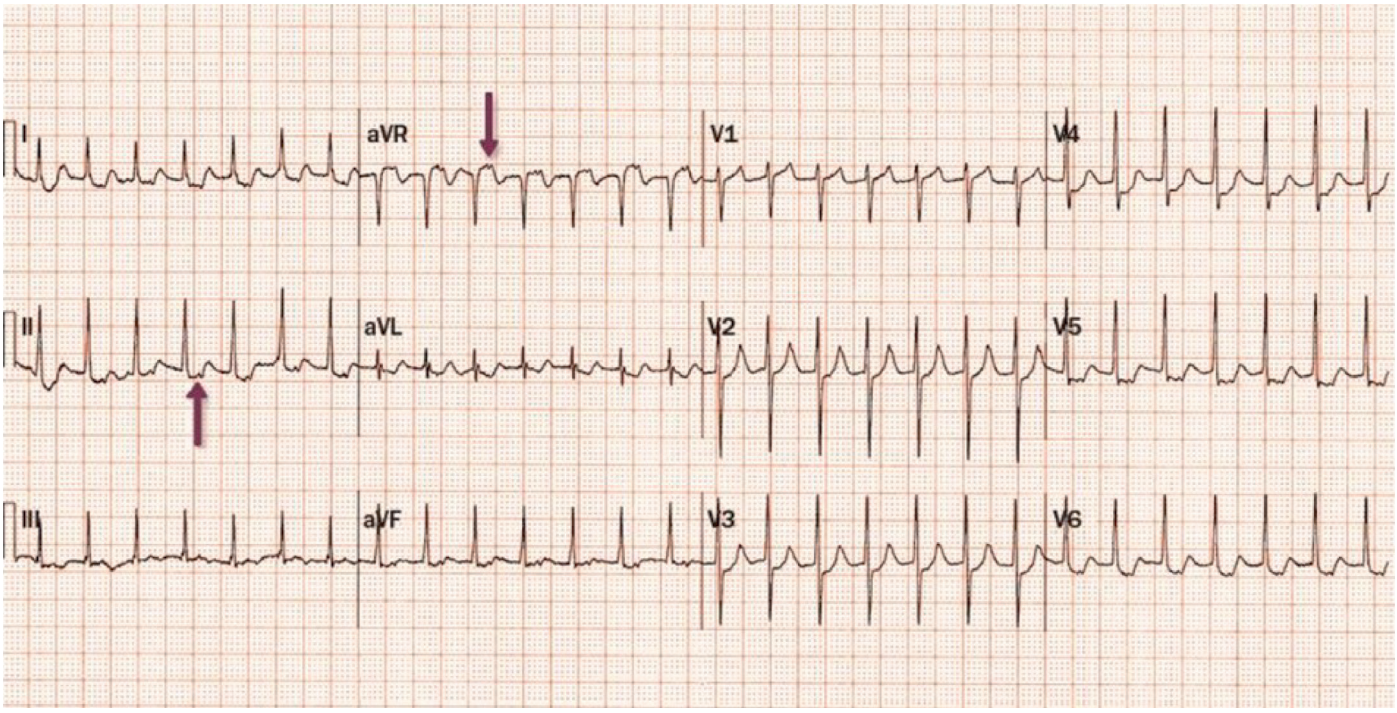
WPW is a congenital condition involving strands of abnormal conductive cardiac tissue between the atria and ventricles that cause a preexcitation pattern on an ECG and provide an AP as one limb of a reentrant tachycardia circuit or SVT. Symptomatic presentation usually occurs during the teenage years or early adulthood. Pregnancy may exacerbate symptoms. Approximately 25% of patients with a Wolff-Parkinson-White ECG pattern are incapable of retrograde conduction via the AP and therefore cannot have orthodromic AVRT, but they can have antidromic AVRT or preexcited AF with rapid rates as described earlier (Fig. 31.15).

Asymptomatic patients generally have a benign prognosis; however, the initial presentation may be ventricular fibrillation (VF).[56] The risk of SCD associated with WPW is highest in the first two decades of life.[55–57]

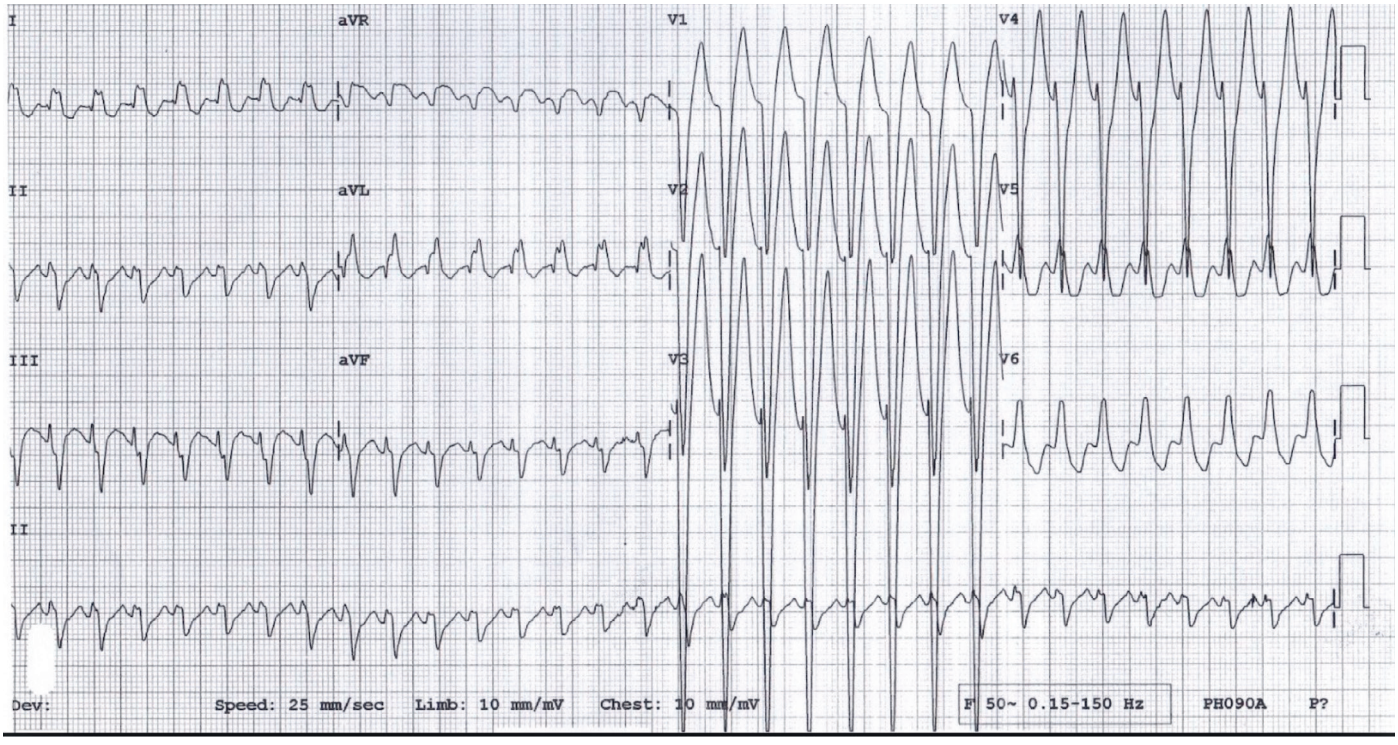
In recent years, the use of ECGs for screening before sports participation or before medical and surgical procedures has identified increasing numbers of asymptomatic individuals with a WPW ECG pattern. The optimal management of these patients is not definitively known. In its simplest form, risk stratification uses



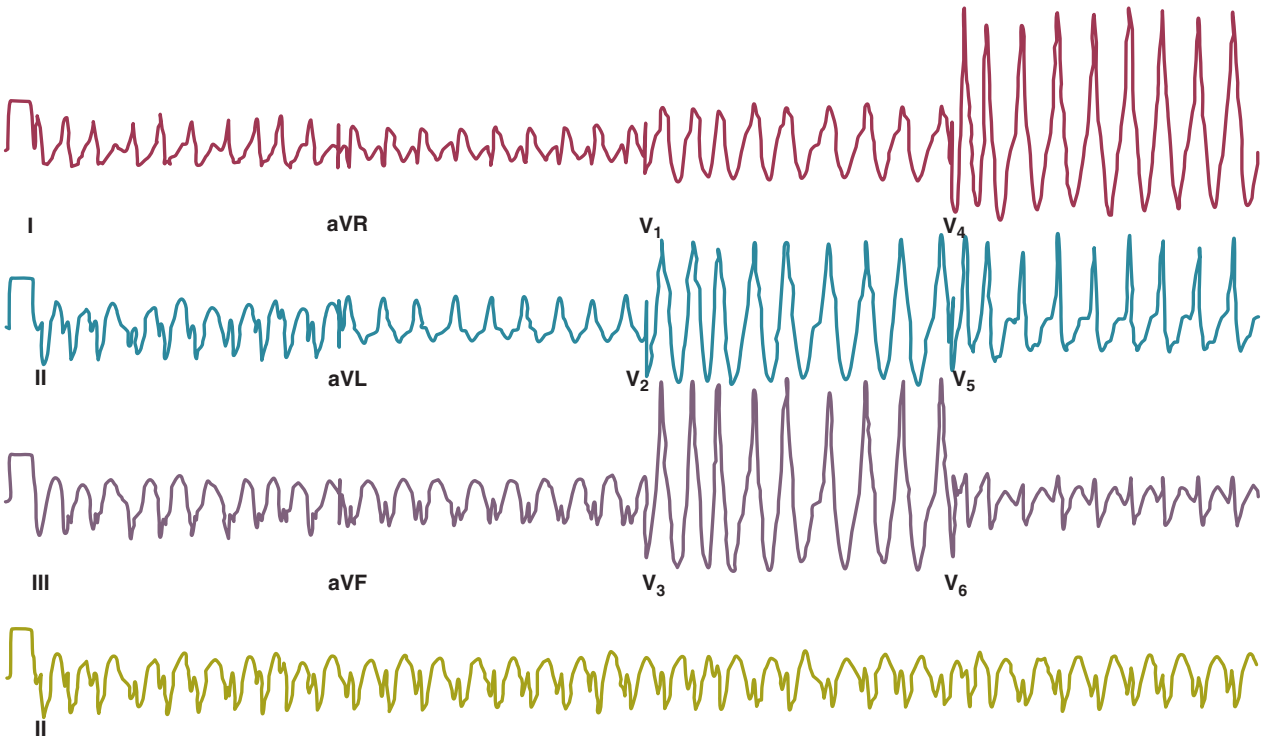
• **Fig. 31.12** Typical atrioventricular nodal reentry tachycardia (AVNRT) and normal sinus rhythm after conversion. *Upper panel,* the arrow points to the P waves, which are inscribed at the end of the QRS complex, seen best in the inferior leads and as a slightly positive R′ (pseudo-R′) in lead V1. The reentrant circuit involves anterograde conduction over a slow atrioventricular node pathway, followed by retrograde conduction in a fast atrioventricular node pathway. Typical AVNRT is a type of short RP tachycardia. *Lower panel,* when the patient is in sinus rhythm, the *arrow* indicates where the R′ is absent in V1.



• **Fig. 31.13** Orthodromic atrioventricular reentrant tachycardia. The *arrows* point to the P waves, which are inscribed in the ST segment after the QRS complex. The reentrant circuit involves anterograde conduction over the atrioventricular node, followed by retrograde conduction over an accessory pathway; this results in a retrograde P wave with short RP interval.



• **Fig. 31.14** Antidromic atrioventricular reentrant tachycardia using an R-sided accessory pathway as the antegrade limb of the reentrant circuit, and the atrioventricular node as the retrograde limb.



• **Fig. 31.15** Twelve-lead electrocardiogram (ECG) tracing from a patient with atrial fibrillation and Wolff-Parkinson-White syndrome. A 12-lead electrocardiogram (ECG) tracing from a patient with Wolff-Parkinson-White syndrome shows preexcited atrial fibrillation with rapid ventricular response. A rapid, "irregularly irregular" wide QRS tachycardia is present. Preexcited atrial fibrillation, as seen here, may degenerate to ventricular fibrillation.

noninvasive testing (e.g., Holter or exercise stress test) to ascertain the true loss of preexcitation at physiologic heart rates, which suggests a benign pathway that would not be able to conduct rapidly to the ventricles[58,59] (Fig. 31.16). Inability to clearly demonstrate loss of manifest preexcitation during stress testing warrants consideration for more invasive EP testing depending on the patient's preference and occupation.

Treatment of Preexcited AF

If the patient is hemodynamically stable, IV ibutilide or IV procainamide can be used to slow conduction over the AP with the additional benefit of possibly terminating AF.[60,61] β-Blockers, calcium blockers, digoxin, or any drug that slows conduction over the AV node is absolutely contraindicated because they will slow AV node conduction and cause more conduction over the rapidly conducting AP and put the patient at risk for VF. If the patient is hemodynamically unstable, direct current cardioversion should be performed.

Preexcitation Variants

Although APs may be located anywhere along the right or left AV grooves, two variants with characteristic locations deserve mention. *Paroxysmal junctional reciprocating tachycardia* is a form of AV reentry that can be incessant. The antegrade limb of the circuit is the normal AV conduction system. The retrograde limb is a concealed, decrementally conducting AP usually located in the posterior septum.

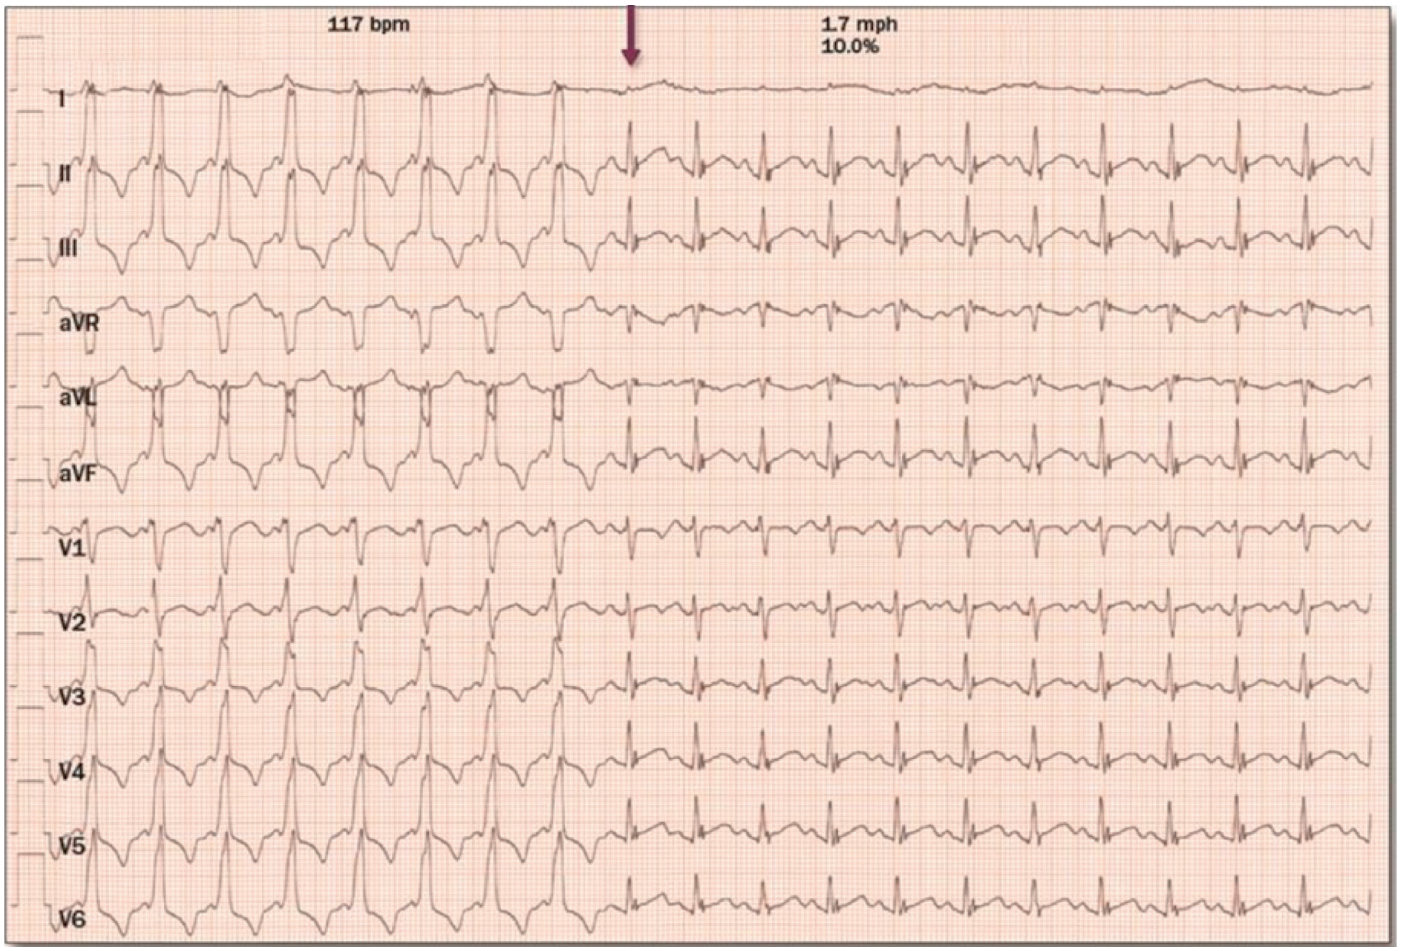
Atriofascicular pathways (Mahaim fibers) connect the right atrium to various locations along the right bundle branch and conduct only in the antegrade direction with decremental properties similar to the AV node. During sinus rhythm, preexcitation is minimal or absent. During SVT, a regular wide QRS typical left bundle branch block (LBBB) pattern tachycardia with 1:1 retrograde P waves is seen because the tachycardia uses the Mahaim pathway in the antegrade limb and the AV node in the retrograde limb.[62]

There are rare tachycardias that use two APs for the SVT circuit, one in the antegrade direction and one in the retrograde direction bypassing the AV node entirely. These usually have a wide complex on the ECG with 1:1 retrograde P waves and do not respond to any treatments directed at the AV node.

Atrial Tachycardia

Focal AT is a fast rhythm from a discrete atrial origin, discharging at a rate that is generally regular between 100 and 250 beats/min.[63] A long RP interval is typical of AT because the rhythm is driven by the atrium and conducts normally to the ventricles; the ECG typically shows a P wave with a morphology that differs from sinus and is seen near the end of or shortly after the T wave (Fig. 31.17).

Automatic ATs can occur along the crista terminalis, near the ostium of the coronary sinus, along the tricuspid and mitral annulus, in either atrial appendage, or within or in close proximity to the pulmonary veins. Automatic ATs are very sensitive to catecholamines.[64] Although they may manifest in the absence of structural heart disease or obvious precipitants, they also are commonly associated with chronic lung disease, pneumonia, myocardial (atrial) infarction, and acute alcoholic binges. Amphetamine or cocaine abuse also may precipitate automatic ATs. Nonsustained focal AT



• **Fig. 31.16** Abrupt loss of preexcitation during exercise testing. During exercise treadmill testing, this patient abruptly lost preexcitation at a heart rate of 117 beats/min. Beginning abruptly with the beat under the *arrow,* the PR interval normalizes and the QRS changes from preexcited to narrow. *bpm,* Beats/min; *mph,* miles/hr.

is common, especially in the ICU setting, and often does not require treatment. However, sustained ATs with rapid ventricular rates can lead to hemodynamic instability and, if left untreated, tachycardia-mediated cardiomyopathy.

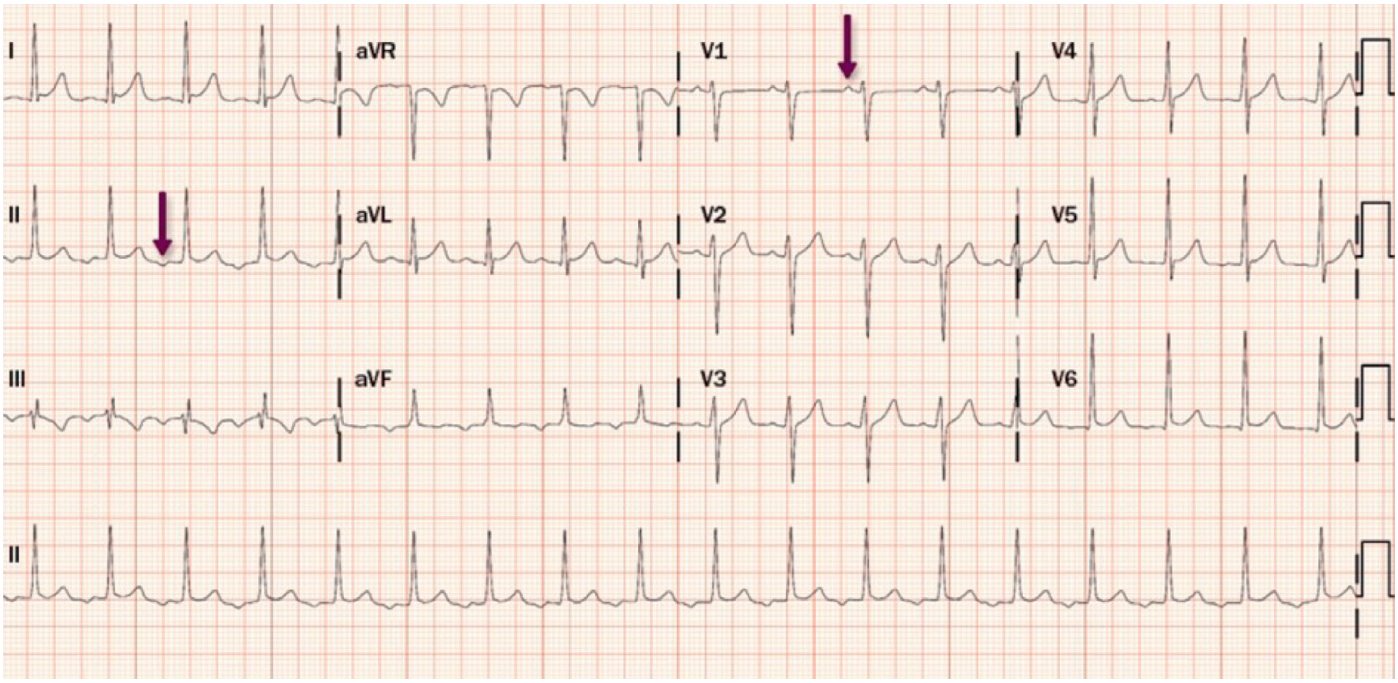
Intraatrial reentry is another form of AT usually associated with structural heart disease[65]; approximately 50% of patients with intraatrial reentry have evidence of structural heart disease. In patients without obvious structural disease, subtle changes such as scarring and fibrosis as the result of hypertension, diabetes, or other systemic diseases provide the substrate for reentry. Microreentrant or macroreentrant ATs from the left atrium after AF ablation occur in approximately 50% of patients.[65,66] A variety of reentry circuits have been described after AF ablation, including a path around the mitral annulus (perimitral flutter), reentry involving the left atrial roof, and reentry around regions of scarring in the right or left atria.

The ECG of intraatrial reentry shows flutter waves of variable morphologies depending on the origin of the flutter and variable AV block. Persistent elevation of the ventricular rate may result in a tachycardia-mediated cardiomyopathy, which can be reversed when the ventricular rate is controlled. Intraatrial reentry tachycardia is prone to develop after cardiac surgery for congenital anomalies; reentry occurs around structural barriers such as suture lines.

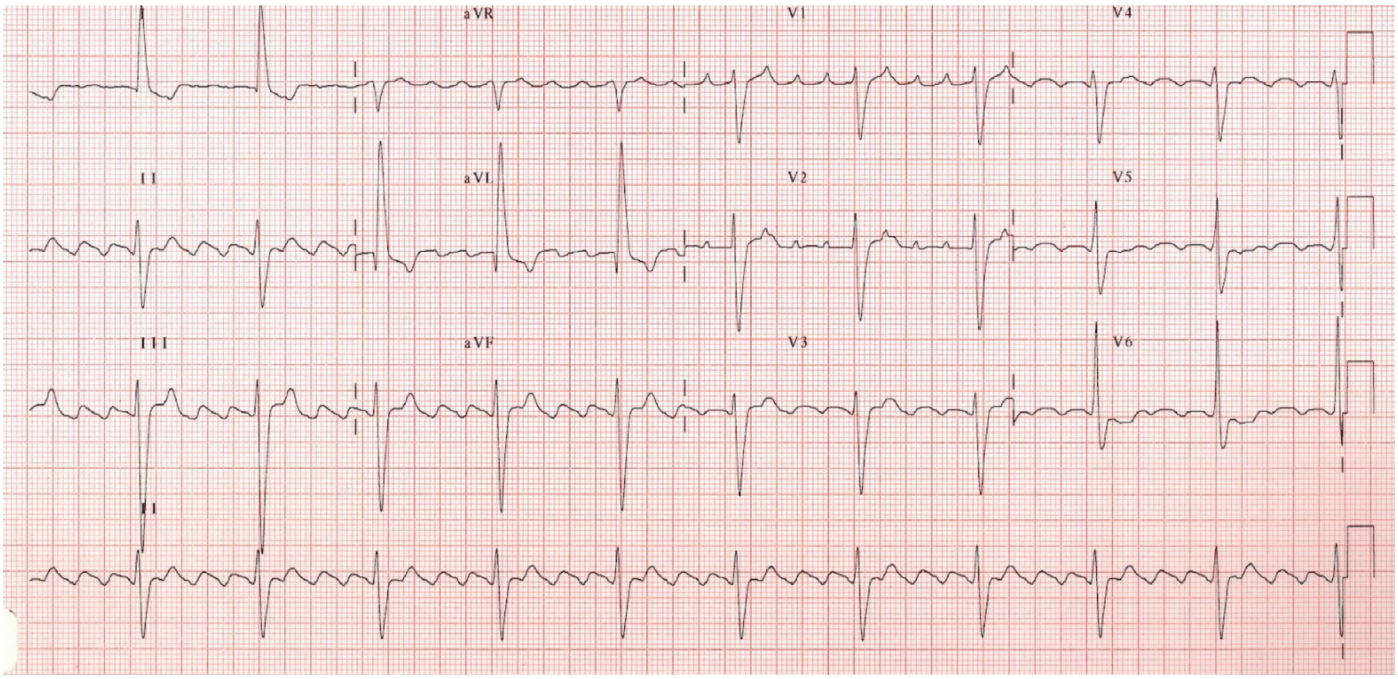
Atrial Flutter

Atrial flutter is the most common type of intraatrial reentry. The reentrant circuit of typical atrial flutter traverses (with either counterclockwise or clockwise rotation) through an isthmus formed by the inferior vena cava, tricuspid valve, eustachian ridge, and coronary sinus ostium. Counterclockwise rotation is most common and results in negative "flutter" waves in ECG leads II, III, aVF, and V6. Atrial activity in lead V1 is positively directed if there is no underlying structural heart disease (Fig. 31.18). Clockwise atrial flutter produces oppositely directed flutter waves in these leads.

Atrial rates generally range between 250 and 350 beats/min; however, slower rates may be seen in the presence of pharmacotherapy, marked right atrial enlargement, or a large amount of atrial tissue scarring.[67] Ventricular rates in atrial flutter are variable but can be rapid at 150 beats/min when there is 2:1 atrial conduction to the ventricles. When a patient with SVT presents with a heart rate of 150 beats/min, atrial flutter with 2:1 AV conduction should be high in the differential diagnosis.



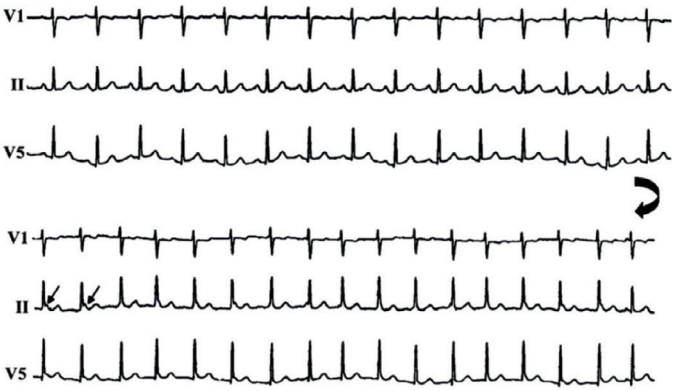
• **Fig. 31.17** Atrial tachycardia. The *arrows* point to the P wave, which are inscribed before the QRS complex. The focus of this atrial tachycardia was mapped during electrophysiologic study to an area near the left inferior pulmonary vein.



• **Fig. 31.18** Typical counterclockwise right atrial flutter.

Treatment for (typical and atypical) intraatrial reentry is similar to that outlined for AF (see following text). Patients with atrial flutter are thought to have the same risk of thromboembolism as patients with AF; therefore recommendations for anticoagulation should mirror those for patients with AF. The next step in the decision tree for intraatrial reentry is rate control versus rhythm control, discussed in detail later. Special care must be taken to avoid inadvertent slowing of the intraatrial reentry with antiarrhythmic medications (typically class IC agents such as propafenone) enough to precipitate 1:1 AV conduction and subsequent hemodynamic deterioration. Radiofrequency ablation is first-line curative therapy for typical atrial flutter if medications fail. Most other types of intraatrial reentry can also be mapped and cured with radiofrequency ablation.

• **Fig. 31.19** Multifocal atrial tachycardia is characterized by three or more morphologically distinct (nonsinus) P waves, atrial rates of 100 to 130 beats/min, and variable atrioventricular block. Note the irregularity of the rhythm as well as the different P-wave morphologic appearances *(arrows)* with different PR intervals.



• **Fig. 31.20** Surface electrocardiographic recording from leads V1, II, and V5 in a patient with junctional tachycardia. The *upper panel* shows sinus rhythm. The *lower panel* shows tachycardia onset with the characteristic finding of dissociation of the QRS and P waves (*narrow arrows* on P waves). The *large arrow* signifies continuous recording.

Sinus node reentry is a particular type of intraatrial reentry that occurs within the sinus node, the perinodal atrial tissue, or both. Although the mechanism may be difficult to prove clinically, most investigators agree that the P wave may be *nearly* identical to sinus rhythm, suggesting that the reentry exit point may differ slightly from sinus pacemaker beats. Average rates generally are 130 to 140 beats/min (range 80–200 beats/min). This arrhythmia can be treated medically or with catheter ablation.

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia (MAT) is defined as a rapid, irregular rhythm with at least three distinct P-wave morphologies (nonsinus), atrial rates of 100 to 130 beats/min, and variable AV block (Fig. 31.19). It may be difficult to distinguish MAT from AF on physical examination or even on a single ECG tracing, so a 12-lead ECG is indicated to confirm the diagnosis.[68] On the ECG of MAT, unlike AF, there is a distinct isoelectric period between P waves.

MAT is commonly associated with pulmonary disease and sometimes occurs in the setting of CHF; therefore it is frequently seen in the ICU setting. It has been reported in patients with cancer, lactic acidosis, pulmonary emboli, renal disease, and infection. Hypoxemia frequently is present. MAT may be exacerbated by digitalis or theophylline toxicity, hypokalemia, hypomagnesemia, and hyponatremia.

Treatment of Multifocal Atrial Tachycardia

Treatment is usually is directed at elimination of the underlying precipitants and slowing conduction at the AV nodal level to control the heart rate. Metoprolol (used cautiously when bronchospasm is present) or verapamil may provide atrial and ventricular rate control and occasionally restore sinus rhythm.[69,70] Potassium and magnesium supplements may help suppress MAT. Amiodarone has also been useful in restoring sinus rhythm.[71] Digoxin toxic MAT is managed by withholding digoxin and/or administering potassium, lidocaine, phenytoin, and/or digoxin-specific antigen-binding fragments. MAT does not respond to direct current cardioversion[72] and is not amenable to catheter ablation because of the multiple origins of atrial beats. *Digoxin will not slow the rate of MAT.*

Nonparoxysmal AV Junctional Tachycardia, and Junctional Ectopic Tachycardia

Nonparoxysmal AV junctional tachycardia is an automatic tachycardia originating in the AV node caused by enhanced (abnormal) automaticity from an ectopic focus in the AV junction (including the His bundle) (Fig. 31.20). It occurs at a rate of 70 to 130 beats/min; AV dissociation (often isorhythmic) may be seen, and when present, excludes the diagnosis of AVRT and makes AVNRT highly unlikely.

When it is irregular, junctional tachycardia may be misdiagnosed as AF or MAT. Nonparoxysmal AV junctional tachycardia is associated with injury to the myocardium such as cardiac surgery, MI, or rheumatic fever and can occur in the setting of digitalis toxicity.[73] Hypokalemia may cause or exacerbate this arrhythmia. Sympathetic stimulation increases the tachycardia rate.

Junctional ectopic tachycardia, a specific type of junctional tachycardia, is also an automatic tachycardia originating in the AV node. It primarily affects children and infants and can be incessant, causing tachycardia-mediated cardiomyopathy. Infants and children with acquired or congenital junctional ectopic tachycardia have a high rate of death owing to SCD, heart failure, or uncontrollable, incessant tachyarrhythmias.[74] Amiodarone, which may suppress the tachycardia or control its rate, should be administered when heart rates less than 150 beats/min cannot be achieved by other means.[75]

Treatment of Junctional Tachycardia

β-Blockers and calcium channel blockers are first-line therapy for junctional tachycardia, simultaneous with treatment of the underlying cause. Catheter ablation can eliminate tachycardia while preserving AV conduction if the arrhythmia cannot be controlled by medications.[76–78]

Sinus Tachycardia

In normal individuals, the sinus rate at rest is between 60 and 100 beats/min. Sinus tachycardia is usually a normal reflex response to changes in physiologic, pharmacologic, or pathophysiologic stimuli, such as exercise, emotional upset, fever, infection, hemodynamic or respiratory compromise, thyrotoxicosis, poor physical conditioning, sympathomimetic or vagolytic agents, or anemia. The resulting increase in cardiac output usually is beneficial and appropriate for the underlying condition. The sinus heart rate generally does not exceed 180 beats/min, except in young patients, who may achieve rates higher than 200 beats/min during vigorous exercise.[79] Sinus tachycardia usually resolves when conditions return to baseline.

TABLE 31.1 Differential Diagnosis of Sinus Tachycardia

Etiologic Category	Specific Disorders
Hemodynamic	Heart failure—systolic and diastolic heart failure caused by ischemic, valvular, or nonischemic myopathy Loss of circulating blood volume—gastrointestinal bleeding, anemia, shifts of intravascular fluid owing to changes in colloidal osmotic pressure or inflammation Septic shock—dehydration Vascular shunts—intracardiac as well as aortovenous malformations, fistulas Pulmonary embolism
Metabolic and neurohumoral	Sepsis—infections and inflammatory conditions Hyperthyroidism Paget disease of the bone Pheochromocytoma Carcinoid syndrome Beriberi heart disease Carcinoma Hyperpyrexia Acidosis Exercise
Pharmacologic	Sympathomimetic agents—isoproterenol, epinephrine, or dopamine Vagolytic agents, atropine, acopolamine Vasodilators—nitrates, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, hydrazine, as well as centrally acting vasodilators Thyroid preparations, caffeine, and nicotine Bronchodilators, including theophylline and terbutaline Anesthetic agents, including spinal anesthetics, causing peripheral vasodilation Drugs of abuse—amphetamines, cocaine, "ecstasy," cannabis
Neurologic/psychological	Pain Fear, anxiety, and hysteria Hyper–β-adrenergic phase of neurocardiogenic syncope Autonomic dysfunction such as with diabetes

The differential diagnosis for sinus tachycardia is presented in Table 31.1.

Sinus tachycardia is often present in ICU patients and sometimes is difficult to distinguish from other SVTs. When observed over time, sinus tachycardia has a variable rate that gradually accelerates and gradually decelerates without abrupt changes. The P-wave morphology of sinus tachycardia is upright in leads I, II, aVF, and V4 to V6. Sinus tachycardia should slow transiently with vagal maneuvers or IV adenosine. If adenosine administration produces AV block, the P-wave morphology can be clearly seen if a 12-lead ECG is run in rhythm strip mode. A negative P wave in any of leads I, II, aVF, and V4 to V6 excludes a sinus mechanism. P waves that are negative in lead I suggest a left atrial origin. Differentiation of "high" right AT P waves from sinus tachycardia can be difficult. Comparison of the 12-lead P-wave morphology to that of an older 12-lead ECG tracing (if obtainable) when the patient was clearly in normal sinus rhythm may help to distinguish normal sinus rhythm from AT.

Inappropriate sinus tachycardia (IST) is defined as sinus tachycardia that is unexplained by physiologic demands at rest, with minimal exertion, or during recovery from exercise. Crucial to this definition is the presence of associated symptoms that include weakness, fatigue, lightheadedness, and uncomfortable sensations, such as heart racing. Patients with IST commonly show resting heart rates above 100 beats/min and average rates that are above 90 beats/min in a 24-hour period.[80] The cause of IST is unclear, and mechanisms related to dysautonomia, neurohormonal dysregulation, and intrinsic sinus node hyperactivity have been proposed.

Management of SVT

Management of Regular Narrow Complex Supraventricular Tachycardia

Acute tachycardia treatment begins with careful assessment of the 12-lead ECG, to make an estimated diagnosis of the tachycardia mechanism (Box 31.2). The first step in treatment of narrow complex PSVT is vagal maneuvers: Valsalva and carotid sinus massage (after auscultation of the carotids to exclude bruits). These maneuvers should be performed with the patient in the supine position, and if executed properly, will often terminate the SVT or unveil a primary atrial mechanism (AT, AF, or atrial flutter). If the arrhythmia does not have an atrial mechanism, medical interventions should then be designed to interrupt AV nodal conduction.

Adenosine is the initial drug of choice for acute management of PSVT. An initial intravenous dose of 6 mg may be followed (2 minutes) by 12 mg if 6 mg is unsuccessful. Adenosine should terminate more than 90% of AVNRT and AVRT. This agent is also effective for terminating sinus node reentry and automatic ATs, particularly those originating near the crista terminalis where vagal innervation is rich. Termination may be transient because of adenosine's short half-life (10 seconds) but at least the tachycardia

• BOX 31.2 Differential Diagnosis of Narrow and Wide QRS Tachycardias

Narrow QRS (≤120 msec) Tachycardias

Regular
- Physiologic sinus tachycardia
- Inappropriate sinus tachycardia
- Sinus nodal reentrant tachycardia
- Focal atrial tachycardia
- Atrial flutter
- Atrial fibrillation with very fast ventricular response
- Atrioventricular nodal reentrant tachycardia
- Nonparoxysmal or focal junctional tachycardia
- Orthodromic atrioventricular reentrant tachycardia
- Idiopathic ventricular tachycardia (especially high septal ventricular tachycardia)

Irregular
- Atrial fibrillation
- Atrial focal tachycardia or atrial flutter with varying atrioventricular block
- Multifocal atrial tachycardia

Wide QRS (>120 msec) Tachycardias

Regular
- Antidromic atrioventricular reentrant tachycardia
- Any regular atrial or junctional reentrant tachycardias with:
  - Aberration/bundle branch block
  - Preexcitation/bystander accessory pathway
- Ventricular tachycardia/flutter

Irregular
- Atrial fibrillation or atrial tachycardia with varying block conducted with aberration
- Antidromic atrioventricular reentrant tachycardia with a variable ventriculoatrial conduction
- Preexcited atrial fibrillation
- Polymorphic ventricular tachycardia
- Torsades de pointes
- Ventricular fibrillation

mechanism will be elucidated. Tachycardia termination suggests a supraventricular mechanism that includes the AV node as a requisite part of the circuit. Transient AV block unveiling rapid P waves suggests AT. No response to adenosine suggests a possible ventricular origin.[81,82]

IV verapamil, IV diltiazem, or IV β-blockers are next in line to interrupt AV nodal conduction; they are usually effective for PSVT termination when adenosine fails. AV block without arrhythmia termination again suggests the diagnosis of AT. Because of their longer half-lives these agents may be effective for treatment of tachycardia recurrences after initial success with adenosine. Sinus node reentry may respond to any of the therapies described earlier.

Emergent or urgent direct current cardioversion is indicated when PSVT results in angina pectoris, CHF, or hypotension. Techniques for, and limitations of, direct current cardioversion are discussed later in the chapter. Automatic tachycardias (including MAT), as discussed earlier, usually do not respond to direct current cardioversion.

Management of Irregular Narrow Complex Supraventricular Tachycardia

Acute tachycardia treatment begins with careful assessment of the 12-lead ECG to make an estimated diagnosis of the tachycardia mechanism (see Box 31.2). Irregular narrow complex SVTs are most commonly AF (discussed later) or AT. Automatic AT can be difficult to manage with pharmacotherapy. Vagal maneuvers may produce AV block but may not terminate ATs. Precipitants, such as hypoxia, lactic acidosis, pulmonary emboli, renal disease, and infection, should be treated or eliminated whenever possible. β-Blockers may slow the atrial rate but rarely restore sinus rhythm. Adenosine may produce sinus rhythm; however, tachycardia may resume as soon as the drug is metabolized.[83] IV amiodarone is first-line therapy if it is important to eliminate the tachycardia because of rapid ventricular rates; it usually does not exacerbate heart failure or cause proarrhythmia in the setting of preexisting LV dysfunction.

Management of Regular and Irregular Wide Complex Supraventricular Tachycardia

Again, acute tachycardia treatment begins with careful assessment of the 12-lead ECG to make an estimated diagnosis of the tachycardia mechanism (see Box 31.2). When SVT is wide complex, it is very important to examine a 12-lead ECG when the patient is in normal rhythm (if one is available) to determine if the wide complex simply represents a preexisting bundle branch block. If there is evidence of AV dissociation, the wide complex tachycardia is almost certainly VT and should be treated as such. If 1:1 conduction is seen, the mechanism is likely SVT. Vagal maneuvers—Valsalva and carotid sinus massage (after auscultation of the carotids to exclude bruits)—should again be performed as first-line treatment.

Treatment of regular wide QRS tachycardia with 1:1 AV association should be directed at blocking conduction via the AP. Adenosine can be used as first-line therapy; because of its short half-life adenosine poses little risk, unless it precipitates AF. Adenosine may terminate antidromic tachycardia (at the AV node in the retrograde direction), but it will not affect ATs conducting rapidly across an AP, and may actually cause that conduction to be transiently faster. Intravenous ibutilide (1 mg infused over 10 minutes; a second 1-mg dose may be given by infusion after a 10-minute wait, if necessary) or IV procainamide will block antegrade AP conduction and may terminate acute episodes of AF or flutter with conduction over an AP.[60]

IV verapamil and IV diltiazem are contraindicated in the presence of wide QRS tachycardia (especially irregular wide QRS tachycardia) because they will block AV nodal conduction and allow preferential, more rapid conduction to occur over an AP. Their hypotensive effects may make patients hemodynamically unstable and contribute to the onset of VF. IV digoxin is contraindicated for the same reasons.

Direct current cardioversion should be available whenever treatment of a wide QRS tachycardia is undertaken. If, at baseline, the patient exhibits signs of hemodynamic compromise (angina, heart failure, or hypotension), drug therapy should be eschewed and direct current cardioversion used to promptly restore sinus rhythm. If hemodynamic instability develops during drug therapy, direct current cardioversion should be performed immediately. Direct current cardioversion also should be the next elective therapy when pharmacotherapy is unsuccessful.

Chronic Treatment of Supraventricular Tachycardia

First-line chronic therapy for most reentrant SVTs is catheter ablation after medical therapy fails.

TABLE 31.2 Definition of Atrial Fibrillation: A Simplified Scheme

Term	Definition
Paroxysmal AF	• AF that terminates spontaneously or with intervention within 7 days of onset • Episodes may recur with variable frequency
Persistent AF	• Continuous AF that is sustained >7 days
Long-standing persistent AF	• Continuous AF >12 months in duration
Permanent AF	• The term "permanent AF" is used when the patient and clinician make a joint decision to stop further attempts to restore and/or maintain sinus rhythm • Acceptance of AF represents a therapeutic attitude on the part of the patient and clinician rather than an inherent pathophysiologic attribute of AF • Acceptance of AF may change as symptoms, efficacy of therapeutic interventions, and patient and clinician preferences evolve
Nonvalvular AF	• AF in the absence of rheumatic mitral stenosis, a mechanical or bioprosthetic heart valve, or mitral valve repair

AF, Arial fibrillation.

Atrial Fibrillation

AF is the most common sustained supraventricular arrhythmia and places patients with concomitant risk factors at increased risk of stroke. More than 2 million people in the United States have AF and this number is expected to rise as the population ages. In the United States, the percentage of Medicare fee-of-service beneficiaries with AF in 2010 was reported as 2% for those younger than 65 years of age and 9% for those older than 65 years of age.[84] The prevalence of AF increases with increasing age.

AF is an SVT with uncoordinated atrial activation and consequently ineffective atrial contraction. Symptoms of AF range from nonexistent (asymptomatic) to severe; the most common symptom is fatigue. Frequent hospitalizations, hemodynamic abnormalities, and thromboembolic events related to AF result in significant morbidity and mortality. AF is associated with a fivefold increased risk of stroke,[85] and stroke risk increases with increasing age.[86] A pathognomonic ECG has (1) irregular R-R intervals (when AV conduction is present), (2) absence of distinct P waves, and (3) irregular atrial activity. Table 31.2 outlines the types of AF.

Any disturbance of atrial architecture potentially increases susceptibility to AF. Such changes (e.g., inflammation, fibrosis, and hypertrophy) occur most commonly in the setting of underlying heart disease as the result of hypertension, coronary artery disease (CAD), valvular heart disease, cardiomyopathies, and heart failure, which tend to increase left atrial pressure, cause atrial dilation, and alter wall stress.[87] Similarly, atrial ischemia from CAD and infiltrative diseases such as amyloidosis, hemochromatosis, and sarcoidosis can also promote AF. Extracardiac factors that promote AF include hypertension, sleep apnea, obesity, use of alcohol/drugs, and hyperthyroidism, all of which have pathophysiologic effects on atrial cellular structure and/or function.

In the critically ill, AF may be a sign of disease severity rather than an arrhythmic disease entity. Critically ill patients are often in a hyperadrenergic state, which may increase ectopic triggers and shorten atrial refractoriness when fibrosis has already created a suitable reentrant substrate.[88]

Management of AF

The mechanisms of AF are shown in Fig. 31.21.[89]

Rate Control

Control of the ventricular rate is the first line of therapy for AF. Rate control is most frequently achieved using digoxin, β-blockers, calcium channel blockers (verapamil or diltiazem), or combinations of these agents. IV diltiazem has the combination of efficacy, ease of parenteral delivery, and tolerance that makes this agent an attractive option in the critical care setting. Verapamil should be administered cautiously to patients with significant LV dysfunction. Although digoxin is effective in controlling rates at rest, exercise rate control is not often achieved. Digoxin has traditionally been used for rate control in patients with concomitant LV dysfunction and CHF, but some recent studies have shown an increased mortality, so it should be used with caution and careful monitoring.[90] IV amiodarone may result in less hypotension than diltiazem when used for rate control in the ICU,[91,92] and it has the advantage of being 100% bioavailable (critically ill patients may not absorb oral drugs). The target heart rate for an effective rate control target was liberalized in the 2010 guidelines to a resting heart rate less than 100 beats/min.[93] Approaches to selecting drugs for rate control for AF are shown in Fig. 31.22.

Rhythm Control

To achieve rhythm control for AF a combination of approaches, including cardioversion, antiarrhythmic drugs, and radiofrequency catheter ablation, can be used in the setting of appropriate anticoagulation and rate control. Randomized clinical trials comparing outcomes of a rhythm control strategy using antiarrhythmic drugs with a rate control strategy in patients with AF failed to show a superiority of rhythm control on mortality for either strategy.[94,95]

Strategies for rhythm control based on type of heart disease are outlined in Fig. 31.23. In the ICU setting, rate control should always be the first line of therapy unless a patient is hemodynamically unstable and effective rate control cannot be achieved because of the risk of hypotension from the medications. In that setting, urgent cardioversion is recommended. If the patient is hemodynamically stable, decisions to restore normal sinus rhythm, and by what method, can be made electively once the rate is controlled and the patient is stabilized. If rhythm control is favored in the ICU setting, IV amiodarone would be the first drug of choice. Once the patient's condition has stabilized, transition to a less toxic oral

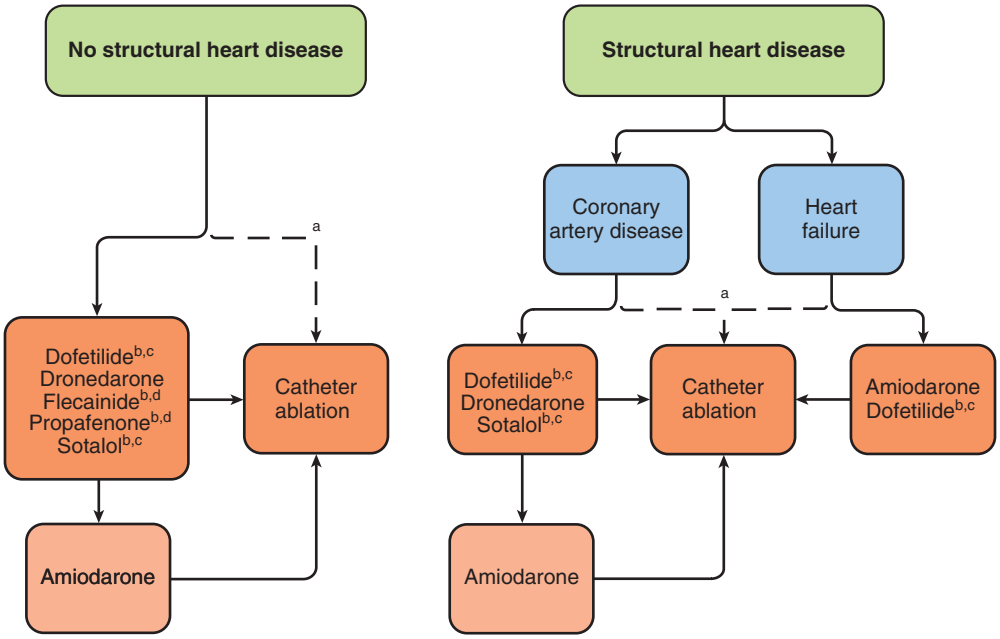
• **Fig. 31.22** Approach to selecting drug therapy for ventricular rate control. Drugs are listed alphabetically. [a]β-Blockers should be instituted after stabilization of patients with decompensated heart failure *(HF)*. The choice of β-blocker (e.g., cardioselective) depends on the patient's clinical condition. [b]Digoxin is not usually first-line therapy. It may be combined with a β-blocker and/or a nondihydropyridine calcium channel blocker when ventricular rate control is insufficient and may be useful in patients with heart failure. [c]In part because of concern over its side effect profile, use of amiodarone for chronic control of ventricular rate should be reserved for patients who do not respond to or are intolerant of β-blockers or nondihydropyridine calcium antagonists. *COPD,* Chronic obstructive pulmonary disease; *CV,* cardiovascular; *HF,* heart failure; *HFpEF,* heart failure with preserved ejection fraction; *LV,* left ventricular.

medication can be made, and often there is no ongoing requirement for antiarrhythmic therapy at all once the critical illness has passed.

Stroke Prevention

Prevention of embolic strokes is the most important goal of therapy for AF. Ischemic stroke risk among patients with nonvalvular AF is stratified using the $CHADS_2$ (Congestive heart failure, Hypertension, Age ≥75 years, Diabetes mellitus, Prior Stroke or TIA or Thromboembolism [doubled]) and CHA_2DS_2-VASc (CHA_2DS_2-VASc, Congestive heart failure, Hypertension, Age ≥75 years [doubled], Diabetes mellitus, Prior Stroke or TIA or thromboembolism [doubled], Vascular disease, Age 65 to 74 years, Sex category) risk scoring systems outlined in Table 31.3.[96–97,98] Antithrombotic therapy should be individualized based on shared decision making after discussion of the absolute risks and relative risks of stroke and bleeding, and the patient's values and preferences (see Table 31.3). Bleeding risk can be assessed using the HAS-BLED score (Hypertension, Abnormal renal/liver function, Stroke history, Bleeding history or predisposition, Labile international normalized ratio, Elderly [≥65 years], Drugs/alcohol concomitantly).[99]

Selection of antithrombotic therapy should be based on the risk of thromboembolism irrespective of whether the AF pattern is paroxysmal, persistent, or permanent. For patients with atrial flutter, antithrombotic therapy is recommended according to the same risk profile used for AF. For patients with nonvalvular AF (see Table 31.2 for definitions) and a CHA_2DS_2-VASc score of 0, it is reasonable to omit antithrombotic therapy. For patients with nonvalvular AF and a CHA_2DS_2-VASc score of 1, no antithrombotic therapy or treatment with an oral anticoagulant may be considered. For patients with nonvalvular AF and a CHA_2DS_2-VASc score of 2 or higher,



• **Fig. 31.23** Strategies for rhythm control in patients with paroxysmal and persistent atrial fibrillation (AF). Catheter ablation is only recommended as first-line therapy for patients with paroxysmal AF (class IIa recommendation). Drugs are listed alphabetically. [a]Depending on patient preference when performed in experienced centers. [b]Not recommended with severe LVH (wall thickness >1.5 cm). [c]Should be used with caution in patients at risk for torsades de pointes ventricular tachycardia. treatment with anticoagulation is indicated.[89] With the advent and proven safety profile of the novel oral anticoagulants (NOACs), there are currently several choices for oral anticoagulation in AF. Efficacy and safely of NOACs are shown in Table 31.4.[100] All NOACs have been extensively studied and show improved rates of stroke prevention and lower bleeding risks than warfarin.

No studies, with the exception of the SPAF (Stroke Prevention in Atrial Fibrillation)-1 trial, show benefit for aspirin alone in preventing stroke in patients with AF.[101,102] The usefulness of ASA in stroke prevention for AF has recently been questioned and currently may not have any role at all.[103]

Valvular AF is defined (see Table 31.2) as that occurring in a patient with rheumatic mitral stenosis, mitral valve repair, and mechanical or bioprosthetic heart valve. All other types of AF are nonvalvular. For patients with AF who have mechanical heart valves, warfarin is the only choice for anticoagulation, and the target international normalized ratio (INR) intensity (2.0–3.0 or 2.5–3.5) should be based on the type and location of the prosthesis.

Management of AF in the ICU

Appropriate management of AF in the ICU should include treatment (or elimination) of potential precipitants and β-blockade (given the hyperadrenergic state of many ICU patients) as the initial pharmacotherapy of choice. Hemodynamic impairment owing to AF should be treated with urgent or emergent direct current cardioversion.[88] Restoration of sinus rhythm may be very difficult and impractical when a severe metabolic derangement or multisystem organ failure is present.[104] Patients with adrenergically mediated AF should be managed with β-blockers or calcium blockers if blood pressure permits. Amiodarone is another option for both rate control and ultimate restoration of normal sinus rhythm in patients with AF refractory to β-blockade alone.

IV ibutilide is a class III agent that prolongs action potential by blocking the rapid component of the delayed rectifier current and can be used for AF termination.[105,106] Patients receiving IV ibutilide should be carefully monitored (on telemetry for 4 to 8 hours) for QT prolongation and possible development of torsades de pointes (TdP).[105] If AF recurrence needs to be prevented and sinus rhythm maintained, institution of antiarrhythmic therapy with IV amiodarone is recommended in the ICU setting.

Anticoagulation in the ICU

The intensivist rarely sees ideal candidates for classic anticoagulation because many patients have recent or active bleeding (gastrointestinal, intracerebral), and a variety of coagulopathies that make anticoagulation absolutely or relatively contraindicated. The intensivist must carefully weigh the risks and benefits of anticoagulation for each individual patient. Difficult decisions about the safety of both short-term and long-term anticoagulation may be compounded by concomitant disease processes. At times, transesophageal echocardiography TEE may be the only possible (partial) insurance against emboli.

Direct Current Cardioversion

Direct current cardioversion should be performed with the patient under deep sedation. The preferred drug for deep sedation before cardioversion is propofol.[107] Dosing must be individualized based on body weight, level of illness, and other intercurrent medical conditions. A bolus of 2 mg/kg usually is effective for elective cardioversion but may be excessive in a critically ill patient.[108] Propofol's adverse effects include apnea, bradycardia, hypotension, nausea, and pain and burning at the IV injection site, which can be minimized by giving local lidocaine. Propofol overdose is treated with ventilation and oxygen, elevation of the legs, increasing flow

TABLE 31.3 Comparison of the $CHADS_2$ and CHA_2DS_2-Vasc Risk Stratification Scores for Subjects With Nonvalvular Atrial Fibrillation

Definition and Scores for $CHADS_2$ and CHA_2DS_2-VASc		Stroke Risk Stratification With the $CHADS_2$ and CHA_2DS_2-VASc Scores	
	Score		Adjusted Stroke Rate (%/year)
$CHADS_2$		**$CHADS_2$**[a]	
Congestive HF	1	0	1.9
Hypertension	1	1	2.8
Age ≥75 years	1	2	4.0

Congestive HF	1	0	0
Hypertension	1	1	1.3
Age ≥75 years	2	2	2.2
Diabetes mellitus	1	3	3.2
Stroke/TIA/TE	2	4	4.0
Vascular disease (prior MI, PAD, or aortic plaque)	1	5	6.7
Age 65–74 years	1	6	9.8
Sex category (i.e., female sex)	1	7	9.6
Maximum score	9	8	6.7
		9	15.20

[a]These adjusted stroke rates are based on data for hospitalized patients with AF and were published in 2001. Because stroke rates are decreasing, actual stroke rates in contemporary nonhospitalized cohorts might vary from these estimates.

$CHADS_2$, Congestive heart failure, Hypertension, Age ≥75 years, Diabetes mellitus, Prior Stroke or TIA or Thromboembolism (doubled); *CHA_2DS_2-VASc,* Congestive heart failure, Hypertension, Age ≥75 years (doubled), Diabetes mellitus, Prior Stroke or TIA or thromboembolism (doubled), Vascular disease, Age 65 to 74 years, Sex category; *HF,* heart failure; *MI,* myocardial infarction; *PAD,* peripheral artery disease; *TE,* thromboembolism; *TIA,* transient ischemic attack.[96,97]

rates of IV fluids, and if needed, administration of pressor agents and anticholinergic agents. Regardless of who administers sedation, expert ability to manage the patient's airway must be immediately available when propofol is used.

Transthoracic impedance influences current flow and procedural outcome of cardioversion. Impedance is influenced by a variety of factors, including placement of the defibrillation pads, the phase of ventilation (impedance is lower with expiration than with inspiration), distance between electrodes, pressure on electrodes (air does not conduct well), size of electrodes, time between discharges (waiting as long as 3 minutes may provide continued decreases in impedance), and patient body habitus (heavier weight or increased body mass index decreases success).[109,110] Optimal paddle size ranges from 8 to 12 cm. Anteroposterior position of the patches are the best vectors for energy delivery to the atria[109] (Fig. 31.24).

A conductive gel or paste must be used between the metal electrodes and the chest skin to lower impedance and prevent skin burns.[109] Modern defibrillators have biphasic waveforms that are more effective per joule output than monophasic waveform defibrillators. When initial attempt at cardioversion is not successful, switching from self-adhesive pads to handheld paddles applied with manual pressure can increase current delivery and promote procedural success.

R-wave synchronization should be ensured during cardioversion of any arrhythmias with well-defined QRS complexes. Failure to do so could lead to shock delivery within the "vulnerable period" of the T wave and induction of VF. Electrical cardioversion is contraindicated in the presence of digitalis toxicity; VF may ensue.

Poor success of cardioversion for AF can be related to arrhythmia duration (>1 year), larger left atrial diameters (>5 cm), untreated hyperthyroidism, mitral stenosis, electrolyte disturbances, CHF, or improper performance of the cardioversion procedure itself. Use of concomitant antiarrhythmic drugs (especially amiodarone) may help maintain sinus rhythm when early recurrence is suspected.

Anticoagulation for Cardioversion

Anticoagulation plays a pivotal role in minimizing the risk of emboli (and strokes) during elective cardioversion of AF.[111] Classic recommendations for management of AF of more than 48 hours duration include 3 weeks of therapeutic warfarin (to achieve a prothrombin time [PT]/INR of 2.0–3.0) before direct current shock administration and (at least) 4 more weeks of warfarin after the procedure. The same efficacy is currently being demonstrated with all of the NOACs in randomized clinical trials.[112–114] Although emboli may be less frequent with atrial flutter,[109] it is clear that they occur[115] and the recommendations are the same as for AF.

Short-term therapeutic anticoagulation with heparin before cardioversion (followed by oral anticoagulants in the usual manner) combined with TEE is also an acceptable way to proceed if cardioversion is to be done immediately.[116] TEE is useful for detecting left atrial thrombi because it provides an excellent, minimally invasive view of the left atrial appendage. Embolic rates (0.5% vs. 0.8%) are similar between conventional and TEE-guided approaches.[117] Patients with thrombi seen on TEE should receive anticoagulation for 4 to 6 weeks and have demonstrable resolution of clot by repeat TEE before cardioversion is attempted again.[114]

Perioperative AF

Postoperative AF occurs in 25% to 50% of patients after open heart surgery. Increased age is the most consistent risk factor.[118] With the projected increase in the number of elderly patients undergoing cardiac operations, the incidence of postoperative AF is likely to increase. Postoperative AF is associated with stroke,[119] increased cost,[120] and mortality.[121] β-Blockers, nondihydropyridine calcium channel blockers, and amiodarone are useful as treatments in patients with postoperative AF and may be initiated preoperatively in some patients.[120]

In a meta-analysis of patients undergoing coronary revascularization, those who received preoperative statin therapy had less AF

TABLE 31.4 Efficacy and Safety of Novel Nonvitamin K Antagonists Versus Warfarin in Patients With and Without Significant Valvular Heart Disease

Drug/Dosage	VHD	No VHD	Interaction *P*
Stroke or Systemic Embolism			
Dabigatran 150 mg vs. warfarin	HR, 0.59 95% CI, 0.37–0.93	HR, 0.67 95% CI, 0.52–0.86	0.63

• **Fig. 31.24** Anteroposterior electrode placement for cardioversion of atrial fibrillation and flutter. Anteroposterior electrode placement for cardioversion of atrial fibrillation and flutter. A, Right parasternal anteroposterior electrode placement. B, Left parasternal anteroposterior electrode placement. In each instance, the current vector transverses a critical mass of atrial myocardium. The right parasternal position has more of the right atrium between the electrodes and may be advantageous in patients with biatrial disease. The left parasternal position has a smaller interelectrode distance and less lung between electrodes. (Adapted from Ewy GA. The optimal technique for electrical cardioversion of atrial fibrillation. *Clin Cardiol.* 1994;17:79–84.)

than those not treated with statins.[123] No published data exist for patients undergoing valvular or other heart surgery. The COPPS (Colchicine for the Prevention of the Postpericardiotomy Syndrome) substudy examined the efficacy and safety of colchicine for AF prevention.[122] Patients receiving colchicine had a reduced incidence of AF (12% vs. 22% at 30 days postoperatively). The colchicine group also had a shorter length of hospital stay. This has yet to become the standard of care because further study is still required.

The Prophylactic Oral Amiodarone for the Prevention of Arrhythmias That Begin Early after Revascularization, Valve Replacement, or Repair (PAPABEAR), a large randomized controlled trial, compared perioperative amiodarone with placebo and showed significant reduction in postoperative atrial tachyarrhythmias in the Amiodarone treated group.[124] Toxicity risks were reduced because amiodarone was used only for a short duration. The study did not demonstrate any reduction in mortality rates. The data for

perioperative amiodarone use for cardiac surgery are intriguing; however, incremental benefit beyond β-blockade alone has not yet been shown. Currently amiodarone should be reserved for postoperative AF in patients for whom β-blockers alone have failed, and use of amiodarone should be limited to 6 to 12 weeks postoperatively to prevent long term-side effects.

Antithrombotic medication should be administered to patients in whom postoperative AF develops, as is recommended for nonsurgical patients, taking into account bleeding risks associated with the recent surgery.[125]

Special Considerations for the Intensivist Treating AF

Patients in an intensive care setting frequently have the substrate for reinitiation of atrial or ventricular arrhythmias even after they are apparently controlled. Such factors include hypoxemia, excess circulating (endogenous and exogenous) catecholamines, CHF, fever (sepsis), and pulmonary emboli, Many of these conditions have overlapping features. Prophylaxis against arrhythmia recurrence shares many of the limitations of acute antiarrhythmic therapy. Drugs administered orally may not be well absorbed and IV agents (amiodarone) may be most useful. Digoxin, dofetilide, and sotalol are renally excreted and must be carefully managed (or avoided) to prevent complications in patients with renal failure or insufficiency. Amiodarone is hepatically excreted and has the benefit of safety in patients with renal insufficiency or renal failure on dialysis.

Most digitalis toxicity–related supraventricular arrhythmias result in relatively slow heart rates and are reasonably well tolerated hemodynamically. Accelerated junctional rhythm and paroxysmal AT with block tend to terminate spontaneously after digoxin is stopped.

Antiarrhythmic Drugs for Maintenance of Sinus Rhythm

AF is associated with an increased incidence of death and embolic events.[126,127] However, large randomized studies comparing rate control (allowing the patient to remain in AF with a controlled rate) versus rhythm control with antiarrhythmic drugs (AADs) have not shown a reduction in mortality or thromboembolic events.[128–131] In fact, the rhythm control strategy was associated with higher rates of adverse events: drug side effects, hospitalizations, and stroke. The failure to show a benefit of the rhythm control strategy may have been secondary discontinuation of anticoagulation in the rhythm control arm that resulted in an increase incidence of strokes from episodes of subclinical/asymptomatic AF. A higher percentage of the rate control group remained on anticoagulation during follow-up. Because of these data, the American College of Cardiology, American Heart Association, European Society of Cardiology, and the Heart Rhythm Society have published guidelines recommending the rhythm control strategy with AADs only as a means to reduce symptoms attributable to AF, and not as a way to reduce mortality or thromboembolic risk.[132] However, many physicians still consider a rhythm control strategy in patients younger than 60 years because that group was not well represented in the randomized studies. In addition, chronic AF renders future attempts at rate control more difficult, and the long-term consequences of AF are still unclear.[133]

AADs are classified by the Vaughn-Williams classifications into four groups. Class I drugs affect sodium channels. Class II drugs act on β-receptors. Class III drugs affect potassium channels. Class IV drugs act on calcium channels. Class I drugs are further divided into class IA, IB, and IC based on their relative affinity for sodium channels.

Class 1A drugs such as quinidine, procainamide, and disopyramide are rarely used because of their risk of QT prolongation and resultant TdP, low efficacy rates, and increased risk of noncardiac side effects.[134,135]

Flecainide, a class 1C drug, was developed in the 1970s. Its primary electrophysiologic effect is block of the rapid sodium current responsible for phase 0 of the cardiac action potential. It is administered twice daily at a dose of 50 to 200 mg.[136] The Cardiac Arrhythmia Suppression Trial (CAST) demonstrated an increased mortality associated with flecainide use in patients with a prior MI when it was used to suppress premature ventricular beats.[137] Therefore flecainide is not recommended in patients with coronary disease, prior MI, or decreased LV function.[138] One adverse effect is QRS widening on the ECG; when this is seen at normal heart rates, the drug should be discontinued. Flecainide has negative inotropic effects related both to its sodium channel blocking properties and to the reduced drug clearance in patients with heart failure. Flecainide can also convert AF to atrial flutter with a slowing of the atrial cycle length, which can result in 1:1 conduction through the AV node and resultant rapid ventricular rate. Therefore flecainide should always be used concomitantly with another drug that slows AV nodal conduction such as a β-blocker or calcium blocker. Uncommon noncardiac side effects include dizziness, visual disturbances, nausea, and neurologic symptoms.

Propafenone, a class 1C drug, was approved in the United States in 1989. It has sodium channel blocking properties similar to flecainide. However, unlike flecainide it also can block potassium channels, calcium channels, and β-adrenergic receptors.[139] Like flecainide, propafenone should not be used in patients with structural heart disease, CAD, or prior MI. Also like flecainide, it can convert AF to atrial flutter, resulting in atrial cycle length slowing with potentially rapid 1:1 AV conduction, and should be given concomitantly with a β-blocker or calcium blocker.

Sotalol, a class III drug, was developed in the 1960s. It is a nonselective β-blocker that exerts it antiarrhythmic effects through inhibition of the delayed rectifier potassium current, which causes a dose-dependent prolongation of the action potential duration, atrial and atrioventricular nodal refractory periods, and the QT interval.[140] Despite its β-blocking properties, it is not a negative inotrope because of a concomitant increase in contractility caused by action potential duration prolongation.[141] However, the β-blocking properties can still exacerbate reactive airway disease. Even though sotalol prolongs the QT interval, when it is used properly, the risk of TdP is less than 1%.[142] TdP attributed to sotalol is usually the result of drug interactions when it is used concomitantly with other drugs that prolong the QT interval.

Sotalol is administered twice daily at a starting dose of 80 mg and has a half-life of approximately 8 hours. In patients with a creatinine clearance of 40 to 60 mL/min, the dose should be reduced to once daily. If the creatinine clearance is less than 40 mL/min, sotalol use is not recommended. Per U.S. Food and Drug Administration guidelines, sotalol must be initiated in the hospital with telemetry monitoring. The ECG should be checked daily to evaluate the QT interval. If the QT interval is less than 500 msec and the patient is not bradycardic, the dose can be increased in 40-mg increments to a maximum dose of 240 mg twice daily.

Dofetilide, a class III drug, was approved in the United States in 2000. Dofetelide blocks the rapid component of the delayed rectifier potassium current, and unlike most other antiarrhythmic drugs it has minimal effects on other ion channels. It prolongs the QT interval; thus its main adverse effect is TdP. Initiation of dofetelide requires a 3-day hospitalization for telemetry monitoring

to observe the QT interval and adjust dosing. The starting dose of dofetelide is 125 to 500 μg twice daily based on creatinine clearance. An ECG to access the QT interval must be taken 2 hours after each dose and the dose should be adjusted as needed.

Dofetilide has demonstrated efficacy and safety when used in patients with reduced LV systolic function and/or CAD.[143,144] In the Symptomatic Atrial Fibrillation Investigative Research on Dofetelide (SAFIRE-D) study, 40% to 60% of patients receiving dofetilide remained in sinus rhythm at 1 year compared with only 25% given placebo ($P = 0.001$).[145] In the Danish Investigations of Arrhythmias and Mortality On Dofetilide (DIAMOND) study, 1518 patients with LV dysfunction and symptomatic heart failure were randomly assigned to receive placebo or dofetilide; there was no difference in mortality between the 2 groups at 18 months.[146]

Amiodarone, a class III drug, is the most commonly used AAD for maintenance of normal sinus rhythm in AF. It was first developed in the 1960s for the treatment of angina, and subsequently in the 1970s, its antiarrhythmic properties were recognized. Amiodarone blocks multiple ion channels and therefore has a wide range of electrophysiologic effects on cardiac tissue.[147] Amiodarone is highly lipophilic with a very large volume of distribution and an extremely long and variable elimination half-life on the order of weeks to months.[148] The loading dose of amiodarone is 800 mg daily divided into 2 to 3 doses per day for 7 to 10 days. The dose is then reduced to 400 mg daily for several weeks and ultimately the maintenance dose is 200 mg daily. [148]

Amiodarone is consistently the most effective AAD for AF suppression in all studies of comparative drug efficacy. Unfortunately, amiodarone has multiple short-term and long-term side effects that limit its use. Amiodarone contains a significant amount of iodine, and is structurally similar to thyroid hormone triiodothyronine (T_3), and thyroxine (T_4). Therefore it inhibits both peripheral conversion of T_4 to T_3 and entry of T_3 and T_4 into cells, resulting in both hypothyroidism and hyperthyroidism.[149] Up to one-quarter of patients may develop clinically relevant thyroid dysfunction while using the drug.[149] Nonspecific gastroenterologic symptoms, such as nausea, are common and may resolve with dose reduction.[148] Severe hepatotoxicity is rare (<3%) but minor abnormalities in transaminases are common.[148] Pulmonary toxicity occurs in approximately 2% of patients; patient age and duration of therapy are significant risk factors.[150] Pulmonary toxicity may present at any time during amiodarone treatment and usually presents as cough with subsequent development of dyspnea and fever.[151] Chest radiography reveals diffuse infiltrates, consolidation, and pleural thickening. Pulmonary function tests show evidence of restrictive physiology and impaired diffusion capacity. Computed tomography scanning of the chest shows evidence of fibrosis and ground-glass opacities.[151,152] Electrophysiologic side effects include bradycardia and QT prolongation, which occur in almost all patients, but the incidence of TdP is rare (<0.5%). Cutaneous side effects include photosensitivity, and rarely a blue discoloration of the skin. Neurologic side effects include tremor, neuropathy, and cognitive impairment, which is rare.[153]

In the Canadian Trial of Atrial Fibrillation (CTAF), amiodarone was superior to both sotalol and propafenone for maintaining normal sinus rhythm. Sixty-five percent of patients using amiodarone versus 37% of patients using sotalol or propafenone were free of AF recurrence.[154] In the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial (SAFE-T), sotalol was superior to placebo but inferior to amiodarone for maintaining sinus rhythm in patients with persistent AF ($P < 0.001$). In the subset of patients with ischemic heart disease, amiodarone and sotalol were equally efficacious.[155]

Dronedarone, a class III drug, is a noniodinated benzofuran derivative with a structure similar to amiodarone. Dronedarone has the addition of a methy-sulfonyl group instead of the toxic iodine moieties, which reduces its interaction with thyroid physiology, decreases its lipophilicity, and shortens its plasma half-life.[156,157] Similar to amiodarone, dronedarone blocks a wide array of cardiac ion channels.[157] Dronaderone is administered at a dose of 400 mg twice a day, and pharmacokinetics are not significantly influenced by age, gender, weight, or renal function. Serum creatinine can rise with dronedarone because of inhibition of creatinine secretion but this does not reflect renal impairment.[156] In the ATHENA (A Placebo-Controlled, Double-Blind, Parallel Arm Trial to Assess the Efficacy of Dronedarone 400 mg bid for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in patients with Atrial Fibrillation/Atrial Flutter) trial, dronedarone was associated with a reduction in the composite endpoint of hospitalization owing to cardiovascular events or death when compared with placebo.[159] However, in another study (ANDROMEDA [Antiarrhythmic Trial with Dronedarone in Moderate to Severe Congestive Heart Failure Evaluating Morbidity Decrease], dronedarone was associated with an increase in mortality when compared with placebo.[158] Based on this study, dronedarone should be avoided in patients with CHF and should not be used as a rate control agent in patients with long-standing persistent or permanent AF.

Ranolazine is currently approved as an antianginal medication, but because of its ability to block sodium, potassium, and calcium currents, it is being evaluated for the treatment of both atrial and ventricular arrhythmias.[161] Ranolazine is administered twice daily and has a half-life of 7 hours. It is predominately metabolized in the liver, and the manufacturer does not recommend dose adjustment for renal and hepatic failure.[162] There have been several studies that have shown ranolazine is effective for AF suppression,[163,164] but current guidelines do not recommend it as a primary rhythm control agent. One recent study [165] showed that the combination of ranolazine and dronedarone was superior to placebo for suppression of AF; therefore ranolazine may have a role as a second AAD in select patients. The most common side effects include headache, dizziness, nausea, and constipation. Ranolzine prolongs the QT interval, but its inhibition of the late sodium current is protective against TdP.[166]

Ibutelide, a class III drug, is an IV-only potassium channel blocker that activates late inward sodium current. It has a structure similar to sotalol and is used for acute termination of AF and atrial flutter.[167] It has minimal hemodynamic effects and can be used safely in patients with structural heart disease and prior MI. Ibutelide prolongs the QT interval and has been associated with an increased risk of TdP (~0.4%).[168] It is administered as a 1-mg infusion over 10 minutes, with a repeat 1-mg infusion 10 minutes later if the first dose is not effective. Patients must be monitored closely for at least 4 hours after the infusion is complete to ensure that the QT interval returns to baseline.

Ventricular Arrhythmias

The intensivist must be prepared to recognize and manage ventricular arrhythmias. Cardiologists and electrophysiologists are often available to help management and prescribe long-term treatments. Therefore this section focuses on pathophysiology, ECG patterns, and intensive care treatment of ventricular arrhythmias. We briefly address chronic therapy.

The emergency treatment of cardiac arrest, implantable defibrillators, and pacemakers is covered in Chapters 1 and 5.

Mechanisms of Ventricular Arrhythmias

Reentry is the most common mechanism for sustained ventricular arrhythmias. Three conditions are required for reentry. The first is the presence of two contiguous pathways separated by a central region of inexcitable tissue. Second is unidirectional block in one of the pathways. Third is a zone of slow conduction in one of the pathways to allow recovery and excitation of the region of block, which allows the circuit to perpetuate. Reentry conditions can occur in the border zone of a healed MI scar or from functional disturbances in conduction and refractoriness as can happen during ischemia, CHF, or electrolyte disturbances.

The second mechanism of sustained VT is *enhanced automaticity* caused by impulse formation in cells that otherwise do not activate spontaneously. Diseased cardiac tissue is particularly susceptible to development of enhanced automaticity. Automatic cells (in the AV node, the His-Purkinje system, or the ventricles) may usurp the sinus node by means of enhanced automaticity in the setting of increased sympathetic activity, metabolic disturbances, or drug toxicity.

The third mechanism of VT is *triggered activity*, which can be caused by either early afterdepolarizations (EADs) or delayed afterdepolarizations (DADs). Both types of afterdepolarizations occur when oscillations in membrane potential reach the threshold for action potential formation, resulting in abnormal impulse formation. EADs are caused by delayed inactivation of inward ion currents during the plateau phase of the action potential. EADs are thought to be important in the genesis of TdP. DADs result from increased intracellular calcium, which can be caused by drug toxicity, metabolic disturbances, and ischemia. Digitalis toxicity is the classic example of DAD-induced triggered activity. Digitalis inhibits the sodium ion–potassium ion (Na^+-K^+) pump, thereby increasing intracellular Na^+, which in turn increases intracellular calcium ion (Ca^{2+}) via the Na^+-Ca^{2+} exchange current.[169] Idiopathic outflow tract VT may also result from DADs (cyclic adenosine monophosphate–mediated triggered activity).[170]

Approach to Ventricular Arrhythmias in the Critically Ill

New ventricular arrhythmias warrant an assessment of electrolytes, oxygenation, and acid-base status. An ECG should be obtained to distinguish monomorphic from polymorphic ventricular tachycardia (PMVT), to elucidate the morphology of ventricular premature contractions (PVCs) and non-sustained ventricular tachycardia (NSVT), and to examine the QT interval. Routine measurement of cardiac enzymes is not mandatory with the onset of each arrhythmia unless ischemia is suspected clinically, or there are ECG changes of ischemia. Movement of intracardiac catheters can result in mechanically induced arrhythmias. If arrhythmias are thought to be due to catheters, catheter position may be confirmed by radiography.

A comprehensive discussion of ACLS is beyond the scope of this chapter. Current recommendations for the management of adult cardiac arrest are discussed in Chapter 1 of this book and are summarized in recently published ACLS guidelines.[171]

Premature Ventricular Contractions

PVCs are common in patients with and without structural heart disease. Patients can be asymptomatic even when the PVCs are frequent or symptomatic with relatively few PVCs.[172] The vast majority of patients with PVCs without structural heart disease have a benign prognosis.[173] In the presence of CHF and LV dysfunction, PVC frequency does not predict SCD,[174] but several studies have demonstrated an association between frequent PVCs and a potentially reversible cardiomyopathy, which can resolve after catheter ablation.[175–180] It is currently believed that a PVC burden greater than 24% can be responsible for a cardiomyopathy.[181]

Diagnostic evaluation of PVCs should include a 12-lead ECG to determine the possible presence of underlying structural or electrical heart disease, such as myocardial scar (Q waves or fractionated QRS complex), prolonged or shortened QT interval, or presence of ventricular hypertrophy. The ECG is also important to determine the morphology of the PVCs, which can help determine their origin. In any patient with frequent or symptomatic PVCs, an echocardiogram should be obtained to exclude underlying structural heart disease. In selected cases a magnetic resonance imaging scan can be useful to determine pathologic etiologies of PVCs, such as dilated cardiomyopathy, hypertrophic cardiomyopathy, sarcoidosis, amyloidosis, and arrhythmogenic right ventricular (RV) cardiomyopathy.

Treatment of PVCs

In patients without structural heart disease and mild symptoms, the first step in treatment is to reassure and educate patients that they are not at risk for any serious adverse events. For patients with moderate or severe symptoms and structurally normal hearts, medication with β-blockers or nondihydropyridine calcium antagonists is first-line therapy, although their effectiveness in suppressing the PVCs may be limited.[182] When β-blockers and calcium blockers fail, antiarrhythmic drugs can be used, but the risk-benefit ratio in patients without structural heart disease is unknown and proarrhythmia is a concern. Catheter ablation of PVCs is recommended for highly selective patients who remain very symptomatic despite conservative treatment, or for patients with a very high PVC burden associated with a decline in LV function (Fig. 31.25).

Nonsustained Ventricular Tachycardia

Nonsustained ventricular tachycardia (NSVT) is defined as consecutive ventricular beats lasting between 3 complexes and 30 seconds' duration with a cycle length exceeding 100 beats/min.[183] It is a common finding both in patients with structurally normal or abnormal hearts.[184,185] NSVT is common in patients with ischemic heart disease and dilated cardiomyopathies.[183] Although NSVT in a structurally normal heart is generally benign, there are certain things to consider. Polymorphic NSVT requires a careful assessment for coronary ischemia. Athletes have an increased incidence of NSVT[186,187] and when seen, an evaluation for the presence of a hypertrophic cardiomyopathy is warranted. Catecholaminergic polymorphic ventricular tachycardia (CPVT) can present as exercise-induced NSVT (see later). NSVT in a structurally normal heart can also represent idiopathic VT, an inherited arrhythmia syndrome, such as long QT, short QT, or Brugada syndrome (see later). The finding of NSVT warrants further evaluation (Box 31.3 and Table 31.5).

Diagnostic evaluation of NSVT should begin with a 12-lead ECG to determine the possible presence of underlying structural or electrical heart disease such as myocardial scar (Q waves or fractionated QRS complex), prolonged or shortened QT interval, or presence of ventricular hypertrophy. ECG is also helpful for

• BOX 31.3 Evaluation of Patients With Nonsustained Ventricular Tachycardia

Standard Evaluation

History
- Prior cardiovascular disease?
- Hypertension, known cardiac disease?
- Syncope or near-syncope?
- Sustained palpitations?
- Relation of symptoms to exercise?

Family history
- SCD, inherited arrhythmia syndromes, coronary artery disease, cardiomyopathy?

Medications
- QT-prolonging drugs, sodium channel blockers, drug interactions?

Physical examination
- Evidence of cardiac disease

Twelve-lead ECG
- Q-waves, ischemic changes, prolonged or fractionated QRS, QT prolongation or shortening, ST elevation V1-V3, early repolarization, epsilon waves, or anterior T-wave inversion

Echocardiography
- Ventricular chamber dimensions and thickness, wall motion, systolic and diastolic function, valvular function, congenital anomalies, pulmonary arterial systolic pressure

Laboratory
- Serum electrolytes, renal function

Further Evaluation

Exercise testing
- Suspicion of coronary artery disease, exercise-related symptoms, borderline QT interval

Coronary arteriography
- Suspicion of coronary artery disease or coronary artery anomaly

Cardiac MRI
- Suspicion of ARVC, HCM, cardiac sarcoidosis, congenital anomalies

Genetic testing
- Suspicion of inherited arrhythmia syndrome, family history of inherited arrhythmia syndrome

Electrophysiologic testing
- Sustained palpitations without diagnosis, suspicion of AV block, coronary artery disease with NSVT, and moderate LV dysfunction

ARVC, *Arrhythmogenic right ventricular cardiomyopathy;* AV, *atrioventricular;* ECG, *electrocardiogram;* HCM, *hypertrophic cardiomyopathy;* LV, *left ventricular;* MRI, *magnetic resonance imaging;* NSVT, *nonsustained ventricular tachycardia;* SCD, *sudden cardiac death.*

TABLE 31.5 Nonsustained Ventricular Tachycardia With Apparently Normal Heart

NSVT Clinical Presentation	ECG	Risk of Sudden Cardiac Death	Diagnostic Evaluation	Alternative Diagnostic Considerations	Treatment	Treatment to Be Considered	Key References
Typical RVOT	LBBB, inferior axis, axis transition V3-V4	Very rare	Standard	Differentiate from ARVC	β-Blocker, verapamil, IC drugs with symptoms	Catheter ablation	Latif et al.[187a]
Typical LVOT	Inferior axis, transition, V3	Very rare	Standard	RVOT VT	β-Blocker, verapamil, class IC drugs with symptoms	Catheter ablation	Latif et al.[187a]
Idiopathic reentrant LV tachycardia	RBBB, LS axis	Very rare	Standard EP testing	Ischemic heart disease, CM	Verapamil if symptomatic	Catheter ablation	Latif et al.[187a]
Other focal VT	Multiple morphologies, monomorphic	Uncommon	Exercise testing or catecholamine stimulation	Ischemic heart disease, CM	β-Blocker for the arrhythmia	Catheter ablation	Latif et al.[187a]
Exercise	Multiple	Increased risk when NSVT in recovery	Ischemic heart disease, cardiomyopathy	CPVT	Underlying disease	β-Blockers, flecainide	Jouven et al.[187b], Frolkis et al.[187c]
Athlete	Multiple	If it disappears with increased exercise, low risk	Evaluate for latent HCM or ischemic heart disease	HCM	No treatment, training can continue	None	Biffi et al.[187d,187e]
Hypertension valvular disease	Multiple morphology	As without arrhythmia	Consider ischemic heart disease	Ischemic heart disease, CM	Treat HTN	β-Blocker	Zipes et al.[187f]
Polymorphic VT	Polymorphic	High	Evaluated for CAD, CPVT, inherited arrhythmia syndromes	Purkinje fiber–triggering focus	Underlying disease	Revascularization, ICD, β-blocker, catheter ablation	Sauer and Newton-Cheh[187g]
TdP VT	Long QT, TdP	High	Medications, congenital LQTS	Medications, K^+, Mg^{2+}, Ca^{2+}	Stop medications, correct electrolytes	ICD, β-blocker

determining the morphology of the NSVT, which can help determine its origin. An echocardiogram should be obtained to exclude underlying heart disease. In selected cases, an MRI can be useful to determine pathologic etiologies of NSVT such as dilated cardiomyopathy, hypertrophic cardiomyopathy, sarcoidosis, amyloidosis, or arrhythmogenic RV cardiomyopathy.

Treatment of Nonsustained Ventricular Tachycardia

Treatment of NSVT originating from the RV or LV outflow tract is required only if the arrhythmia is symptomatic, incessant, or produces LV dysfunction. The treatment of LV or RV outflow tract NSVT is either medical with a β-blocker, a nonhydropyridine calcium blocker, a class IC antiarrhythmic medication, or with catheter ablation. NSVT owing to a focal mechanism can also occur from a LV papillary muscle and can be treated medically with β-blockers, nonhydropyridine calcium blockers, or with catheter ablation.

Treatment of NSVT and suspected ischemic heart disease warrants an evaluation for coronary ischemia and should be focused on improving coronary perfusion. A patient with a LV ejection fraction less than 35% and NSVT should be considered for an ICD.[188–190] In patients with less severe LV dysfunction (ejection fraction 35%–50%) and a history of a prior MI, syncope, or symptomatic NSVT, an electrophysiologic study may be indicated. If the electrophysiologic study demonstrates inducible sustained VT, an ICD should be implanted.[191] NSVT is one of several risk factors for SCD in hypertrophic cardiomyopathy. Patients with hypertrophic cardiomyopathy should have their risk scores calculated to determine if implantation of an ICD is warranted.[192] If the nonsustained VT is determined to be CPVT, the risk of SCD is high and β-blocker therapy and possible placement of an implantable cardioverter-defibrillator (ICD) are recommended[193] (see later text).

If the NSVT is TdP, electrolyte abnormalities that can prolong repolarization need to be corrected and medications that can prolong the QT interval eliminated.

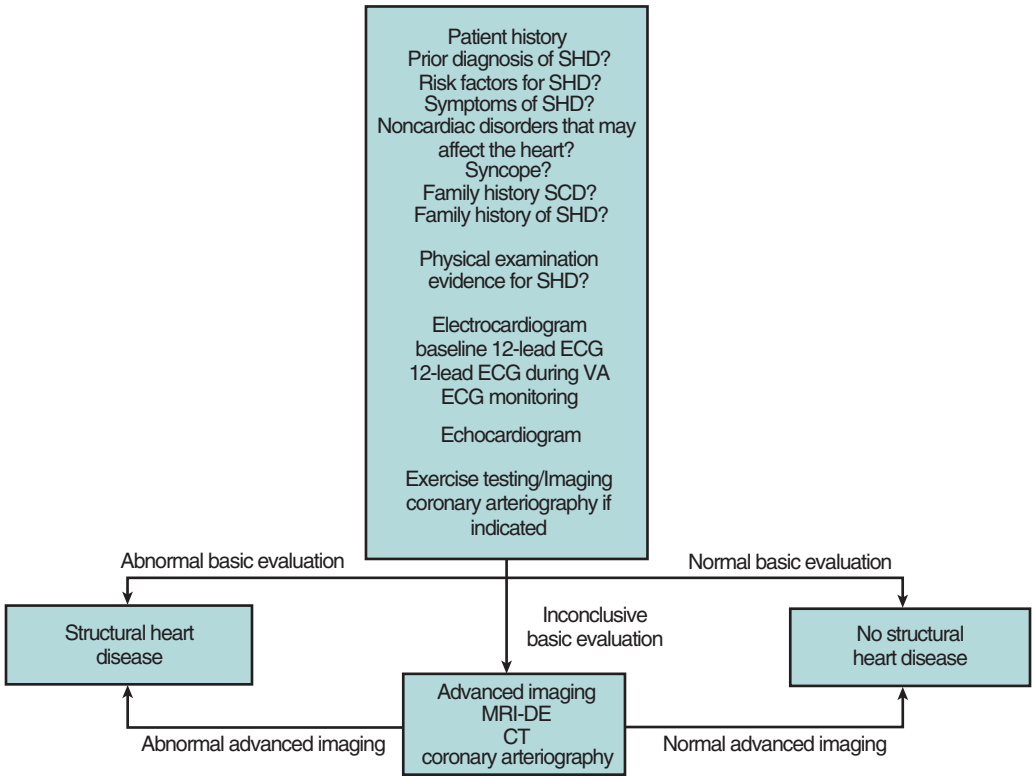
Antiarrhythmic drug therapy can be considered for patients with symptomatic recurrent NSVT that is not alleviated by revascularization, optimization of medical therapy, or treatment of reversible causes, but no study has demonstrated a mortality benefit of suppression of NSVT either with antiarrhythmic medication or catheter ablation. Patients with defibrillators (ICDs) and NSVT have an increased frequency of shocks and all-cause mortality. These patients should have their ICDs programmed with long VT detection times and high VF detection rates to avoid unnecessary shocks and to potentially improve prognosis.[194,195]

Sustained Ventricular Tachycardia

Monomorphic ventricular tachycardia is defined as sustained when it lasts longer than 30 seconds. In evaluating a patient with sustained ventricular tachycardia it is important to determine if the patient has any structural heart disease (Fig. 31.26). A 12-lead ECG, an echocardiogram, and often a cardiac catheterization are essential to make this determination. If the echocardiogram is normal, a cardiac magnetic resonance imaging scan is sometimes indicated to look for myocardial scar not seen on the echocardiogram, arrhythmogenic RV cardiomyopathy, nonischemic cardiomyopathy, hypertrophic cardiomyopathy, cardiac sarcoidosis, or amyloidosis.

Ischemic Sustained Ventricular Tachycardia

The vast majority of patients with sustained monomorphic VT (SMVT) have structural heart disease with most—54% to 59%—having ischemic heart disease. Most patients with SMVT and



• **Fig. 31.26** Evaluation for the presence or absence of structural heart disease. *CT,* Computed tomography; *ECG,* electrocardiogram; *MRI-DE,* magnetic resonance imaging with delayed enhancement; *SHD,* structural heart disease; *VA,* ventricular arrhythmia.

ischemic heart disease have a myocardial scar that is a sequel of a prior MI, which is the substrate for the VT. Transient myocardial ischemia is an uncommon cause of SMVT. Therefore while most patients will be referred for a coronary angiogram, it is unlikely that treatment of the ischemia alone will prevent recurrence of the monomorphic ventricular tachycardia.[196,197]

Treatment of SMVT

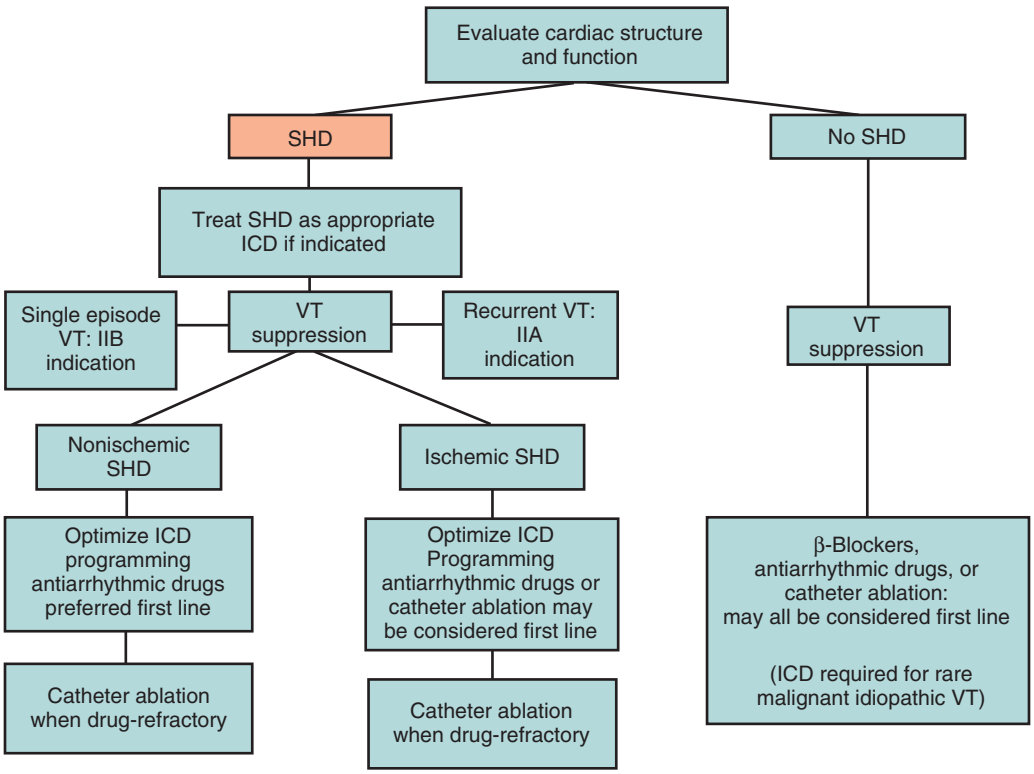
The treatment of SMVT is dependent on the patient's symptoms, hemodynamic status, and underlying heart disease. When it occurs in patients without structural heart disease it generally has an excellent prognosis.[191,199] Rarely idiopathic VT can be life-threatening when the arrhythmia has a short coupling interval or rapid rate.[200] In patients without structural heart disease and an ECG showing a QRS morphology consistent with an outflow tract tachycardia an IV β-blocker may be effective in terminating the VT (see later text) (Fig. 31.27).

The single most effective agent for terminating VT in the presence of structural heart disease is amiodarone.[191] Sustained VT in the setting of reduced ventricular systolic function is associated with an increased mortality.[196,197,201,204] Implantation of an ICD is indicated for patients with structural heart disease and sustained VT[205] because it has been demonstrated to improve survival.[196,197,208] There is no evidence that antiarrhythmic therapy alone improves survival. Further, AADs have a significant risk of proarrhythmia and thus they should be used only when an ICD is implanted. Sotalol and amiodarone have been shown to decrease number of appropriate ICD therapies, but they should not be used without an ICD in place.[209] For patients with ischemic myocardial scar and near-normal systolic function, ICD implantation is also recommended because it can simplify management and follow-up of these patients. However, there is no study that has shown a mortality benefit of this strategy. Both appropriate and inappropriate ICD shocks are associated with an increased mortality and reduced quality of life. The increase in mortality is usually attributed to worsening cardiac disease and not a specific consequence of the shocks.[210–212]

Catheter ablation is becoming an important alternative to the use of antiarrhythmic medication for the treatment of SMVT. In patients with a prior MI, reduced ejection fraction, and sustained VT, catheter ablation has been shown to significantly reduce recurrence of VT.[213] Consensus statement and guidelines recommend catheter ablation for VT only when antiarrhythmic drugs are not effective. More recent studies, however, have shown that catheter ablation is preferred over escalation of antiarrhythmic drug therapy.[214]

Sustained Polymorphic VT/VF

PMVT is defined as a ventricular arrhythmia where the morphology of the QRS complexes changes with each beat, at a rate of more than 100 beats/min. This differs from VF, which is a chaotic tachycardia without identifiable QRS complexes. TdP is a PMVT, which occurs in the setting of a prolonged QT interval where the QRS complexes twist around an isoelectric baseline[215] (Fig. 31.28). TdP is strongly associated with electrolyte abnormalities or drugs that delay repolarization. When this arrhythmia is suspected, a search for underlying factors that can be corrected should be undertaken. PMVT or VF in the absence of ischemia, electrolyte abnormalities, or drugs that prolong the QT interval suggests the presence of an inherited arrhythmia syndrome such as long QT, short QT, Brugada, or CPVT (Table 31.6) (see later text). To make

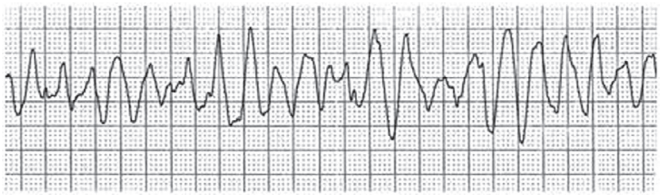


• **Fig. 31.27** Evaluation and management of sustained monomorphic ventricular tachycardia. *ICD,* Implantable cardioverter-defibrillator; *SHD,* structural heart disease; *VT,* ventricular tachycardia.

these rarer diagnoses, it is important to obtain a 12-lead ECG as close as possible to the arrhythmic event where the pathognomonic abnormalities will be seen on the ECG (Fig. 31.29).

Treatment of Polymorphic VT or VF

A detailed discussion of the management of cardiac arrest is provided in Chapter 1. The treatment of VF is immediate defibrillation.



• **Fig. 31.28** Torsades de pointes. The ventricular tachycardia on the electrocardiogram appears to rotate around a horizontal axis—hence, the name torsades de pointes, from the French "twisting of the points." (Adapted from Gupta A, Lawrence AT, Krishnan K, et al. Current concepts in the mechanisms and management of drug-induced QT prolongation and torsades de pointes. *Am Heart J.* 2007;153:891–899.)

The rhythm in patients with TdP should be cardioverted if the arrhythmia is sustained; if it recurs, atrial pacing at rates of at least 90 beats/min can be effective. During cardiac arrest, patients treated with IV amiodarone have a higher probability of survival than those treated with IV lidocaine. Once patients are resuscitated from VF or PMVT, the initial diagnostic step is to exclude an acute coronary syndrome or MI.[217–218] Emergency coronary angiography and revascularization may significantly improve prognosis.[216,219,220] Once ischemia is treated or ruled out, an echocardiogram is recommended to assess structure and function of the ventricles. When there is no reversible cause of PMVT or VF, ICD implantation is the next step.[221,222] Catheter ablation may be considered for patients with recurrent PMVT or VF when a consistent PVC morphology triggers the arrhythmia.[223,224,226] These VPCs are repetitive, usually narrow, and originate from the Purkinje network where they can be targeted for catheter ablation. Even if catheter ablation is effective in these patients, an ICD is usually still indicated.[225]

Post-MI patients with a LV ejection fraction of less than 35% are at high risk for SCD in the first 3 months while the ventricle is healing. They may benefit from a wearable defibrillator during this healing phase. The LV function should be reassessed 40 days

TABLE 31.6 Conditions That Can Cause Polymorphic VT/VF in the Absence of Structural Heart Disease and Potential Therapies

Clues	Test to Consider	Diagnoses	Therapies
Long QT/T-wave alternans	ECG/monitor	Congenital LQTS	β-Blockers/stellatectomy
TdP pattern	Epinephrine challenge		Avoid QT-prolonging drugs
History of seizures	Genetic testing		Mexilitine/flecainide (LTQ3)
Specific trigger (loud noise)			Pacemaker/ICD
Long QT/T-wave alternans	ECG/Monitor	Acquired LQTS	Mg^{2+}/K^{+}
TdP pattern			Stop offending drug
Renal failure			Temporary pacing
New medication or drug abuse			
AV block	ECG/monitor	Bradycardia	Pacemaker

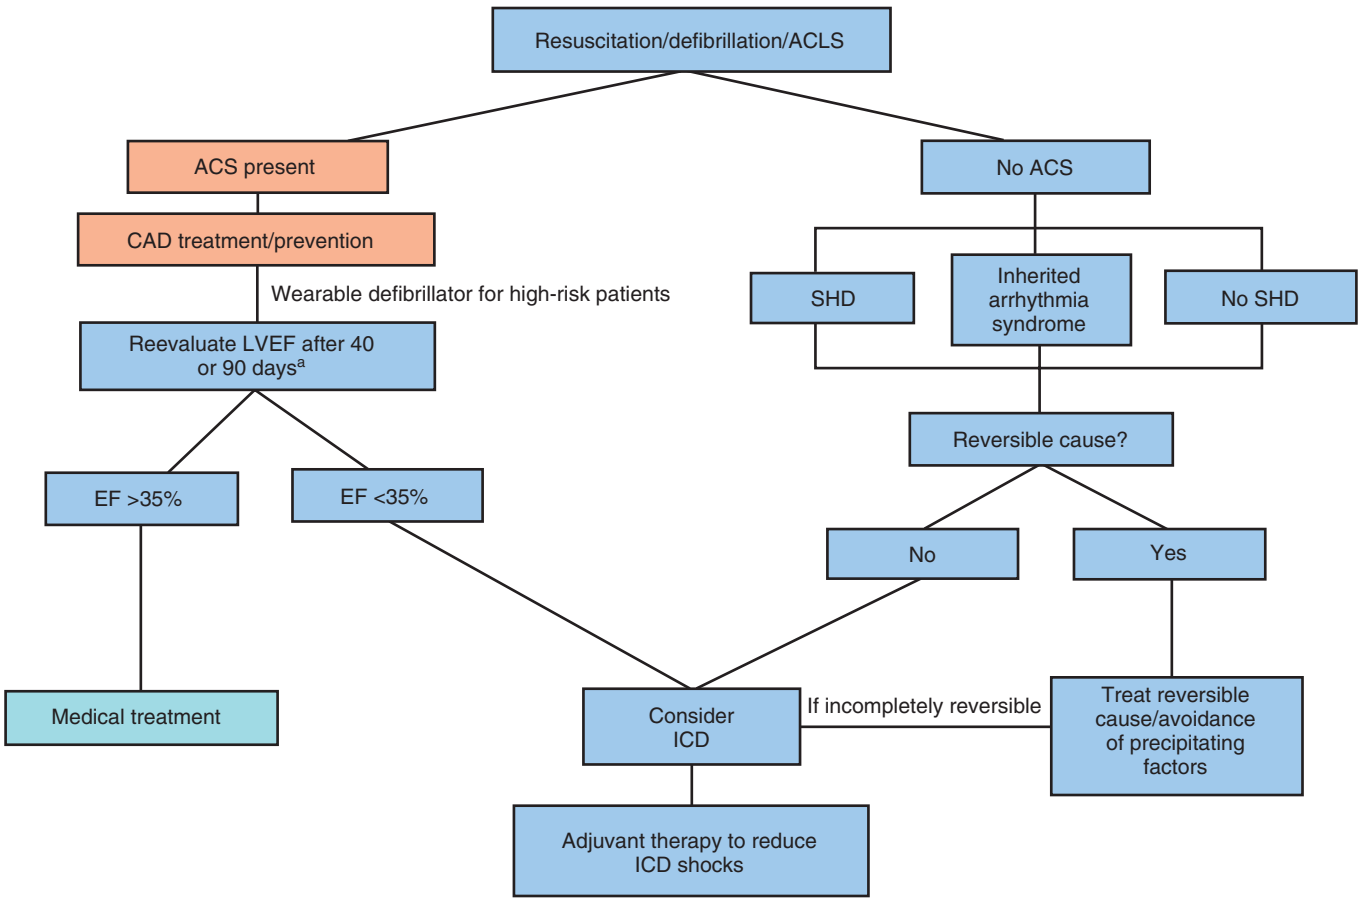
after infarction, and if still less than 35%, implantation of an ICD is recommended. Patients who are treated with coronary revascularization after an MI are also at risk if the LV ejection fraction is less than 35% and may also benefit from a wearable defibrillator. LV function should be reassessed at 90 days after revascularization in that group to determine if they are candidates for ICD implant (Fig. 31.30).

VT/VF Storm

VT/VF storm is defined as three or more episodes of VT or VF within 24 hours requiring either cardioversion/defibrillation or antitachycardia pacing therapy from an ICD.[227,232] These patients should be evaluated for reversible causes such as electrolyte disturbances, proarrhythmia from a medication, acute ischemia, or valvular disease. Patients with VT/VF storm should be evaluated for treatment with sedation, intubation, or mechanical hemodynamic support, which by themselves can reduce arrhythmia burden. β-Blockers have been shown to improve short-term outcomes and can be used with amiodarone to improve outcomes.[233] Lidocaine is rarely effective in this setting.[234] Implantable defibrillator detection criteria and therapies should be reprogrammed to prevent shocks from potentially self-terminating episodes of VT and favor antitachycardia pacing therapy. Catheter ablation should be considered



• **Fig. 31.30** Algorithm for treatment of sustained polymorphic ventricular tachycardia/ventricular fibrillation. Left ventricular function should be reassessed at 40 days after myocardial infarction or 90 days after revascularization. *ACS,* Acute coronary syndrome; *ACLS,* Advance Cardiovascular Life Support; *CAD,* coronary artery disease; *EF,* ejection fraction; *ICD,* implantable cardioverter-defibrillator; *LVEF,* left ventricular ejection fraction; *SHD,* structural heart disease.

early after hospitalization for patients with continued arrhythmias; studies have shown a beneficial effect on both VT recurrence and long-term survival.[235,236] As a last resort, neuroaxial modulation with left cardiac sympathetic denervation and spinal cord stimulation can be used for patients who cannot be stabilized by other means to reduce arrhythmia burden.[227,229,237]

Ventricular Arrhythmias in Patients With LV Assist Devices

Left ventricular assist devices (LVADs) are used both as a bridge to transplantation and as permanent destination therapy. However, their use does not eliminate ventricular arrhythmias, which still occur in 25% to 49% of patients after LVAD implantation.[216,234,238–248] LVADs provide hemodynamic support during episodes of ventricular arrhythmias, but patients may still experience palpitations, dyspnea, and right heart failure. Antiarrhythmic drugs are rarely effective in patients with LVADs; thus catheter ablation often is required.[241,246,249,250] Ventricular arrhythmias in patients with LVADs are associated with an increased risk of overall mortality.

Ventricular Arrhythmias Associated With an Acute Myocardial Infarction

The incidence of VT and VF during acute ST-elevation MIs from the Gusto-I (Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries) trial was 10.2%, 3.5% VT, 4.1% VF, and 2.7% both VT and VF.[251] Of these arrhythmias, 80% to 85% occurred in the first 48 hours. In patients with acute non–ST-elevation MIs or unstable angina, the overall incidence of VT or VF was only 2.1%.[252] VT occurred in 0.8%, VF in 1%, and VT and VF in 0.3%. The median time to arrhythmia was 78 hours.

Classification of ventricular arrhythmias during AMI is based on the time of arrhythmia onset. VT or VF occurring in the first 48 hours is considered an epiphenomenon and does not require long-term treatment. VT or VF occurring after the first 48 hours reflects the development of an arrhythmic substrate and may require permanent solutions because of the increased risk of SCD in these patients.

Phase 1a ventricular arrhythmias occur in the first 2 to 10 minutes and it is postulated that reentry is the dominant mechanism.[253–256] Phase 1b arrhythmias occur after approximately 10 to 60 minutes of coronary occlusion. Although the exact mechanism of phase 1b arrhythmias is unknown, it has been postulated that they may reflect abnormal automaticity induced by LV wall stress[257] or may be due to increased catecholamine release.[160,258,259] Delayed phase arrhythmias occurring 6 to 48 hours after MI are VPCs, nonsustained VT, and accelerated idioventricular rhythm, which can occur in up to 50% of patients.[260,261] It is believed that delayed arrhythmias arise from abnormal automaticity in surviving Purkinje cells located in the subendocardium.[262,263] Chronic phase arrhythmias occur after 48 hours of an AMI. Patients in whom sustained monomorphic VT develops after 48 hours usually have sustained large infarcts with resultant severe LV dysfunction. The VT is usually reentrant around the area of scar and can be quite rapid with heart rates greater than 180 beats/min.[264–266]

The autonomic nervous system contributes to the development of ventricular arrhythmias associated with an MI; excess sympathetic tone may be responsible.[267,268] Autonomic imbalance can increase sodium-potassium adenosine triphosphate (Na-K-ATPase) activity and enhance potassium conductance, which lead to hyperpolarization of the myocardial cell membrane.[269] Sympathetic activity will also increase the influx of calcium, which can enhance both automaticity and triggered activity. The evidence that sympathetic activity is important in the genesis of arrhythmias associated with AMIs comes from a study of 49 patients with VT storm.[270] Compared with patients receiving antiarrhythmic therapy, those treated with a β-blocker or stellate ganglionic blockade had a lower 1-week (22% vs. 82%) and overall mortality (33% vs. 95%) at 1 year. It was once thought that serious ventricular arrhythmias could occur within a period of minutes after reperfusion in patients with an AMI. However, it has been shown that serious ventricular arrhythmias rarely occur, although the incidence of accelerated idioventricular rhythm may be increased.[271,272]

Less Common Substrates

Idiopathic VT

Idiopathic VTs originate from a "line of fire"—areas in the RV outflow tract (90%), LV outflow tract, aortic cusps, or mitral annulus—that have a higher potential to become electrically active than the rest of the ventricle.[273] The most common form (RV outflow tract tachycardia) has a typical ECG pattern of left bundle branch block with an inferior frontal lead axis (tall R waves in leads II, III, and aVF). When the precordial transition occurs in lead V3 and the ratio of the R and S waves in lead V2 during VT divided by this ratio during sinus rhythm exceeds 0.6, a LV outflow tract origin is suspected (Fig. 31.31). Outflow tract tachycardias are adenosine-sensitive and are thought to be the result of cyclic adenosine monophosphate–mediated DADs.[170] They can be facilitated by catecholamine infusion.

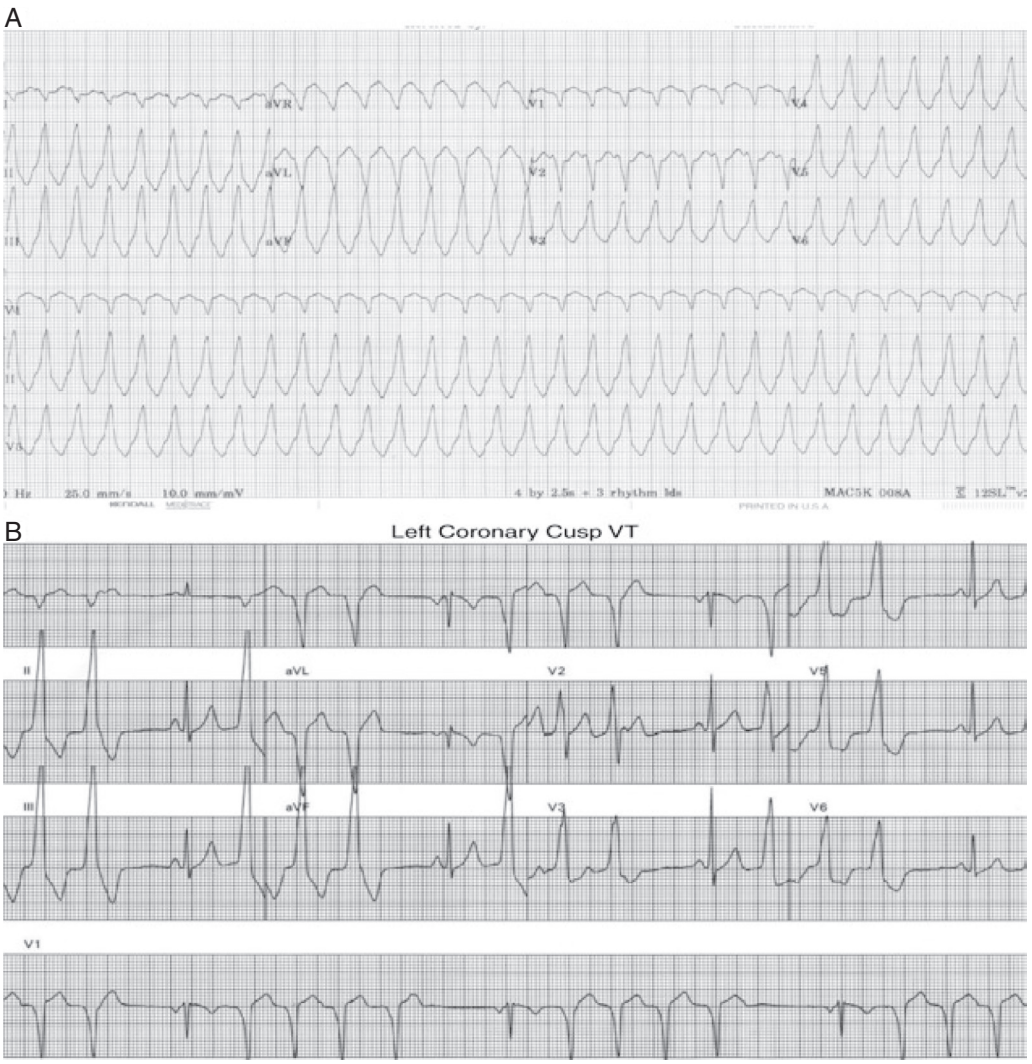
Another idiopathic LV tachycardia manifests as a relatively narrow right bundle branch block (RBBB), left-axis deviation tachycardia. This reentrant tachycardia is referred to by several different names, including fascicular VT, verapamil-sensitive VT, and Belhassen VT. The arrhythmia is due to macroentry in the terminal Purkinje fibers in the left distal third of the apical septum (Fig. 31.32). To ablate it, the lower third of the septum is mapped to look for the sharpest, earliest Purkinje potential during the tachycardia.[274,275]

Treatment of Idiopathic VT

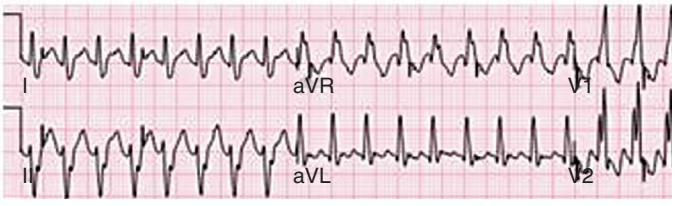
Treatment depends on patients' symptoms and the effect on overall LV function. Treatment is required only if the arrhythmia is symptomatic, incessant, or produces LV dysfunction. β-Blockers and nonhydropyridine calcium channel blockade are low-risk therapies to be used as first-line therapy but they have modest effectiveness.[276,277] Treatment with antiarrhythmic medication such as sotalol, flecainide, mexiletine, or amiodarone is more effective but has the inherent risks of side effects and proarrhythmia. Catheter ablation for RV outflow tract tachycardia is very successful with a low risk of complications. Catheter ablation for LV outflow tract tachycardia, fascicular VT, and focal VT from sites such as the papillary muscles are more procedurally complex and success rates are lower, but ablation therapy can still be curative.[278–280]

Arrhythmogenic RV Dysplasia

The ECG of patients with arrhythmogenic right ventricular dysplasia may have inverted T waves in the right precordial leads (V1, V2, and V3). In addition, an upward deflection, called an epsilon wave, may be seen just after the QRS complex and is due to late RV activation (Fig. 31.33).[281] The QRS duration may be prolonged, often with a complete or incomplete RBBB pattern. Ventricular arrhythmias in ARVD have a left bundle branch block



• **Fig. 31.31** A, Right ventricular outflow tract ventricular tachycardia *(VT).* B, Left coronary cusp VT.



• **Fig. 31.32** Verapamil-sensitive ventricular tachycardia in a 12-year-old.

configuration, as they originate from the right ventricle, and may be catecholamine-sensitive and exacerbated during exercise. VT caused by ARVD may be confused with right ventricular outflow tract VT because they have similar ECG appearances and similar clinical characteristics.

Presentation is most common between the ages of 10 and 50 years, with a mean age at diagnosis of approximately 30 years.[282] The male gender has been reported to have a more malignant course. The majority of patients who are diagnosed with ARVC are symptomatic at presentation; the most common symptoms are palpitations, syncope, atypical chest pain dyspnea, and RV failure.[283] The first manifestation of the disease can be SCD. In northern Italy it has been reported that ARVC accounts for 22% of sudden deaths in patients younger than 35 years, but in the United States ARVC appears to be a less common cause of sudden death, accounting for only 4% of deaths in young athletes.[284]

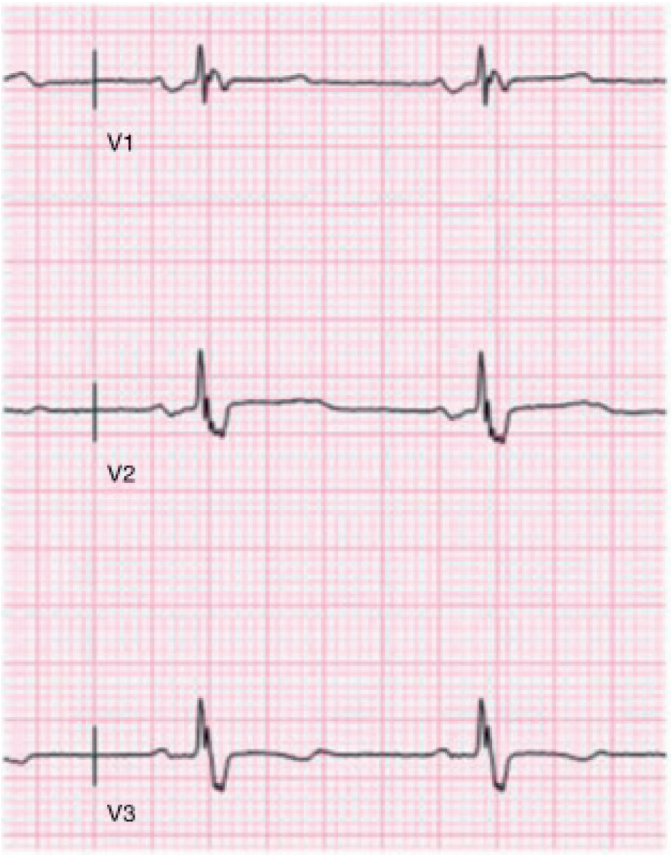
ARVD is caused by mutations in a variety of genes, most of which encode desmosomal proteins; more than 30% of cases are familial. There are two patterns of inheritance: the more common autosomal dominate form, and an autosomal recessive form associated with a cardiocutaneous syndrome including hyperkeratosis of the palms and soles and wooly hair (Naxos disease).[285] ARVD occurs in patients with significant RV disease; hallmark findings are RV dilatation, RV dysfunction, and regional RV wall motion abnormalities. LV involvement is also common in patient with ARVD and increases with age and duration of ARVD.[286] These findings are best seen on magnetic resonance imaging.

Treatment of Arrhythmogenic RV Dysplasia

Electrophysiologic studies are not predictive in defining a high-risk group for SCD. Sotalol and amiodarone seem to be effective to treat arrhythmias in ARVD. Patients diagnosed with ARVD who have had syncope episodes have NSVT, or moderate ventricular dysfunction (either RV or LV), and should have implantation of a prophylactic ICD.[287,288]

Long QT Syndrome

Long QT syndrome (LQTS) is a potentially life-threatening condition characterized by delayed myocardial repolarization that produces a long corrected QT interval.[289] The incidence is estimated to be 1 in 2000. Patients with LQTS are at risk for TdP-mediated syncope, seizures, and SCD (Fig. 31.34). There is a 13% incidence of cardiac arrest or SCD in untreated patients.[290] Although there are now 13 mutations that can cause LQTS, mutations in three major LQTS genes (*KCNQ1, KCNH2,* and *SCN51*) account for more than 75% of cases and are characterized, respectively, as LQT1, LQT2, and LQT3. LQT1 is associated with events during exertion, LQT2 is associated with events occurring after hearing a sudden loud noise, and LQT3 is associated with events at rest or sleep. There are characteristic ECG patterns for each of the three variants, although the clinical scenario often correlates to the specific gene mutation better than the ECG pattern. LQT1 has a broad T wave, LQT2 has a bifid T wave, and LQT3 has a long isoelectric segment and a narrow T wave (Fig. 31.35). The LQT3 pattern appears similar to the ECG seen in hypocalcemia.[291,292]



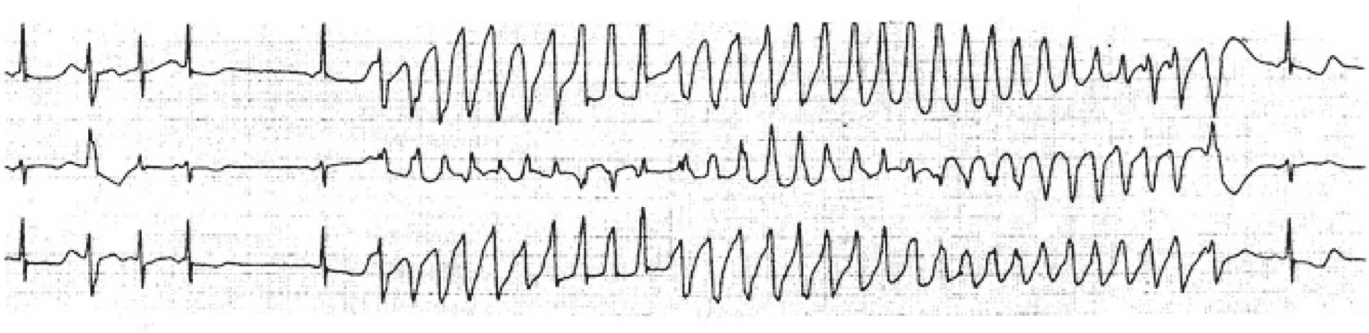
• **Fig. 31.33** The electrocardiogram shows arrhythmogenic right ventricular dysplasia (ARVD) with epsilon wave. Note the T-wave inversion in V3 and the incomplete right bundle branch block pattern. The upward deflection after the QRS in V1 is termed an epsilon wave and is classic for ARVD.

Treatment of Long QT Syndrome

Risk stratification of patients is made based on symptoms, genotype, sex, and corrected QT interval as shown in Fig. 31.36.[290] The mainstay of treatment is β-blockers, which are very effective in LQT1 and moderately effective for LQT2 and LQT3.[293] Cardiac pacing may be used in patients with LQTS who remain symptomatic despite β-blockers, particularly those in whom bradycardia facilitates TdP or bradycardia limits β-blocker administration. Patients with LQT3 may derive particular benefit from pacing because bradycardia is common in these patients.[294] ICDs are used in patients with continued symptoms despite β-blockers. It has now become accepted practice to place ICDs in patients who have recurrent TdP despite conventional therapy, aborted cardiac arrest, or other high-risk features.[295] Left cardiac sympathetic denervation (left stellate cardiac ganglionectomy) is another rarely used method to reduce cardiac events in patients with LQTS, which can be effective for patients who have multiple ICD shocks despite medial therapy.[296]

Brugada Syndrome

The Brugada syndrome (first described in 1992) is characterized by an ECG showing RBBB (complete or incomplete) with ST-segment elevation in leads V1 to V3 and ventricular arrhythmias: PMVT or VF.[297] Three distinct ECG patterns have been identified. Type 1 features a "coved"-type ST segment (>2 mm) elevation and a negative T wave in leads V1 and V2. Type 2 features a "saddleback" ST-T configuration in those leads caused by two notches in the T wave. Type 3 patterns can have a coved or



• **Fig. 31.34** Arrhythmia onset in long QT syndrome. Three simultaneous (and distinct) electrocardiogram channel recordings in a patient with QT prolongation and runs of continuously varying polymorphic ventricular tachycardia (torsades de pointes [TdP]). TdP may resolve spontaneously or progress to ventricular fibrillation and cardiac arrest. (From Chiang C, Roden DM. The long QT syndromes: genetic basis and clinical implications. *J Am Coll Cardiol.* 2000;36:1–12.)

• **Fig. 31.35** Long QT *(LQT)* patterns. (From Roden DM. Clinical practice. Long-QT syndrome. *N Engl J Med.* 2008;358:169–176.)

saddleback morphology in leads V1 and V2 (Fig. 31.37). Moving the right precordial leads up to the second or third intercostal space or using bipolar chest leads may increase the sensitivity of detecting these abnormalities and should be performed when there is doubt about the diagnosis.[298,299] The cellular mechanism responsible for the ST-segment elevation is early repolarization of the ventricular epicardium as a result of rebalancing of currents at the end of phase I of the action potential. The transient outward potassium current overwhelms inward currents. The ECG abnormalities may be unmasked by procainamide and flecainide.

Brugada syndrome is caused by a mutation in the sodium channel gene *SCN5A,* which decreases the sodium channel activity. The mutation has an autosomal dominant pattern with variable penetrance. Males are more likely to be affected and also have an increased risk of sudden death. Different mutations in *SCN5A* account for LQT3 and a recent report suggests a genetic (and perhaps clinical) link between the Brugada syndrome and LQT3. In Japan and Southeast Asia, the Brugada syndrome may account for 40% to 60% of cases of idiopathic VF. Febrile illnesses may trigger arrhythmic events in patients with Brugada syndrome.[300]

Treatment of Brugada Syndrome

Currently there is no effective drug therapy for this disease. A patient with any of the Brugada pattern ECGs coupled with a history of cardiac arrest, syncope, or VT should have an ICD implanted. Asymptomatic patients with the Brugada pattern on ECG should not receive a defibrillator; clinical monitoring is advised. During electrical storm caused by Brugada syndrome, isoproterenol infusion can be useful in lessening arrhythmia burden.[301]

Catecholaminergic Polymorphic VT

CPVT, also known as familial catecholaminergic polymorphic VT, occurs in the absence of structural heart disease or other syndromes.[302–311] It typically manifests in childhood as syncope or aborted cardiac arrest. The ECG is normal in sinus rhythm. Two types of PMVTs have been described. The first is typical PMVT with continuously varying QRS morphology. The second is a bidirectional tachycardia demonstrating alternans of the QRS complexes.[307,310] CPVT is caused by calcium overload, delayed afterdepolarizations, and triggered activity that causes VT or VF. Mutations in two genes have been identified to cause CPVT: the cardiac ryanodine receptor gene (autosomal dominant) and the calsequestrin 2 gene (autosomal recessive).[307–309]

Treatment of Catecholaminergic Polymorphic VT

β-Blockers are the cornerstone of therapy and dosing may be titrated according to exercise response.[312] In 40% of patients, arrhythmia control remains inadequate despite dose optimization during repeat exercise testing. ICDs are the therapeutic option of choice in these patients.[222,313,314]

Short QT Syndrome

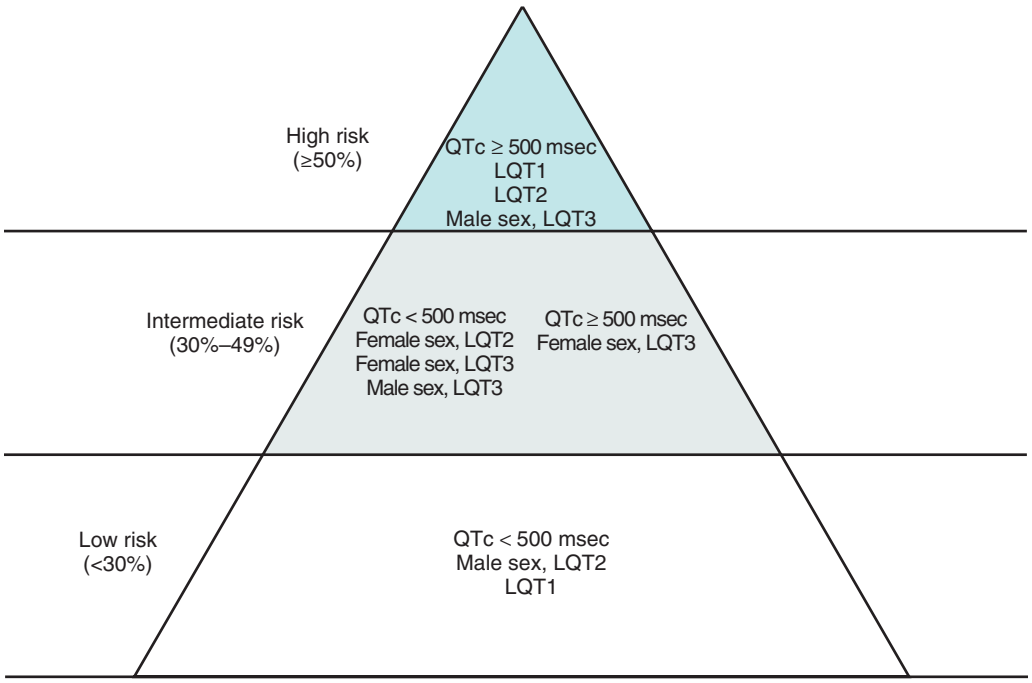
Short QT syndrome (SQTS) is a heritable primary electrical disease characterized by an abnormally short QT interval (<350 msec) and a propensity for AF, SCD, or both[315] (Fig. 31.38). Shortening of effective refractory periods combined with increased dispersion of repolarization is the likely substrate for reentry and life-threatening tachyarrhythmias. It is important to differentiate patients who have an isolated short QT interval and those who meet the criteria for SQTS.[316] As in LQTS, more than one relevant genetic mutation has been identified.

Treatment of Short QT Syndrome

Patients with a short QT interval only (≥330 msec) and no clinical history, family history, or genotype criteria are classified as low risk and warrant no therapy. Patients with a markedly short QT (<330 msec) and no clinical history, family history, or genotype criteria are classified as intermediate probability for SQTS; referral to an electrophysiologist for additional evaluation is warranted. Patients with a QT interval less than 350 msec and a positive clinical history, positive family history, or positive genotype criteria are classified as high risk and treatment with an ICD is recommended (Table 31.7).[317,318] The relative value of diagnostic criteria points is summarized at the bottom of the table.

Short-Coupled Torsades de Pointes

Short-coupled TdP (SC-TdP) occurs in patients with structurally normal hearts and unremarkable ECGs (normal QT intervals). In this syndrome, TdP is caused by short-coupled (<300 msec)



• **Fig. 31.36** Proposed scheme for risk stratification of patients with long QT *(LQT)* syndrome according to genotype and sex. *QTc,* Corrected QT interval. (From Priori SG, Schwartz PJ, Napolitano C, et al. Risk stratification in the long-QT syndrome. *N Engl J Med.* 2003;348:1866–1874.)

ventricular premature beats. It is a rare, potentially fatal disorder whose pathophysiology is unknown. The prognosis is poor and effective pharmacologic therapy has not been identified. ICDs may be the best option. Short-coupled TdP shares features with idiopathic VT, and speculation is that it may respond to catheter ablation if a single PVC focus (usually from the Purkinje system) is the consistent trigger.[223,319]

Electrical Shocks

Patients who experience electrical shock (including lightning strikes) sustain a wide spectrum of injuries with unique pathophysiologic characteristics that require special management. Patients with serious electrical burns admitted to the ICU are trauma patients and should be treated accordingly. Initial prediction of outcome for patients who have experienced an electrical shock is difficult, because the full degree of injury often is not initially apparent. SCD resulting from VF is more common with low-voltage alternating current, whereas asystole is more frequent with electric shocks from direct current or high-voltage alternating current. Fatal arrhythmias are more likely to be caused by horizontal current flow (hand to hand); current passing in a vertical fashion (from head to foot) more commonly causes myocardial tissue damage. Lightning strike is unique because it causes cardiac and respiratory arrest, resulting in a 25% to 30% mortality rate.[320]

Aggressive and prolonged cardiopulmonary resuscitation (CPR) in patients who have experienced electrical shock is indicated for several reasons.[321] First, cardiac arrhythmias and prolonged respiratory arrest may be the only clinical problem, especially in patients struck by lightning. Second, patients who experience electrical

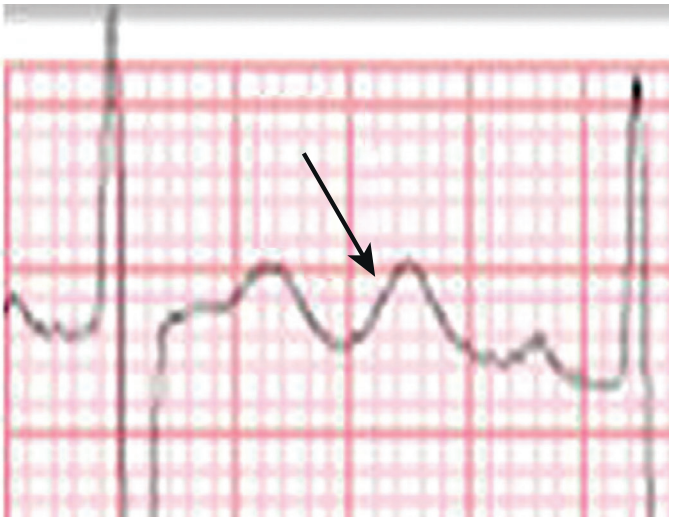
shock commonly are young and have few or no comorbid conditions. These young patients may survive prolonged CPR with no or minor sequelae. Keraunoparalysis, in which the extremities (usually the legs), become transiently cold, cyanotic, pulseless, and mottled, may masquerade as irreversible neurologic injury in patients who have been electrocuted. For practical purposes, guidelines for CPR as issued by the American Heart Association[171] still apply. The algorithm for asystole acknowledges that "atypical clinical features" need to be considered in deciding whether CPR should be continued after initial unsuccessful attempts. If more than one person has been electrocuted at a scene of injury, standard triage practices need to be modified, especially in those struck by lightning. Most patients who do not experience cardiac or respiratory arrest will survive.[322] Thus the usual triage principles should be reversed: First responders should focus initially on patients who appear clinically dead *before* patients who show signs of life are treated.



• **Fig. 31.39** Hypokalemia. Prominent U waves are seen *(arrow).*

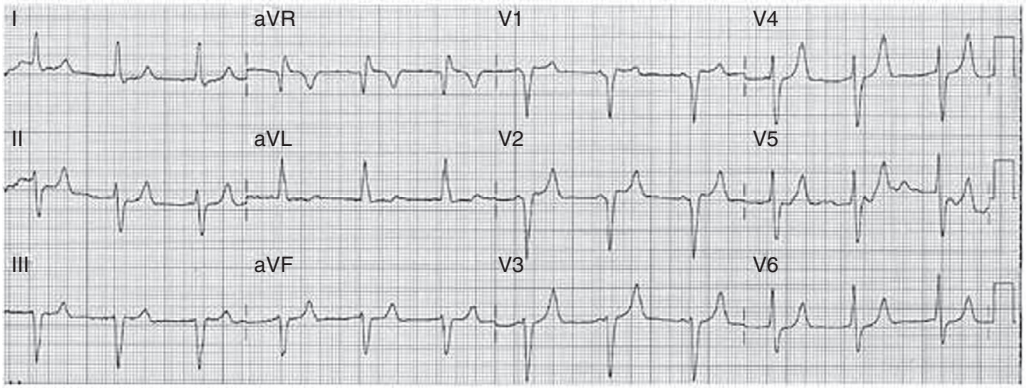
Electrolyte, Endocrine, and Metabolic Abnormalities

Electrolyte and metabolic abnormalities are common in the critically ill and may affect cardiac depolarization or repolarization. Patients may have synergistic or opposing effects of multiple abnormalities. Arrhythmias will develop when patients are exposed to factors resulting in enhanced automaticity, delayed conduction, or changes in refractoriness. The ECG may be the first clue that an electrolyte or metabolic abnormality is present.

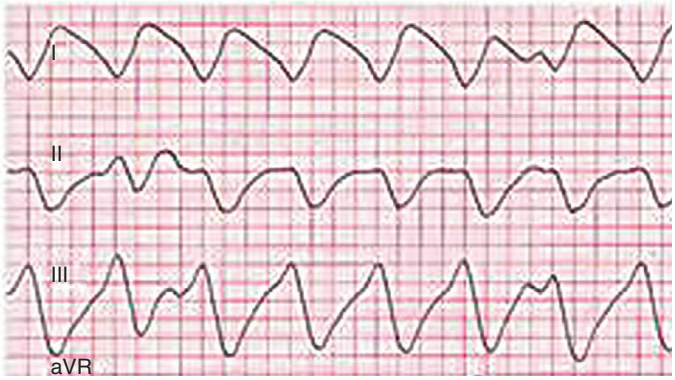
Hypokalemia delays repolarization and prolongs the action potential duration. Hypokalemia results in a characteristic U wave on the ECG (Fig. 31.39). As the hypokalemia becomes more severe, the U wave increases in amplitude, and T-wave amplitude decreases. Eventually the T wave and the U wave may fuse, giving the appearance of a single widened T wave. This creates a prolonged QT interval, which may result in TdP. Hypokalemia leads to EADs and triggered arrhythmias. The risk of hypokalemia-induced arrhythmia is increased in patients receiving digitalis and during myocardial ischemia.[323]

Hypomagnesemia and hypokalemia often coexist. Both contribute to QT prolongation, which can lead to TdP. Repletion of magnesium ion (Mg^{2+}) is an important adjunct to the management of hypokalemia. *Hypermagnesemia* is uncommon and is usually associated with renal failure. It usually is not associated with arrhythmogenesis.

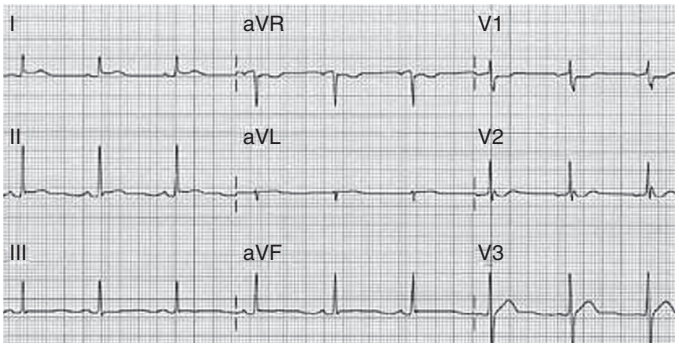
Hyperkalemia suppresses automaticity and slows conduction. As the serum potassium increases, the ECG follows a characteristic stepwise pattern of derangement. The first sign of hyperkalemia on the ECG is peaked T waves, defined as T waves greater than 10 mm in the precordium and 6 mm in the limb leads.[324] In addition to being peaked, the T waves typically appear narrow. At a potassium level of greater than 6.0 mmol/L, T-wave peaking is pronounced, the P wave will begin to lose amplitude, and the QRS complex begins to widen. At potassium levels greater than 7 mmol/L, the P wave is no longer visible and QRS widening progresses. The ensuing ECG pattern is known as sinoventricular rhythm (Fig. 31.40).[325] Sine waves may become present as the widened QRS complex blends into the T wave (Fig. 31.41).[323] An abnormal ECG may be the initial sign of dangerous hyperkalemia. and therapy should begin immediately to eliminate the hyperkalemia



• **Fig. 31.40** Sinoventricular rhythm, In severe hyperkalemia, P waves are no longer visible. QRS widening also occurs. This rhythm is difficult to distinguish from an accelerated idioventricular rhythm. (From Baltazar RF. *Basic and Bedside Electrocardiography.* Philadelphia: Lippincott Williams & Wilkins; 2009.)



• **Fig. 31.41** Sine waves seen in severe hyperkalemia. (From *New England Journal of Medicine* Image Challenge. Available at: http://www.nejm.org/action/showImageChallenge?ci=05032012. Accessed June 13, 2012.)



• **Fig. 31.42** Hypercalcemia. A short QT segment is noted. This patient had a calcium level of 16 mg/dL. (From Baltazar RF. *Basic and Bedside Electrocardiography.* Philadelphia: Lippincott Williams & Wilkins; 2009.)

and stabilize the heart. Patients with renal insufficiency may be particularly susceptible to hyperkalemia.

Treatment of Hyperkalemia

The most rapid means of treating arrhythmic toxicity of hyperkalemia is IV administration of calcium. The effect of IV calcium administration begins in minutes but is relatively short-lived (30–60 minutes). As a result, calcium should not be administered as monotherapy for hyperkalemia but should be combined with other therapies that drive extracellular potassium into the cells. The ECG should be monitored to ensure that signs of hyperkalemia are reversing. Calcium can be given as either calcium gluconate or calcium chloride. The dose of calcium gluconate usually administered is 1000 mg (10 mL of a 10% solution) infused over 5 to 10 minutes. The usual dose of calcium chloride is 500 to 1000 mg (5–10 mL of a 10% solution) infused over 5 to 10 minutes. Continuous cardiac monitoring is essential. The dose of either can be repeated after 6 hours if the ECG changers persist or recur.

Regular insulin (10 units) is another therapy for treatment of hyperkalemia. Insulin will redistribute K^+ from the extracellular to the intracellular space, but it will not lower total body potassium stores. Insulin administration should be followed by 50 mL of 50% glucose to ensure that the patient does not subsequently become hypoglycemic. After acute treatment of hyperkalemia has been accomplished by moving the potassium from the extracellular space to the intracellular space, treatment must focus on removal of potassium from the body. The most common method is administration of the cation-exchange resin sodium polystyrene sulfonate (Kayexalate). The usual dose is 15 g given 3 to 4 times daily. If medical therapies do not achieve sufficient reduction of potassium levels, hemodialysis can be performed to reduce total body potassium levels. When treating hyperkalemia by any means, care must be taken to avoid precipitous reduction, especially in patients taking digitalis glycosides.[171]

The principal electrocardiographic feature of *hypercalcemia* is a shortening of the QT interval (Fig. 31.42).[325] This finding is not associated with arrhythmias but needs to be differentiated from SQTS. The principal finding in *hypocalcemia* is prolongation of the QT interval. Unlike in hypokalemia, the T wave is normal in size. QT interval prolongation results from lengthening of the ST segment, not a broadening of the T wave (Fig. 31.43). In severe hypocalcemia, both PR and QRS intervals are prolonged.[325] Second-degree or third-degree AV block has also been reported. J waves have occasionally been reported owing to hypocalcemia.[323]

Acquired QT Prolongation

The most common causes of acquired QT prolongation are drugs or toxic substances, electrolyte abnormalities, hypothermia, and central nervous system injury. Drug-induced QT prolongation

• **Fig. 31.43** Hypocalcemia. A prolonged QT interval is the principal finding in hypocalcemia. The serum calcium level is 7.2 mg/dL. (From Baltazar RF. *Basic and Bedside Electrocardiography.* Philadelphia: Lippincott Williams & Wilkins; 2009.)

usually is the result of delayed rectifier potassium current (I_{Kr}) blockade.[106] Pharmacologic causes of QT prolongation are listed in Box 31.4. Drug-induced TdP is managed initially with IV magnesium sulfate. Isoproterenol and temporary pacing can be used to increase ventricular rates, shorten QT intervals, and help prevent recurrent arrhythmias until the effects of the offending agent diminish.

Metabolic Derangements

In addition to electrolyte abnormalities, metabolic derangements can cause arrhythmias and characteristic ECG changes. *Hypothermia*, both from accidental exposure as well as from therapeutic cooling after cardiac arrest, has classic findings on ECG (Fig. 31.44).[326] As the core body temperature drops below 32°C, conduction slows, resulting in sinus bradycardia, prolonged PR and QT intervals, as well as junctional rhythms.[327] The finding of an Osborn or J wave (an upward deflection at the terminal portion of the R wave, before the J point) is a hallmark of hypothermia. Although classically associated with hypothermia, the Osborn wave may also be a sign of other conditions such as sepsis and diabetic ketoacidosis (which can be hypothermic conditions), as well as normothermic conditions such as neurologic insult and hypercalcemia.[328] Hypothermia may also cause artifact or oscillations on the ECG tracing from shivering.

Hypothyroidism can cause slowing of conduction, resulting in sinus bradycardia, low voltage, prolonged PR and QT intervals, and intraventricular conduction delays. *Hyperthyroidism* may cause the opposite effect, resulting in sinus tachycardia, premature atrial complexes, and even may precipitate AF.

Conclusions

The intensivist must have a keen awareness of patterns, mechanisms, precipitants, and treatment of cardiac arrhythmias. The intensivist must remember that all antiarrhythmic therapies (pharmacologic and nonpharmacologic) have the potential for adverse effects. Reducing and eliminating arrhythmia precipitants may be safer and more effective than dramatic interventions. Antiarrhythmic drugs should be chosen carefully based on each patient's type of heart disease and the side effect profile of each drug, with telemetry monitoring always in place. Direct current cardioversion for both supraventricular and ventricular tachycardias should be used early whenever a patient is hemodynamically unstable. Anticoagulation for AF in the ICU can be challenging because of potential bleeding

risks in the critically ill, but it must be addressed in all AF patients to reduce stroke risk. Acute treatment of AF should be rate control and anticoagulation; decisions about restoring normal sinus rhythm can be made electively (unless there is hemodynamic instability). Ablation therapy is effective for most SVTs, idiopathic VTs, and may be used as adjuvant therapy for patients with frequent appropriate ICD shocks. Ablation therapy is also successful for treatment of symptomatic AF, with the highest success in patients with paroxysmal AF. ICDs are the therapy of choice for primary prevention of SCD in patients with persistently (>3 months) decreased ejection fractions. ICDs are also indicated for secondary prevention of sustained VT or cardiac arrest or if no reversible, precipitating cause is identified. Consultation with a cardiac electrophysiologist should be an integral part of the critical care physician's routine.

Key Points

- Intensivists managing arrhythmias must have expertise in electrocardiography, pharmacokinetics, pharmacodynamics, and have bedside clinical acumen.
- Patients in an intensive care setting frequently have active arrhythmia precipitants: hypoxemia, excess circulating catecholamines, CHF, fever (sepsis), pulmonary emboli, and electrolyte and other metabolic disturbances. Treating these arrhythmia precipitants should be the first-line goal, because that alone may cure many arrhythmias.
- Intensivists may be the first to see a variety of clinical conditions that have distinct manifestations on the surface ECG. Recognition of these ECG patterns and their characteristic arrhythmias may be lifesaving in critically ill patients.
- Diagnosis and management of complex arrhythmias may be facilitated by consultation with a cardiac electrophysiologist.
- All antiarrhythmic therapies (pharmacologic and nonpharmacologic) have the potential for adverse effects and these effects must be understood before implementing each therapy.
- Antiarrhythmic drugs can slow the atrial rate in atrial flutter potentially allowing 1:1 AV conduction and very rapid ventricular rates. Antiarrhythmic drugs can slow the rate of VTs, resulting in potential failure of an ICD to sense a ventricular arrhythmia that is slower than the programmed rate cutoff. Antiarrhythmic drugs can raise pacing and defibrillation thresholds potentially necessitating device reprogramming.
- In patients with AF and preexcitation, AV nodal blocking agents must be avoided to prevent rapid conduction over the AP and dangerously rapid ventricular rates.
- Direct current cardioversion of any supraventricular or ventricular tachyarrhythmia should be performed urgently when there is concomitant angina pectoris, CHF, or hypotension.
- Anticoagulation for AF in the ICU can be challenging because of potential bleeding risks in the critically ill, but it must be addressed in all patients with AF to reduce stroke risk.
- Acute treatment of AF should be rate control and anticoagulation; decisions about restoring normal sinus rhythm can be made electively (unless there is hemodynamic instability).
- Stored electrogram data from permanent pacemakers and ICDs can be assessed to help the intensivist determine the recent history of arrhythmia type, frequency, rate, and duration.
- First-line elective therapy for most SVTs and some VTs in patients with structurally normal hearts is radiofrequency ablation.
- Ablation therapy using pulmonary vein isolation (plus or minus other ablation strategies) is successful for treatment of symptomatic AF, with the highest success in patients with paroxysmal AF and structurally normal hearts.
- Left ventricular dysfunction is the most important predictor of cardiac death in patients with ventricular arrhythmias. Long-term management of sustained ventricular arrhythmias in the setting of a decreased ejection fraction usually requires the implantation of an ICD.

Review Questions

1. A patient under your care suddenly develops a paroxysmal supraventricular tachycardia. Which of the following is the drug of first choice to acutely increase atrioventricular (AV) nodal refractoriness?
a. Amiodarone
b. Adenosine
c. Diltiazem
d. Lidocaine
Answer: b. Adenosine is a naturally occurring substance and in 1990 was approved by the U.S. Food and Drug Administration as the treatment of choice for acute therapy of supraventricular tachycardia (SVT). Adenosine has negative chronotropic effects in the sinoatrial node, depresses conduction, and increases refractoriness in the AV node. Adenosine has a half-life of 10 seconds owing to rapid metabolism. Adenosine can cause flushing, dyspnea, chest pain, and nausea. These effects usually resolve within 30 to 60 seconds. Adenosine is a very effective drug for treatment of an acute SVT, with the ability to terminate the arrhythmia in more than 90% of cases. Adenosine is initially administered as a rapid bolus of 6 mg over 1 to 2 seconds. If the arrhythmia is not terminated within 3 minutes, a 12-mg bolus can be given in a similar fashion. Rarely a dose of 18 mg is used.

2. Which of the following is the most common cellular mechanism for the development of ventricular tachycardia in patients with ischemic heart disease?
a. Reentry
b. Early afterdepolarization
c. Delayed afterdepolarization
d. Enhanced automaticity
Answer: a. In the absence of structural heart disease, the primary mechanism for ventricular tachycardia is believed to be triggered activity or an automatic mechanism. In the presence of ischemic heart disease the predominate mechanism is reentry. After a myocardial infarction a scar is created with surviving islands of cardiac myocytes. This can result in slow and discontinuous conduction and/or block in conduction through the viable tissue. These changes create the ideal electrophysiologic and anatomic substrate for developing reentrant arrhythmias.

3. Which antiarrhythmic drug is not safe to use in a patient with a prior myocardial infarction?
a. Flecainide
b. Amiodarone
c. Dronedarone
d. Sotalol
Answer: a. Flecainide is a class IC antiarrhythmic drug and is recommended as a first-line agent for conversion and maintenance of sinus rhythm in patients with normal hearts and atrial fibrillation. It is not used in patients with a prior myocardial infarction or coronary artery disease based on the Cardiac Arrhythmia Suppression Trial published in 1989. This study was designed to investigate the efficacy of moricizine, flecainide, or encainide in patients after a myocardial infarction with reduced ejection fractions and frequent ventricular ectopic beats. Although flecainide was effective in suppressing ventricular ectopy, there was a threefold increase in arrhythmic deaths compared with placebo.

Hypertensive Crises

SERGIO L. ZANOTTI-CAVAZZONI

CHAPTER OUTLINE

Introduction and Terminology

Pathophysiology

Approach to Management
- Should the Blood Pressure Be Lowered Acutely?
- How Much Should the Blood Pressure Be Lowered?
- Which Medication Should Be Used to Lower the Blood Pressure?

Specific Clinical Considerations
- Hypertensive Encephalopathy
- Hypertensive Crisis in Cerebrovascular Accidents
- Acute Aortic Dissection
- Hypertensive Crises in Pregnancy
- Postoperative Hypertension
- Catecholamine-Associated Hypertensive Crisis

Conclusions

Introduction and Terminology

Hypertension is a common clinical disorder and one of the most common preventable contributors to disease and death. Estimates indicate that almost 30% of the U.S. adult population has elevated blood pressure.[1] Furthermore, one-third of these patients are unaware of their diagnosis, and of those who are diagnosed and treated, only 34% have adequate control of their blood pressure.[2] Severe elevations in blood pressure, hypertensive crises, occur in about 1% of patients with chronic hypertension.[1] Most patients with significantly elevated blood pressure (systolic pressure ≥180 mm Hg and/or diastolic pressure ≥120 mm Hg) do not have evidence of acute end-organ damage or symptoms. However, a small subset can experience significant acute end-organ damage and these patients require immediate treatment to prevent irreversible organ dysfunction.

The report of the Eighth Joint National Committee on Evidence-Based Guidelines for the Management of High Blood Pressure in Adults defines hypertension as a systolic pressure of 140 mm Hg or higher and/or a diastolic pressure of 90 mm Hg or higher.[3] The Eighth Joint National Committee on Evidence-Based Guidelines for the Management of High Blood Pressure in Adults also provides targets and guidelines for long-term treatment of patients with hypertension based on age and comorbid conditions such as diabetes mellitus and chronic renal disease. The terms *malignant hypertension* and *accelerated hypertension* are no longer used. Hypertensive crises are defined as severe elevations in blood pressure. Although some experts suggest reference blood pressure values (systolic pressure ≥180 mm Hg and/or diastolic pressure ≥120 mm Hg), it is preferable to evaluate acute elevations of blood pressure within the context of each individual patient and the effects of a given blood pressure on organ function in that patient. For example, an acute raise in diastolic blood pressure to a value of 100 mm Hg can cause significant damage in a previously normotensive individual, whereas a diastolic pressure of 130 mm Hg may be tolerated in a patient with a history of uncontrolled hypertension. As we will see, these patients will require different therapeutic approaches.

A *hypertensive emergency* is a severe elevation in blood pressure associated with the presence of acute end-organ damage. Hypertensive emergencies require immediate control of blood pressure, within 1 to 2 hours to prevent further organ damage. This usually requires the use of intravenous (IV) medications and invasive monitoring (arterial line) in a high-dependency unit such as the intensive care unit (ICU). The principal systems susceptible to acute end-organ damage from severe elevations in blood pressure include the central nervous, cardiovascular, and renal systems (Fig. 32.1). Several clinical situations are associated with hypertensive emergencies (Box 32.1). The absolute level of blood pressure and the time course of this elevation determine the development of a hypertensive emergency. However, acute end-organ damage can occur at different blood pressure values in different patients. Therefore it is more useful to define hypertensive emergencies with the presence of acute end-organ damage as opposed to specified numbers of systolic or diastolic blood pressure. True hypertensive emergencies are uncommon. Based on large claims databases it is estimated as one to two cases per million per year. Based on retrospective studies it is estimated that hypertensive emergencies constitute less than 1% of all visits to an adult emergency department for one year.[4] In addition to initiating immediate therapeutic interventions, patients with a hypertensive emergency may require further diagnostic evaluation to determine the cause of their elevated blood pressure. Depending on the population studied, 20% to 50% of patients presenting with a hypertensive emergency have a secondary cause of hypertension identified.[5]

Severe elevations of blood pressure in the absence of acute-end organ damage do not constitute a hypertensive emergency and occur far more frequently. In these clinical situations blood pressure

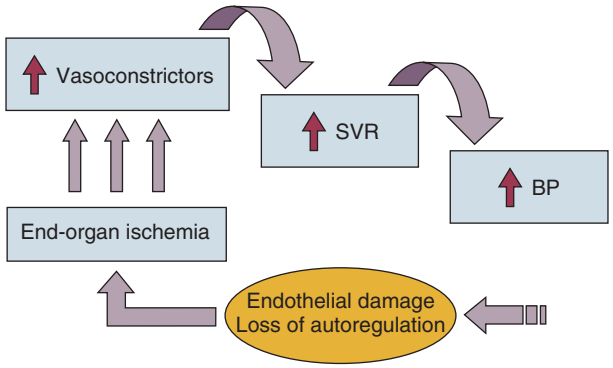
Hypertensive encephalopathy
Cerebrovascular accident
Acute aortic dissection
Acute left ventricular failure
Acute myocardial infarction
Acute renal failure
Preeclampsia/eclampsia
Catecholamine excess states
Postoperative hypertension



• **Fig. 32.2** Pathophysiology of hypertensive emergency. Increase in humoral vasoconstrictors leads to increased systemic vascular resistance *(SVR),* which raises blood pressure. As blood pressure *(BP)* increases, endothelial damage results in loss of autoregulation and organ ischemia. Organ ischemia increases release of vasoconstrictors, and a vicious circle is initiated.

can be lowered more gradually, over 24 to 48 hours. This usually can be accomplished with oral medications and does not require invasive hemodynamic monitoring in an ICU. These elevations of blood pressure can be associated with chronic stable organ dysfunction, such as stable angina, chronic renal insufficiency, or previous cerebrovascular accident, without evidence of acute end-organ damage.

Pathophysiology

The underlying pathophysiology of hypertensive crises is still not fully understood. The transition of mild hypertension or normotension to a hypertensive crisis is usually caused by an event that leads to an abrupt increase in blood pressure. Situations associated with this event may include cessation of hypertensive medications with potential rebound effects, consumption of illicit drugs, and severe pain, as well as several clinical syndromes. Blood pressure (BP) is determined by the product of cardiac output (CO) and systemic vascular resistance (SVR): BP = CO × SVR. In most hypertensive crises, the initial rise in blood pressure is secondary to increased systemic vascular resistance. The rise in systemic vascular resistance is believed to be caused by humoral vasoconstrictors.[6] With the increase in blood pressure, mechanical stress on the arteriolar wall leads to endothelial damage and fibrinoid necrosis of the arterioles.[6,7] Vascular damage leads to loss of autoregulatory mechanisms, ischemia, and acute end-organ damage, which prompts further release of vasoconstrictors and initiates a vicious cycle (Fig. 32.2).[6,7]

Approach to Management

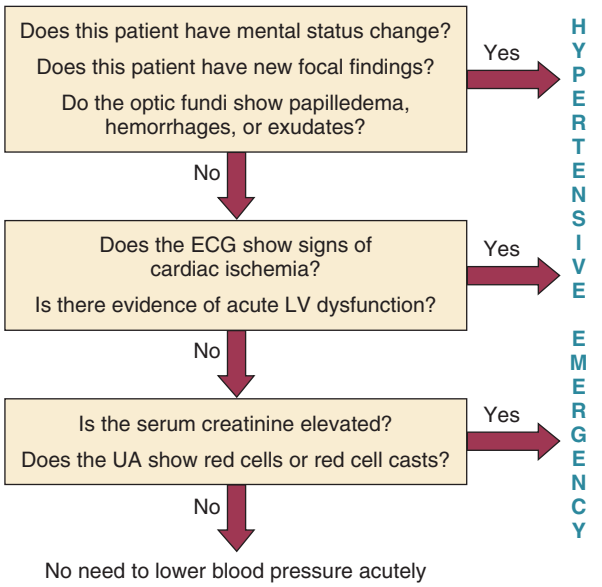
Despite the abundance of evidence providing guidance and support to the long-term benefits of treating chronic hypertension, there is a paucity of high-level evidence to guide clinicians in the treatment of hypertensive emergencies. However, a systematic approach with consideration of underlying pathophysiology can help the clinician to avoid common pitfalls in the clinical management of patients with hypertensive crises. The most common pitfall in treating patients with hypertensive crises involves treating numbers without evaluating individual patients for acute end-organ damage. This usually is associated with inappropriate use of IV drugs with the potential for precipitous and harmful drops in blood pressure. A methodical approach to patients with severe elevations in blood pressure can help establish safe and effective treatment. To that effect, the clinician should address three fundamental questions:

1. Should the blood pressure be lowered acutely?
2. How much should the blood pressure be lowered?
3. Which medication should be used to lower the blood pressure?

Should the Blood Pressure Be Lowered Acutely?

To answer this question, the clinician must determine if there is evidence of acute end-organ damage. In patients with hypertensive emergencies (the presence of acute end-organ damage), the blood pressure should be lowered acutely to a safe target to prevent further end-organ damage. An organized approach in the evaluation of the patient is necessary. A focused history should determine a previous diagnosis of hypertension, medication history, use of illicit drugs or over-the-counter agents with potential hypertensive effects, and the presence of symptoms consistent with neurologic, visual, cardiac, or renal dysfunction. Physical examination should confirm vital signs. It is important to measure blood pressure adequately and in both upper extremities. Pulses should also be checked in all extremities, as inequalities in blood pressure or pulses can exist with aortic dissection. In addition, a thorough neurologic and cardiopulmonary examination should evaluate possible signs of end-organ failure such as altered mentation, new focal neurologic deficits, or cardiogenic pulmonary edema. A funduscopic examination of the eyes should be done to look for signs of acute papillary edema or new retinal hemorrhages. A set of simple diagnostic tests can complete the evaluation for acute end-organ damage. An electrocardiogram (ECG) to rule out active ischemia and a chest x-ray to assess for pulmonary edema or signs of aortic pathology can help the clinician to evaluate the cardiopulmonary system. Abnormalities in blood urea nitrogen, creatinine, and the urinalysis (red blood cell casts) suggest renal involvement. Additional tests may be indicated based on the individual characteristics of each case. An algorithm to establish the presence of acute end-organ damage at the bedside when evaluating patients is presented in Fig. 32.3.

If there is evidence of acute end-organ damage based on the clinical evaluation, the patient's blood pressure should be lowered acutely. However, if after a careful systematic clinical evaluation, the examination and diagnostic tests do not show evidence of acute end-organ damage, the blood pressure does not require immediate reduction. It is important to emphasize that the presence or absence of acute end-organ damage and not the numerical value of the blood pressure should dictate the acuity with which blood pressure reduction should be achieved.

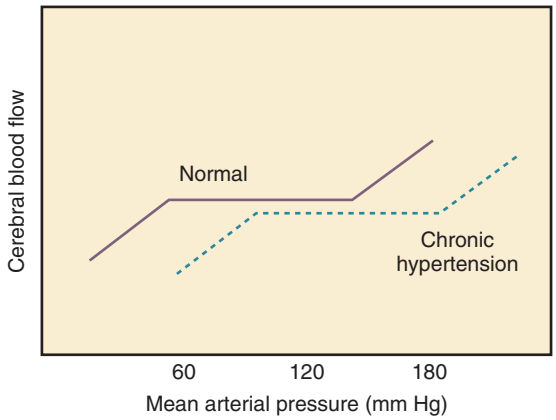


• **Fig. 32.3** Evaluation algorithm for hypertensive emergency. Systematic evaluation for possible acute end-organ damage can proceed according to this scheme. If the answer to any of the questions is "Yes," the patient has a hypertensive emergency and blood pressure should be lowered acutely. If the answer to all questions is "No," the patient does not have a hypertensive emergency and the blood pressure can be lowered gradually. *ECG,* Electrocardiogram; *LV,* left ventricular; *UA,* urinalysis.

How Much Should the Blood Pressure Be Lowered?

Once the decision to lower a patient's blood pressure acutely is made, the next step should be to establish a safe therapeutic target for the blood pressure reduction. The goals for treating hypertensive emergencies are to lower blood pressure to a level that prevents ongoing acute end-organ damage and at the same time to avoid iatrogenic damage caused by precipitous falls in blood pressure causing hypoperfusion to organs. Understanding the autoregulation of blood pressure in normal states and in patients with chronic hypertension is essential to achieve these goals.

Different organs can autoregulate and maintain a constant blood flow through a range of mean arterial pressures (MAPs). Under normal conditions cerebral autoregulation keeps blood flow constant between MAPs of 60 to 150 mm Hg.[8] When the MAP drops, cerebral arteries dilate, and if the MAP rises, they constrict to maintain a constant blood flow to the brain. Drops in the MAP below the lower limit of autoregulation lead to hypoperfusion resulting in brain ischemia. Rises in the MAP above the higher limit of autoregulation lead to acute end-organ damage from hypertension (hypertensive emergency). In the case of the brain, this may result in hypertensive encephalopathy. With chronic hypertension, compensatory functional and structural changes occur in the vasculature.[9,10] These changes will shift the autoregulatory curve to the right.[11] The autoregulatory curve for cerebral blood flow in healthy individuals and in patients with chronic hypertension is shown in Fig. 32.4. Hence, patients with chronic hypertension have a higher tolerance to elevated blood pressures, as their autoregulatory curve is shifted to the right. This explains why many patients present with severely elevated blood pressure and no evidence of acute end-organ damage. However, rapid reductions of blood pressure to "normal" levels can fall below the lower autoregulatory capacity of the circulation in a chronically hypertensive patient. This phenomenon explains the hypoperfusion of vital organs and the development of renal failure or cerebral



• **Fig. 32.4** Autoregulation of cerebral blood flow. Cerebral blood flow autoregulation curves are depicted for normotensive *(solid purple line)* and chronic hypertensive *(dashed blue line)* states.

ischemia often seen when blood pressure is lowered too far or too fast.[12] Based on these principles, most experts would recommend that for most hypertensive emergencies the goal should be to lower MAP by 15% to 25% over a period of several minutes to hours, depending on the clinical situation.[13] Reduction of blood pressure to normal levels may be warranted in special situations such as those involving patients with aortic dissection or previously normotensive patients with a postoperative hypertensive emergency.

Which Medication Should Be Used to Lower the Blood Pressure?

The ideal medication to treat a hypertensive emergency should have a rapid onset of action, high potency, immediate reversibility, no tachyphylaxis, and minimal or no adverse effects. Although there is no perfect medication, several agents with some of these characteristics are summarized in Table 32.1. There are a limited number of studies comparing agents in terms of clinical outcomes. With no clear outcome data, the selection of an agent is based on the clinical scenario, pharmacologic characteristics of the drug, and availability. Parenteral agents that are useful in treating hypertensive emergencies are further discussed (in alphabetical order).

Clevidipine

Clevidipine is an ultra–short-acting dihydropyridine calcium channel antagonist that is approved for IV use to treat severe hypertension. Clevidipine has vasoselective properties with a rapid onset of action and a very short half-life (<1 minute).[14] Clevidipine is metabolized by red blood cell esterases; therefore its use is not affected in patients with renal and/or hepatic failure. Clevidipine reduces blood pressure by a direct and selective effect on arterioles. It does not produce reflex tachycardia, and its effect on reducing afterload is often associated with increased cardiac output. Clevidipine is administered intravenously as a continuous drip. The initial dose is usually 1 to 2 mg/h with adjustments as needed to obtain the desired response in blood pressure. The maintenance dose is usually 4 to 6 mg/h; however, higher doses may be required in certain clinical situations. Small studies have compared clevidipine to nitroprusside for the treatment of severe hypertension in anesthetized patients undergoing surgery.[15,16] These studies showed that clevidipine had similar effects on blood pressure control with less effect on cardiac filling and heart rate. Although clevidipine has not been studied extensively in other clinical situations, its characteristics make it an attractive option for the treatment of hypertensive emergencies outside the operating room. In addition to its intraoperative use it has received increased attention in neurologic hypertensive emergencies.[17,18] Clevidipine is not recommended in patients with severe aortic stenosis (owing to the high risk of severe hypotension) or in patients with disordered lipid metabolism (because it is administered in a lipid-laden emulsion). Clevidipine's emulsion contains soy and eggs and it is contraindicated in patients with documented allergies to these substances.

Esmolol

Esmolol is an ultra–short-acting cardioselective, β-adrenergic agent that can be administered intravenously for the treatment of hypertensive emergencies.[19] Esmolol has a rapid onset of action

TABLE 32.1 Pharmacologic Agents Used in Treating Hypertensive Emergencies

Drug	Dosing	Elimination Half-Life	Onset of Action	Duration of Effect	Advantages	Disadvantages
Clevidipine	Initial dose 1–2 mg/h with titration Maintenance dose 4–6 mg/h	Initial half-life 1 min	2–4 min	15 min	Rapid action, titratable, not metabolized by liver or kidney	Rapidly metabolized in pseudocholinesterase-deficient patients
Esmolol	200–500 μg/kg over 1–4 min, then 50 μg/kg per minute for 4 min, and titer, then infuse 50–300 μg/kg per minute	9 min	2 min	18–30 min	Easily titratable; cardioselectivity	Use with caution in patients with heart failure or asthma
Fenoldopam	Initial dose, 0.1 μg/kg per minute with titration every 15 min, no bolus	5–10 min	5 min	30–60 min	Induces both a diuresis and natriuresis	Use with caution in patients with glaucoma
Labetalol	Bolus 20 mg, then 20–80 mg every 10 min for maximum dose 300 mg. Infuse at 0.52–2 mg/min	5 h	2–5 min	2–4 h	No reflex tachycardia	Use with caution is patients with asthma, heart failure, or bradycardia
Nicardipine	Initial dose, 5 mg/h to maximum of 15 mg/h	40–60 min	10–20 min	1–4 h	Minimal cardiodepressant effects; minimal dose adjustments required	Possible adverse effects include hypotension, headache, and flushing
Nitroprusside	Initial dose, 0.25 μg/kg per minute, maximum dose 8–10 μg/kg per minute	14 min	Within seconds	3–4 min	Immediate onset of effect	Hypotension; coronary steal; cyanide toxicity; light sensitivity; requires frequent monitoring

(within 2 minutes), a short elimination half-life (approximately 9 minutes), and a rapid offset of action (within 15 to 30 minutes after stopping infusion).[20] Esmolol is rapidly metabolized by red blood cells and is not dependent on renal or hepatic function.[20] These properties enable easy titration of the drug and make it attractive in situations of a hypertensive emergency associated with intense adrenergic responses or tachycardia. This agent is available for IV use, both as a bolus and as a continuous infusion. The usual dose is 0.5 mg/kg as a loading dose, followed by a maintenance infusion of 25 to 300 μg/kg per minute titrated to the patient's individual response.[20] Esmolol has been found effective in controlling postoperative hypertension and tachycardia in several clinical studies.[21–23] Esmolol has also been used successfully to treat hypertensive emergencies under other various clinical situations.[24,25] Esmolol seems to be more effective in situations when both blood pressure and tachycardia are present and there are no problematic issues with β-blockade (severe systolic cardiac dysfunction or asthma). It is often used in conjunction with other agents to achieve a better response.

Fenoldopam

Fenoldopam is a selective dopamine agonist that causes systemic and renal vasodilation by stimulating dopamine-1 adrenergic receptors.[26,27] Fenoldopam is administered intravenously and has a rapid onset of action (5 minutes) and a short duration of action (30 to 60 minutes).[27] It is rapidly metabolized by conjugation in the liver to inactive metabolites that are excreted by the kidney. The plasma elimination half-life is approximately 5 to 10 minutes.[27] Fenoldopam is administered as a continuous infusion (without a bolus dose), at an initial dose of 0.1 μg/kg per minute; this dose is titrated by 0.05 to μg/kg per minute based on desired effect up to a maximum dose of 1.6 g/kg per minute.[26] The most common adverse effects of the drug are related to its vasodilator properties and include hypotension, headache, reflex tachycardia, and flushing.[26] Fenoldopam also increases intraocular pressure and should be used with caution in patients with glaucoma.[28] Fenoldopam has been demonstrated to be safe and effective in postoperative hypertension.[29] Two clinical studies in severely hypertensive patients found fenoldopam to be comparable in efficacy to sodium nitroprusside.[30,31] Because of its effects on the renal vasculature and its ability to increase urine output, fenoldopam has been proposed as a renal protective drug.[32] In the setting of a hypertensive emergency, protective effects of fenoldopam on renal function have not been confirmed. However, because it does not affect renal function adversely and does not have increased toxicity in patients with renal failure, it may be a useful alternative to sodium nitroprusside in patients with hypertensive emergency and renal failure.

Labetalol

Labetalol is a combined α- and β-adrenergic receptor blocker that is approved for both oral and IV use in the treatment of hypertension. Labetalol lowers blood pressure by decreasing systemic vascular resistance by α_1-blockade and at the same time counteracts the reflex tachycardia from vasodilation through its β-blocker effect.[33,34] Labetalol reduces peripheral vascular resistance while maintaining cerebral, renal, and coronary blood flow. Unlike other β-blockers, labetalol does not reduce cardiac output. When administered intravenously it has a rapid onset of action (2–5 minutes) with peak hypotensive effect occurring within 5 to 10 minutes and lasting 2 to 4 hours.[35] The drug is primarily metabolized by the liver and has a plasma elimination half-life of about 5 hours.[33] Labetalol is usually administered intravenously at a loading dose of 20 mg, followed by incremental doses of 20 to 80 mg every 10 minutes until the target blood pressure is achieved or a maximal dose of 300 mg has been reached. An alternative regimen is a continuous infusion starting at 1 to 2 mg/min and titrated upward to achieve a desired blood pressure endpoint. Adverse effects of labetalol include orthostatic hypotension, bronchospasm (should be avoided in asthma patients), heart failure, and significant bradycardia (should be avoided in the presence of sinus bradycardia or heart block greater than first degree). Labetalol has been shown to be effective in a wide range of clinical situations associated with hypertensive emergencies.[33,34,36–39]

Nicardipine

Nicardipine is a short-acting calcium channel antagonist that produces selective arteriolar dilation. Nicardipine decreases systemic vascular resistance, without producing reflex tachycardia while maintaining or increasing cardiac output.[40] IV nicardipine has a rapid onset offset of action (the major effect lasts 10–15 minutes, and the plasma elimination half-life is 40–60 minutes), making it easily titratable when treating hypertensive emergencies.[41,42] An initial dose of 5 mg/h is recommended, increasing the infusion rate by 2.5 mg/h every 5 to 15 minutes (to a maximum rate of 15 mg/h) until the desired hemodynamic response is achieved. Once the target blood pressure is achieved, the infusion rate can be reduced to 3 mg/h and adjusted to maintain the desired endpoint. The drug is rapidly distributed throughout the body and is metabolized by the liver into inactive metabolites. Nicardipine should be avoided or used cautiously in patients with aortic stenosis, in patients with cardiomyopathy receiving β-blockers, and in patients with impaired hepatic function. Several studies have documented the utility and safety of nicardipine in patients with hypertensive emergencies. Randomized studies have demonstrated that nicardipine has similar efficacy when compared to nitroprusside in the management of postoperative hypertension.[41,43]

Nitroprusside

For many years sodium nitroprusside was the standard IV drug administered for hypertensive emergencies. Because of its potential side effects and the appearance of safer and easier to use alternatives it has fallen in disfavor in the view of many experts. However, it is still available and remains a viable alternative today in many settings. Nitroprusside is a potent balanced arterial and venous vasodilator that decreases both cardiac afterload and preload. Nitroprusside has a rapid onset of action (2–3 minutes) and a short serum half-life (1–2 minutes) and may be easily titrated.[44] Because of its potent effects on blood pressure, use of nitroprusside requires invasive hemodynamic monitoring (arterial line for continuous blood pressure monitoring). Nitroprusside is typically begun at 0.3 μg/kg per minute and increased by 0.2 to 1 μg/kg per minute every 3 to 5 minutes as needed until a maximum of 8–10 μg/kg per minute. Cyanide and thiocyanate are metabolites of nitroprusside with potential toxic effects. Cyanide is released nonenzymatically from nitroprusside. Cyanide is converted to thiocyanate by the liver. Finally, the kidney excretes thiocyanate. The total dose of nitroprusside and the presence of liver or renal dysfunction increase the risk of toxicity. Cyanide toxicity can be associated with lactic acidosis, mental status changes, and hypotension. Signs of thiocyanate toxicity include delirium, headaches, nausea, abdominal pain, and muscular spasms.[45] To reduce possible toxicity, the duration of treatment with nitroprusside should be limited and the maintenance rate of infusion should not exceed 2 μg/kg per minute. In patients requiring higher doses of

nitroprusside, an infusion of thiosulfate is recommended to decrease the risk of toxicity.[46] Hydroxocobalamin has also been demonstrated to prevent and treat possible cyanide toxicity associated with the use of nitroprusside. Patients taking nitroprusside should be carefully monitored with special attention focused on unexplained acidosis or dropping serum bicarbonate concentrations. Despite these concerns, nitroprusside has been used successfully in the treatment of hypertensive emergencies for many years and with proper precautions toxicity is seldom encountered.

Other Agents

Several other agents have been used to treat severely elevated blood pressure. Many of them have been abandoned secondary to the emergence of safer and more efficacious alternatives. However, there are a few agents that despite some limitations compared to the drugs previously discussed may be useful in particular situations. Nitroglycerin directly interacts with nitrate receptors producing predominantly venous dilation. Because of its favorable effects on coronary perfusion and its ability to reduce preload, it is a drug well suited for treating hypertensive emergencies associated with myocardial ischemia or acute left ventricular failure.[47] Several clinical studies have shown the safety and efficacy of nitroglycerin for the treatment of hypertension after cardiac surgery.[48–50] Nitroglycerin is administered as a continuous infusion. The starting dose is 5 μg/min, and this dose can be titrated until a maximum of 200 μg/min is reached.

Phentolamine is an α-adrenergic blocking agent that may be used for the management of catecholamine-induced hypertensive emergencies, such as pheocromocytoma.[51] Phentolamine is administered intravenously in 1- to 5-mg boluses. The effects are immediate and may last up to 15 minutes. This drug may cause arrhythmias and angina. Once the blood pressure is controlled, a long-acting α-adrenergic blocking agent such as oral phenoxybenzamine can be started.

Enalaprilat is an angiotensin-converting enzyme inhibitor that can be administered intravenously. Its onset of action is within 15 minutes and its duration of action is 12 to 24 hours.[52,53] The usual dose is of 1.25 mg IV every 6 hours, titrated by increments of 1.25 mg at 12- to 24-hour intervals to a maximum dose of 5 mg every 6 hours.[54] The degree of blood pressure reduction with enalaprilat correlates directly with the pretreatment levels of angiotensin II and plasma renin activity.[55] Enalaprilat is especially useful in hypertensive emergencies associated with scleroderma crises.[56]

Hydralazine is a vasodilator that has been used in pregnancy-related hypertensive crises for many years. However, it has unpredictable effects on blood pressure and a long half-life. Nicardipine and labetalol are better choices for treating pregnant patients with hypertensive emergencies in the ICU.

Specific Clinical Considerations

Hypertensive Encephalopathy

When rises in MAP exceed the upper limits of the cerebral blood flow, autoregulatory curve endothelial damage with extravasation of plasma proteins can lead to cerebral edema.[57] Hypertensive encephalopathy, the clinical manifestation of this phenomenon, is characterized by headache, visual disturbances, confusion, and focal or generalized weakness. If untreated, hypertensive encephalopathy can lead to coma and death.[58] Magnetic resonance imaging has demonstrated that the majority of the cases involve the cortical regions of the brain.[59] However, hypertensive encephalopathy with brainstem involvement has also been described.[60,61] The differential diagnosis of hypertensive encephalopathy includes several neurologic syndromes (Box 32.2). These should be quickly ruled out by imaging of the brain and other pertinent diagnostic tests. Treatment should be instituted immediately. The goal is to reduce the MAP by 15% to 20% within the first 1 to 2 hours.[62] The hallmark of hypertensive encephalopathy is improvement of symptoms once the blood pressure is controlled. Caution should be taken not to cause worsening neurologic symptoms from hypoperfusion caused by lowering the MAP. Drugs suitable for treating hypertensive encephalopathy include nicardipine, labetalol, fenoldopam, and nitroprusside.

Hypertensive Crisis in Cerebrovascular Accidents

Hypertension is common after both ischemic and hemorrhagic strokes. Extreme elevations in blood pressure have been associated with poor outcomes after ischemic and hemorrhagic stroke.[63,64] Significant elevations in blood pressure after strokes raise concerns for the potential development of reinfarction, cerebral edema, increased hemorrhage size, or hemorrhagic transformation of ischemic lesions. However, after acute stroke the cerebral vasculature's ability to autoregulate blood flow is impaired.[65] During this time, flow to the brain is highly dependent on MAP. Even modest reductions in blood pressure can compromise blood flow to the brain during this period with the potential for increased secondary neurologic damage. Optimal treatment of blood pressure during stroke is still not a settled debate. Based on available evidence the approach to the acute management of high blood pressure in the setting of acute strokes differs for ischemic and hemorrhagic strokes. In ischemic strokes, current guidelines recommend withholding therapy for hypertension in the acute phase unless the patient will receive thrombolysis, there is evidence of concomitant acute end-organ damage, or excessive elevations in blood pressure are present (arbitrarily selected as systolic blood pressure [SBP] >220 mm Hg or diastolic blood pressure >120 mm Hg).[66] Acute blood pressure management for patients with ischemic stroke who are candidates for reperfusion therapy is summarized in Box 32.3. For hemorrhagic strokes, the concerns over lowering cerebral perfusion pressure need to be balanced by potential hematoma growth with elevated blood pressure. Two recent clinical trials randomly assigned patients with acute spontaneous intracerebral hemorrhage to an SBP target of <140 mm Hg or <180 mm Hg. The first study, INTERACT2 (Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage

• BOX 32.3 Guidelines for Treatment of Hypertension in Ischemic Cerebrovascular Accidents in Patients Who Are Candidates for Acute Reperfusion Therapy

Patient otherwise eligible for acute reperfusion therapy except that BP is >185/110 mm Hg:
- Labetalol 10–20 mg IV over 1–2 min; may repeat ×1; or
- Nicardipine 5 mg/h IV, titrate up by 2.5 mg/h every 5–15 min to desired effect (maximum 15 mg/min)

If BP is not maintained at or below 185/110 mm Hg; do not administer rtPA

Management of BP during and after rtPA or another reperfusion therapy to maintain BP at or below 180/105 mm Hg:
- Monitor BP every 15 min for 2 h from initiation of rtPA therapy, then every 30 min for 6 h, and then every hour for 16 h

If systolic BP >180–230 mm Hg or diastolic BP >105–120 mm Hg:
- Labetalol 10 mg IV followed by continuous IV infusion 208 mg/min; or
- Nicardipine 5 mg/h IV, titrate up by 2.5 mg/h every 5–15 min to desired effect (maximum 15 mg/min)

If BP not controlled or diastolic BP >140 mm Hg, consider IV sodium nitroprusside

BP, *Blood pressure;* IV, *intravenously;* rtPA, *recombinant tissue-type plasminogen activator.*

Trial 2) suggested that acutely lowering the SBP to 140 mm Hg or lower was safe and associated with nonsignificant benefits on death and major disability.[67] However, the results of ATACH-II (Antihypertensive Treatment of Acute Cerebral Hemorrhage II) cast doubts on the benefits of targeting an SBP of 140 mm Hg or lower.[68] Close examination of these trials reveals that the achieved blood pressures in the first 24 hours were lower in ATACH-II compared with INTERACT2. Both trials support the safety of SBP lowering to 140 mm Hg. Current guidelines state that in patients with intracerebral hemorrhage and SBP between 150 and 220 mm Hg who do not have contraindication to acute blood pressure treatment, lowering of SBP to 140 mm Hg is safe and can be effective for improving functional outcome.[69] IV labetalol or nicardipine are most commonly used as first-line therapies.

Acute Aortic Dissection

Aortic dissection is a life-threatening complication of hypertension caused by a tear in the intima of the aorta. This tear is then propagated by the aortic pulse wave. The aortic pulse wave (first derivative of pressure measured over time [dP/dt]) is dependent on myocardial contractility, heart rate, and blood pressure. The presenting symptom is usually severe, sharp chest pain of abrupt onset. Chest x-ray may be associated with a widened mediastinum. The diagnosis is best made with contrast-enhanced computed tomography or transesophageal echocardiography.[70,71] Aortic dissections are classified as type A (proximal to the left subclavian artery, involving the ascending aorta) or type B (distal to the left subclavian artery, involving the descending aorta).[71] The goal of treatment is rapid reduction of the pulsatile wave (dP/dt) and aortic stress. Both MAP and cardiac output must be controlled to achieve this goal and prevent further propagation of the dissection in the aorta. In patients with aortic dissection, the MAP and heart rate should be reduced to normal values as quickly as possible. Combining a vasodilator (nitroprusside, nicardipine, fenoldopam) with a β-blocker (esmolol, metoprolol) is recommended.[72] All patients with aortic dissection need emergent cardiovascular surgical evaluation. Type A dissections usually require emergent surgery to prevent serious complications such as acute aortic insufficiency, hemopericardium, and cardiac tamponade.[73] Type B dissection is often managed medically. Indications for surgery in type B dissections include complications such as leak, rupture, and impaired flow to vital organs (see Chapter 33).

Hypertensive Crises in Pregnancy

Hypertension is a common complication of pregnancy and is responsible for 18% of maternal deaths in the United States.[74] The spectrum of disease varies from mild increases in blood pressure to severe pregnancy-related syndromes with hypertensive emergencies such as preeclampsia and eclampsia.[75] Hypertension in pregnancy is defined as an SBP of 140 mm Hg or higher or diastolic pressure 90 mm Hg or higher. Preeclampsia is a pregnancy-specific condition defined by new-onset hypertension, proteinuria (>300 mg/24 h) and pathologic edema during gestation. Eclampsia is defined by the development of seizures or coma in a pregnant patient with preeclampsia. The challenge in pregnant patients with hypertensive crises is to lower the blood pressure to prevent maternal end-organ damage while minimizing acute changes in placental perfusion that could negatively affect the well-being of the fetus. Treatment of severe preeclampsia and eclampsia includes delivery of the fetus, magnesium sulfate for the prevention and treatment of seizures, and appropriate blood pressure control. The goal is to reduce the diastolic blood pressure to 100 mm Hg or the MAP by 20%. Historically, hydralazine has been preferred in pregnant patients for its safety profile from a fetal perspective. However, data suggest it may not be the most effective or safe agent for this patient population.[76] For pregnant patients in need of acute lowering of blood pressure in the ICU, drugs such as labetalol and nicardipine are probably better options.[77,78] Nitroprusside is reserved for refractory cases, as a last resort, and for short periods because of concerns for potential fetal cyanide toxicity. Finally, angiotensin-converting enzyme inhibitors such as enalaprilat are contraindicated in the second and third trimesters because of the increase in fetal and neonatal morbidity and mortality.

Postoperative Hypertension

Postoperative hypertension deserving of immediate IV treatment consideration has been arbitrarily defined as an SBP greater than 190 mm Hg or a diastolic blood pressure greater than 100 mm Hg on two consecutive readings after surgery. Previous history of hypertension, high body mass index, age, and the grade of surgical stress are recognized risk factors for developing postoperative hypertension.[79] Severe increases in arterial blood pressure in the immediate postoperative period can result in serious complications, such as heart failure, arrhythmia, myocardial ischemia, wound hemorrhage, and cerebral hemorrhage.[80] Considering the deleterious effects of prolonged postoperative hypertension, many authors have recommended aggressive treatment.[80] The goal of treatment is similar to other hypertensive emergencies: decrease blood pressure to safe levels and at the same time avoid complications related to hypotension. Although some clinicians believe that postoperative hypertension should be treated aggressively based on the potential for acute end-organ damage, others recommend evaluating for possible causes of hypertension, such as pain, hypercarbia, hypoxemia, and urinary retention, before initiating antihypertensive drugs. As most patients in the postoperative period are unable to take oral medications, even patients with no clear evidence of

acute end-organ damage will receive IV medications. In patients with a previous history of hypertension a reasonable goal is to reduce MAP by 20%. In patients with no previous history of hypertension, the goal is to reduce blood pressure to normal levels. Clevidipine, nitroprusside, labetalol, and nicardipine have all been extensively studied in cardiac, vascular, and neurosurgical settings. Nitroglycerin is commonly used in postcoronary bypass surgery, and fenoldopam has been proposed for clinical settings with increased risk of renal ischemia.

Catecholamine-Associated Hypertensive Crisis

A hypertensive crisis related to excess catecholamines can result from several causes. Consumption of sympathomimetic agents (amphetamines, cocaine, phencyclidine, and certain diet pills), decongestants (ephedrine, pseudoephedrine), and other agents (atropine, alkaloids) can result in excessive catecholamine release and hypertension. Withdrawal from β-blockers or α-blocking agents can cause a rapid surge in catecholamines and hypertension. In these cases, reinitiating of the particular drug may be sufficient to treat the elevated blood pressure. Additional causes include pheochromocytoma, autonomic dysfunction (i.e., Guillain-Barré syndrome), and ingestion of tyramine in conjunction with monoamine oxidase inhibitor therapy. As a rule, in catecholamine-related hypertension the use of β-blockers as initial therapy should be avoided. Loss of β-adrenergically mediated vasodilation leaves α-mediated vasoconstriction unopposed and may cause further elevation in blood pressure. Pheochromocytoma is a rare tumor that produces excess catecholamine and can cause severe hypertension. Symptoms commonly associated with pheochromocytoma include headache, palpitations, diaphoresis, abdominal pain, anxiety, and hypertension. Some patients may present with orthostatic symptoms. For patients with a hypertensive emergency associated with pheochromocytoma, the drug of choice is phentolamine. Once blood pressure is controlled a β-blocker can be added to control tachycardia. For less critical situations or after acute hypertension is controlled, the oral agent phenoxybenzamine can be used.

Conclusions

Hypertension is a common disease among patients admitted to the ICU. Severe elevations in blood pressure most often are associated with no symptoms and no evidence of acute end-organ damage. However, a subset of patient with severe elevations in blood pressure will incur acute end-organ damage and require immediate treatment to prevent ongoing and potentially irreversible organ damage. The hallmark of a hypertensive emergency is the occurrence of acute end-organ damage in the presence of elevated blood pressure. As discussed previously, there are no specific blood pressure values to define this clinical situation. Intensivists must be adept at quickly and systematically evaluating patients with elevated blood pressures for evidence of acute end-organ damage. When present, they should act quickly to reduce blood pressure to safe levels. In the absence of acute end-organ damage, intensivists should exercise caution and not fall into the trap of treating numbers with the potential risk of causing more harm to patients owing to abrupt drops in blood pressure. True hypertensive emergencies require rapid reductions of blood pressure with IV drugs, close blood pressure monitoring, and should occur in a high-acuity setting. Once the blood pressure has been stabilized, it is important to initiate a transition to an oral regimen for long-term control of blood pressure.

Key Points

- Hypertension is a common clinical disorder in patients admitted to the ICU. Severe elevations in blood pressure most often are not associated with symptoms or evidence of acute end-organ damage.
- A *hypertensive emergency* is a severe elevation in blood pressure associated with the presence of acute end-organ damage. Hypertensive emergencies require rapid reductions of blood pressure to safe levels.
- The treatment of a hypertensive crisis is guided by (1) whether the blood pressure should be lowered acutely, (2) how much it should be lowered, and (3) what medication should be used.
- The ideal medication to treat a hypertensive emergency would have a rapid onset of action, high potency, immediate reversibility, no risk of tachyphylaxis, and minimal or no adverse effects.
- Parenteral agents with specific indications in the treatment of hypertensive crises include clevidipine, esmolol, fenoldopam, labetalol, nicardipine, and nitroprusside.

Review Questions

1. Which of the following factors is most important in determining if a patient has a hypertensive emergency?
   a. Systolic blood pressure 200 mm Hg or higher
   b. Diastolic blood pressure 110 mm Hg or higher
   c. Mean arterial pressure ≥120 mm Hg or higher
   d. Presence of acute end-organ damage
   e. Presence of severe headache
   Answer: d. Hypertensive emergencies are defined by the presence of acute organ damage. Key organs that can be affected by an acute elevation of blood pressure resulting in a hypertensive emergency include the brain, heart, and kidneys. It is important to understand that blood pressure numbers in isolation cannot be used to diagnose a hypertensive emergency. Previously normotensive patients may have acute organ damage at lower blood pressures and, conversely, chronically hypertensive patients may tolerate very elevated blood pressure without evidence of acute organ damage.
2. Patients who are chronically hypertensive and poorly controlled will usually exhibit changes in capacity to autoregulate cerebral blood flow in relation to MAP (relationship between blood flow and mean arterial pressure = autoregulation curve). Which of the following statements is *most* correct with respect to the autoregulation curve in a chronically hypertensive patient?
   a. The curve changes to a linear relationship (i.e., changes in flow are directly proportional to changes in MAP).
   b. Changes in the autoregulation curve are important only if the patient develops shock or severe hypotension.
   c. The curve shifts to the right, which means that the patient is more likely to suffer cerebral ischemia with rapid correction of blood pressure to "normal levels."
