   d. The curve shifts to the left, which means patients are more capable of tolerating high MAP without developing acute organ damage.
   Answer: c. Under normal conditions cerebral autoregulation will keep cerebral blood flow between MAP of 60 and 150 mm Hg. In chronically hypertensive patients this relationship is changed so that the autoregulation curve shifts to the right. This means that chronically hypertensive patients are better prepared to tolerate higher MAPs without developing acute organ damage or a hypertensive emergency. Conversely, owing to this shift chronically hypertensive patients are much more likely to develop ischemia/hypoperfusion with rapid correction of blood pressure to normal levels. This concept is very important and it informs our therapeutic conduct at the bedside. This is why most experts recommend a target reduction of 15% to 25% of the MAP for most hypertensive emergencies.
3. Which of the following statements is *most* correct regarding use of antihypertensive agents for the therapy of a hypertensive crisis?
   a. Intravenous therapy is mandatory for the therapy of hypertensive urgencies.
   b. The antihypertensive therapy should rapidly reduce the patient's blood pressure to the normotensive range.
   c. A short-acting intravenous drug is the optimal agent for lowering the patient's blood pressure.
   d. Nitroprusside alone is the therapeutic agent of choice for lowering the blood pressure in an acute aortic dissection.
   Answer: c. With a short-acting intravenous drug, the clinician has the ultimate control on achieving a precise blood pressure target. Oral therapy can be used to treat some hypertensive urgencies such as postoperative hypertension with a functioning gut. Reduction of the blood pressure to less than 90 mm Hg systolic, or even by as little as 35% of the initial mean arterial pressure, has been associated with major organ dysfunction, coma, and death. In hypertensive crises the mean blood pressure should be initially reduced by 15% to 20%. Nitroprusside, when used to treat hypertension associated with a dissecting aortic aneurysm, should be used in combination with an intravenous β-blocker.
4. Which of the following factors is most important in determining the need to immediately decrease the blood pressure in a patient presenting with an ischemic stroke?
   a. Presence of altered mental status
   b. Extent of infarct on computed tomography scan
   c. Systolic blood pressure 200 mm Hg or higher
   d. Decision to use systemic thrombolytic
   Answer: d. Management of hypertension in the setting of an acute ischemic stroke is based on an understanding of changes that occur in the capacity to autoregulate blood flow in the injured brain. During an acute ischemic stroke the autoregulation curve for cerebral blood flow in relation to MAP becomes linear. In other words, perfusion becomes directly dependent on MAP owing to loss of autoregulation. Normally the body will compensate by increasing MAP to preserve flow to the areas of the brain surrounding the infarct. Decreases in blood pressure can cause secondary neurologic injury be expanding the infarct size. Based on this concept, current recommendations are to tolerate high blood pressures in the setting of an acute ischemic stroke. The main factor to change this approach would be the use of systemic thrombolytics. In patients receiving thrombolytics the systolic blood pressure must be keep below 180 mm Hg to decrease the risk of hemorrhage.
5. Which of the following is *most* correct concerning treatment of hypertension associated with aortic dissection?
   a. Blood pressure target with aortic dissection is a 25% reduction in mean arterial pressure.
   b. Blood pressure lowering target with aortic dissection should be achieved within first hour.
   c. Combination of a β-blocker and a vasodilator is optimum therapy.
   d. Avoiding dropping blood pressure below the autoregulatory range is paramount in the therapy of aortic dissection.
   Answer: c. Rationale:
   Reducing the shearing force characterizes the rate of change of pressure with respect to time (or dP/dt, the aortic pulse wave [first derivative of pressure measured over time]) to minimize the impact of each cardiac cycle on dissection and is one of the most important principles of therapy of elevated blood pressure with aortic dissection. Blood pressure should be lowered to normal and should be accomplished within 15 to 30 minutes, even at the expense of going below the autoregulatory range for blood pressure. Drug choices include nitroprusside plus esmolol; fenoldolpam plus esmolol; nicardipine plus esmolol; or intravenous labetalol.

Outcomes and Prognosis
Summary

Thoracic aortic dissection (TAD) occurs with communication between the thoracic aorta lumen and wall with a separation of the thoracic aortic wall layers. TAD is to be contrasted with thoracic aortic aneurysm (TAA), which is defined as dilation of the thoracic aorta to a diameter of 1.5 times normal or larger. TAA is a risk factor for TAD. TAA, although an important morbidity that may be associated with acute catastrophic leakage and death, is in and of itself not the acute emergency signified by a TAD. TAD is a cause of sudden cardiac death (unexpected cardiac death within an hour after onset of symptoms).[1] After acute type A dissection the mortality is 1% to 3% per hour for the first 24 hours following diagnosis. The International Registry of Acute Aortic Dissection reported an overall mortality of 27.4% with this condition. Surgical mortality was 26% for proximal (type A dissection) versus 58% for medical management, and for distal (type B dissection) mortality was 10.7% for medical management and 31% for surgical management.[2]

History

In 1819, Laenec introduced "aortic dissection" into the medical literature when he described an intimal tear distal to the aortic valve associated with a longitudinal space in the aortic wall postmortem.[3] An report in 1761 described aortic dissection and pericardial tamponade as the causes of death of King George II.[4] In 1863, Peacock reported a summary of findings in 80 patients with aortic dissection and classified the disease into three stages: intimal tear, propagation of the dissection with the potential for rupture, and recanalization of the lumen.[5] In 1896, Marfan described the aortic connective tissue abnormality now known to be associated with this entity.[6] In 1952 DeBakey was the first to repair an aortic aneurysm using a cadaver graft.[7] In 1955, DeBakey and colleagues treated a descending TAD with resection and reapproximation of dissected layers with graph interposition.[8]

Types of Thoracic Aortic Dissection

The thoracic aorta is divided anatomically into the ascending portion, the transverse portion, and the descending portion.[9] The ascending aorta has two sections: the aortic root (valvular annulus and sinuses) and the tubular portion extending to the origin of the innominate artery. The transverse portion of the aorta is a short segment, and the brachiocephalic arteries come off this portion of the aorta. The descending thoracic aorta begins immediately distal to the left subclavian artery and extends to the diaphragm. The anatomic location of the TAD has important clinical and prognostic implications. The most commonly used classification scheme for TAD is the Stanford system (Fig. 33.1), which has mostly replaced the first classification system, the DeBakey system (see Fig. 33.1). An advantage of the DeBakey system is that it does distinguish between dissections that are confined only to the ascending aorta (DeBakey type II) and dissections that involve the entire aorta (DeBakey type I). Using the Stanford system, which is more simplistic, any involvement of the ascending aorta classifies the dissection as a Stanford A, whereas lack of ascending aorta involvement classifies the dissection as a Stanford type B.

Risk Factors for Thoracic Aortic Dissection

Multiple risk factors for TAD have been identified.[9] Men are at greater risk for developing TAD than women; approximately two-thirds of patients with TAD are male.[10] The sex distribution is consistent across different classifications of aortic dissection. Women with TAD are more likely than men to have a history of hypertension. Women are older at the time of diagnosis of TAD compared with men. The average age at diagnosis of TAD is 65 years and is younger for type A TAD than for type B TAD.[9] Specific risk factors for TAD are shown in Table 33.1. It is thought that the higher the blood pressure, the greater the probability of

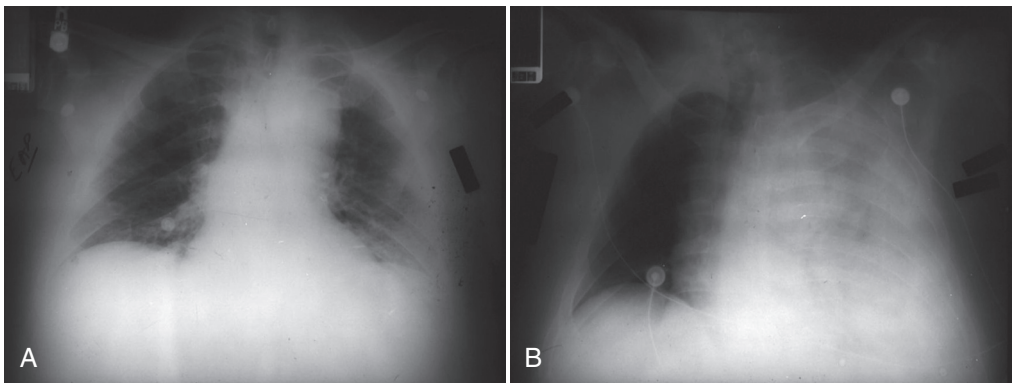
aortic dissection. In the presence of coarctation of the aorta, acute dissection typically occurs proximally rather than distal to the coarctation. The majority of patients with aortic dissection have hypertensive disease at the time of diagnosis.[11] Ascending aortic aneurysm is an independent risk factor for the development of aortic dissection. As the aortic diameter increases, the propensity for developing TAD increases. In patients without connective tissue disorder, a diameter above 5 cm is used as the surgical indication for elective ascending aortic repair. It is thought that blood pressure control decreases the occurrence of aortic dissection. However, hypertension is not thought to be the sole cause of dissection in a given patient. Many think that pregnancy is an independent risk factor for aortic dissection, although analysis of the available data and the conclusions from these data are hampered by the small number of patients affected and coexisting additional predisposing factors such as hypertension.[12–14] In addition to blunt trauma, TAD may be induced after establishing antegrade or retrograde arterial perfusion during cardiopulmonary bypass. Intraaortic balloon counterpulsation use may also trigger aortic dissection. There is increased risk of type A TAD after aortic valve replacement, especially with larger aortic diameters.[15] Finally, diagnostic angiography and cardiac catheterization may be complicated by aortic dissection (see Table 33.1).[15]

Pathophysiology

The aortic wall is composed of three layers: the innermost intima, the media (smooth muscle and elastic connective tissue), and the outermost adventitia. Hemodynamic stresses to the aortic inner walls can result from risk factors such as prolonged hypertension or inherently weakened connective tissue walls as seen in some connective tissue syndromes or a bicuspid aortic valve that alters the flow pattern of blood ejected out of the aorta. A dissection may be initiated by an intimal tear or ulceration with entry of blood into the medial layer facilitated by degeneration from normal aging or compounded by the risk factors listed in Table 33.1. A classic aortic dissection is classified by an intimal tear into the media of the aortic wall, resulting in separation of the medial layer and formation of a false channel, allowing blood to flow into this channel. An intramural hematoma (IMH) caused by rupture of the vasorum can also be the trigger for a dissection when an accumulation of blood separates the medial layers; in this circumstance, the inciting entrance tear is initially lacking. IMH can also occur if the is no distal exit tear in the media. In this situation blood is stagnant within the aortic wall with thrombosis leading to the hematoma. IMH can progress to an aortic dissection if the distal intimal layer ruptures and a true false channel forms.[16] IMH is more common in the elderly hypertensive patient's descending aorta. Aortic atheromatous plaque rupture or penetrating atheromatous ulcers can also disrupt the aortic wall and result in aortic IMH dissection.[17] Aortic rupture may occur in the setting of aortic dissection if the adventitia of the false lumen tears. This may cause extravasation of blood into the pericardium (tamponade), the chest (hemothorax), or retroperitoneum (Fig. 33.2).

Patients with aortic ulcers are older than those with IMH. TAD has been reported after heart transplation.[18] Inflammatory diseases of the aorta such as giant cell arteritis (large vessel or Behçet's disease vasculitis) may also lead to dissection.[19] Once aortic dissection has occurred, a true and false lumen are typically created. The false lumen of a TAD has the potential to extend both distally and proximally. There are usually fenestrations between the true and false lumen, and distal branch vessels may arise from either lumen. Frequently the false lumen can compress the ostium of the true lumen and cause malperfusion syndrome, depending on the distribution of the occluded vessel. Sequelae of malperfusion syndromes can include myocardial infarction, cerebral vascular accident, spinal cord ischemia (paralysis), renal or mesenteric infarct, or lower extremity ischemia (see Fig. 33.2).

Rupture is the most common cause of death during the early acute phase of TAD. The most frequent rupture route leading to death is into the pericardium causing tamponade. Compromise of arch vessels may lead to neurologic symptoms and injury. Death may also occur with involvement of the aortic root, producing primary ostial compromise and acute myocardial infarction or severe aortic regurgitation. Rarely, fistulas and high-degree heart block may be produced. The thin wall of any residual pseudoaneurysm after TAD tends to enlarge and over time is at high risk of rupture. Total thrombosis of the false lumen is rare, whereas distal reentry into the true lumen may help decompress the false lumen and increase the chance of survival. Postoperative false lumen patency is a predictor of late mortality.[20]



• **Fig. 33.2** Chest radiograph with a widened mediastinum (A) with subsequent rupture of the thoracic aortic aneurysm into the left pleural space (B).

Diagnosis

Symptoms

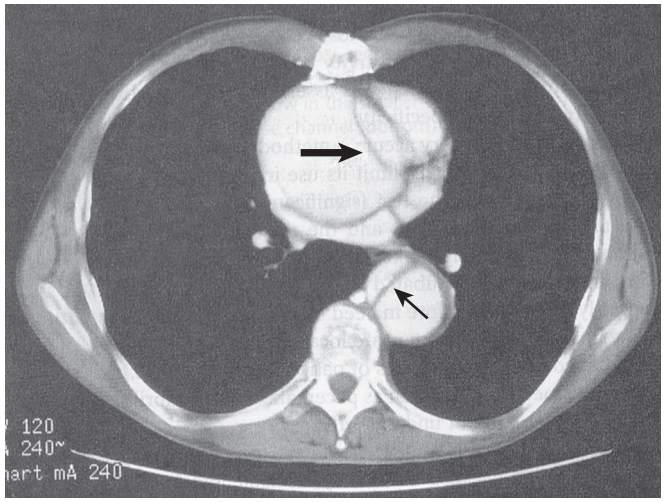
The diagnosis of acute TAD is complicated by the infrequent occurrence of this clinical condition as well as the diagnostic difficulty and is particularly problematic because of the potential catastrophic outcome.[21] Typical symptoms of TAD are excruciating, severe at onset, pain of a sharp and tearing nature. The location of the pain (anterior chest, neck, jaw, inner scapular, and lumbar/abdominal) is linked to the location of the dissection. Symptoms, other than pain, include visceral symptoms (vomiting, diaphoresis, and syncope). Chronicity is defined as presentation later than 2 weeks from the onset of symptoms.

Physical Examination

Although physical examination findings may be absent, if present, they are useful in directing the clinician's attention to this diagnosis.[21] Inequality of pulses in the upper extremity and a blood pressure differential of 20 to 30 mm Hg between the two extremities may be seen based on the location of the dissection. A new aortic regurgitation murmur occurs in a significant number of patients. Proximal dissection may also interfere with coronary artery blood flow. Most commonly the right coronary artery is affected and patients may present with an inferior myocardial infarct and evidence of ischemia in the inferior leads. Echocardiogram may demonstrate severe right ventricular failure. Rupture into the pericardium typically results in pericardial tamponade. Pericardial tamponade is supported by findings of jugular venous distention, muffled heart tones, tachycardia, and hypotension. Mass compression effects can produce findings such as superior vena cava syndrome, Horner syndrome, hoarseness, dyspnea, or dysphagia. Syncope is seen in 1 of 10 cases of TAD and likely results from cerebral malperfusion or hypotension secondary to cardiogenic shock or tamponade. Vasovagal pain response may also be a potential etiology of syncope. When syncope is related to hypovolemic shock from rupture through the adventitia into the pleural space, the prognosis is grave.

Laboratory Findings

Laboratory evaluation is usually not helpful in the diagnosis of acute aortic dissection. A meta-analysis demonstrated that cardiac troponin was elevated in 26.6% of acute aortic dissection (range 23%–33%) and was significantly associated with short-term mortality.[22] A normal D-dimer level combined with a low aortic dissection score (≤1) supports ruling out acute aortic dissection.[23]



• **Fig. 33.3** Computed tomographic angiogram demonstrating a thoracic aortic dissection. This Stanford type A dissection extends from the ascending aorta (*large arrow* pointing to the intimal flap) to the descending aorta (*smaller arrow* pointing to the intimal flap).

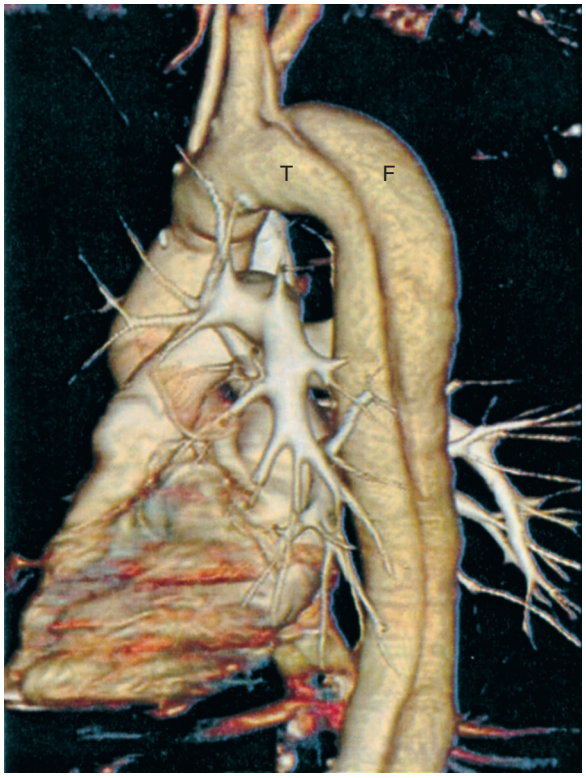
Imaging

Chest Radiograph

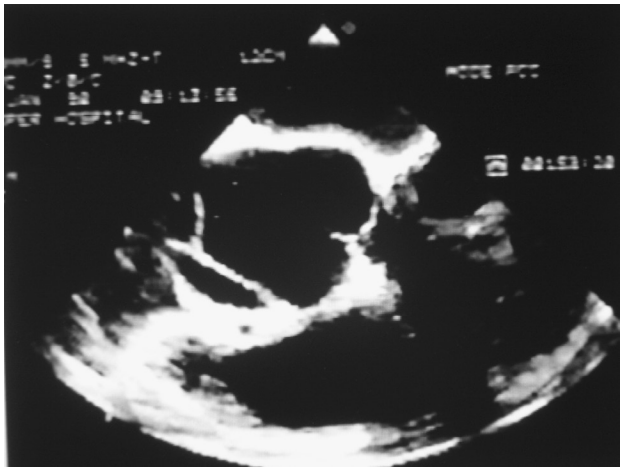
The great majority of patients with TAD have abnormalities on the chest radiograph. A normal chest radiograph may therefore help in decreasing the likelihood of aortic dissection. A study by Klompas looked at 1337 chest radiographs in patients with TAD and reported abnormalities in 90% of patients.[24] The most common changes associated with dissection are abnormal aortic contour, widening of the mediastinum, pleural effusion, displacement of intimal calcification, abnormalities of the aortic knob, and displacement of the trachea or nasogastric tube to the right. In the absence of an abnormal aortic contour or mediastinal widening, a diagnosis of dissection is less likely.

Computed Tomography

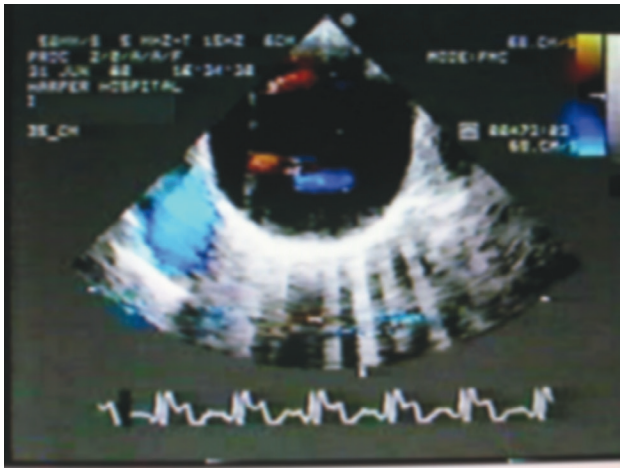
The most common diagnostic modality used for diagnosis of TAD is computed tomography (CT) (Fig. 33.3). A CT angiogram shows high sensitivity and specificity in diagnosis and exclusion of TAD.



• **Fig. 33.4** Volume-rendered enhanced image from computed tomographic angiography study showing true *(T)* and false *(F)* lumens in the descending thoracic aorta. (From Kapustin AJ, Litt HI. Diagnostic imaging for aortic dissection. *Semin Thorac Cardiovasc. Surg.* 2005;17:219–213.)



• **Fig. 33.5** Transesophageal echocardiogram image showing intimal flap in the ascending aorta extending to the aortic annulus. (Courtesy Priscilla Peters, Cooper University Hospital, Camden, NJ.)



• **Fig. 33.6** Image from a transesophageal echocardiogram revealing an intimal flap in the descending aorta. Color Doppler shows flow through two fenestrations in the flap. (Courtesy Priscilla Peters, Cooper University Hospital, Camden, NJ.)

It is the optimal imaging modality for ruling out aortic dissection in patients with low clinical pretest probability. Limitations of this technique include use of ionizing radiation and contrast media, the need for transfer to the imaging station, and limited ability to access the aortic valve. Advantages are ready availability, turnaround time, delineation of entire aorta, and diagnosis of other disorders causing the patient's symptoms. Advances in CT angiographic techniques—such as spiral multidetection scanner technology that allows volume-rendered, three-dimensional reconstruction of a CT angiogram—are likely superior to magnetic resonance images (Fig. 33.4 provides an example of the technology).

Echocardiography

Transthoracic echocardiography (TTE) should be performed early in the evaluation of any patient in whom the diagnosis of ascending aortic dissection is entertained. If a pericardial effusion is present, signs of tamponade can be identified. TTE can help identify aortic dissection if multiple views are obtained—specifically, suprasternal, subcostal, and right parasternal views. The intimal flap may be identified within the lumen with motion that is not synchronized with the surrounding structures. To minimize the chance of a false-positive result, the flap should be visualized in more than one view. The addition of color Doppler helps to identify flow artifacts (as opposed to an intimal flap) within the ascending aorta by demonstrating flow between the true and false channels at the site of an intimal tear and by showing a difference in the timing or direction of flow within the two lumens.[25] Color Doppler permits detection and quantification of aortic regurgitation. TTE is especially useful for diagnosing dissections involving the ascending aorta but is much less sensitive for descending dissections. If a dissection is not visualized in the patient with chest pain, finding regional wall motion abnormalities may suggest the alternative diagnosis of coronary ischemia.

Transthoracic echocardiography (TEE) (Fig. 33.5) can be performed safely on most critically ill patients in a monitored setting.[26,27] To avoid precipitating hypertension, tachycardia, or gagging (straining) in a patient with suspected dissection, conscious sedation should be administered. Nearly all of the thoracic aorta can be visualized, including most of the arch. The area from the distal ascending aorta to the midarch, however, is difficult to evaluate with TEE because of interposition of the airway between the esophagus and the aorta.[28] The sensitivity of TEE for TAD is close to 100%, but specificity is lower, owing primarily to reverberation artifacts that may be visualized within the ascending aorta, simulating an intimal flap.[29] Color flow Doppler with TEE may demonstrate flow through or on either side of the suspected intimal flap (Fig. 33.6). TEE is helpful for evaluating involvement of the coronary ostia and aortic valve. As with TTE, regional and overall

ventricular wall motion can be evaluated and the presence of pericardial effusion can be determined.

Aortography

Once the gold standard for diagnosis of TAD, aortography fell into disfavor as the diagnostic study of choice owing to its invasive nature and a relatively high false-negative rate.[30] The sensitivity of aortography is lower than that of CT, and its specificity is no better. Reliance on iodinated contrast does not ensure direct visualization of a thrombosed lumen or intramural hematoma, or occasionally even to confirm the presence of a second, false lumen.[31] Although it is not a first-line diagnostic technique, early aortography with endovascular stent graft intervention as a treatment for distal malperfusion syndrome in type B dissections has become more common. These interventions are directed at stenting across intimal tears to reduce false lumen flow, stenting open an occluded true lumen, fenestration of intimal flaps, and opening occluded branch vessels.[32,33]

Magnetic Resonance Imaging

The most reliable diagnostic finding with magnetic resonance imaging (MRI) is demonstration of two lumens separated by an intimal flap. Gadolinium-enhanced magnetic resonance angiography allows the visualization of blood flow, which can be used to detect the presence and magnitude of aortic regurgitation or to demonstrate communication between the true and false lumens at the site of an intimal tear. An intimal flap can be identified in most cases, except when the false lumen is completely thrombosed. The diagnostic accuracy of MRI for aortic dissection approaches 100%.[34] Problems with MRI include (1) that it cannot be performed in patients with pacemakers or defibrillators, aneurysm clips, or ferrous metal implants; (2) claustrophobia; and (3) life support equipment (ventilators, monitors, intravenous [IV] infusion pumps) with associated logistical issues. Image acquisition, despite advances in the technology, is more time-consuming than with CT. Because it entails no radiation exposure, MRI may be an appropriate initial study in the stable patient[29] and for long-term follow-up evaluation.[29,35]

Summary

Table 33.1 shows a comparison of diagnostic imaging modalities for evaluation of TAD. The 2010 American Heart Association guidelines for diagnosis of dissection give a Class I recommendation for using urgent TEE, MRI, or CT angiogram to determine a definitive diagnosis in patients with high clinical suspicion.[36] If the initial diagnostic test result is negative in patients with high clinical suspicion, a second imaging modality should be completed. Fig. 33.7 shows the diagnosis algorithm from the 2010 guidelines for the diagnosis and management of TAD.

Perioperative Management

General Principles

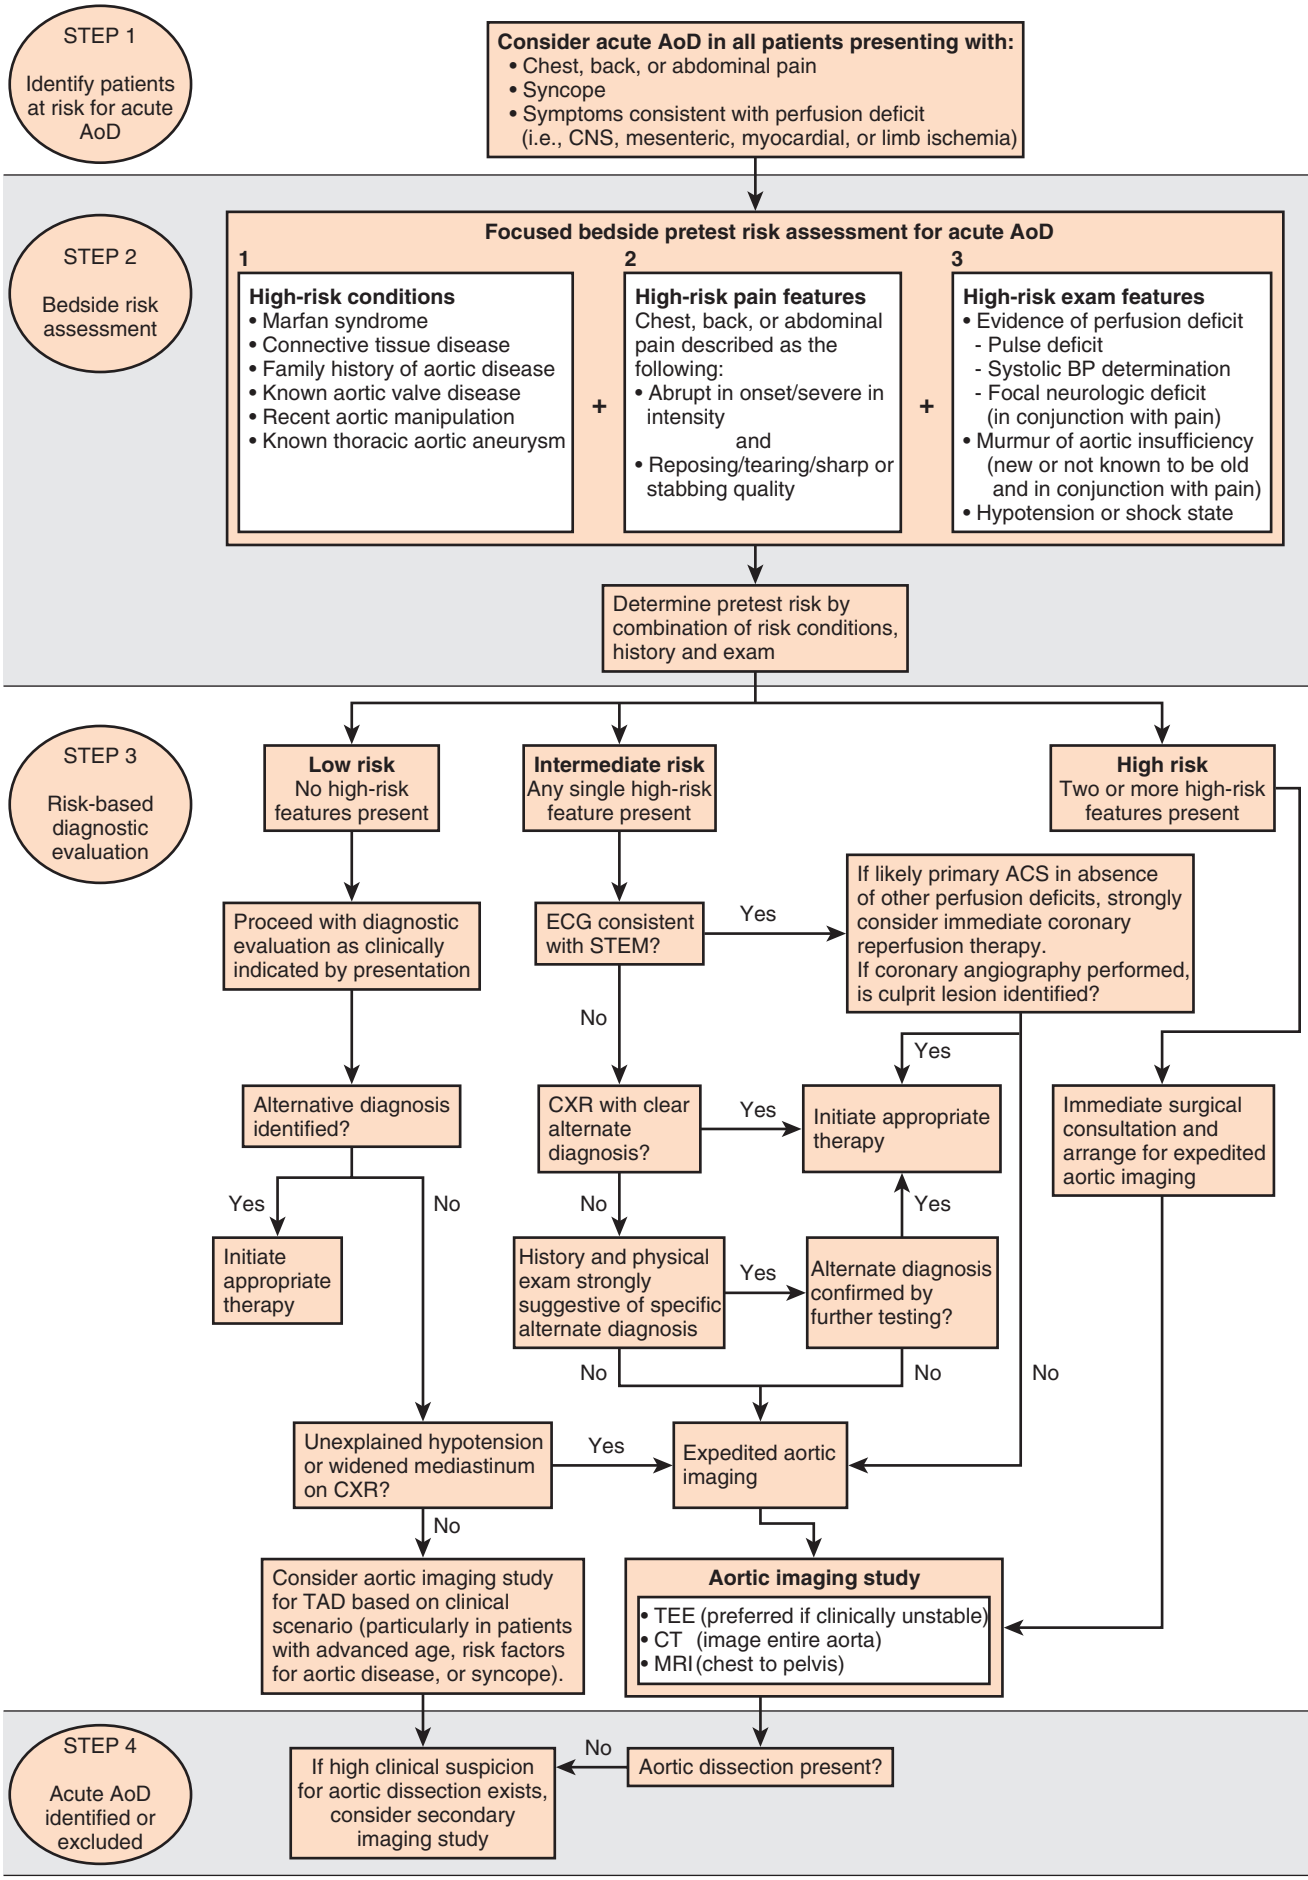
Medical therapy is critical for survival with both type A and type B TAD.[37–40] Immediate initiation of medical therapy is imperative, both before surgical intervention for type A TAD and as definitive therapy for patients with type B TAD that is uncomplicated. The primary objectives of therapy are rapidly normalizing arterial blood pressure in hypertensive patients and reducing the force of left ventricular contractility in all patients. Following admission to the intensive care unit, vital signs are monitored continually; blood pressure should be compared between upper extremities, and the same for carotid pulses. Arterial line insertion is indicated. A radial arterial line on the side of higher blood pressure or a femoral arterial line is placed. For type B dissection, a right radial arterial line is preferred. IV drugs are indicated for medical therapy. To limit shear force, which is propagating the dissection, it is important to control the rapidity of the rise of the systole, which is done by avoiding tachycardia (goal heart rate is 60–75 beats/min), depressing contractility, and decreasing blood pressure. Because blood pressure is maintained at low normal, a Foley catheter is recommended to judge adequate tissue perfusion. Pain is a marker of continued dissection of a TAD, and subsiding of pain can be assumed to be a marker of halting of dissection. Medical therapy is the treatment of choice for uncomplicated type B TAD. It may also be successfully used in patients who are poor surgical candidates or in select patients who have been diagnosed with subacute dissections who are awaiting surgical intervention.

The mortality of nonoperative management of type A dissection may be up to 1% to 2% per hour in the early phase after symptom onset.[41] The goals of medical management should be stabilization, management of hypertension, and evaluation of neurologic and metabolic function while the operating room is being prepared for the patient. Most centers favor transport directly to the operating room after the surgical team has been mobilized to avoid any delay that would increase mortality. Exceptions to this rule are patients who may present with severe malperfusion that may preclude operative intervention (severe cerebral or visceral ischemia). These exceptions need to be thoroughly evaluated with CT scan and neurologic consultation if central nervous system issues are present. In patients presenting with severe acidosis and elevated lactate levels, CT scan of the abdomen to evaluate for bowel infarction, which if present may make the patient inoperable, is indicated.

Initial postoperative management is heralded by the need to prevent hypertension. Because of multiple suture lines used during the reconstruction, hypertension can result in excessive postoperative bleeding from the mediastinum or cause aortic suture lines to disrupt. Most patients have hypertrophic ventricles from long-standing hypertension, and control of blood pressure in the initial postoperative period can be difficult and requires IV vasodilators, β-blockers, or calcium channel blockers. Lifelong control of hypertension will be required. Most patients who undergo type A dissection repair have evidence of residual dissection within the arch and descending aorta and a 15% risk for progressive aneurysmal dilatation. Many patients have a history of malignant or refractory hypertension and will require multiple oral agents in the outpatient setting to keep them normotensive. Blood pressure control over time is important to reduce the incidence of late false channel aneurysm development and decreases the risk of rupture. Periodic evaluation of the status of the aorta over time after successful therapeutic intervention is needed and is typically done with CT scan. After repair of a type A dissection, Signs of persistent back pain, new left pleural effusion, or organ hypoperfusion may indicate that the residual type B dissection is unstable and that the patient may require a second endovascular procedure to stabilize the residual descending aorta.

Specific Medications

Control of blood pressure and heart rate in the presence of TAD is essential.[42] IV β-blockers are the first line of therapy for aortic dissection and are immediately initiated to avoid tachycardia, which may occur with some medications chosen to lower blood pressure.[43] β-Blockers, in addition to controlling heart rate, also depress



STEP 1
Identify patients at risk for acute AoD
Consider acute AoD in all patients presenting with:
• Chest, back, or abdominal pain
• Syncope
• Symptoms consistent with perfusion deficit (i.e., CNS, mesenteric, myocardial, or limb ischemia)
STEP 2
Bedside risk assessment
Focused bedside pretest risk assessment for acute AoD
1
High-risk conditions
• Marfan syndrome
• Connective tissue disease
• Family history of aortic disease
• Known aortic valve disease
• Recent aortic manipulation
• Known thoracic aortic aneurysm
+
2
High-risk pain features
Chest, back, or abdominal pain described as the following:
• Abrupt in onset/severe in intensity
and
• Reposing/tearing/sharp or stabbing quality
+
3
High-risk exam features
• Evidence of perfusion deficit
- Pulse deficit
- Systolic BP determination
- Focal neurologic deficit (in conjunction with pain)
• Murmur of aortic insufficiency (new or not known to be old and in conjunction with pain)
• Hypotension or shock state
Determine pretest risk by combination of risk conditions, history and exam
STEP 3
Risk-based diagnostic evaluation
Low risk
No high-risk features present
Intermediate risk
Any single high-risk feature present
High risk
Two or more high-risk features present
Proceed with diagnostic evaluation as clinically indicated by presentation
ECG consistent with STEM?
Yes
If likely primary ACS in absence of other perfusion deficits, strongly consider immediate coronary reperfusion therapy.
If coronary angiography performed, is culprit lesion identified?
No
Yes
Alternative diagnosis identified?
CXR with clear alternate diagnosis?
Yes
Initiate appropriate therapy
Immediate surgical consultation and arrange for expedited aortic imaging
Yes
No
No
Yes
Initiate appropriate therapy
History and physical exam strongly suggestive of specific alternate diagnosis
Yes
Alternate diagnosis confirmed by further testing?
No
No
No
Unexplained hypotension or widened mediastinum on CXR?
Yes
Expedited aortic imaging
No
Consider aortic imaging study for TAD based on clinical scenario (particularly in patients with advanced age, risk factors for aortic disease, or syncope).
Aortic imaging study
• TEE (preferred if clinically unstable)
• CT (image entire aorta)
• MRI (chest to pelvis)
STEP 4
Acute AoD identified or excluded
If high clinical suspicion for aortic dissection exists, consider secondary imaging study
No
Aortic dissection present?

• **Fig. 33.7** Algorithmic flow diagram approach to diagnosis or exclusion of aortic dissection. *ACS,* Acute coronary syndrome; *AoD,* aortic dissection; *BP,* blood pressure; *CNS,* central nervous system; *CT,* computed tomography; *CXR,* chest x-ray; *ECG,* electrocardiogram; *MRI,* magnetic resonance imaging; *TAD,* thoracic aortic dissection; *TEE,* transesophageal echocardiography; *STEM,* ST segment elevation myocardial infarction. (Modified with permission from Hiratka LF, Bakris, GL, et al. 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic dissection. *Circulation.* 2010;121:e266–e369.)

contractility and lower blood pressure, both goals of therapy. IV esmolol is the ideal drug as it is a quick-onset and short-acting agent and can be titrated to effect. IV diltiazem is an alternative to esmolol for decreasing contractility and avoiding tachycardia when there are contraindications to the use of β-blockers, such as in the active asthmatic. This target blood pressure will then be anticipated to persist for 6 to 8 hours.

Nitroprusside is the vasodilator of choice for blood pressure control and is begun after the initiation of esmolol when blood pressure lowering is required. Nitroprusside acts by decreasing both preload and afterload. Because it may be associated with reflex tachycardia, it is added only after a β-blockade is in place. Tachycardia should always be avoided in the presence of aortic dissection. Labetalol is an alternative choice to esmolol plus nitroprusside and is given as a loading dose of 10- to 40-mg boluses (based on degree of blood pressure response) every 10 to 15 minutes until target blood pressure is reached or 300 mg is delivered. Duration of action for IV labetalol is approximately 4 hours. Table 32.1 reviews drugs used in the medical therapy of acute TAD.

Operative Approach

Ascending Aortic Dissections

Surgical intervention is indicated in all patients with proximal dissections, with the exception of patients with serious concomitant conditions that preclude surgery.[44] Stroke is the most common contraindication to surgery because there is real concern that anticoagulation (cardiopulmonary bypass) as well as reperfusion can result in further neurologic deterioration by converting the ischemic stroke to a hemorrhagic stroke. Every attempt must be made to perform a careful neurologic assessment before undertaking surgical intervention. Additional evidence of severe malperfusion (bowel ischemia) is also a contraindication to surgery. In certain instances inoperable patients may be managed with a stent graft to the ascending aorta via retrograde approach or transapical approach.[45]

Preoperative evaluation is essential to assess for the presence of aortic regurgitation, pericardial effusion, the extension of the dissection into the major aortic branches, and the localization of entry and reentry sites. CT angiography helps to delineate visceral and renal vessel involvement and end-organ perfusion. The presence of thrombosis in the false lumen yields information that can be helpful in planning the surgical approach.[46]

The operative mortality rate for patients with aortic dissections ranges from 5% to 10% and may approach 70% in cases with complications. The independent predictors of operative mortality include the presence of cardiac tamponade, the site of the tear, the time to operation, the presence of renal/visceral ischemia, renal dysfunction, and the presence of pulmonary disease.[47]

Once the diagnosis of ascending aortic dissection is made, cardiac surgical consultation should be obtained and the patient transported directly to the operating room. There is no indication for preoperative cardiac catheterization. Not infrequently patients present with inferior cardiac ischemic changes (electrocardiogram leads II, III, aVF). Proximal disruption of the right sinus of Valsalva is very common and can result in right main coronary malperfusion. This also becomes evident as right ventricular failure or inferior wall ischemia and is identified on intraoperative TEE. Left main coronary malperfusion is almost uniformly fatal and is infrequently encountered.

Intraoperatively general anesthesia is induced. If cardiac tamponade is suspected, care must be taken to avoid cardiovascular collapse secondary to a loss of adequate preload when general anesthesia is induced. A TEE probe is then placed and a careful examination is performed. This should include evaluation of right and left ventricular function; extent of the intimal dissection from the sinus of Valsalva to the descending aorta; evaluation of aortic, mitral, and tricuspid valve function; and presence of a pericardial effusion.

Intraoperative planning should involve focus on two key elements: (1) restoration of competent aortic valvular function and (2) resection and reconstruction of all areas of disease in the ascending aorta.

Standard techniques for surgical reconstruction involve cardiopulmonary bypass with circulatory arrest. Arterial cannulation is performed in the femoral artery, innominate artery, or axillary artery. Venous cannulation is usually performed in the right atrium, and cardiopulmonary bypass is then initiated. A cross clamp is then applied across the ascending aorta, and the heart is arrested with retrograde cardioplegia. During this time the patient is then cooled for a period of circulatory arrest. During the cooling period, the ascending aorta is resected down to the sinotubular junction and the extent of dissection is evaluated.

At this time the aortic valve is evaluated for leaflet pathology, and the sinus of Valsalva must be inspected to determine if this is the origin of the initial intimal tear. The right coronary ostium can frequently be disrupted from the intimal dissection, and if it cannot be reconstructed, coronary artery bypass grafting must be undertaken to prevent ischemia and myocardial infarction.

If there is no primary tear site in the sinus of Valsalva, most surgeons favor reconstruction of the aortic root with glue aortoplasty and valve resuspension.[48] Indications for performing a full aortic root replacement with a valved conduit and a left and right coronary artery reimplantation (Bentall operation) include a tear through the sinus of Valsalva or an aortic valve that cannot be reconstructed. This can be performed with a mechanical valved conduit, pericardial conduit, or porcine heterograft.[48–52] Valve-sparing aortic root replacement may be also performed in patients who have a long life expectancy. This complex procedure requires resection of all aorta distal to the annulus, creation of neosinuses, and coronary artery reimplantation with reconstitution of aortic lumen continuity.[53]

Reconstruction of the distal aortic arch is performed during circulatory arrest with the patient cooled to 15°C to 25°C. Cerebral

perfusion is often maintained during the circulatory arrest period and may be accomplished either antegrade (flow maintained in the axillary or innominate artery) or retrograde (flow through the superior vena cava). Current surgical practice favors the use of the antegrade techniques, as they improve cerebral oxygenation and increase the length that circulatory arrest can safely be performed without neurologic or systemic sequelae.

The distal aortic arch is frequently reconstructed with a glue aortoplasty (such as a hemiarch) or a total arch reconstruction with branch graft reconstruction if there is severe disruption at the level of the cerebral vasculature.

In addition, stent grafting of the distal thoracic aorta may be performed in an antegrade fashion during a period of circulatory arrest (stented elephant trunk technique). This may stabilize the distal aorta, prevent future aneurysmal dilation, or facilitate a proximal endovascular landing zone for future endovascular therapy should that become necessary.[54]

After reconstruction of the aortic arch, a Dacron graft is sewn to the distal arch and full cardiopulmonary bypass is reinitiated. The Dacron graft is then anastomosed to the sinus of Valsalva (or valve conduit), thus restoring continuity from the heart to the aortic arch. The patient is then rewarmed and weaned from cardiopulmonary bypass.

Descending Aortic Dissection and Endovascular Therapy

Uncomplicated acute type B dissection is best managed medically. Approximately 15% of patients with this type of dissection develop aneurysmal degeneration and require surgical intervention within 5 years of the initial event. The indications for performing early surgery in patients with distal dissections are the rapid expansion of a dissecting aneurysm, rupture into the left chest, impending rupture, persistent and uncontrollable pain, or impairment of the blood flow to an organ or limb.[44,55–57] Open surgical repair carries extremely high morbidity and mortality, and endovascular stent grafting is the currently favored approach for the acute treatment of malperfusion.[58,59]

Organ malperfusion and ischemia in patients with aortic dissections are caused by encroachment on the aortic lumen (true) that provides the blood supply to a branch vessel. The lumen supplying blood to the branch vessel may be the true lumen or the false lumen. A stent is deployed through the percutaneous approach within the lumen supplying the branch vessel to hold the lumen open by displacing the intimal flap toward and overcoming the pressure from the other lumen. To overcome the high pressures in the other lumen, a balloon fenestration procedure may be combined with the stent procedure.

The clinical success of endovascular stent placement for aortic dissection ranges from 76% to 100% with a reported 30-day mortality rate of up to 25%.[59–64] Data on the long-term follow-up of these patients are scarce.

The goals of treatment are coverage of the primary tear site, exclusion of the false lumen, restoration of blood flow to the true lumen, and restoration of organ perfusion and limb perfusion. Covered thoracic stent grafts are usually deployed from the left subclavian artery to the middle descending aorta. If the initial tear site begins at the origin of the subclavian artery, the proximal landing zone is advanced across the subclavian artery to the left common carotid. If there is evidence of a dominant vertebral system on CT scan, or clinical concern for left arm ischemia, a subclavian to carotid bypass graft can be performed via a separate neck incision. The use of intravascular ultrasound has also gained favor to ascertain that the graft is deployed correctly in the true lumen of the dissection.

About 13% of patients with aortic dissections receive stent-graft treatment and this proportion is steadily increasing. With more data available and more advancement in operator expertise, stent graft placement may, in the future, become the standard treatment for most cases of distal aortic dissection, because waiting for the complications to occur may not be prudent given that the operative mortality rate in these situations approaches 70%.[62]

Treatment of Aortic Intramural Hematoma and Atherosclerotic Aortic Ulcer

The treatment of patients with both aortic intramural hematomas and atherosclerotic aortic ulcers is similar to that for patients with classic aortic dissections and depends on the aortic site involved. Both aortic IMH and atherosclerotic aortic ulcer are more common in the descending aorta and therefore are treated with aggressive medical therapy. Medical therapy should consist of the optimal control of blood pressure, a maximum rate of aorta pressure rise over time (dp/dt max or "shearing force"), as well as close long-term follow-up. Surgery is preferred for the treatment of patients with intramural hematomas and atherosclerotic aortic ulcers in the ascending aorta and aortic arch, and for patients with progressive dilatation and aneurysm formation of the aorta, irrespective of the site of involvement.[65–69] In a meta-analysis of 143 patients with aortic intramural hematomas, of whom 30 patients (21%) died, 20 deaths (67%) were due to aortic dissection or rupture.[70]

Interest has also grown in the use of endovascular treatment of type A aortic dissection with short segment stent grafting in high-risk nonoperable patients.[71] Use of short segment grafts to cover an ascending tear is possible if the dissection is limited to the aorta just above the sinotubular junction and there is no associated valvular compromise. Placement may be performed retrograde or antegrade through the apex of the left ventricle.

Outcomes and Prognosis

The rationale for surgical treatment of acute type A TAD is universally recognized. Patients with acute ascending aortic dissection treated medically fare far worse than those with dissection involving the descending aorta. Little controversy exists over the treatment of choice for the acute type B variety. For most patients, unless life- or limb-threatening vascular compromise is present, medical therapy is considered superior to surgical treatment.[72,73] If a complication such as rupture necessitating emergency surgery arises, however, the mortality rate is very high. Fortunately, this occurs infrequently. If operation is required for type B TAD within the first 2 weeks, mortality remains high.[74] Analysis of all early postoperative complications shows a much lower stroke rate for descending aorta repairs compared with repair of ascending dissections, although the incidence of pulmonary complications and spinal cord injury is higher.

Summary

Aortic dissection is caused by a tear in the intima of the aorta that is propagated by the aortic pulse wave. The aortic pulse wave, or "shearing force," depends on a combination of myocardial contractility, heart rate, and blood pressure. The risk factors for aortic dissection include advanced atherosclerosis, connective tissue diseases, and aortic coarctation. Dissections involving the area proximal to the left subclavian artery are considered to be type A, and when this area is not involved they are considered to be type B (involving the descending aorta only). Chest pain is the typical presenting symptom, and the classic chest radiographic finding is a widened mediastinum. Diagnosis is best made either with a contrast-enhanced CT scan or TEE. Dissection is usually diagnosed using CT scanning with and without contrast enhancement, which demonstrates a gray-white false lumen predominantly filled with a clot alongside a bright white, dye-filled true aortic channel. Dissecting thoracic aortic aneurysms involving the arch and descending aorta that do not interfere with major vessel outflow are typically managed medically with blood pressure control. Aneurysms involving the ascending aorta are typically surgically treated. Aneurysms of the ascending aorta may dissect proximally, producing a murmur of aortic insufficiency or acute pericardial tamponade. Distal migration may produce an obstruction of the major vascular outflow vessels or a rupture into the thorax. Occasionally, a leak may occur into the thorax, which on occasion is diagnosed in time to allow lifesaving surgery. The propagating force for a dissection is the change in pulse over the change in time or the maximum shearing force. This shearing force is minimized by a combination therapy of keeping the pulse in the low normal range, normalizing blood pressure, and decreasing inotropy. Dissection of the aorta is a hypertensive emergency in which normalization of blood pressure is indicated.

Key Points

- Men are at greater risk for developing TAD than are women; approximately two-thirds of patients with TAD are male.
- There is an increased risk of type A TAD after aortic valve replacement, especially with larger aortic diameters.
- Rupture is the most common cause of death during the early acute phase of TAD.
- The most common diagnostic modality used to diagnose TAD is CT.
- Advances in CT angiographic techniques—such as spiral multidetection scanner technology that allows volume-rendered, three-dimensional reconstruction of the CT angiogram—are likely superior to magnetic resonance images.
- The primary objectives of therapy are rapidly normalizing arterial blood pressure in hypertensive patients and reducing the force of left ventricular contractility in all patients.
- Once the diagnosis of ascending aortic dissection is made, cardiac surgical consultation should be obtained and the patient should be transported directly to the operating room.
- If cardiac tamponade is suspected, care must be taken to avoid cardiovascular collapse secondary to a loss of adequate preload when general anesthesia is induced.
- If there is no primary tear site in the sinus of Valsalva, most surgeons favor reconstruction of the aortic root with glue aortoplasty and valve resuspension.

Review Questions

1. Which one of the following is *most correct* concerning acute aortic dissection?

a. Dissections of the descending aorta mandate surgical treatment.

b. In the presence of hypertension, blood pressure lowering should be targeted for a 15% reduction.

c. Pain is considered a marker for ongoing dissection.

d. Compression of aortic valvular ring may produce a murmur of aortic stenosis.

Answer: c. Unless a descending aortic dissection compromises a vessel coming off of the aorta, surgery is typically not indicated and medical management (blood pressure control) is the sole therapy. Normalization of the blood pressure is indicated. Pain implies continued dissection with wall separation. Proximal dissection into the aortic ring may lead to aortic insufficiency, not aortic stenosis.

2. Which one of the following antihypertensive regimens would be most appropriate for normalizing blood pressure in the presence of an aortic dissection?

a. Intravenous hydralazine

b. Intravenous esmolol and intravenous nitroglycerin

c. Oral clonidine

d. Intravenous esmolol and intravenous nitroprusside

Answer: d. The approach to blood pressure management with an aortic dissection is to rapidly normalize blood pressure while controlling rate to avoid tachycardia and bradycardia. An intravenous β-blocker (initiated first) plus a balanced vasodilator is the preferred regimen. Nitroprusside is a balanced vasodilator and has a rapid onset and offset of action.

3. Which one of the following is the preferred diagnostic method for acute thoracic aortic dissection?

a. Computed tomographic angiogram

b. Magnetic resonance angiography (MRA)

c. Aortography

d. Transthoracic echocardiography

Answer: a. Volume-rendered, three-dimensional reconstruction-capable computed tomographic angiography is the preferred initial diagnostic test for aortic dissection showing high sensitivity and specificity. Aortography is less desirable because of its invasiveness and false-negative rate. Diagnostic accuracy of MRA is high, approaching 100% in technically adequate studies. MRA is handicapped by exclusions for study such as pacemakers, metal implants, and supportive devices. Transthoracic echocardiography is an important diagnostic test to look for pericardial effusion (proximal dissection), aortic insufficiency, or compromise of coronary artery blood flow as complications of dissection but not for diagnosis itself. Transesophageal echocardiography is highly diagnostic for ascending aorta dissections.

General Principles of Postoperative Intensive Care Unit Care

DAMON H. CLARK AND HEIDI L. FRANKEL

CHAPTER OUTLINE

General Principles
- Admission Criteria
- Discharge Criteria
- Structure and Staffing of Surgical Intensive Care Unit
- Intraoperative History

Best Practices: General Postoperative Care
- Pain, Agitation, and Delirium
- Recovery From General Anesthesia
- Mechanical Ventilation
- Ventilator Liberation
- Ambulation
- Prophylaxis
- Nutrition
- Glucose
- Drains

Surgical Complications
- Hemorrhage
- Anastomotic Leak
- Abdominal Compartment Syndrome
- Necrotizing Soft Tissue Infection/Wound Complications
- Pulmonary Embolism
- Acute Coronary Syndrome
- Acute Kidney Insufficiency
- Chronic Critical Illness

Specific Surgical Specialty Operations
- Noncardiac Thoracic Surgery Care
- Vascular Surgery
- Abdominal Surgery
- Abdominal Organ Transplantation
- Trauma

General Principles

Admission Criteria

A predictable number of patients (15%) undergoing elective, urgent, or emergent surgical procedures can be expected to require care in an intensive care unit (ICU).[1] ICU beds should be reserved for patients with a reversible condition and reasonable prospect of substantial recovery and admission criteria should reflect this principle.[2] Established procedures, clinical judgment, and recognition of local resources and limitations should guide development and use of ICU admission criteria.[3,4]

Admission to an ICU is a decision that can be made by the surgeon and anesthesiologist in the preoperative phase in patients undergoing elective surgery. Elderly patients and/or those with significant comorbidities may require ICU admission for postoperative monitoring and care. The type of surgical procedure and the anticipated duration of surgery may also lead to a preoperative plan of ICU admission in the postoperative period. Patients undergoing liver transplantation or open abdominal aortic aneurysm repair, for example, traditionally require planned ICU admission for access to physicians and/or advanced care providers and bedside nurses unencumbered by other responsibilities. However, other patients may merely require more intensive bedside nursing that cannot be provided on a typical surgical ward. For example, this might include vascular surgery patients after distal arterial bypass for frequent neurovascular checks. In some settings, step-down units or extended-stay postanesthesia care units might be the appropriate setting to provide this care.

Patients, particularly after emergent operations, with unanticipated intraoperative complications, such as significant hemorrhage, shock, and respiratory failure, may also require ICU admission. Significant intraoperative hemorrhage may require ongoing blood product resuscitation and frequent analysis of complete blood cell counts, clotting factors, and lactic acid levels to monitor for continued hemorrhage. Patients in whom intraoperative shock develops require determination of etiology to guide therapy. Those with acute respiratory failure and/or inability to liberate from mechanical ventilation generally require ICU admission. These patients warrant examination and evaluation of radiologic data to evaluate for pneumothorax, hemothorax, lobe collapse, and/or malposition of the endotracheal tube. Obtaining an arterial blood gas (ABG) sample to determine hypercapnic versus hypoxic respiratory failure will afford appropriate ventilator adjustments. Measuring

intraabdominal compartment pressure and monitoring ventilator peak airway pressure may be key to evaluating those at risk for abdominal compartment syndrome.

Discharge Criteria

Patients admitted to ICUs should have constant evaluation and review of their clinical status to determine when such care is no longer necessary or beneficial. ICUs may benefit from a baseline set of objective criteria that can be used as a guide to determine which patients are ready for transfer (Table 34.1). These guidelines should be developed in concert with downstream units in consideration of available resources, particularly regarding nursing capability. Further, those who are deemed to no longer benefit from ICU care because of a deterioration in clinical status can also transfer.[3]

TABLE 34.1 Intensive Care Unit Discharge Criteria

Respiratory	
Stable oxygen requirement for 24 h (unchanged or improved)	Y/N
Acceptable ABG (or patient's baseline ABG)	Y/N
Adequate work of breathing	Y/N
On chronic but stable ventilator settings without need for frequent changes	Y/N
Sepsis	
Hemodynamic/respiratory system stable with fluid resuscitation completed	Y/N
Vasoactive infusions off (excluding a single (1) fixed-dose vasopressor)	Y/N
No evidence of end-organ hypoperfusion (lactate ≤2.5 mmol/L)	Y/N
Cardiovascular	
No ECG/cardiac enzyme evidence of active ischemia	Y/N
Stable hemodynamics with no chest pain	Y/N
Gastrointestinal	
No evidence of active GI bleed with hemostasis achieved and stable hemoglobin for 24 h	Y/N
Endocrine	
DKA resolved with: 1. HCO_3^- ≥18 mg/dL for two consecutive electrolyte panels at least 4 h apart 2. No evidence of anion gap acidosis 3. Blood glucose levels stabilized without insulin drip 4. Not requiring frequent electrolyte replacement	Y/N
Diabetes insipidus being managed with PO intake alone?	Y/N
Electrolytes normalized	Y/N
Neurologic	
Resolving neurologic status requiring less frequent neuro checks (≥every 4 h)	Y/N
No evidence of new focal deficit	Y/N
Surgical	
PACU recovery complete?	Y/N
Meets above criteria and fluid, respiratory, cardiac, and bleeding risks resolved, not requiring intense monitoring/intervention	Y/N

Structure and Staffing of Surgical ICU

Structure

ICUs are currently structured to have a designated geographic location in the hospital, specialized monitoring devices, and advanced therapeutic capabilities. Surgical ICUs (SICUs) can be general and admit patients from all surgical subspecialties, or they may be superspecialized (trauma, transplant, and cardiac). There are no compelling data to support the superiority of superspecialized surgical ICUs over general ones.

The basic ICU organizational structure of an open versus closed format is particularly germane in the care of a surgical patient. In an open ICU format the primary surgeon is responsible for patient care, order entry, and family communication. In a closed ICU format the patient's care is transferred to an intensivist who cares only for patients admitted to the ICU. There has been evidence that shows the benefit of decreased mortality and morbidity in the closed ICU format.[5,6] This would be particularly true in settings where a busy operative surgeon would have great difficulty responding rapidly to a patient with an emergency in the ICU. On the other hand, most surgical ICU patients are admitted in an elective fashion, so the ICU team should be fully cognizant of surgeon preferences, care paradigms, and desire for communication. In practicality, even in fully closed ICUs, the operative surgeon must be notified of patient status as recognition of and therapy for specific issues might require further surgery.

Whether in an open, closed, or hybrid ICU, a multidisciplinary team approach led by an intensivist is best practice to care for the critically ill patient. This team includes the critical care physician, nurse, registered dietician, pharmacy, physical therapist, respiratory therapist, and social worker. Multidisciplinary ICU teams optimally use extensively researched evidence-based guidelines to develop institutional protocols and guidelines. For example, guidelines for the management of sepsis, ventilator management, sedation, nutrition, and bedside ultrasound have improved patient outcomes and care.[7,8] Additionally, SICU teams benefit from the use of checklists and bundles of care. Checklists ensure that important aspects of critically ill patients care are addressed daily. Use of checklists to review daily goals dramatically improves understanding of the plan and may decrease the ICU length of stay.[9] Bundling evidence-based care practices in a more easily remembered format allows ICU teams to provide and keep up with the most up-to-date critical care practices. Bundles addressing ventilator-associated events, central line bloodstream infections, catheter-associated urinary tract infections, pressure ulcer prevention, and sepsis management have been shown to improve patient outcomes.[10]

Staff

The ICU provides close monitoring and care of patients by experienced physicians, nurses, respiratory therapists, dieticians, pharmacists, social workers, and other ancillary staff. The appropriate intensivist/patient ratio should be 1 intensivist to 14 patients to complete rounds in a timely fashion and provide high-quality patient care and education of trainees.[11] ICU nurse/patient ratios range from 1:3 to 2:1, depending on the complexity of the patients and interventions they require such as extracorporeal membrane oxygenation, continuous renal replacement therapy, and prone positioning. Nurse practitioners, physician assistants, dieticians, pharmacists, respiratory therapists, and physical therapists dedicated to the ICU improve compliance with evidence-based care and patient outcomes.[12–15]

Ideally, the ICU should be covered 24/7 with an attending intensivist. Several studies show that a 24/7 intensivist model improves morbidity and resource utilization but does not improve mortality.[16,17] This is particularly true in academic institutions with fellow coverage. Community and nonacademic ICUs may see a decrease in mortality with a 24/7 staffing model.

Intraoperative History

Efficient and effective communication among the surgeon, anesthesiologist, and intensivist should occur routinely after surgery. Studies have shown that postoperative handovers are typically informal, brief, and often incomplete.[18] Incomplete transfer of patient information between the teams can lead to medical errors and patient harm.[19] Using standardized checklists for patient handover from the operating room (OR) to the ICU improves quantity and quality of transmitted medical information[20] (Fig. 34.1).

During the transfer of the patient from the OR and/or postanesthesia care unit, a detailed sign-out to the ICU physician, nurse, and respiratory therapist should be conducted. This should commence with a discussion of the patient's past medical/surgical history, medications, allergies, and comorbidities. A detailed description of the surgical procedure, patient positioning, unexpected events, and anticipated course should occur. The patient's airway (standard vs. difficult requiring advanced intubation techniques), type of endotracheal tube used and/or currently in place, and the intraoperative mechanical ventilation settings, unexpected ventilator changes, ABG results, and patient current oxygenation requirement should be conveyed to the ICU team. The patient's estimated blood loss, quantity of intravenous fluid, number of blood products transfused, vasopressor use, and urine output should be strictly recorded and discussed with the ICU team. The insertion of invasive monitoring/resuscitation lines, transesophageal echocardiography, urinary catheter, enteric tubes, and postsurgical drains should be communicated to the ICU team. Intraoperative and postoperative medications, including antibiotics, analgesia, antiemetics, steroids, and the patient's home medications, require acknowledgment.

Certain preoperative medications should be continued in the perioperative period. Glucocorticoids should be administered at the traditional preoperative dose, without a need for superphysiologic "stress" dosing.[21] The use of unnecessary high-dose glucocorticoids can lead to hyperglycemia, increased risk of infection, and wound complications. Patients taking β-blockers should continue their preoperative regimen in the postoperative period if hemodynamically stable.[22] Other antihypertension medications such as calcium channel blockers, diuretics, and angiotensin-converting enzyme inhibitors should be held until the patient is observed to be hemodynamically stable postoperatively. Antiseizure medications, bronchodilators, and thyroid replacement therapy should be given preoperatively and continued in the postoperative period. Long-acting hyperglycemia medications such as lantus insulin, metformin, and glyburide should be withheld until the patient is stable in the postoperative period and can tolerate a consistent, uninterrupted diet to prevent episodes of hypoglycemia.

Best Practices: General Postoperative Care

Pain, Agitation, and Delirium

Most ICU patients who require mechanical ventilation benefit from pain control, light sedation, early mobility, and screening/treatment of delirium. The use of a narcotic analgesic as a first-line

agent for the treatment of pain and agitation should be attempted. Fentanyl is typically the narcotic of choice in mechanically ventilated patients because of its excellent analgesia properties, rapid onset and short duration of effect, and lack of active metabolites during its metabolism. The use of nonopioid pain medications such as ketamine, acetaminophen, and gabapentin may lead to decreased opioid use in perioperative SICU patients.[23–25] When sedative medications are required for discomfort and agitation, the choice of agent should be easy to titrate, be of rapid onset and short-acting, and have a low incidence of hemodynamic instability and depressed respiratory drive. Historically, propofol and benzodiazepines have been used for sedation. However, benzodiazepines have also been shown to increase the incidence of delirium and ventilator time and propofol may be associated with a syndrome of acidosis and cardiac instability that may be greater in young patients.[26] An alternative sedative to consider is dexmedetomidine, an α_2-adrenoreceptor agonist with analgesic and sedative properties. Compared with the use of benzodiazepines, dexmedetomidine may decrease episodes of delirium and decreased duration of mechanical ventilation.[27,28] Patients may also be treated with dexmedetomidine after liberation from mechanical ventilation to improve sleep hygiene and prevent delirium in the ICU.[29] Patients who are treated with dexmedetomidine should be closely monitored for hypotension and bradycardia.

ICU patients who require significant analgesia and/or sedation owing to significant surgery or injury should be monitored and treated with analgesia and sedation scores. Analgesia and sedation scores provide a universal numerical score that allows communication between the multidisciplinary teams caring for these critically ill patients. The Richmond Agitation-Sedation Scale (RASS) allows the physicians to communicate in a universal language with team members the goal and actual sedation level of ICU patients[30] (Table 34.2). The Critical Care Pain Observation Tool uses facial expression, body movements, muscle tension, and compliance with the ventilator to develop a pain level score that allows the multidisciplinary team to know if the current analgesia plan is effective or needs to be altered. The Confusion Assessment Method for the ICU (CAM-ICU) can be used to monitor ICU patients for delirium, which is common in critically ill patients owing to their underlying illness, surgical history, and medications used for analgesia and sedation. With reduction in the targeted level of sedation and lightened RASS scores, assessment with the CAM-ICU leads to decreased burden of delirium, duration of mechanical ventilation, and decreased duration of ICU and hospital stay.[30,31] Updated ICU analgesia, sedation, and delirium protocols using RASS and CAM-ICU documentation result in decreased benzodiazepine dose, delirium, and duration of mechanical ventilation, ICU, and hospital stay.[32]

ICU-acquired dependence, possible addiction, and withdrawal should be a focus of ICU physicians when caring for patients requiring opioids. Patients in the ICU receiving opioids for more than 7 days may develop significant dependence, risk for withdrawal, and signs/symptoms similar to opioid-addicted patients' withdrawal when the opioids are discontinued.[33] The use of multimodality analgesia (α_2-antagonists, acetaminophen, nonsteroidal antiinflammatory drugs, and slow weaning of opioids in the ICU patient should be used to prevent withdrawal/dependence.[34] Currently there is no evidence that ICU opioid use leads to outpatient opioid use, but more investigation is needed.[35] In addition to the possibility of dependence and addiction, opioid analgesia produces side effects of somnolence, depressed respiratory effort, vomiting, and ileus. The use of neuraxial and peripheral nerve blocks can achieve adequate pain control, improve outcomes, and decrease the amount of opioid use and its side effects.[36,37]

TABLE 34.2 Richmond Agitation-Sedation Scale

Score	Term	Description
+4	Combative	Overtly combative and violent; danger to staff
+3	Very agitated	Pulls on/removes tubes or catheters; aggressive toward staff
+2	Agitated	Frequent nonpurposeful movement; patient-ventilator dyssynchrony
+1	Restless	Anxious or apprehensive but without aggressive vigorous movements
0	Alert and calm	
–1	Drowsy	Not fully alert but with >10-second awakening with eye contact
–2	Light sedation	<10-second awakening with eye contact to voice
–3	Moderate sedation	Any movement but without eye contact to voice
–4	Deep sedation	No response to voice but movement with physical stimulation
–5	Unarousable	No response to voice or physical stimulation

Recovery From General Anesthesia

Approximately one-third of patients admitted to the SICU require mechanical ventilation,[38] exposing them to the effects of medications administered for analgesia and sedation. Inadequate sedation can lead to patient-ventilator asynchrony, patient agitation/discomfort, and self-extubation. Excess sedation can lead to longer duration of mechanical ventilation, longer ICU/hospital length of stay, and increased risk of delirium.[39,40] Patients requiring sedation may benefit from sedation holidays, Spontaneous Awakening Trials (SAT) and the pairing of these with ventilator liberation protocols, Spontaneous Breathing Trials (SBT).[41,42] Daily multidisciplinary rounds and/or standardized ICU protocols should be used to identify patients eligible for sedation holidays or administration of light or no sedation. Patients to be excluded from SAT include those with active neurologic pathology (i.e., active seizures, ethanol withdrawal, or intracranial hypertension) and severe respiratory failure with no plan to wean the ventilator and extubate. SATs have resulted in decreased sedation and increased RASS scores.[43]

Postoperative patients admitted to the ICU may have hypothermia, or core temperature less than 36°C. Hypothermia in postsurgical patients can result in coagulopathy and consequent hemorrhage. Patients with mild hypothermia (32°C–36°C) can undergo passive external rewarming with coverage with warm

blankets and increasing the temperature of the ICU room. Moderate hypothermia (28°C–32°C) in patients should be treated with active external rewarming with forced-air warming systems, heated blankets, and radiant heat. For severe hypothermia (<28°C), active core rewarming with intravenous warmed crystalloid and blood products, warm fluid irrigation into the pleural/peritoneal cavity, and/or endovascular warming devices should be used. In the OR most patients are treated with a combination of forced-air warming, intravenous fluid warmers, and increased temperature of the OR.

An assessment of volume status should be undertaken by reviewing the anesthesia records for fluids/blood products given, estimated blood loss, duration of surgery, and urine output. The use of isotonic crystalloid (0.9% normal saline solution, or balanced solutions such as lactated Ringer solution and Plasma-Lyte [Baxter Healthcare, Deerfield, IL]) should be used in increments of 500 to 1000 mL for depleted volume status in the absence of anemia and hemorrhage. Isotonic crystalloid bolus should be used until the patient's mean arterial pressure is more than 65 mm Hg, urine output is 0.5 mg/kg per hour, and perfusion of vital organs is demonstrated by normalization of serum lactic acid. The use of focused echocardiography in the ICU may be used to monitor resuscitation efforts versus the use of invasive monitoring devices.[44] Once the patient has been determined to achieve adequate resuscitation, the patient should be transitioned to a maintenance fluid of 0.45% normal saline solution with 5% dextrose to prevent catabolism.

Mechanical Ventilation

Postoperative patients admitted to the ICU may be mechanically ventilated or develop de novo acute respiratory failure. If the latter is true, the first step is to establish a patent and protected airway. This may not necessarily entail endotracheal intubation; a nasopharyngeal or oropharyngeal airway may suffice. Physical examination, bedside ultrasound, chest radiograph, ABG, and other laboratory values should be obtained immediately in both groups. For patients admitted to the ICU without an endotracheal tube, diagnostic studies may discover a pneumothorax, pleural effusion, or pulmonary edema that can be managed acutely and prevent intubation and mechanical ventilation. Inadequate awakening or rebound from general anesthesia may also be identified and treated.

Mechanical ventilation is typically set at respiratory rate (RR) of 12 to 16 breaths/min, positive end-expiratory pressure (PEEP) of 5 cm H_2O, and fraction of inspired oxygen (F_{IO_2}) of 1.0, unless more modest settings have been used successfully in the OR. To prevent the development of barotrauma and worsening lung injury, tidal volumes of 6 mL/kg are appropriate.[45] Frequent monitoring of ABG and oxygen saturation of arterial blood (Sa_{O_2}) should be used to wean F_{IO_2} below 0.4 to prevent oxygen toxicity. If the patient is still under the effect of general anesthesia and is not overbreathing the ventilator, it generally does not matter which mode of ventilation is selected. Intermittent mandatory ventilation, with or without pressure support, is used more frequently in surgical than in medical ICU patients as patients emerge from general anesthesia. Once fully awakened and physiologically stable, rapid assessment of readiness for extubation is appropriate. Unlike with patients in the medical ICU, it might be entirely appropriate to extubate those in the SICU without a trial SBT period, much as in the OR—once awake and able to lift the head as a gauge of strength.

Adult respiratory distress syndrome (ARDS) is defined by acute onset hypoxemia, bilateral infiltrates on CXR and absence of left heart failure. Common causes of ARDS include sepsis, trauma, aspiration event and inhalation injuries, all of which are common in patients admitted to the ICU postoperatively. ARDS is categorized as mild (partial pressure of arterial oxygen [Pa_{O_2})]/F_{IO_2} ratio <300), moderate (<200), and severe (<100).[46] The gold standard for managing ARDS with conventional ventilator mode settings is with low tidal volume (6 mL/kg) to decrease the incidence of ventilator-associated barotrauma.[47] However, most data from ARDS studies have been acquired in patients in medical ICUs. Surgical patients may be at a greater risk for damage from atelectasis, and those with large abdominal incisions and packing may require use of higher tidal volumes. Measurement of transpulmonary pressure through esophageal monitoring may be of benefit.[48] Other therapies may be added in patients with ARDS who continue to have significant hypoxia while using low-tidal ventilation. Prone positioning therapy and sedation with short-term neuromuscular blockade have both been shown to decrease mortality in ARDS patients.[49,50] Prone positioning can be used in surgical patients with so-called open abdomens and spine immobilization, although greater care is required. Other ventilator strategies such as high levels of PEEP, inversed inspiratory/expiratory (I:E) ratio, high-frequency oscillator ventilation, and airway pressure release ventilation (APRV) can be considered. These rescue modes use different methods to achieve the same goal of increasing mean airway pressure while preventing increased peak airway pressures. APRV uses a very high I:E ratio and short pressure release time, allowing the buildup of intrinsic PEEP and the use of spontaneous breathing. Studies have shown APRV to be at least equivalent to low–tidal volume ventilation in safety and outcomes in SICU patients.[51–53] Extracorporeal membrane oxygenation can be used as a last resort in the management of ARDS and has shown some promise in improving mortality in ARDS; however, the risk of postoperative bleeding must be considered.[54]

Ventilator Liberation

In postoperative ICU patients with improved/resolved hypoxia, hemodynamic stability, and no neurologic pathology, who have been ventilated for several days, formal assessment for the readiness to be extubated is appropriate. SBTs are performed during spontaneous breathing with or without low pressure support (<5 mm Hg). SBTs are typically 30 minutes in duration and include close monitoring for tachypnea, hypoxia, hypercapnia, distress, and other signs of respiratory distress. A rapid shallow breathing index (RSBI), which is the tidal volume/respiratory rate, is the one proven numerical parameter to predict successful extubation during an SBT. A rapid shallow breathing index below 105 is predictive of a successful and sustained extubation.[55] Standardized weaning protocols in ICUs reduce the duration of mechanical ventilation, weaning duration, and ICU length of stay.[56]

Ambulation

ICU-acquired weakness and neuropsychiatric disease (delirium) are long-term complications of critical illness. Immobilization, analgesia, sedation, and physiologic stress from critical illness may contribute to these complications. ICU care that minimizes sedation and encourages early mobilization of mechanically ventilated patients early to the course of a patient's critical illness can result in improved patient outcome, including ICU and hospital length of stay.[57–60]

Prophylaxis

Stress gastrointestinal bleeding in ICU patients may occur as a result of impaired mucosal barrier protection. Risk factors for stress ulcer bleeding in ICU patients include 48 hours of mechanical ventilation and coagulopathy. In these high-risk patients proton pump inhibitor or histamine-2–blocker therapy should be started to decrease the incidence of gastrointestinal bleeding. Patients receiving enteral nutrition may not require additional stress ulcer prophylaxis.[61]

The postoperative SICU patient is at high risk for venous thromboembolism (VTE) via the Virchow triad of stasis, endothelial injury and hypercoagulability. VTE is a common cause of morbidity and mortality in postoperative critically ill patients. The incidence can range from 10% in low-risk patients to 80% in high-risk patients such as those with multitrauma. The Caprini score is a point-based system used to quantify VTE risk, and it is recommended that perioperative patients with a score greater than or equal to 7 should receive chemical prophylaxis[62,63] (Table 34.3). Mechanical prophylaxis for VTE includes intermittent compression devices that are used independently in low-risk patients and in concert with chemical prophylaxis in high-risk patients.[64] ICU patients at high risk for VTE, including multitrauma and major surgery patients, should receive low–molecular-weight heparin (LMWH).[65] Unfractionated heparin (UFH) should be used in moderate risk ICU patients for VTE prophylaxis. Even for ICU patients at high risk of bleeding there may be a benefit of early chemical VTE prophylaxis without increased risk of bleeding complications.[66]

Stopping anticoagulation during the perioperative period may increase thromboembolic risk, whereas initiating or continuing anticoagulation increases the risk of hemorrhage with surgical procedures. The risks of thromboembolic events, hemorrhage, and the specific medication used must be taken into account when determining stop and start times of anticoagulation in surgical patients.[67] Patients receiving anticoagulation for major risk factors such as prosthetic cardiac valves and recent venous and/or arterial thromboembolism should have medication withheld for as short a time as possible. Resumption of anticoagulation can occur once hemostasis has been achieved in postoperative patients. Warfarin typically is resumed within 12 to 24 hours after surgery; if the patient is tolerating an oral diet, hemostasis is achieved and no further planned procedures are planned.[68] Warfarin is resumed at the preoperative dose and may require 5 to 10 days to reach therapeutic levels. Because of this, patients at high risk of thromboembolic events should be treated with bridging LMWH or UFH until the international normalized ratio becomes therapeutic. Direct oral anticoagulants (DOACs) are a relatively new generation of anticoagulants that include a direct thrombin inhibitor (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban). DOACs have rapid onset of action and do not require bridging anticoagulation with LMWH and UFH. Because of the rapid onset of action, resumption of DOAC therapy is delayed for 2 to 3 days after adequate hemostasis is achieved in postoperative patients. Although expensive, agents to reverse DOAC action now are available.

Ventilator-associated pneumonia (VAP) is a hospital-acquired infection that develops in 10% of mechanically ventilated patients after 48 to 72 hours of endotracheal intubation.[69] VAP prevention is achieved through routine ICU hygiene practices and several special approaches and techniques. Noninvasive positive-pressure ventilation can be used in select patients who have an easily treated cause of their respiratory failure and can maintain adequate protection of their airway. Prevention of VAP also includes the routine use of SAT and SBT with extubation as soon as feasible,[70] early mobility, and head of bed elevation to 30 to 45 degrees.[70] Subglottic secretion drainage ports should be used for patients who require intubation longer than 48 hours.[70] Oral care with chlorhexidine, oral/digestive decontamination, and prophylactic probiotics are

special approaches that have been shown to reduce VAP.[70] Critically ill patients who require emergent intubation in the prehospital setting or emergency department have higher risks of VAP.[71,72] While these critically ill patients are in the emergency department, they should undergo VAP preventive measures such as chlorhexidine oral care, subglottic secretion drainage, and head of bed elevation to 30 degrees if feasible. In centers with high rates of VAP in SICU patients, the use of silver-coated endotracheal tubes should be considered.

Nutrition

Critically ill patients are in a catabolic stress state and malnutrition leads to worse outcome. Well-nourished patients can be managed without supplemental nutrition for a week or so if critical illness or features of the surgical procedure prevent its use. In other patients, early enteral nutrition results in decreased morbidity, mortality, and ICU costs.[73] ICU patients require 25 to 30 kcal/kg per day and 1.2 to 2.5 g/kg per day of protein based on ideal body weight. In most patients, enteral nutrition can be begun within 24 to 48 hours of ICU admission and critical illness. Initiating nutrition that delivers 8 to 10 kcal/kg per day within 7 days is optimal.[74] Early initiation of enteral nutrition in critically ill postoperative patients can be considered in those managed with an open abdomen, frequent trips to the OR, and a stable dose of vasopressor therapy.[75–77]

Provision of enteral nutrition in the critically ill patient may require placement of an oral or nasal gastric tube. Gastrically placed tubes with continuous feeding is typical as postpyloric enteral nutrition does not necessarily lower rates of aspiration or improve food tolerance.[78] The risk of aspiration can be decreased by elevating the head of bed 35 to 40 degrees and use of continuous infusion and prokinetic agents. Frequent checking of gastric residuals should not be part of routine care in patients receiving enteral nutrition. Evaluating patients for abdominal distention, nausea, and worsening abdominal pain should be used to assess the patient's tolerance of gastric feeds. If gastric residuals are checked, then volumes of 500 mL or less should not prompt stopping enteral nutrition.[79,80] Patients at high risk for aspiration may benefit from postpyloric enteral access.[79]

Parenteral nutrition may be required in critically ill patients who are not tolerating enteral nutrition, with intolerance expected to last at least 7 days. Historically, parenteral nutrition has been found to have complications associated with central venous access placement, infectious complications, and hyperglycemia. The current literature supports the use of parenteral nutrition in patients unable to tolerate enteral nutrition. Patients receiving parenteral compared to enteral nutrition may have similar infection rates, complications, lengths of stay, and mortality if assiduous care is taken to avoid central line infections.[81,82]

Providing adequate nutrition has been shown to improve outcomes in patients with severe acute pancreatitis. The use of enteral nutrition in these patients is safe and decreases mortality, hospital length of stay, and systemic infections.[83]

Glucose

Hyperglycemia in the perioperative patient admitted to the ICU may be due to a history of diabetes, stress response to critical illness, nutritional therapy, and/or sepsis. Hyperglycemia in this patient population has been shown to increase mortality and risk of wound and infectious complications. The use of subcutaneous or intravenous continuous insulin therapy with a target glucose level of less than 180 mg/dL leads to decreased perioperative complications and fewer episodes of hypoglycemia[84] compared with more aggressive targets.

Drains

Prophylactic drains are placed postoperatively to monitor bleeding and anastomotic leak (AL) and to decrease the accumulation of soft tissue edema. Drains also may be useful to decrease intra-abdominal pressure from ascites and to detect bile leaks after liver resection.[85] In general, drains used to monitor bleeding should be removed 1 to 2 days after surgery when the risk of bleeding has decreased. Drains placed to monitor ALs leaks are typically removed within 3 to 5 days of the operation or after adequate enteral nutrition is initiated. Drains left in place to decrease postoperative edema and seroma formation are often left for longer durations. The SICU team should closely monitor the volume of drain output, the appearance of the drain output, and any acute changes in the output. Surgical drains have their own complications, including intraabdominal and wound infections, increased abdominal pain, decreased pulmonary function, and bowel injury.[86,87]

Surgical Complications

Hemorrhage

Perioperative hemorrhage after elective, emergent, or urgent procedures is a frequent cause for or feature of ICU admission. Persistent postoperative hypotension is most commonly due to bleeding and the ICU team should be scrupulous about surveillance. Rapid identification and appropriate management of perioperative hemorrhage can prevent shock and multisystem organ failure. It is ideal to diagnose hemorrhage before hypotension develops.[88] The use of hemodynamic monitoring, physical examination, and monitoring laboratory values such as hemoglobin and lactate are useful clues to identify hemorrhage.

Before most operations that warrant ICU admission, baseline laboratory values such as hemoglobin, hematocrit, coagulation panel, and blood type and cross-match should be available for the patient.[89] Perioperative communication among the surgeon, anesthesiologist, and critical care team should be ongoing during the surgery and during transition to the ICU to manage operative hemorrhage. If significant and major bleeding occurs perioperatively, transfusing patients with a high ratio of plasma to platelets to red blood cells leads to improved survival, decreased hemorrhage, and improved hemostasis.[90,91] In ICU patients when blood products are not readily available, resuscitation with isotonic crystalloids with a goal of mean arterial pressure (MAP) above 65 mm Hg and normalization of lactic acid. Avoidance of excess infusion of crystalloid in patients with hemorrhage compared with transfusion of blood products is also beneficial.[92] In patients with hypovolemic shock caused by sepsis, trauma, or following surgery the use of colloid versus crystalloid resuscitation shows no difference in mortality or renal failure.[93,94] Colloids are more expensive and some (hydroxyethyl starches) may increase the risk of death or acute kidney injury; we therefore preferentially use crystalloid for resuscitation.

Careful inspection of the surgical field before closure is the best method for prevention of postoperative hemorrhage. In the postoperative phase, the patient should be monitored for signs of hemorrhage: tachycardia, shock, oliguria, altered mental status, and increasing surgical site pain and distention. Patients with

hemodynamic instability and signs of hemorrhage should have immediate surgical reexploration. Postoperative ICU patients with progressive anemia but hemodynamic stability may be managed more conservatively. Conservative management includes ICU monitoring of hemodynamics, hemoglobin, and urine output with transfusions as necessary. Patients with intraluminal sources of hemorrhage may be treated with endoscopic and endovascular techniques to stop the bleeding. Extraluminal sources of bleeding may be treated with angioembolization.

Anastomotic Leak

Anastomotic leak (AL) is one of the most devastating surgical complications resulting in significant morbidity and mortality. AL occurs in 3% to 21% of patients with an associated mortality of 3T to 22%.[95–97] The wide variation in the rates of AL may be due to the presentation of early and dramatic leaks versus late and subtle leaks. Historically, AL occurs by postoperative day 5, but studies have shown mean days to AL of 12 days.[96] Postoperative patients may present with signs of AL with fever, elevated white blood cell count (WBC), tachycardia, hypotension and enteric contents in the perianastomotic drain. The diagnosis of AL may be difficult with relevant studies showing low sensitivity. Computed tomography (CT) scanning with oral contrast has a sensitivity of 50% in diagnosing AL, contrast swallow 21%, and 14.4% via perianastomotic drain examination.[98] CT scanning with oral contrast may be the modality of choice for assisting in the diagnosis of AL, because it also allows for the detection of associated pathology such as intraabdominal abscess.[99] Endoscopy may be more sensitive and is used to diagnose ALs in critically ill patients.[99]

Typically the management of AL has been surgical, with revision of the anastomosis, diversion, and wide local drainage. However, in hemodynamically stable patients, small ALs may be managed with intravenous antibiotics, percutaneous drainage, and close monitoring.[96,97] Patients who are able to undergo nonoperative management are typically diagnosed late in the postoperative course because of a more indolent presentation of the AL.[97] Further, minimally invasive management using endoscopically deployed stents may be possible.[100] Surgical management should be used for patients in septic shock and with generalized peritonitis.

Abdominal Compartment Syndrome

Intraabdominal hypertension (IAH) is defined as intraabdominal pressure (IAP) greater than 12 mm Hg. Abdominal compartment syndrome (ACS) is defined as IAP greater than 20 mm Hg with new and/or worsening end-organ dysfunction.[101] Intraabdominal pressures are measured via the bladder pressure. Measurement of bladder pressure steps include placement of 50 mL of saline solution into the bladder via the Foley catheter and clamping the catheter, and insertion of a needle attached to the manometer into the collecting port of the Foley catheter tubing, where the patient lying flat the pubis symphysis is the zero mark. Alternatively, ACS may be defined by an abdominal perfusion pressure (APP). APP is the difference between MAP and IAP. A target goal APP of more than 60 mm Hg has been shown to improve outcomes in patients with IAH/ACS. Hypotensive patients with some level of IAH/ACS may have even more decreased perfusion of abdominal viscera. ACS can be caused by severe abdominal trauma, intraabdominal and retroperitoneal hemorrhage, and excessive crystalloid and blood product administration. Diminished abdominal wall compliance after abdominal wall reconstruction, deep burns to the abdominal wall, and elevated body mass index increase the risk for ACS.

In addition to elevated IAP, patients with ACS will present with a tense and distended abdomen on physical examination. There may be an increased peak airway pressure and/or decreased tidal volumes on mechanical ventilation. Patients with ACS may develop oliguria, elevated serum creatinine, and elevated serum potassium. ACS may also lead to shock and decreased cardiac output owing to caval compression.

Patients with abdominal hypertension or early ACS without physiologic compromise may be managed nonsurgically. This approach involves decreasing the resuscitation volume and administration of sedation and neuromuscular blockade. If ACS is secondary to a large volume of intraabdominal ascites, various catheters can be used for percutaneous drainage. The standard approach to the treatment of ACS is through surgical decompression of the abdomen via celiotomy.[101,102] After celiotomy, a temporary negative-pressure dressing may be placed, but ACP may still develop in these patients who should be closely monitored.

Necrotizing Soft Tissue Infection/Wound Complications

Necrotizing soft tissue infection (NSTI) may occur at a recent surgical site or from a primary infection. NSTI is an aggressive infection that may involve the skin, subcutaneous tissues, fascia, and/or muscles. NSTI causes extensive morbidity and mortality rates of 25% to 35%.[103] Postoperative patients in whom fever, cellulitis, and surgical site drainage develops should be assessed for NSTI. NSTI may be difficult to diagnose early and differentiate from other soft tissue infections. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score is a point system of laboratory values developed to assist with the diagnosis of NSTI (Table 34.4). An LRINEC score of 6 or greater has a positive predictive value of 92%; a score of less than 6 has a negative predictive value of 96%.[104] Radiographs and CT scans may show NSTI by visualizing soft tissue gas with or without an associated abscess. CT scanning has been shown to be more sensitive than conventional radiology and should be used in patients in stable condition with any question of the diagnosis.[105] These infections are caused most commonly by group A *Streptococcus*, *Clostridium perfringens,* and polymicrobial bacteria that include methicillin-resistant *Staphylococcal aureus*. During the evaluation of a patient for possible NSTI, if there is any question of the diagnosis, management requires surgical exploration of the soft tissue site in question.

Treatment of these infections requires, prompt surgical debridement, administration of broad-spectrum antibiotics, isotonic crystalloid resuscitation with an initial bolus of 30 mL/kg to achieve an MAP above 65 mm Hg, lactate level normalization, and supportive care in the ICU.[7] Early operative debridement is a major determining factor in the outcomes of these patients. The operative debridement should be aggressive and may require limb amputation.[106] Once in the ICU these patients require significant supportive care, including analgesia and dressing changes. NSTI patients will require multiple trips to the operating room for aggressive debridement.

Surgical site infections (SSIs) consist of superficial infections (skin and subcutaneous tissue) and deep infections (fascia and muscle). Patients are at high risk of developing SSIs during emergency surgery with colon injury, perioperative hypothermia, and after receiving large-volume blood transfusions perioperatively.[107] SSIs are typically caused by normal skin flora such as *S. aureus* or by common enteric

TABLE 34.4 LRINEC Score

Variable	Value	Score
C-reactive protein (mg/L)	≥150	4
White blood cell count (10,000/uL)	<15	0
	15–25	1
	>25	2
Hemoglobin (g/dL)	>13.5	0
	11–13.5	1
	<11	2
Sodium (mmol/L)	<135	2
Creatinine	<1.6 mg/dL	0
	>1.6 mg/dL	2
Glucose	≤180 mg/dL	0
	>180 mg/dL	1

From Wong CH, Khin LW, Heng KS, et al. The LRINEC (Laboratory Risk Indicator for Necrotizing Fasciitis) score: a tool for distinguishing necrotizing fasciitis from other soft tissue infections. *Crit Care Med.* 2004;32:1535–1541.

organisms such as *Enterococcus* strains and *Escherichia coli*. Administering perioperative antibiotics for 24 hours to target common bacterial pathogens decreases the rates of SSIs. SSIs are diagnosed by physical examination targeted at identifying cellulitis, swelling, and purulent drainage from the surgical wound. Treatment consists of intravenous antibiotics, opening of the surgical wound, and possible debridement in the operating room. Fascial dehiscence is a surgical complication that often occurs along with SSIs and perioperative intraabdominal infections. Patients in whom fascial dehiscence develops must undergo repeat surgical exploration, evaluation for underlying surgical infection, and reclosure of the fascia.

Enterocutaneous fistulas may result from inflammatory bowel disease or as a complication of a surgical procedure and can result in significant morbidity and mortality (7%).[108] In patients in whom the abdomen has been left open as part of a damage control operation, the fistulas may communicate directly with the environment, so-called enteroatmospheric fistulas.[109] The management of fistulas must address the presence of an intraabdominal collection, including abscess, and control of accompanying systemic signs of sepsis. Further, high-output fistulas (>500 mL/day) may require electrolyte correction and rehydration with isotonic crystalloids.[109] Nutritional support typically uses parenteral nutrition to afford closure of the fistula. In select patients with distal, low-output (<200 mL/day) fistulas, the use of enteric nutrition may be appropriate. Local wound care and negative-pressure dressings are used to protect the skin and control the fistula effluent. Octreotide may decrease the volume of effluent from a high-output fistula but generally will not assist in its closure, particularly in the presence of factors hostile to healing—foreign bodies, previous radiation, active infection, epithelialization, neoplasm, and obstruction distal to the fistula.[108]

Pulmonary Embolism

Pulmonary embolism (PE) is the obstruction of the pulmonary artery by thrombus, air, or fat. PE leads to significant morbidity with a 30-day mortality of 3.9% and a 1 year rate of 9.2%.[110] Patients in the SICU are at high risk of PE owing to recent major surgery, immobilization, trauma, and comorbidities such as obesity and tobacco use.[111] In a majority of patients with PE, the thrombus originates from iliac, femoral, and popliteal veins. Patients with PE can present with signs and symptoms of chest pain, shortness of breath, tachycardia, and symptoms of extremity deep vein thrombosis. PEs can lead to alterations in the ventilation-perfusion ratio and acute lung inflammation, resulting in hypoxia. Massive PE or PE in a patient already critically ill with compromise may cause significant hemodynamic instability. Hemodynamic compromise develops as the result of blockage of a main or major branch of the pulmonary artery with resultant increased pulmonary vascular resistance. This elevated pulmonary vascular resistance leads to right heart dilation. The right heart dilation compresses the left heart and leads to decreased preload and cardiac output.

Diagnostic modalities such as D-dimer testing and ventilation-perfusion scanning are not reliable or feasible in critically ill surgical patients. D-dimers are normally elevated in perioperative patients. CT pulmonary angiography is diagnostic in stable patients with concern for a PE.[112] Hemodynamically unstable patients should undergo bedside echocardiography to assess for right heart dilation and functional compromise. Once the diagnosis of PE is made, the treatment is therapeutic anticoagulation. Patients who have hypoxia and hypotension resulting from PE require supplemental oxygen, possible mechanical ventilation, resuscitation, and vasopressor treatment as needed. Hemodynamically unstable patients with PE should be considered for thrombolysis therapy or surgical versus endovascular embolectomy. In SICU patients with recent surgery, active hemorrhage, or intracranial hemorrhage, it may not be safe to consider anticoagulation or thrombolysis. These patients should undergo inferior vena cava filter placement to prevent additional PE and possible embolectomy.

Acute Coronary Syndrome

Critically ill patients are at high risk of myocardial injury/acute coronary syndrome after emergent surgery, long procedures with excessive blood loss, postoperative acute kidney insufficiency, and vasopressor administration.[113] Acute coronary syndrome in the SICU may not present typically (i.e., with substernal chest pain) owing to the administration of analgesia, mechanical ventilation, and other medications and support devices that may mask signs and symptoms. Critically ill patients may present with cardiac arrhythmias and unexplained shock without concomitant chest pain and dyspnea. Diagnosis of acute coronary syndrome requires an electrocardiogram, cardiac biomarker evaluation, and bedside echocardiography to evaluate kinetic and cardiac wall abnormalities. Treatment in SICU patients often requires the use of supplemental oxygen, pain control with narcotic analgesia, β-blockers for the prevention of ventricular arrhythmias, and statin therapy. The use of antiplatelet therapy and anticoagulation must be balanced with the patients risk for hemorrhage. A cardiologist should be consulted for percutaneous coronary diagnosis and intervention specifically for ST-elevation myocardial infarctions. A restrictive blood transfusion threshold may not be safe in the face of acute coronary syndrome.[114]

Acute Kidney Insufficiency

The development of acute kidney insufficiency (AKI) in the perioperative period can lead to increased morbidity and mortality. Older patients with ischemic heart disease and congestive heart failure who undergo emergency or high-risk surgery are at increased

risk of developing AKI.[115] AKI develops in 25% of SICU patients and leads to a threefold increase in hospital death.[116] The Risk, Injury, Failure, Loss, and End-Stage Kidney Disease (RIFLE), Acute Kidney Injury Network (AKIN), and Kidney Disease Improving Global Outcomes (KDIGO) criteria are three methodologies to classify the severity of renal failure.[117–119] Prerenal AKI in the SICU is typically caused by hypovolemia and often is the result of bleeding. Patients with impaired cardiac function and euvolemia/hypervolemia may also develop prerenal AKI. Acute tubular necrosis that leads to AKI is caused by hypovolemia, shock, and nephrotoxic agents. Evaluating serum and urine electrolytes and osmolality can be used to distinguish between these two types of AKI. Postrenal AKI is the result of obstruction to urine flow. The potential etiology of AKI in SICU patients includes damage to ureters and obstruction of urinary drainage, as seen when the urinary catheter is kinked or clotted.

Prevention of AKI in the SICU requires adequate volume repletion and maintaining MAP goals above 65 mm Hg. Other therapies, such as administration of bicarbonate, N-acetyl cysteine, colloid volume replacement, and dopamine, have not been shown to prevent AKI.[120–122] The initial treatment of patients with AKI is correction of severe electrolyte abnormalities and management of symptomatic volume overload. Patients with hyperkalemia should receive calcium to decrease cardiac irritability; insulin and bicarbonate both provide temporary correction. Renal replacement therapy and potassium binders provide more long-term correction of hyperkalemia; however, use of the latter may not be possible in the face of an ileus of fresh intestinal anastomosis or discontinuity of gastrointestinal tract. The use of diuretics has not been shown to prevent or improve AKI; however, they may assist with fluid balance.[123] Renal replacement therapy is indicated in ICU patients with severe fluid overload, hyperkalemia, uremic encephalopathy, and severe metabolic acidosis. Patients in the ICU may require continuous renal replacement therapy for severe hemodynamic instability and persistent metabolic acidosis; however, the data do not consistently show a benefit over intermittent or hybrid methods of dialysis.

Chronic Critical Illness

Most patients improve and return to baseline status after appropriate surgical care. Others have persistent critical illness, develop repeated bouts of sepsis, and continue to require mechanical ventilation and other forms of support. Patients with chronic critical illness have prolonged mechanical ventilation, profound weakness, neuroendocrine dysfunction, impaired anabolism, delirium, and skin breakdown.[124] Prolonged mechanical ventilation (PMV) has been defined as undergoing mechanical ventilation in the ICU for longer than 21 days.[125,126] Patients requiring PMV have higher mortality rates (40%), increased readmission rates, and increased total health care costs.[126] Patients who typically require PMV are older, sicker, and have more frequent diagnosis of pancreatitis, acute respiratory distress syndrome, pneumonia, and septic shock.[126]

Patients who survive chronic critical illness typically are functionally dependent owing to physical impairments, pain, and significant psychosocial issues.[124,127,128] A multidisciplinary approach to care is required for patients with chronic critical illness. Patients with PMV may be sent to centers that specialize in weaning from mechanical ventilation and rehabilitation. The most important role of the ICU in chronic critical illness is prevention by following protocols for decreased sedation, early mobility, and physical therapy.[58] Adequate nutrition and protein without underfeeding or overfeeding patients leads to decreased ICU complications, costs, and mortality.[129] Neurorehabilitation and close monitoring and treatment for posttraumatic stress disorder should be used in these patients. Frequent meetings between the ICU and surgical teams and the patient's family should occur to understand goals and define prognosis and expectations. Formal palliative care consults should be considered for patients with chronic critical illness to discuss achievable goals of treatment and alternatives to continued critical care.[130]

Specific Surgical Specialty Operations

Noncardiac Thoracic Surgery Care

Thoracic surgery cases requiring ICU admission postoperative include pulmonary resection, treatment of pleural disease (empyema, pneumothorax), diaphragm hernia repair, esophagectomy, and chest wall tumor resection. Many of these patients have pulmonary dysfunction and require pulmonary function testing to identify those at high risk for postoperative hypoxia and complications. Thoracic surgery patients are typically older, have cardiovascular comorbidities, are active smokers, and have chronic obstructive pulmonary disease.[131,132] Typical complications, as discussed earlier, are common and should be monitored for and treated accordingly. Patients may have prolonged ICU stays after thoracic surgery if there is difficulty controlling pain, and in the face of debility, cardiac arrhythmias and prolonged air leaks after pulmonary resection.[133]

Intravenous fluids are typically administered in reduced amounts to decrease the risk of postoperative respiratory distress and failure in patients after thoracic surgery. Patients who undergo pulmonary resection may be high risk for persistent hypoxia based on their pulmonary function test results and may require prolonged mechanical ventilation and oxygen therapy. High-flow nasal cannula can be used as an adjunct to prevent intubation in hypoxic thoracic surgery patients.[134] Prolonged air leak (>5 days) after pulmonary resection may lead to increased risk of pneumonia and empyema.[135] Most air leaks resolve on their own with continued tube thoracostomy, but patients with persistent air leak may require pleurodesis or reoperation to repair the lung parenchyma/bronchus leak. Atrial fibrillation is the most common cardiac-related complication after thoracic surgery. Because atrial fibrillation in this patient population is usually temporary and self-limiting, the initial treatment is with β-blockers or calcium channel blockers for rate control.[136] All patients who develop cardiac arrhythmias do require electrocardiogram and cardiac enzyme monitoring to evaluate for acute coronary syndrome. New-onset atrial fibrillation after esophagectomy may occur because of anastomotic leak and should prompt investigation, particularly if it occurs after the first 24 hours postoperatively.[137] Postoperative pain from thoracotomy is significant and can lead to noncompliance with chest physiotherapy and early mobility. The use of epidural catheters for this patient population can improve pain control and improve respiratory function and mobility.[138,139] Early postoperative mobility and chest physiotherapy is key to prevent atelectasis and pneumonia. With the development of minimally invasive thoracic surgery/video-assisted thoracoscopic surgery, thoracic surgery patients have decreased pain, early mobility, and decreased incidence of atrial fibrillation, pneumonia, and prolonged air leak.[140,141] Chest tubes that are placed after lung resection, pleurodesis, or any type of thoracic pleura violation are typically kept at −20-mm Hg wall suction for 24 to 48 hours; and if no persistent leak the chest tube is placed to water seal and removed if follow-up chest x-ray shows no significant pneumothorax or pleural effusion.

Vascular Surgery

Patients undergoing vascular surgical procedures for arterial disease have a high incidence of concomitant coronary artery disease; 50% to 70% of vascular surgery patients have ischemic heart disease and 30% to 50% have had a previous myocardial infarction.[142] Perioperative myocardial ischemia is the primary cause of death of patients after major vascular procedures.[143] Increased oxygen demand owing to the stress of surgery, pain, hypotension, and perioperative tachycardia in this high-risk group can lead to myocardial ischemia and plaque rupture.[144] Perioperative vascular surgery patients require adequate pain control, hemodynamic monitoring, and continuation of home doses of β-blocker and statins. Currently there are insufficient data to support initiating β-blocker therapy de novo. AKI is another significant complication of vascular surgery and leads to increased mortality rates of 60% to 80%.[145] AKI develops in vascular surgery patients as the result of preexisting renal disease, radiologic contrast administration, suprarenal aortic clamping, acute blood loss anemia, and vasopressor use. AKI treatment in these patients requires crystalloid resuscitation, blood product transfusion for anemia, and avoidance of nephrotoxic agents. Thoracotomy and celiotomy for aortic aneurysm repair puts patients at risk for PMV, pneumonia, and ARDS. These patients are best treated with low lung volume ventilation strategies. Vascular surgery patients undergoing celiotomy for aortic aneurysms are at risk for abdominal compartment syndrome and bowel ischemia. Postoperative persistent metabolic acidosis and shock is suggestive of bowel ischemia requiring CT scan, endoscopy, and surgical exploration for diagnosis. Neurovascular checks, blood and mucous per rectum, and severe abdominal pain with or without peritonitis are relevant features of the physical examination after major aortic procedures.

Abdominal Surgery

Patients who undergo abdominal surgery require critical care for continued resuscitation, monitoring, and management of sepsis, hemorrhage, and respiratory failure. Resuscitation entails administration of isotonic crystalloid and blood products to achieve adequate circulating volume, MAP above 65 mm Hg, urine output to 0.5 mL/kg per hour, and clearance of serum lactate levels. Recently there has been a shift away from invasive monitoring to achieve resuscitation goals to assessing volume responsiveness via noninvasive means, and to restricting crystalloid volume administration with consideration of earlier use of vasopressors.[146] In postoperative patients with tenuous enteric anastomoses, the use of vasopressor therapy may be ill advised.

Many ICU patients require close monitoring for sepsis owing to surgical site infection and AL after abdominal operations. Prophylactic intravenous antibiotics should be given for less than 24 hours to prevent surgical site infection. Patients in the ICU with intraabdominal sepsis require surgical source control and therapeutic intravenous antibiotics to prevent local and hematogenous spread. Most common organisms involved in intraabdominal sepsis are gram-negative species such as *E. coli* and gram-positive species such as *Enterococcus*. Patients most common begin a combination of vancomycin, extended-spectrum penicillins, metronidazole, and higher-generation cephalosporins with escalation or de-escalation based on culture results.[147] The recommended duration of intravenous antibiotics for intraabdominal infections with source control and associated bacteremia is 7 days.[148] Procalcitonin levels can be measured to guide the duration of antibiotics with cessation at procalcitonin levels of less than 0.5 ng/mL.[149]

Staged procedures in which the abdomen is left open and/or bowel is left in discontinuity after resection may be appropriate for those in extremis or too unstable for definitive surgery. After the initial procedure, patients require ICU resuscitation, metabolic corrections, administration of blood products for anemia and coagulopathy correction, and warming to achieve normothermia. After these goals are achieved, typically within 24 to 48 hours, the patient is returned to the operating room for a definitive procedure and possible celiotomy closure. Therapy after definitive surgical treatment requires prevention of ICU-related complications by early mobility and extubation, VTE prophylaxis, stress ulcer prophylaxis, and early enteral nutrition. Patients with an open abdomen who receive early enteral nutrition have better outcomes compared with those who have enteral nutrition delayed until abdominal closure.[75] After patients have definitive abdominal closure, they should undergo frequent measurements of abdominal compartment pressures and monitoring of urinary output and mechanical ventilation requirements to watch for ACS. Typically the skin and subcutaneous tissues remain open after fascia closure and are treated with serial dressing changes and negative-pressure wound therapy.

Abdominal Organ Transplantation

Patients undergoing liver transplantation require ICU admission because of long operative time, significant intraoperative and postoperative blood transfusion requirements, and postoperative respiratory failure. Those with renal failure may require renal replacement therapy. The use of fast-track extubation and other care protocols results in improved outcomes and decreased mortality.[150,151] Liver transplant patients frequently have postoperative hemorrhage owing to significant perioperative coagulopathy and thrombocytopenia. The correction of coagulopathy and thrombocytopenia should be achieved before reexploration if patients are hemodynamically stable and without ACS.

Early liver transplantation dysfunction may be diagnosed in the first few days after transplantation through elevated liver serum tests. Technical errors during surgery may lead to hepatic artery thrombosis, biliary duct anastomosis stricture, or leak, which can be evaluated by Doppler ultrasound of the liver. Hyperacute rejection (HAR) after liver transplantation is rare and due to ABO cross-match issues. HAR presents as elevated bilirubin, encephalopathy, weakness, thrombocytopenia, coagulopathy, fever, and hypotension within a few hours of transplantation. Doppler ultrasound displays thrombosis of the portal vein and absence of biliary duct obstruction in patients with HAR. Treatment of HAR is supportive therapy with retransplantation. Acute rejection after liver transplantation may also occur over the first 6 to 8 weeks after liver transplantation and is due to cell-mediated attacks on the liver, and thus is rarely a feature of the initial postoperative ICU stay. Patients with acute rejection typically present with fatigue, low-grade fever, and elevated transaminase levels, but rarely is the patient critically ill. Prevention and treatment of acute rejection entails the use of prednisone, calcineurin inhibitors, and antimetabolite drugs. These immunosuppression regimens can cause complications, such as diabetes, renal failure, hypertension seizures, and increased susceptibility to infection. Most of these symptoms are dose dependent and can be limited by dose adjustments.

The most common cause of mortality in these patients after liver transplantation is infection. Infection-based mortalities account

for more than 60% of the deaths in liver transplant recipients.[152] Signs and symptoms of fever, leukocytosis, cellulitis, and pain may be absent owing to immunosuppression, making the diagnosis of infection difficult. Prolonged surgical time and large amounts of fresh frozen plasma transfusion lead to an increased risk of infectious complications in transplant patients.[153] Infections that occur early in the patient's posttransplant period (first 6 weeks) typically are the result of bacterial infections related to the surgical procedure, invasive monitors, ventilator, or other iatrogenic causes. Perioperative antibiotic regimens should include broad-spectrum antibiotics to cover methicillin-resistant *S. aureus* and other multidrug-resistant bacteria and fungus. Intraabdominal infections are most commonly due to leak from the biliary anastomosis. Intraabdominal infections are best treated with intravenous antibiotics, percutaneous drainage, and reexploration if the patient is in septic shock or symptoms do not improve. Invasive critical care devices such as central venous catheters, endotracheal tubes, and urinary catheters should be removed as early in the ICU course as possible to prevent hospital-acquired infections. During the first 6 months of immunosuppression transplant patients are at high risk of opportunistic infections. A regimen of trimethoprim-sulfamethoxazole and ganciclovir is used to prevent the opportunistic infections with *Pneumocystis carinii* and cytomegalovirus.

Trauma

The tertiary trauma survey usually occurs after initial resuscitation and surgical treatment and may be initiated once the patient has arrived in the ICU. A tertiary trauma survey includes a full physical examination to look for missed injuries, a review of laboratory values and radiographic data, and a detailed medical history of the patient. Trauma patients who require admission to the ICU often require continued resuscitation for hemorrhagic shock. These patients should have blood product resuscitation with a high ratio of red blood cells to plasma to platelet transfusion ratio.[90,154] Trauma patients with major hemorrhage have improved mortality rates with these high transfusion ratios. The use of tranexamic acid in trauma patients with hemorrhagic shock may also provide some mortality benefit, especially if delivered rapidly after bleeding.[155,156] Damage control resuscitation involves early control of hemorrhage and gross contamination, permissive hypotension, avoidance of crystalloids, and early use of blood components (plasma and platelets) in a high ratio in patients requiring greater than 10 units of red blood cells leads to improved hemostasis and reduces deaths caused by hemorrhage.[90,154,157] Reversing metabolic acidosis and hypothermia with the use of fluid/blood product warmers and body-warming devices also aids in correction of coagulopathy in trauma patients. Trauma hospitals using protocols for blood product resuscitation (massive transfusion protocol) will improve the mortality rate, decrease the amount of blood products used, and decrease the amount of crystalloid used.[158]

Damage control laparotomy uses the surgical technique of rapid control of hemorrhage and contamination; postoperative resuscitation with correction of coagulopathy, hypothermia, and acidosis; and subsequent definitive repair of injuries.[159] Damage control laparotomy is used in concert with damage control resuscitation to improve mortality rates in trauma patients. Patients undergoing damage control laparotomy present to the ICU with negative-pressure abdominal dressings used to remove toxic intraperitoneal fluid, reduce the risk of fistula formation, and prevent evisceration of intraabdominal contents. Negative-pressure dressings may also allow the visualization of continued hemorrhage or enteric content leak. Negative-pressure dressings do not completely eliminate the risk of ACS, leading to the need for frequent evaluation of bladder pressure, hemodynamic monitoring, and evaluation of the mechanical ventilator peak airway pressures. When the patient's hemodynamic and physiologic status has improved, typically within 24 to 48 hours, a return to the operating room for definitive treatment can be undertaken.

Traumatic brain injury (TBI) is a leading cause of death after a major traumatic injury. The role of ICU management of TBIs is to prevent secondary brain injury caused by hypotension, hypoxia, and seizures. Hypotension at any point during hospitalization of patients with TBI increases their risk of death.[160] Blood product resuscitation and emergent control of hemorrhage are key to preventing hypotension. Endotracheal intubation and appropriate oxygenation with mechanical ventilation is required in patients with Glasgow Coma Scale scores less than 8. Temporary hyperventilation may be used to reduce carbon dioxide levels to reduce intracranial pressures until surgical decompression of intracranial mass lesions. Platelet levels below 100,000 μL and international normalized ratio higher than 1.5 may lead to progression of intracranial hemorrhage.[161,162] Treating these patients with plasma and platelet transfusions and/or administration of factor VII and prothrombin complex concentrate may decrease progression of intracranial hemorrhage.[163] Seizures after TBI can lead to elevated intracranial pressures, increased metabolism, and increased secondary brain injury. The use of phenytoin or levetiracetam for 7 days will decrease the number of TBI-associated seizures.[164]

Pain control in trauma patients is key to improving patient's early mobility and pulmonary toilet, which have been shown to decrease the incidence of pneumonia, delirium, duration of mechanical ventilation, and ICU length of stay. In patients who have no contraindications and especially in patients with thoracic trauma, epidural analgesia has been shown to improve pain control and overall outcome.[165] Trauma patients with intact intestinal continuity should have early (24 hours) enteral nutrition started even in the face of stable levels of vasopressors or an open abdomen.[75,79] VTE chemical prophylaxis should be started immediately because of the high risk of VTE formation in trauma patients. Patients with active hemorrhage or significant TBI should have initiation of chemical VTE prophylaxis delayed until these injuries are stabilized.[66]

Key Points

- ICU beds are a limited resource and should be reserved for patients with medical needs requiring ICU-level care, a reversible disease, and a reasonable prospect of a meaningful recovery.
- A multidisciplinary team approach with evidence-based guidelines, checklist, and bundles should be used to provide best practice care for ICU patients.
- The use of universal pain and sedation scores such as RASS, the Critical Care Pain Observation Tool, and CAM ICU allows for communication between the teams caring for the patient. Light sedation, early mobility, and delirium screening can improve ICU patient outcomes.

- ARDS is best managed with low tidal volumes of 6 mL/kg and assisted with prone positioning and neuromuscular blockade.
- Mechanically ventilated patients who are assigned weaning protocols. treated with minimal sedation, and achieve early mobility have decreased time of mechanical ventilation and ICU length of stay.
- Patients with a Caprini score higher than 7 and/or after major surgery and trauma should receive chemical VTE prophylaxis when clinical risk of hemorrhage is minimal to reduce the risk of increased morbidity and mortality related to VTE.
- Enteral nutrition goals of critically ill patients include provision of 25 to 30 kcal/day and 1.2 to 2.5 g/kg of protein per day. Early initiation of nutrition has been shown to decrease morbidity and mortality.
- Patients with hemorrhagic shock should be treated with a high ratio of plasma to platelets to red blood cells to decrease hemorrhage and improve hemostasis.
- AKI leads to a significant risk of in-hospital mortality with prevention of AKI with adequate volume repletion and MAP above 65 mm Hg.
- Surgical specialties have a variety of treatments and complications specific to their specialty. These complications often depend on their patients' comorbidities before surgery and the specific surgery they have undergone.

Review Questions

1. Which of the following preoperative medications should be continued in the immediate perioperative period for patients undergoing a major general surgery procedure?
   a. Diuretics
   b. Calcium channel blockers
   c. Glucocorticoids
   d. Metformin
   Answer: c. Glucocorticoids should be continued at their standard dose for major general surgery procedures to prevent hypotension caused by adrenal suppression. Calcium channel blockers and diuretics should be held perioperatively to prevent hypotension and possibly worsening hypotension associated with hemorrhage or sepsis. Metformin should be held perioperatively until the patient is tolerating uninterrupted nutritional intact to avoid hypoglycemia if diet is interrupted.
2. Which of the following medications may lead to a decrease in the episodes of delirium when used as sedation in mechanically ventilated patients?
   a. Dexmedetomidine
   b. Benzodiazepines
   c. Gabapentin
   d. Morphine
   Answer: a. Dexmedetomidine is an α_2-adrenoreceptor agonist that has been shown to decrease anxiety, duration of hyperactive delirium, and time of mechanical ventilation in patients with delirium. Benzodiazepines have been shown to increase rates of delirium and increase duration of mechanical ventilation and ICU length of stay. Morphine (opioid) and gabapentin (nonopioid) analgesia medications typically are not used for sedation.
3. The patient with the following diagnosis should be excluded from daily spontaneous awakening trials (SAT)?
   a. Septic shock
   b. Active seizures
   c. Open abdomen
   d. Deep venous thrombosis
   Answer: b. Patients with active seizures often require significant sedation to break and prevent seizure activity, and an SAT may lead to recurrence and worsening of seizures. Septic shock, open abdomen, and deep vein thromboses do not prevent decreasing sedation and attempting to get the patient to follow commands and perform a spontaneous breathing test/trial.
4. Mortality can be improved in patients with adult respiratory distress syndrome (ARDS) with which of the following techniques?
   a. Tidal volume of 10 mL/kg
   b. Inversed inspiratory/expiratory ratio
   c. Prone positioning
   d. High-frequency oscillator ventilation
   Answer: c. Prone positioning has been shown in peer-reviewed medical literature to improve mortality and oxygenation by improving ventilation-perfusion matching and decreasing shunt flow. Low tidal volume (6 mL/kg) ventilation with supplemental positive end-expiratory pressure and fraction of inspired oxygen has been shown to improve mortality in ARDS. Inversed inspiratory/expiratory ratio and high-frequency oscillator ventilation have not been shown to improve mortality in peer-reviewed medical literature.
5. Which of the following techniques does not decrease the incidence of ventilator-associated pneumonia (VAP)?
   a. Emergent intubation in prehospital setting to protect airway
   b. Elevating the head of the bed 30 to 45 degrees
   c. Chlorhexidine oral care
   d. Subglottic secretion drainage
   Answer: a. Emergent intubation has been shown to increase the risk of VAP. Elevation of the head of the bed, chlorhexidine oral care, and subglottic secretion drainage have all been shown to decrease VAP rates in ICU patients.
6. Which of the following patients will likely require parenteral nutrition?
   a. A patient requiring stable low-dose vasopressors
   b. A patient with high-output proximal enterocutaneous fistula
   c. A patient with open abdomen
   d. A patients with gastric residuals of 300 mL
   Answer: b**.** Patients with high-output proximal enterocutaneous fistulas require total parenteral nutrition owing to the lack of absorption of enteral nutrients and worsening of the fistula output. Patients receiving low-dose vasopressors and with open abdomens can tolerate enteral nutrition without complications. Gastric residuals should not be checked on a routine basis, and if they are enteral nutrition should only be held in patients with volumes higher than 500 mL.
7. Optimal resuscitation strategy in patients with hemorrhagic shock includes which of the following?
   a. Transfusion of red blood cells (RBCs)
   b. Infusion of isotonic crystalloids
   c. Infusion of colloids
   d. Transfusion with a high ratio of plasma to platelets to red blood cells
   Answer: d. High-ratio transfusions replace lost clotting factors and decrease the amount of RBCs given in patients with hemorrhage. Isotonic crystalloids, colloids, and RBCs given to patients with active hemorrhage do not replace clotting factors, cause dilution, and lead to an increased number of RBCs transfused.
8. The most sensitive study to diagnose an anastomotic leak after esophagectomy is
   a. Contrast swallow study
   b. Endoscopy
   c. Computed tomography (CT) scan with oral contrast
   d. Examination of perianastomotic drain content
   Answer: b. Endoscopy has a higher sensitivity than the other studies to detect anastomotic leak and also allows possible minimally invasive management of leaks with stent deployment. Contrast swallow, CT scan, with oral contrast and drain content all have low sensitivities of 7% to 50%.

9. The next step in management in a patient with an extremity wound causing concern for necrotizing soft tissue infection and hemodynamic instability would be which of the following?
a. Obtaining plain films
b. Obtaining a CT scan
c. Admission to the ICU for antibiotics and resuscitation
d. Emergent surgery for surgical exploration and debridement
Answer: d. Patients with necrotizing soft tissue infection require emergent operative drainage and debridement and exploration will provide a definitive diagnosis. CT scan, ICU admission for antibiotics and resuscitation, and plain films will only delay definitive management without providing a definitive diagnosis.

10. Prevention of acute kidney injury in ICU patients includes which of the following?
a. Low-dose dopamine
b. N–acetyl cysteine
c. Volume repletion with isotonic crystalloid
d. Administration of bicarbonate
Answer: c. Keeping patients euvolemic with crystalloids to continue adequate renal perfusion has been shown to decrease the incidence of ICU and perioperative acute kidney insufficiency (AKI). N–acetyl cysteine and bicarbonate have not been shown to decrease the incidence of AKI. Low-dose dopamine may increase renal perfusion but has not been shown to decrease the incidence of AKI.

- Pancreatitis
- Gastrointestinal Bleeding
- Elevated Liver Function Test Results
- Miscellaneous

Conclusion

Specialized intensive care units (ICUs) are becoming increasingly common. Cardiothoracic critical care has become an emerging subspecialty of critical care focused on ensuring that patients who have undergone major cardiac procedures are closely monitored in an ICU setting. These patients require this level of care during the immediate postoperative period, as they are more likely to be unstable during that critical time during their care. The goal of ICU providers is to identify and address potential problems early to prevent further long-term complications. Although there are many hospital-specific, or even surgeon-specific, protocols used to facilitate care, often the role of the critical care specialist is to identify when a patient's status dictates deviating from routine care to ensure patient safety and prevent complications. This role has become increasingly valued as the population of patients undergoing cardiothoracic surgery becomes sicker, older, and more medically complex with respect to comorbid conditions.[1] This chapter covers the most essential aspects of cardiothoracic critical care starting with immediate postoperative complications followed by organ-system-specific complications that are encountered later in the course of care. For any complications discussed, treatment strategies are provided to readers to mitigate any downstream effects.

Early Postoperative Care

Admission to the ICU

Transport of the patient from the operating room (OR) to the ICU, while seeming routine, can actually engender patient complications. Therefore upon admission to the ICU, both the nursing staff and the providers should conduct a careful check to ensure a safe transition. Common sources of transport and transition-related problems include loss of a secure airway, changes in ventilation and acid/base status from manual bag-valve-mask ventilation, inadvertent medication changes that can lead to loss of sedation, hypotension or hypertension, and arrhythmias. Catheters and monitoring devices can be dislodged, so accurate transduction and monitoring should be confirmed to ensure that any observed disruptions or changes reflect actual patient changes instead of spurious findings.[2]

Another important aspect of admission to the cardiothoracic ICU is direct communication between the ICU and OR staff. Ideally, a verbal handoff should be given from both the surgical and anesthesiology teams. Although automated vital sign capture, electronic health records, and remote telemetry access have all improved transparency between the OR and the postoperative setting, the best practice involves verbal communication. Direct verbal communication between teams ensures questions can be raised, thereby minimizing errors and miscommunications. Although there is no single handoff system or protocol that has been found to be most effective, it is widely held that team-based approaches and standardized handoffs improve patient outcomes.[3,4] As such, the handoff should be conducted as a team, including nursing, respiratory, perfusion, and physician or other providers, spanning multiple disciplines, ICU, OR, and anesthesia. This ensures that all members of the team with essential information or questions will be present during the discussion of the patient's operative course. Some of the basic elements of a standardized handoff from OR to ICU are covered in Box 35.1.[2,5]

• BOX 35.1 Basic Protocol for Admission From the Operating Room to the Intensive Care Unit

- Patient age and name
- Operation performed and preoperative diagnosis necessitating procedure
  - Elective vs. emergent
  - Type of anesthesia used
- Premorbid conditions
  - Relevant medical history, being sure to include renal function preoperatively and allergies
  - Surgical history
  - Social history
- Operative course
  - Blood products utilization
  - Fluids given, urine output recorded
  - Intraoperative pressor support required
  - Intraoperative ventricular function
  - Summary of most recent and salient laboratory findings.
- Location access and drains
  - Lines (pulmonary artery catheter measurement)
  - Drains
  - Tubes (endotracheal tube placement at lips or teeth)
  - Pacing wires (atrial, ventricular, polarity)
- Current medications
  - Drips and rates on arrival
  - Timing of most recent intraoperative antibiotics
- Postoperative treatment plan
  - Blood pressure goals
  - Extubation likelihood (fast-track or not), including a discussion of the airway difficulty or ease

Common Postoperative Management Challenges

Fluid and Line Management

Despite adequate resuscitation and even a positive fluid balance in the OR, patients may still require significant fluid administration postoperatively. Cardiopulmonary bypass can trigger a systemic inflammatory response syndrome (SIRS) in which patients experience significant hypovolemia intravascularly even if total body water levels are significantly elevated. Capillary leak is thought to be the mechanism by which SIRS causes this phenomenon of hypovolemia in the setting of fluid overload. Thus aggressive fluid administration may routinely need to be used after cardiopulmonary bypass. Colloids are generally favored over crystalloid for volume replacement to maintain adequate cardiac output (CO), pulmonary artery catheter (PAC), and central venous pressure (CVP) trends.[2] Although the amount of volume required for any individual patient will vary according to his or her hemodynamics and the operative course, many centers use 2 L as a trigger point to consider causes of hypovolemia other than SIRS alone.

If a patient has been deemed to require fluids based on the CVP, CO, and PAC trends, chest tube output and postoperative laboratory test results should also be taken into consideration. If chest tube output is high or hemoglobin/hematocrit levels are found to be low, blood transfusion should be considered. Conservative transfusion strategies are preferred owing to concern of worse outcomes when blood transfusions are required.[2,6]

Another common postoperative finding is high urine output. In this setting, hemodilution or diuretic administration intraoperatively should be suspected and, in that setting, in addition to fluid administration, potassium levels should be monitored closely and replaced as needed.

Once the capillary leak has resolved, careful consideration should be given to clinician-driven diuresis to promote the elimination of the patient's likely fluid overloaded state. Before diuresis, it is preferable that the patient be hemodynamically stable to tolerate the fluid loss.

In the absence of significant postoperative complications, the instruments used for monitoring perfusion, cardiac function, and bleeding can be removed, particularly to minimize the risk of infections. Foley catheters are commonly removed overnight preceding the second postoperative day if the patient has been mobilized, is not undergoing significant diuresis, and does not have a history of urinary retention. The arterial line can be removed once the postextubation blood gas profile has been reviewed and found to be adequate. The Swan-Ganz catheter should be removed once the patient is hemodynamically stable and no longer receiving ionotropic support. The criterion for chest tube removal is generally drainage of less than 100 mL for the previous 8 hours or less than 50 mL over the previous 4 hours. The chest tube drainage should be serosanguineous (drain-blood hematocrit ratio <0.3)

before removal of the chest tube. The pacing wires should be removed before the removal of mediastinal chest tubes because the main complication of wire removal is bleeding and the first clue may be an increased output from these tubes. A chest x-ray should be used to check for pneumothorax after pleural chest tube removal, but it is not necessary after mediastinal chest tube removal.[7,8]

Hypotension and Hypertension

When evaluating hypotension, the most common cause is venous pooling on transfer from the OR. There are several tests for hypovolemia such as the leg raise test or administering a fluid challenge. However, before evaluating physiologic causes, it is important to rule out iatrogenic causes of hypotension including increased rates of medications that cause hypotension, such as analgesics, sedatives, or vasodilators. Vasopressors that support the blood pressure may have run out, been mixed at the wrong concentration, or disconnected from the patient may be another source of hemodynamic instability. Faulty monitoring, such as an improperly calibrated arterial line or height of arterial transducer relative to the patient, can also cause false indicators of hypotension. If the clinician is confident that there are no iatrogenic causes, then physiologic causes should be considered including bleeding, SIRS, myocardial ischemia possibly as a complication of venous graft dysfunction, arrhythmia, tamponade, tension pneumothorax, and auto–positive end-expiratory pressure.[2] The workup should include analysis of the Swan-Ganz catheter measurements, arterial line measurements and waveform, electrocardiogram (ECG), bedside ultrasound, chest x-ray, laboratory tests including complete blood cell count, and examination of the chest tubes for bleeding.

Similar to hypotension, iatrogenic causes of hypertension—such as inadequate sedation or pain control, hypothermia, increased or incorrect dosing, concentration of vasoconstrictors, arterial monitoring transduction positioning, and calibration errors—are also common and must be ruled out. Other important causes include increased sympathetic tone, hypertrophic left ventricle, and preexisting history of hypertension or stroke. In many cases, a nitroglycerine infusion is sufficient to treat postoperative hypertension. Secondary agents are typically determined by the surgeon or by institutional preference. In general, to protect suture lines, surgeons prefer to err on the side of lower blood pressure, particularly in the first few hours postoperatively, although this may compromise renal perfusion in patients who are hypertensive at baseline.[2]

Warming From Hypothermia

Hypothermia (<36°C) is used intraoperatively to preserve cardiac and neurologic function postoperatively. Unfortunately, hypothermia carries the risk of adverse effects, including increased systemic vascular resistance (SVR), increased risk of arrhythmias, shivering, and coagulopathy. Shivering is of particular concern, as it increases oxygen (O_2) consumption while also increasing carbon dioxide (CO_2) production, sometimes precipitating acidosis. Meperidine and dexmedetomadine have been shown to treat shivering.[9,10] The increase in SVR can mask hypovolemia and increase afterload, which increases myocardial demand. The dangerous combination of increased SVR and coagulopathy can also lead to mediastinal bleeding. Without active rewarming with forced air, hypothermia and its complications, particularly the prolongation of anesthetic time half-life, can also prolong intubation times. There is some evidence that the risk of wound infection also increases with hypothermia as well, likely owing to the immunosuppressive effects of hypothermia.[11–13] Therefore upon arrival to the ICU, steps should be taken to increase core body temperature to normal using forced air, as that has been shown to be more effective at expeditiously increasing core body temperature than radiant heaters or warming blankets. By contrast, heated intravenous fluids and heated ventilator circuits can be used to prevent worsening hypothermia, but they have not been found to improve the rewarming process.[14–16]

Weaning to Extubation

The current trend in cardiothoracic surgery is toward early extubation, variably described as extubation within 6 hours or up to 12 hours. Extubation criteria may differ among cardiothoracic groups, but at a minimum patients should be awake with stimulation and following commands, moving all extremities (i.e., without neuromuscular blockade), minimal chest tube drainage (<50 or 100 mL/h), core temperature above 35.5°C, hemodynamically stable with a CO >2.2 L/min per meter squared, free of arrhythmias, ventilator stability with respiratory rate between 12 and 30 breaths/min, and reassuring arterial blood gas (ABG) levels (partial pressure of arterial oxygen [PaO_2]/fraction of inspired oxygen [FIO_2] >150, partial pressure of carbon dioxide [PCO_2] <50 torr, and pH 7.30–7.50). In some institutions, patients in routine cases are extubated in the OR. The criteria for extubation will likely differ in the OR and be institution-specific.

Using the Society of Thoracic Surgeons (STS) risk models, studies have determined that the following preoperative risk factors predispose patients to longer postoperative intubation times: increasing age, chronic obstructive pulmonary disease, tobacco use, chronic kidney disease, peripheral vascular disease, depressed left ventricular fraction (ejection fraction <30%), myocardial infarction within the past 90 days, preoperative ventilation, prior cardiac surgery, or urgent or emergent surgery.[17] Intraoperative risk factors also exist, such as deep hypothermic circulatory arrest, coagulopathy, and long pump runs (>4 hours). Postoperatively, mediastinal bleeding, hemodynamic instability, respiratory failure, and stroke are the major risk factors for prolonged intubation. It is estimated that about 5% to 10% of patients are unable to be extubated early and remain intubated for 48 hours or longer.[17]

Mediastinal Bleeding and Cardiac Tamponade

The primary mechanism for identifying mediastinal bleeding is chest tube drainage. Mediastinal bleeding can either be "surgical"—meaning it requires repair and revision owing to a technical problem that can result from either arterial or venous bleeding—or it can be "medical" (which will not require surgical intervention). Even in the case of suspected surgical bleeding, control of coagulopathies, blood pressure (maintaining lowest perfusing pressures), and shivering can assist in decreasing bleeding, and its associated harm, until surgical intervention can be obtained. Causes of medical bleeding include preoperative and intraoperative anticoagulant medications, transfusion-associated coagulopathies, hypothermia, low calcium levels from transfusions, and underlying medical conditions predisposing the patient to coagulopathy, such as uremia, hepatic dysfunction, or underlying coagulopathies.

Currently the most accurate and effective measure of bleeding is obtained using a thromboelastogram (TEG). The drawback of even the rapid TEG is that the results take some time. However, it remains the most specific test to identify coagulopathies so that

they can be identified and treated in a more targeted manner.[18] In the absence of a TEG, complete blood cell count, calcium levels, full metabolic panel (to evaluate uremia and hepatic function), prothrombin time, international normalized ratio, and fibrinogen levels can all be useful in identifying sources of bleeding requiring correction.

High chest tube output, while troubling, can be medically managed and temporized awaiting a surgical revision, if that is determined to be required. Immediate laboratory work should, along with clinical judgment and patient history, be used to identify any reversible coagulopathies to assist in temporizing or treating surgical or medical bleeding. A complication of cessation of bleeding using prothrombotic agents is clotting off the chest tubes and promoting cardiac tamponade. By contrast, hemodynamically significant cardiac tamponade usually requires either bedside (if emergent) or operative management for treatment. The mechanism for cardiac tamponade is frequently inadequately drained bleeding into the confined mediastinal space, masked by low chest tube output. If the accumulation of blood is fast enough, the external compression of the heart chambers is not compensated for and the resultant low CO can lead to rapid decline and ultimately death. For this reason, it is important to maintain free draining of the chest tubes and to avoid or break up formation of chest tube clots.

The diagnostic signs of cardiac tamponade include decreased chest tube drainage, equalization of cardiac pressures, increased CVP, pulsus paradoxus, and low-voltage ECG. The best test for cardiac tamponade is a transesophageal echocardiogram (TEE).[2] If bedside transthoracic echocardiogram (TTE) is available, then that can be used as the first confirmatory step when obtaining a TEE may be logistically challenging or require too much time. Unfortunately, although bedside ultrasound is an excellent tool, both ventilatory constraints (e.g., hyperinflated lungs) and chest tube or bandage placement may limit clinicians' ability to perform a diagnostically relevant TTE when cardiac tamponade is suspected in the immediate postoperative period.

Common Low–Cardiac Output Scenarios

In taking care of cardiothoracic surgical patients in the early postoperative period, clinicians need to be able to discern certain useful patterns. Knowing these patterns enables clinicians to anticipate problems rather than reacting to problems. Remaining a step ahead of serious complications is critical to prevent significantly compromised perfusion and avoid the creation of a vicious cycle that is more difficult to treat. Table 35.1 shows the common low CO states and their treatment modalities.[19]

TABLE 35.1 Common Low Cardiac Output States and Their Treatment Modalities

Clinical Syndrome/Scenario	Key Characteristics or Predisposing Factors	Treatment
Vasoconstriction from hypothermia	• Core body temperature <36°C • Often, PAD or PCWP <15 mm Hg	• Active warming of patient with forced air • Fluids during rewarming • Vasodilators to maintain MAP 70–80 mm Hg • Ionotropic support to maintain CI >2.0 L/min per m^2
Vasodilation during rewarming	• Active rewarming • PAD or PCWP <18 mm Hg	• Trial of colloid (or crystalloid) fluid boluses, not to exceed 2 L; goal to maintain PAD or PCWP >18 mm Hg • If fluid fails to raise MAP, then vasopressor support may be considered and selected based on CI and relative need for ionotropic support
Copious urine output with low filling pressures	• Use of mannitol or furosemide in operating room • Hyperglycemia • Normal left ventricular function with a short CPB run	• Discontinue use of tesiritide, fenoldopam, or dopamine • Administration of sufficient fluids to maintain CO and filling pressures but overall negative fluid balance

Impaired left ventricular function	• Ischemia from compromised graft flow or incomplete revascularization
	• Reversible myocardial stunning from cardioplegic arrest
	  • Prolonged CBP (>6 h)
	  • Inadequate myocardial protection
		• ECG and possible re-op or catheterization lab for revascularization
		• Ionotropic support
		• Mechanical support:
		  • IABP
		  • Impella
		  • ECMO
		• TEE or TTE to evaluate function if etiology unclear

Diastolic dysfunction or right ventricular failure	• Elevated filling pressures with normal left ventricular function • Preoperative pulmonary hypertension	• Lusitropic drug administration such as milrinone or nesiritide • Diuresis with concomitant colloid administration to maintain intravascular volume while improving diastolic relaxation • Inhaled nitric oxide for patients with underlying pulmonary hypertension

CI, Cardiac index; *CO*, cardiac output; *CPB*, cardiopulmonary bypass; *ECG*, electrocardiogram; *ECMO*, extracorporeal membrane oxygenation; *IABP*, intraarterial balloon pump; *MAP*, mean arterial pressure; *PAD*, pulmonary artery diastolic pressure; *PCWP*, pulmonary capillary wedge pressure; *TEE*, transesophageal echocardiogram; *TTE*, transthoracic echocardiogram.

Postoperative Resuscitation

Cardiac arrest following cardiothoracic surgery deviates from standard cardiopulmonary resuscitation taught in Advanced Cardiac Life Support (ACLS). Importantly, in the setting of postoperative cardiac arrest it is recommended that the FIO_2 be increased to augment the supply of oxygen available to the patient. In all cases, one of the considerations, which is not a recommendation during standard ACLS protocols, is when to open the chest. For ventricular fibrillation (VF) or ventricular tachycardia (VT), it is recommended that three shocks be delivered before a bedside thoracotomy can be considered. For pulseless electrical activity (PEA) and asystolic arrests, pacing wires should be set to DDD (dual pacing for both chambers, dual chamber activity sensing, and dual response) at 90 beats/min at 10 mV, and 3 mg of atropine may also be given. In all cases, ACLS protocol cardiopulmonary resuscitation and epinephrine can be conducted simultaneously with the other considerations discussed.[20,21] Once shocks have been delivered, amiodarone should be given, or at least considered for VF/VT arrests, and atropine with pacing has been considered in the case of PEA/asystole, then chest reopening within 10 minutes of arrest and 24 hours of initial surgery has been found, to be associated with higher survival rates.[22] Several studies show that the timing of chest reopening is imperative, so standardization and training have been found helpful in ensuring staff are prepared for cardiac arrest. In the right hands, survival of arrest in post–cardiac surgical patients can range from 50% to 79%.[20]

Thoracotomy should include three sterile operators, full drapes, sterile cleaning of chest wall, scalpel for cutdown, wire cutters for wire removal, suction, and sternal retractor. Before cardiac massage, grafts should be visualized and then internal cardiac massage is performed using the two-hand technique for 1 minute before assessing rhythm. Internal cardioversion can be performed in the case of VF/VT or massage can be continued for asystole. In all cases, extracorporeal membrane oxygenator support (ECMO) or other forms of cardiac augmentation, such as intraarterial balloon pump (IABP) or Impella device (Abiomed, Danvers, MA) placement,[20] can be considered.

Late Postoperative Care

Consideration of the immediate issues postoperatively can identify those circumstances that may lead to poorer outcomes, but despite meticulous attention patients can develop various organ system dysfunction. The focus now changes to common conditions that may occur postoperatively based on individual organ systems that may be seen in patients undergoing cardiac surgical procedures.

Cardiology

Arrhythmias

Atrial Fibrillation

Postoperative atrial fibrillation (AF) is one of the most common complications in cardiac surgery and occurs in up to 30% to 50% of patients. Patients are at highest risk in the first 5 days, with a peak incidence on postoperative day 2. The mechanisms of AF are multifactorial and still being identified. Surgical procedures and the stress associated with these procedures increased the incidence, but the inflammatory state induced by cardiopulmonary bypass creates a perfect milieu for this supraventricular tachyarrhythmia.[23]

All postoperative cardiac surgical patients should have electrocardiographic monitoring, which can lead to the initial detection of this arrhythmia. An ECG should be performed for diagnostic purposes when AF is first suspected. Documented AF should have duration of at least 30 seconds, but new-onset AF is a first-time occurrence of any duration. The ventricular rate is usually 90 to 180 beats/min with an irregular R-R interval with the loss of a morphologically consistent P wave.

AF is associated with increased mortality and length of stay. The frequency of occurrence makes it the most costly complication after cardiac surgery.[24] There is also an association with cognitive impairment and treatment with antiarrhythmics add to this cost. Given the increased mortality and cost associated with this complication, many studies have been done looking at the prevention of AF after cardiac surgery. There is some support for carvedilol as being superior to metoprolol for preoperative prophylaxis. Although the effects on the occurrence of supraventricular tachyarrhythmia and hospital length of stay were reduced, the influence on other measures of morbidity and mortality after cardiac surgery were unclear.[25] Sotalol and amiodarone are more effective in prophylaxis postoperatively, but adverse effects associated with these agents limit their use to prophylaxis in patients at high risk for postoperative AF. Statins have been shown to be effective in reducing new-onset AF in postoperative patients naïve to statins and deserves further study.[26] Calcium channel blockers and digoxin have no role in postoperative AF prophylaxis.

The previously mentioned modalities are entities that have been initiated preoperatively or perioperatively. Biatrial pacing can be initiated in the immediate postoperative period and has been shown to be effective at prevention of postoperative AF. The efficacy of single-chamber atrial pacing has not been determined.

Treatment of AF in the postoperative setting depends on two factors: onset and stability. In clinically unstable patients, as defined by acute heart failure, hypertension, or myocardial ischemia, electrical cardioversion may be warranted. For patients who are clinically stable, correction of electrolyte, oxygenation, and perfusion abnormalities as well as volume status should be addressed. The onset of AF allows more options after patient stability has been assessed. New-onset AF makes elective cardioversion either chemical or electrical a safe option. In general, cardioversion within 48 to 72 hours after onset is acceptable without investigation for left atrial appendiceal thrombus. A recent study of rate versus rhythm control for AF after cardiac surgery showed no difference in hospitalization days, persistence of AF at 60 days, or rate of complications.[27]

The equivalence in clinical outcomes between rate and rhythm control leaves the decision in the hands of providers. A rate control strategy is best accomplished using β-blockers. They are more effective than nondihydropyridine calcium channel blockers at controlling heart rate. Digoxin has some role in rate control but usually as an adjuvant therapy because of its narrow therapeutic window. Amiodarone can be used as a rate-controlling agent, but it may also lead to chemical cardioversion and care should be taken to rule out a left atrial appendage thrombus.

Rhythm control can be accomplished with either electrical or pharmacologic cardioversion. The first-line agents for pharmacologic cardioversion are dofetilide, ibutilide, flecainide, and propafenone. Flecainide and propafenone are contraindicated in patients with coronary artery disease or structural heart disease and they should not be considered in postoperative cardiac surgical patients. Amiodarone is very effective in both conversion and maintenance of sinus rhythm, but the side effect profile (specifically pulmonary,

liver, and thyroid toxicity) limits its consideration as first-line therapy.

Patients who have AF of greater than 48-hour duration warrant a transesophageal echocardiogram to rule out left atrial appendage thrombus prior to cardioversion (either electrical or pharmacologic). The presence of the left atrial appendage thrombus necessitates anticoagulation for at least 4 weeks before elective cardioversion. After elective cardioversion anticoagulation is indicated for 4 to 6 weeks because there is a lag between the mechanical function and electrical restoration of sinus rhythm that may allow for thrombus formation.

Anticoagulation decreases the risk of stroke significantly in patients with AF. All patients with AF of greater than 48-hour duration should undergo anticoagulation unless there is a specific contraindication. There are multiple scoring systems for risk assessment when deciding about anticoagulation. The most widely used are CHA_2DS_2-VASc (CHA_2DS_2-VASc, Congestive heart failure, Hypertension, Age ≥75 years [doubled], Diabetes mellitus, Prior Stroke or TIA or thromboembolism [doubled]) for stroke risk assessment and HAS-BLED (Hypertension, Abnormal renal/liver function, Stroke history, Bleeding history or predisposition, Labile international normalized ratio, Elderly [≥65 years], Drugs/alcohol concomitantly) for risk of gastrointestinal (GI) bleeding.[28]

Heparin or enoxaparin as a bridge to full anticoagulation with warfarin is the standard and has applicability across all cardiac procedures. Dual antiplatelet therapy has been used but is less effective in stroke prevention and is associated with an increased risk of bleeding. Novel oral anticoagulants are popular because of efficacy and they have no need for routine monitoring of the coagulation profile. Novel oral anticoagulants are contraindicated in renal failure and valve replacement and are difficult to reverse in the event of bleeding.

Ventricular Tachyarrhythmias[29]

Premature ventricular complexes (PVCs) are commonplace after cardiac surgery and are usually related to electrolyte or other metabolic imbalances. They do not increase the risk of malignant dysrhythmias if they are isolated and infrequent. When PVCs are more frequent, then ventricular function may be affected. The management of simple unifocal PVCs does not require antiarrhythmic therapy but only correction of the aforementioned imbalances.

VT and VF are infrequent after cardiac surgery, with a reported incidence of less than 1.5%. The risk factors are multiple, including hypoxia, hypovolemia, electrolyte imbalances, and hemodynamic instability. Reperfusion after cardiopulmonary bypass is unique in cardiac surgery and the effects are limited. Inotropes and antiarrhythmics are frequently used in cardiac surgical units and may further irritate the recently violated myocardium. The area that needs to be investigated thoroughly when ventricular arrhythmias develop is new myocardial ischemia, specifically acute graft closure. These patients can be refractory to traditional antiarrhythmic therapy and intervention with cardiac catheterization or reoperation may be needed.

The principles of ACLS apply in these patients. Hemodynamic instability and sustained VT require electrical cardioversion but stable patients can undergo synchronized cardioversion or antiarrhythmic therapy. Lidocaine is the first choice and is used first as an intravenous bolus and is then administered via maintenance drip. Procainamide is generally a second-line drug. Significant toxicities from both lidocaine and procainamide can develop, especially in patients with renal insufficiency. As a result, amiodarone has become a more preferred choice as the first-line therapy. Amiodarone can be used in patients with impaired cardiac or renal function and is easily transitioned to an oral equivalent. The toxicities associated with amiodarone are still a consideration but benefit outweighs the risk in this population.

Individuals with impaired ventricular function (less than 40% left ventricular ejection fraction) may benefit from automatic implantable cardioversion defibrillation, but there is a waiting period postoperatively before implantation. This period allows time for left ventricular function to recover, which may lead to a reduced arrhythmic potential. These individuals may be fitted with the life vest or temporary external defibrillator until an automatic implantable cardioversion defibrillator can be appropriately implanted.

Bradyarrhythmias[29]

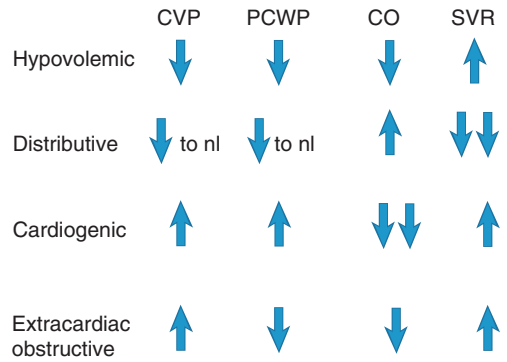
Bradyarrhythmias are common after cardiac surgery, especially after valve surgery. Preoperative sick sinus syndrome (SSS) or atrioventricular block (AVB) should heighten awareness for postoperative rhythm disturbances. Affected individuals will have temporary epicardial wires placed intraoperatively and these bradyarrhythmias may be limited to the immediate postoperative period. Because node recovery in SSS is frequent but unpredictable, recovery from a complete AVB is infrequent. The usual practice is to implant a permanent pacemaker if AVB or severe SSS lasts longer than 5 to 7 days postoperatively.

Shock

Shock is defined as the disruption of perfusion causing cellular injury that is initially reversible but, if left uncorrected, can lead to organ system dysfunctions and ultimately death. The Hinshaw-Cox classification of shock has applicability to the management of postoperative cardiac surgical patients. The basis of this classification is the understanding of cardiac performance variables, preload, afterload, and contractility. There are four categories of shock in this model, each of which has distinct hemodynamic profiles.

1. Hypovolemic shock is a disorder of inadequate preload resulting in impaired cardiac performance based on Starling's law the heart; examples are GI bleeding or dehydration.
2. Distributive shock is a disorder of maldistribution of volume. The issue is not a lack of volume but that the volume has been diverted out of the vascular compartment. There is a vascular dilation that leads to a markedly decreased afterload. An example is septic shock after adequate volume replacement with vasodilation and leaky capillary beds, leading to third spacing of volume or maldistribution of volume out of the vascular space.
3. Cardiogenic shock is the impairment cardiac performance based on a weakness in the muscle or impairment in contractility. An example is an acute myocardial infarction with left ventricular dysfunction.
4. Extracardiac obstructive shock is a disorder of obstruction of blood flow into or out of the heart. Examples are multiple and varied but obstruction is an important component of this disorder. Examples are tamponade, constrictive pericarditis, pulmonary embolism (PE), and tension pneumothorax. To some extent right ventricular (RV) dysfunction can be listed in this category because of its typical hemodynamic profile.

As Fig. 35.1 suggests, hypovolemic shock is a disorder of preload, distributive shock of afterload, and cardiogenic shock of contractility. Extracardiac obstructive shock is the result of a mechanical



• **Fig. 35.1** Hemodynamic profiles in shock. *CO,* Cardiac output; *CVP,* central venous pressure; *nl,* normal; *PCWP,* pulmonary capillary wedge pressure; *SVR,* systemic vascular resistance.

disruption outside of the heart and appears to be a miscellaneous category that does not fall into the confines of this paradigm.

Hypovolemic Shock

Hypovolemic shock is the easiest issue to deal with in the postoperative period. Most cases are optimally monitored intraoperatively with either a transesophageal echocardiogram or PAC and oftentimes both. It is rare for patients to be hypovolemic before their chest is closed. The management of volume is a matter of matching input with output. Drainage from urinary catheter, gastric tubes, and thoracic tubes as well as insensible losses should be accounted for. Most patients will have a CVP monitoring device and sometimes a pulmonary artery catheter. Reasonable goals are a CVP between 8 and 14 mm Hg during positive-pressure ventilation. Pulmonary capillary wedge pressure between 12 and 16 mm Hg should be an adequate preload for most patients. Disorders leading to hypovolemia during the postoperative recovery phase are bleeding, rewarming, diuresis, and on rare occasion, underresuscitation intraoperatively.

Distributive Shock

Cardiopulmonary bypass is an inflammatory-inducing procedure.[30,31] The immune system is activated with an exuberant production of cytokines and other modulators of inflammation. It is not uncommon for a vasoplegic syndrome to develop in patients after cardiopulmonary bypass.[32,33] This may occur in 5% to 25% of patients. This syndrome is manifested by peripheral vasodilation that requires treatment with vasopressors. The hemodynamics in this vasoplegia are consistent with distributive shock and on occasion can be refractory to routine treatment with vasoactive medications. The identified pathways are threefold; (1) activation of adenosine triphosphate–sensitive potassium channels on vascular smooth muscle, (2) activation of an inducible form of nitric oxide synthetase, and (3) a deficiency of vasopressin that may contribute to this vasodilation.[34] Risk factors for developing the vasoplegic syndrome have been identified as preoperative treatment with angiotensin-converting enzyme inhibitors or β-blockers and preoperative requirement of vasopressors. In addition, patients undergoing non–coronary artery bypass grafting surgical procedures were at higher risk for developing the vasoplegic syndrome.[35]

The vasoplegic syndrome carries a poor prognosis, and mortality for individuals with catecholamine refractory vasoplegia for 36 to 48 hours is as high as 25%. The treatment of the vasoplegic syndrome often requires high-dose vasopressors with vasopressin blended in after administration of norepinephrine and phenylephrine. There is no advantage to vasopressin greater than 0.04 units/min and even lower doses may be effective due to vasopressin deficiency. Methylene blue is an intriguing agent that has been used in refractory vasoplegic syndrome.[36] It works by blocking guanylate cyclase, which is the enzyme that catalyzes guanylate triphosphate to cyclic guanylate monophosphate the latter is part of the messenger system that leads to smooth muscle relaxation. Because this vasoplegia is a single insult event, if patients can be supported through the sequela related to this event with minimal organ damage, survival to hospital discharge seems an obtainable goal.

Right Ventricular Failure
Myocardial Dysfunction After Cardiopulmonary Bypass

Cardiogenic Shock

The diagnosis of cardiogenic shock was initially described as a result of non–ST-elevated myocardial infarction. The territory affected is the anterior wall or the left anterior descending distribution, which leads to a markedly reduced left ventricular ejection fraction, hypotension, and high filling pressures with pulmonary edema. Although this remains the most common cause of cardiogenic shock, many other disorders can present with this picture (Box 35.2).

This broad differential has few clinically applicable disorders that are encountered in the postoperative patient. Myocardial dysfunction after cardiopulmonary bypass and ischemic mediated disease are the most commonly encountered reasons for cardiogenic shock in this population.

Myocardial Dysfunction After Cardiopulmonary Bypass

A temporary impairment in contractility is seen after cardiopulmonary bypass. There are multiple theories to explain this, but the concept of myocardial stunning seems to be the prevailing thought at this time. The inflammatory state induced during heart surgery may also play a role in this impairment in contractility seen after the myocardium is reperfused. This is a transient phenomenon and resolves within 24 to 48 hours. Management of these patients includes inotropic support and management of the

volume overload that was related to the vasodilatation and capillary leak seen and addressed intraoperatively.

Ischemia

It is counterintuitive that individuals who have recently had cardiac surgery should become actively ischemic. Technical issues may develop intraoperatively and in the postoperative period that place these grafts at risk. Misplaced sutures, smaller receiving vessels, and inadequate revascularization may lead to postoperative ischemia. In addition, embolic phenomena from atherosclerotic plaque, thrombus, or air from the heart that may not have been completely deaerated can lead to ischemia. Postoperative ECGs should be obtained in all patients. If there are ischemic changes with clinical consequences, the patient may need investigation with cardiac catheterization or reoperation. It is rare that ischemia at this time leads to cardiogenic shock and it is more likely that the decrease in cardiac performance is related to the transient dysfunction described previously.

There is also a syndrome of refractory arrhythmia related to ischemia. Affected patients may develop recurrent ventricular tachycardia that is difficult to control with antiarrhythmics and cardioversion. These individuals also deserve further investigation and if possible, revascularization.

Devices

Multiple temporary devices are available to support a failing ventricle. The device longest in use is the intraaortic balloon pump (IABP).[37] This device can be placed in the aorta with the tip just below the left subclavian artery and may be inserted in the OR or at the bedside percutaneously. The IABP reduces afterload by deflating during systole and improves coronary blood flow by inflating in diastole. Both actions support the failing left ventricle until recovery and improve coronary perfusion.

The TandemHeart (Kardia srl, LivaNova, London, United Kingdom) and the Impella device are temporary devices that can support the systolic function of the failing ventricle.[38] Just introduced, but in limited centers, is an RP Impella that provides support for the failing right ventricle. This is a device that does not require arterial access but does require systemic anticoagulation because of the risk for thrombosis. Data are being gathered on safety and efficacy, but this device will provide another mode of support that has been missing.

ECMO is a modality that moves cardiopulmonary bypass out of the OR and into the ICU. This approach is reserved for the sickest patients and can support the failing heart or lungs and frequently both. It is a labor-intensive method of support. Patients who are candidates and who use ECMO should have a reasonable preoperative prognosis if they can survive this acute insult and sequela. ECMO may also be a bridge to transplantation or a permanent device if applicable. Centers that provide ECMO are limited, but it is becoming more accessible as more centers are developing these programs.

Permanent left ventricular assist devices as a bridge to transplantation or destination therapy are becoming more common. Immediate postoperative care should be provided in certified, specialized centers.[39] These devices are generally not placed in an emergent fashion as patients require rigorous evaluation before implantation.

Extracardiac Obstructive Shock

This form of shock can be the most difficult to recognize and diagnose. Treatment consists of relief of the obstruction and time is of great importance. Patients may appear to be in cardiogenic shock with dyspnea, jugular venous distention, and cyanosis. Attempts at preload reduction may precipitate a deterioration and should be avoided. Volume administration may be the only way to support these patients until the obstruction has been addressed. These are patients who are preload dependent. Vasopressors are usually ineffective because these individuals are maximally vasoconstricted. Pericardial pathology, pneumothorax, PE, and RV dysfunction are diagnoses that must be considered in patients with suspected extracardiac obstructive shock.

Pericardial Disease

Constrictive pericarditis is not often seen in the postoperative patient because the pericardium has just been opened and examined. If there is overt pathology, the surgeon would have addressed it at the time of surgery.

Closure of the pericardium at the end of the surgical procedure is at the discretion of the heart surgeon. The decision and consideration of the benefits of a closed pericardium are considered at the end of the procedure. Pericardial closure makes reoperation in the remote future technically easier and less hazardous. The closed pericardium prevents adherence of the heart to the back of the sternum and these patients will develop fewer pericardial adhesions. There is some evidence that a closed pericardium leads to less tamponade.

Tamponade can be early or late. In the first 24 hours, the anticoagulation has been reversed and freshly disrupted vessels have not had the opportunity to clot, but the drainage tubes may have been ineffective, allowing for accumulation of blood or fluid in the freshly invaded pericardial space. A later tamponade may be seen after pericardial or mediastinal tubes have been removed. Patients may not demonstrate the typical physical findings of hypotension, pulses paradoxus, or equalization of intracardiac pressures. Postoperative echocardiography is diagnostic and the increasing access of portable ultrasonography has been revolutionary. Percutaneous drainage may be dangerous and lead to cardiac laceration as the pericardial effusion may be loculated by adhesions. This should be undertaken only with visualization (if at all) and surgical reexploration/drainage is best.

Pulmonary Embolus

This is a rare disorder in postoperative cardiac surgical patients. Should shock develop after an embolus, thrombolytics are not an option and operative embolectomy may be necessary. Heparinization should be initiated until definitive therapy is available.

Tension Pneumothorax

Most patients emerge from cardiac surgery with multiple thoracostomy tubes. Tension physiology can occur with occlusion or kinking of these tubes. On occasion, loculated pneumothorax or tension bullae can be seen in individuals with bullous lung disease. Careful examination of the tubes, removing the dressing to examine the site, reinforcing connections, and stripping or suctioning may relieve the source of obstruction. A loculated pneumothorax may require separate chest tube or needle decompression. There is danger in patients with bullous lung disease whose conditions are misdiagnosed as loculated pneumothorax. Disruption of these bullae with a needle or chest tube may lead to a bronchopleural fistula that may require surgical correction.

Right Ventricular Dysfunction

RV dysfunction is not uncommon after cardiac surgery. The hemodynamic parameters are similar to extracardiac obstructive shock in that left ventricular filling is low to normal and there appears to be

elevated right-sided filling pressures. The etiology of this disorder is not related to obstruction but to cardiac dysfunction, specifically of the right ventricle. This is more common in those individuals with preexisting pulmonary hypertension as they may be at the limits of their RV compensation. Treatment involves correction of the RV afterload, judicious attention to preload, and some assistance, either mechanical or pharmalogic,[40] with contractility. Nitric oxide may be of benefit after acidosis and hypoxemia have been addressed. Inotropic support with dobutamine, milrinone, and epinephrine may be necessary to support the failing right ventricle. Levosimendan is an inotrope that works by increasing calcium sensitization of troponin C with beneficial effects in RV failure. This agent is not currently available in the United States. With adequate support, RV dysfunction may take 5 to 7 days to resolve.

Pulmonary

Respiratory care in the cardiac surgical ICU has benefited greatly from protocol-driven extubation from mechanical ventilation.[41] The benchmark standard for the STS is 6 hours from the time of arrival in the unit. Some institutions are extubating patients in the OR.[42] Despite these advances, meticulous care must be administered so that the strides can continue to prove beneficial to this population.

Atelectasis

There have been many improvements in surgical techniques, but entering the thoracic cavity and pleura irritation from chest tubes can be painful. Adequate analgesia and incentive spirometry are mainstays in the management in the first 24 to 48 hours. Volume overload can lead to hypoexpansion, especially in the lung bases. Earlier mobilization helps but it also leads to increased blood flow in the bases, which may increase hypoxemia by shunting. Patients can develop fever, impaired gas exchange, and if not addressed, postoperative pneumonia in the areas of atelectasis. Treatment is best begun proactively. Correction of volume overload, pain management, early mobilization, incentive spirometry, and aggressive pulmonary toilet with noninvasive positive pressure may also be beneficial. Continuous positive airway pressure, bilevel positive airway pressure, and EzPAP positive airway pressure system (Smiths Medical, Minneapolis, MN) are modalities that may be used by respiratory therapy that may help to avoid reintubation.

Pleural Effusion

Most patients entering the ICU from the OR will have chest tubes, either mediastinal or pleural, and frequently both. These tubes generally remain in place for 24 to 48 hours or until drainage is usually less than 200 mL for a 24-hour period. The normal amount of pleural fluid is about 10 to 15 mL, which lubricates and allows smooth sliding of the parietal and visceral pleura. The turnover of pleural fluid can be about 1 to 2 L/day, so chest tube drainage will usually be a measurable amount.

These tubes will not allow for an accumulation of significant amount of fluid in the thoracic cavity unless the fluid is loculated or the tube is occluded (by fluid, blood, or mechanical obstruction). Rarely the tube may be malpositioned in a fissure and not able to adequately drain the accumulating fluid. Effusions can become an issue after the tubes have been removed, because this fluid may not be susceptible to more aggressive diuresis. These residual or recurring effusions do not need to be drained unless they are accompanied by respiratory symptoms or impairment in gas exchange. A simple thoracentesis or small pigtail catheter with collection device may be the solution without replacing a larger chest tube.

Pneumothorax

Pneumothorax is not uncommon in the immediate postoperative period and can be corrected by increasing suction on the collection devices. If there is an air leak in the chest tube that is persistent throughout the respiratory cycle, then connections must be examined and reinforced. A more difficult problem is a disruption of a pleura that may take a few days to heal. Occasionally a video-assisted thoracotomy is necessary to correct this defect.

Acute Lung Injury

Cardiopulmonary bypass can lead to a profound inflammatory response, especially in prolonged procedures. Hemodilution and inflammation may lead to reperfusion injury in the lungs. Although this is not a recurring injury to the lung parenchyma, it can lead to a clinical picture similar to the acute respiratory distress syndrome. Reactive airways, diminished pulmonary compliance, decreased PaO_2/FIO_2 ratios, and increased alveolar-arterial gradients may be observed. These individuals will benefit from judicious fluid management and low tidal volume ventilation with increased positive end-expiratory pressure until recovery. The time course to recovery is more rapid than in traditional acute respiratory distress syndrome, unless there is a secondary insult or an inattention to ventilator-induced lung injury.

Transfusion-Related Lung Injury

Transfusion-related lung injury (TRALI) is the most common cause of morbidity or mortality related to the administration of blood products.[43] This results from the deposition of activated neutrophils in the parenchyma of the lung with increased extravascular lung water and an impairment in gas exchange.[44] The current hypothesis is that there is a "two-hit phenomenon." The first insult is that the patient is in a heightened inflammatory state. This sensitizes the individual for the second "hit," which is the transfusion with blood products that further activates or enhances the proinflammatory state.[45] Cardiopulmonary bypass provides the first hit with overall activation of the immune system. The intraoperative or postoperative need for transfusion is the second insult. It is not always possible to avoid transfusion, but there are clear risk factors that increase the incidence of TRALI in these individuals. In a case-controlled study, risk factors were divided into recipient and transfusion related factors[43] (Box 35.3).

Of note, the age of the red blood cells has little or no risk for TRALI. Despite the controversy that surrounds the age in storage of packed red blood cells,[46,47] treatment of TRALI is supportive. The principles that apply to acute lung injury are used in this disorder. Volume restriction and low tidal volume ventilation are mainstays of therapy. There are anecdotal reports that steroids may help but have not proven beneficial in a randomized, controlled fashion and cannot be recommended.

Diaphragmatic Dysfunction[48]

Unilateral diaphragmatic elevation may be an incidental finding on routine chest x-ray after cardiac surgical procedures. This is

• BOX 35.3 Factors Leading to Transfusion-Related Lung Injury

Recipient
Shock
Higher interleukin 8 levels
Liver surgery
Chronic alcohol use and abuse
Higher peak airway pressures on mechanical ventilation
Current smokers
Positive fluid balance
Transfusion
Plasma or whole blood from female donors
Volume of antineutrophil antigen-positive blood
Volume of human leukocyte antigen class II antibodies

From Toy P, Gajic O, Bacchetti P, et al. Transfusion-Related Acute Lung Injury: Incidence and Risk Factors. Blood. *2012;119:1757–1767.*

seldom clinically relevant and is much more infrequent in modern cardiac surgery. Hypothermic injury to the phrenic nerve was the most common etiology but the use of cardiac insulation pads has led to a decrease in incidence. This "stunned" diaphragm may be clinically relevant if the patient has a preexisting unilateral paralysis on the contralateral side resulting in inadvertent bilateral paralysis. The diagnosis of unilateral diaphragmatic paralysis can be made using a fluoroscopic sniff test. Transdiaphragmatic pressures can be measured using lower esophageal and gastric manometry, which are invasive. Bedside ultrasound has been used as a diagnostic tool for both unilateral and bilateral dysfunction and can also be used to monitor recovery of the paralyzed diaphragm.

Deep Vein Thrombosis and Pulmonary Embolism

The rate of deep vein thrombosis (DVT) after cardiac surgery had a reported incidence of 48.3% in the early 1990s. But a larger randomized prospective study from the same institution with the same investigators published several years later reported an incidence of 20%.[49] The major differences between the two studies were the randomization of the second trial and earlier mobilization of patients in this latter trial. These studies also found that the occurrence of DVT in the lower extremity was independent of the side of vein harvesting. The development of DVT could not be explained by the trauma or disruption of the venous system in coronary bypass patients. Current estimates are that DVT occurs in 23% of all ambulating cardiac surgical patients treated with graded compression stockings and aspirin. As with most patients, DVT in cardiac surgical patients is mostly silent and difficult to recognize.

The risk of DVT and PE is increased in individuals with immobility, delayed recovery, or congestive heart failure. The risk may be accentuated in this group by prior history of DVT/PE, recent myocardial infarction, obesity, hyperlipidemia, and heparin-induced thrombocytopenia (HIT).

Given the high risk of DVT in patients undergoing cardiac surgery, the actual incidence of PE is low and fatal PE is negligible. Even though these rates are lower than other major surgical specialties, this should not be an argument against DVT prophylaxis. Strong consideration should be given to prophylaxis in the first 48 hours postoperatively. Sequential decompression devices have been used in patients who remain intubated in the ICU but are not recommended as routine primary prophylaxis after cardiac surgery. There has been no evidence that prophylactic dosing of anticoagulants leads to increased bleeding in routine postoperative cardiac surgical patients if initiated after 48 hours.

Pneumonia

Postoperative pneumonia is common after cardiac surgery with a reported prevalence of between 2% and 10%.[50] As a result, this is the most common infectious complication after cardiac surgery. The first postoperative week finds patients at greatest risk. Not all pneumonias are ventilator associated, although these are considered to be more preventable and have garnered much attention. Independent of the reason for pneumonia, there is an association with increased mortality in the cardiac surgical patients.

The Institution for Healthcare Improvement developed a "bundle" for prevention of ventilator-associated pneumonia that includes five elements:

1. Elevation of the head of the bed
2. Sedation interruption for readiness to wean
3. Peptic ulcer prophylaxis
4. Deep venous thrombosis prophylaxis
5. Daily oral care with chlorhexidine

In addition, Fitch and Whitman[51] identified two risk factors that are independently associated with ventilator-associated pneumonia. Individuals who receive perioperative transfusion of blood products and require reintubation are at much higher risk for postoperative pneumonia.

A series of factors have been recognized that identify patients with a higher risk of developing postoperative pneumonia not associated with mechanical ventilation.[50] Age older than 70 years, chronic obstructive pulmonary disease, preoperative left ventricular ejection fraction less than 60%, the interaction between the transfusion of packed red blood cells, and an increased duration of cardiopulmonary bypass were all independent risk factors that increase the incidence of postoperative pneumonia. These factors were used to create a risk score to predict postoperative pneumonia and cardiac surgical patients. This may be a useful tool in initiating antibiotic therapy earlier because it is becoming increasingly evident that delaying antibiotics in infectious disease is associated with a higher mortality.[52]

Tracheostomy

The optimal timing of tracheostomy is fraught with controversy. There is a trend toward early tracheostomy in respiratory failure. Tracheostomy in cardiac surgery had typically been delayed because of concern over contamination of the sternal wound and an association with mediastinitis. This concern was unfounded. There was also no benefit in patient outcomes in cardiac surgery that would advocate for delaying tracheostomy.[53] There is no evidence for optimal timing of tracheostomy in the cardiac surgical population.

Neurology

A spectrum of neurologic complications may be seen in the postoperative cardiac surgical patient.[54] This is not unexpected because the same risk factors that predispose individuals to heart disease also lead to cerebrovascular disease. Diabetes, hypertension, smoking history, and hyperlipidemia can lead to systemic pathology

TABLE 35.2 Incidence of Stoke Associated With Cardiac Surgery

Type of Surgery	Incidence of Stroke
Isolated CABG	1.4%–3.8%
CABG and valve	7.4%
Isolated valve	4.8%–8.8%
Multiple valves	9.7%
Aortic surgery	8.7%

CABG, Coronary artery bypass grafting.
From Selim M. Perioperative Stroke. *N Engl J Med.* 2007;356(7):706–713.

that is not limited just to heart disease. Neurologic findings in this population can be related to the operative procedure. Different procedures have different risks. A prime example is that of stroke. The risk of stroke is variable depending on the procedure performed (Table 35.2).

Although stroke is a devastating complication of the cardiac surgical population, it is not the only neurologic issue that these patients face. Consideration of postoperative neurologic care can be divided into a more generalized (global) or more localized (focal) process.

Focal Neurologic Dysfunction

Focal or localized neurologic complications in cardiac surgery can be limited, as in transient ischemic attacks (TIAs), or long-lasting with increased morbidity and mortality, as with certain vascular distributions in stroke. Focal neurologic defects related to stroke can be associated with a mortality of up to 20% in the first postoperative month. This can also prolong both ICU and hospital length of stay. Stroke/TIA are the main focal complications but brachial plexus injury and phrenic nerve paresis/paralysis can also be seen.

Stroke[55]

The risk of stroke in cardiac surgery can be minimized but the goal of never having a postoperative stroke is thus far unobtainable. Systemic anticoagulation with high-dose heparin and preoperative identification and intervention in patients with carotid disease have gone a long way minimizing the risk. There are aspects of open-heart surgery that are modifiable, but at times, unavoidable. Cross-clamping and cannulating an atherosclerotic aorta that results in microemboli traveling to the brain remains problematic. Opening the cardiac chambers with entrapment of air and possible air embolus remains another possible source for embolic stroke.

The majority of strokes are embolic and very few are initially hemorrhagic, despite the use of supertherapeutic dosing of heparin in cardiopulmonary bypass. Hemorrhagic conversion can occur in up to 20% of ischemic strokes, whereas embolic strokes present with more focality owing to involvement of a typical vascular territory. Hemorrhagic strokes can have a delayed awakening and coma. Strokes related to hypoperfusion lead to defects in watershed areas where there is a transition between major vascular distributions.

Once a stroke is suspected a computed tomography (CT) scan must be obtained. The timing for an intervention in stroke management is critical but because cardiac surgical procedures last between 3 and 6 hours the time of onset of the stroke is only able to be estimated. The CT scan can show a more discreet stroke, which suggests a more prolonged delay in the identification of the event. These individuals are placed in a more conservative support treatment strategy. Tolerance of a higher perfusion pressure, judicious fluid administration, and limiting anticoagulation and antiplatelet therapy to avoid hemorrhagic conversion are the mainstays of the conservative support strategy. More often in acute stroke (within 3–8 hours) only subtle findings are evident on CT scan. The loss of a gray-white interface, focal effacement, suggestion of a hyperdense area that conforms to neurologic deficit, and the loss of insular ribbon may be seen early in stroke. These individuals would be candidates for possible intervention. Because thrombolytic therapy is contraindicated in the immediate postoperative period, they would be considered for mechanical embolectomy if available. Although magnetic resonance imaging is much more sensitive in the acute stroke, devices, epicardial pacing wires, and the hemodynamic stability of the patient often preclude travel to remote areas that usually house the magnetic resonance scanner.

Anticoagulation is not usually administered in these patients because of the risk of bleeding in the fresh postoperative patient. There is also concern for hemorrhagic conversion in this tenuous vascular distribution. There are certain clinical circumstances that warrant consideration of anticoagulation. Internal carotid dissection, basilar stenosis, and AF with embolic stroke deserve a more in-depth risk-benefit consideration.

The longer the time since surgery that the stroke occurs, the more therapeutic options are available. Thrombolytics may become an option. Intraarterial thrombolytics were shown to be safe and effective in postoperative cardiac surgical patients. Administration of intraarterial thrombolytics was performed within the first 12 days postoperatively (average 4.3 days).[56] Although this is a small series, it opens the discussion and consideration of a previously closed therapeutic avenue.

Transient Ischemic Attacks

TIAs are reversible neurologic defects that spontaneously resolve within the first 24 hours of occurrence. To some extent a TIA is a threatened stroke that abates without neurologic residual. It should be viewed as a warning sign and an in-depth investigation to discover the cause for this near miss should be undertaken. Because there is no obvious ischemia or infarction, anticoagulation after resolution should be a serious consideration.

Brachial Plexus Injury

Injury to the brachial plexus during cardiac surgery is not infrequent but is underdiagnosed and underreported because it is often transient.[57] The mechanisms proposed for this injury are multiple. Hyperabduction of the arms, traction, and compression during sternal retraction and direct trauma owing to insertion of internal jugular lines have been postulated as possible mechanisms of injury. Harvesting of the internal mammary artery with asymmetric sternal retraction has been reported to have a higher rate of plexopathy. It is important to distinguish between brachial plexus injury and ulnar neuropathy. This injury to the ulnar nerve is less frequent after the recognition that this disorder was due to intraoperative positioning and compression of the ulnar nerve in the posterior condylar groove, although transient ulnar neuropathy tends to persist longer than brachial plexopathy.

Phrenic Nerve Injury

This isolated neuropathy, with resultant hemidiaphragm dysfunction,[48] was recognized as being related to cold cardioplegia and

is much less common with the use of cardiac insulation pads. Further discussion of this disorder was reviewed in the pulmonary section.

Global Neurologic Dysfunction

Global neurologic dysfunction is more anxiety-provoking to families than to individual patients. Although seizures can be more focal motor in origin, the progression to status epilepticus and resultant postictal state would argue that this is a global disorder. In addition to seizures, coma, delirium, and cognitive decline are considered in this category of generalized neurologic dysfunction.

Coma

Coma is defined as a state of deep unconsciousness that lasts for a prolonged period. In cardiac surgical patients, the use of anesthetics, opiates, and other central nervous system (CNS) depressants must have time to metabolize before coma is considered. Delayed awakening may be a more appropriate label for this group of patients. When patients are slow to emerge from anesthesia, a CT scan of the brain should be performed. Up to 20% of patients with stroke may have delayed awakening and some may have a hemorrhagic ischemic component.[58] Serial evaluations and documentation are crucial. The Glascow Coma Scale score may be a good starting point and is reproducible across examiners. Individuals with preoperative renal or hepatic dysfunction are at risk for delayed awakening. The proposed mechanism is impaired metabolism of CNS depressant drugs. Individuals with severe heart failure and an idiopathic delayed awakening have a worse prognosis.

Delirium[59]

Delirium is a prevalent issue across all ICUs. There are multiple factors that contribute to this disorder. The aging population, disruption of sleep patterns, CNS active medications, and loss of visual cues in unfamiliar surroundings are a few considerations that should be taken into account. Frequent reorientation, allowing for a more normal sleep-wake environment, and engaging familiar people or family may be useful nonpharmacologic maneuvers. Patients may need sedation if they are a threat to themselves or others, but these agents should be avoided because they may be of transient benefit in the short term and worsen or prolonged the delirium. The hyperadrenergic state that accompanies this delirium may be detrimental in the postoperative patient and should be treated with β-blockers and other antihypertensives. Short-acting agents are preferred because as the delirium lifts, the adrenergic activation may resolve with resultant hypotension. Drug and alcohol withdrawal are an important consideration and a frequently missed diagnosis in the ICU population with delirium.

Cognitive Impairment

Patients who undergo cardiac surgery may exhibit some decrease in cognitive function. Patients were told that they had "pump head," which was attributed to use of cardiopulmonary bypass. A similar decline was seen in "off pump" bypass patients, which would contradict this theory. In addition, a mild postoperative cognitive decline was also seen in noncardiac surgical patients.

This cognitive impairment can be seen in terms of short-term and long-term decline.[60] The short-term decline can be observed for up to several weeks postoperatively. The risk factors include older age and the risks that predispose for cerebrovascular disease. The mechanism of this deterioration is not well understood but there is some resolution within 3 months postoperatively. This area of research has been affected by poorly controlled studies that led to erroneous conclusions.[60] Long-term cognitive impairment in cardiac surgical patients seems to be a function of both aging and concomitant cerebrovascular disease. Just as in short-term decline, these variables may be confounding and limited by the lack of an appropriate control population. Cognitive decline accelerated by cardiac surgery has been postulated, but to this point the evidence is less compelling.

Seizures[61]

Seizures are rare in the immediate postoperative period. Most anesthetic agents are anticonvulsants, and in individuals with status epilepticus general anesthesia is the final step in the treatment algorithm. Seizures in the postoperative population either herald an underlying, unrecognized neurologic defect or are related to drug withdrawal (therapeutic drugs, illicit drugs, or alcohol). On rare occasions, a global tonic-clonic seizure may develop in patients who are hypoglycemic or hypoperfused. These patients need to have correction of their serum glucose and hypoperfused state as a primary treatment. After seizures are controlled, a CT scan of the brain should be performed to rule out CNS pathology. The next step would be an electroencephalogram as some anticonvulsants may be proconvulsants at elevated levels. Some cardiac medications, like lidocaine at toxic levels, may lower the seizure threshold. This can be seen in individuals with renal failure at normal dosing of lidocaine.

Tranexamic acid has proconvulsant activity. This antifibrinolytic agent should be avoided in any individuals with a seizure disorder or in those who have exhibited seizures in the perioperative or postoperative period.[62]

Endocrine

The endocrinologic system is in overdrive after cardiac surgery. The combination of adrenergic stimulation from major surgery and the inflammatory state induced at that time lead to an activation of the stress response.

Pituitary Adrenal Axis

Cardiac surgery leads to a massive outpouring of adrenocorticotropic hormone (ACTH) from the pituitary with subsequent cortisol secretion from the adrenal glands. Despite a return to normal ACTH, cortisol remains elevated. This suggests a hypersensitivity of the adrenal glands to ACTH.[71] Impaired cortisol clearance is also described in critically ill patients. This reduced cortisol breakdown may be related to the effect of stress on the activity and an expression of cortisol-metabolizing enzymes.[72] This effect should be considered when treating individuals who may need exogenous steroids. Stress dosing may need to be adjusted in such patients.

Diabetes

It has been long recognized that diabetics have more complications postoperatively and that poorly controlled diabetics are at even higher risk.[73] Intensive care of the diabetic patient in the ICU was revolutionized by a study in Leuven, Belgium, in 2001.[74] This study investigated the goals of glucose control in the management of hyperglycemic critically ill patients. The randomized controlled trial showed that individuals who had intensive insulin management

had increased morbidity and mortality compared with individuals who underwent a more liberal (routine) management strategy. The intensive insulin group maintained a blood glucose level between 80 and 110 mg/dL, whereas the conventional group had a goal glucose of between 180 and 200 mg/dL. This study was heavily populated by patients who had undergone cardiac surgery. A full 62% to 63% of the enrollees had been cardiac surgical patients and may have affected the conclusions that were generalized to all critically ill patients. What was clear from subsequent studies was that all patients who had cardiac surgery would benefit from tighter glucose control.

The STS published a practice guideline series addressing blood glucose management during adult cardiac surgery in 2009.[75] They recommended that patients should have their glucose controlled during the intraoperative and immediate postoperative period (<180 mg/dL) even if they were not recognized as diabetic.[76] An insulin drip should be used for glycemic. Their conclusions were that this glucose management strategy would:

1. Reduce mortality and morbidity
2. Lower incidence of wound infections
3. Reduce hospital length of stay
4. Enhance long-term survival

It was further recommended that the immediate goal of insulin therapy should be a glucose level less than 180 mg/dL. However, those who require a more prolonged ICU stay (>3 days), the glucose control should be a bit tighter (<150 mg/dL). The transition to subcutaneous insulin should be initiated before discontinuation of an insulin drip.

Care must be taken to avoid hypoglycemia because of an association with increased mortality in individuals who develop pathologically low sugar levels. These patients who have recently had cardiac surgery may be exquisitely sensitive to this hyperactive adrenergic state.

Thyroid

The syndrome of hyperthyroidism has clear indications for treatment, and the effects of thyroid hormone on cardiac function have been well described.[77] Increased CO and AF are possible complications of this syndrome. Hyperthyroidism should be recognized before surgery and treatment should not be altered or changed in the immediate postoperative period. If hyperthyroidism was not recognized before surgery, β-blockers should be aggressively used to control symptoms related to this disorder.

The effects of open-heart surgery on thyroid function have been linked to sick euthyroid syndrome,[78] and this response has been seen in both cardiopulmonary bypass and off-pump surgery.[79] Patients exhibit a normal thyroid-stimulating hormone and thyroxine (T_4) but have a depressed triiodothyronine (T_3) and free T_3 with elevated reverse T_3 (which is the inactive form of T_3). The mechanism is thought to be a decrease in the di-iodination of T_4 to T_3 in the peripheral tissues. Because T_3 is a more active compound, this is considered an adaptive mechanism that reduces catabolism in patients recovering from surgery when they need to be more anabolic.

Low levels of T_3 have been shown to lead to a decreased CO and increased systemic vascular resistance.[80] There have been multiple studies of replacement of T_3 in postoperative cardiac surgical patients and although the hemodynamics improved, there was no change in clinical outcomes. At this point, there is insufficient evidence to recommend routine replacement of T_3 in postoperative cardiac surgical patients.

Renal

Acute kidney injury after cardiac surgery is associated with a significant increase in mortality.[63,64] There are multiple definitions and models for predicting acute kidney injury; as a result the incidence can be anywhere from 3% to 30% of patients.[65] The risk of mortality can exceed 60% and in this population in which mortality is in the range of 2% to 8%, this is a substantial increase in risk. It is this group with the risk of increased mortality that will most probably progress to need renal replacement therapy.

Understanding risk factors that predispose individuals to acute kidney injury is the initial step to minimizing this progression that leads to increased mortality in this population.[66] The incidence of acute kidney injury is low in the range of 1% to 5%, in more conservative estimates, but the consequences are catastrophic. Female gender and left ventricular ejection fraction less than 35% are characteristics that may not be modified. The factors that may be addressed are exposure to angiographic contrast dye, duration of cardiopulmonary bypass, and hypotension during cardiopulmonary bypass. Preoperative consideration as it affects the intraoperative management of this at-risk population is crucial.

Traditionally acute kidney injury has been divided into three broad categories. The prerenal, renal, and postrenal injury categories are based on the breakdown that is a description of the location of the inciting insult. There is some overlap with this generalization, but the categorization is helpful in understanding, evaluating and treating patients with acute kidney injury, and being able to avoid renal replacement therapy.

Prerenal causes relate to impaired perfusion of the kidney. Most commonly prerenal azotemia is related to dehydration. In the immediate postoperative period this is less of an issue given the intensive intraoperative monitoring (TEE, PAC, mean arterial pressure, urine output, and so on). There is an enhanced emphasis on volume resuscitation in the OR. Hypotension, cardiac performance, anemia, and hypoxemia should be investigated and corrected in the immediate postoperative period. Upon admission to the ICU attention should be paid to output (urine, chest tube, gastric, and so on) because this may be the first clue to hypovolemia. In addition, individuals with a prior history of poorly controlled hypertension may require a mean arterial pressure that is higher than may be desirable in routine postoperative cardiac surgical patients. The kidneys may need a higher perfusion pressure to maintain routine function.

Renal causes of acute kidney injury are generally the result of ischemia or nephrotoxicity from diagnostic or therapeutic interventions. Impairment of blood flow or delivery of deoxygenated blood to the kidneys may lead to acute tubular necrosis. This sloughing of the renal tubular cells into the tubules may be a defense mechanism to protect the kidney from further, potentially irreversible damage. Renal tubular endothelium has the capacity to regenerate but these cells are exquisitely sensitive to hypoxia and nephrotoxins.[67] The recovery process has limitations and can be impaired by recurrent insults or prolonged hypoperfusion. Nephrotoxins can have direct tubular toxicity and can be related to the contact time that the tubules are exposed to these toxins. Repeated or concentrated exposure can be equally harmful. An interstitial nephritis can be due to exposure to a causative agent.[68] Penicillins, nonsteroidal antiinflammatory drugs, proton pump inhibitors, or diuretics are the most frequent agents seen in postoperative cardiac surgery. Patients may exhibit an eosinophilia with

eosinophiluria. The treatment is discontinuation of the offending agent, and although eosinophils have a role in this disorder, there is no evidence that corticosteroids have a beneficial effect in treatment.

Postrenal causes of acute kidney injury involve mechanical disruption of the urinary tract, from the kidney to the urethra. The abrupt cessation of urine production is an emergency that should be investigated and corrected before this leads to irreversible kidney damage. Ultrasonography of the kidneys or bladder may pinpoint the site of obstruction or disruption. Insertion or irrigation of a Foley catheter may be diagnostic of the etiology if the blockage is between the urethra and bladder.

The workup of acute kidney injury in postoperative patients should focus on the preoperative risk factors and stage of chronic kidney disease, with special attention to prior exposure to nephrotoxins. A review of intraoperative events with correction of intravascular volume depletion and perfusion defects is essential. Laboratory tests should include serologic evaluation of electrolytes, blood urea nitrogen, and creatinine. Urine should be obtained for electrolytes (to calculate the functional excretion of sodium), urine sediment, eosinophils, and specific gravity, although it must be noted that the fractional excretion of sodium can be affected by diuretics and should be interpreted in this context. Finally, radiologic examination of the urinary tract with ultrasound or CT scanning may be diagnostic. The goal is to halt the progression to renal replacement therapy with the associated increase in mortality postoperatively.

If renal replacement therapy becomes necessary, then hemodialysis is the gold standard for treatment.[69] There are defined serologic and metabolic indicators for initiation of dialysis. Occasionally patients may need to undergo ultrafiltration for volume management. In patients that are hemodynamically unstable, continuous renal replacement therapy is a viable option. This mode of renal replacement therapy is well tolerated hemodynamically but may not be available in all centers where cardiac surgery is performed. Sustained low-efficiency dialysis may be an alternative and can be performed with routine hemodialysis equipment. Initial trials have shown equivalence in clinical outcomes when sustained low-efficiency dialysis is compared to continuous renal replacement therapy.[70]

Hematology

Thrombocytopenia

Platelets have an integral function in the expression of coronary artery disease and are equally important in the postoperative cardiac surgical patient. The cornerstone in the management of ischemic heart disease is the use of antiplatelet agents. These same agents can lead to excessive bleeding in the perioperative and postoperative phase. This is more a function of the action of platelets and not the quantity of platelets.

Thrombocytopenia is defined as a platelet count of 150,000 or less platelets per milliliter and severe thrombocytopenia as 50,000 or less platelets per milliliter. Thrombocytopenia in patients can be due to one of six major mechanisms[81]:

1. Pseudothrombocytopenia
2. Hemodilution
3. Increased platelet consumption
4. Increased platelet destruction
5. Decreased platelet production
6. Increased platelet sequestration

When there is a slow and gradual falling platelet count over 5 to 7 days, this is more consistent with bone marrow failure (production) or consumption. A decrease in platelets within 1 to 2 days after the initial postoperative increase is more suggestive of immunologic etiology. Of these immunologic mechanisms HIT deserves a more in-depth consideration because of the association of HIT with cardiopulmonary bypass[82] and the use of heparin in this postoperative population.

Heparin-Induced Thrombocytopenia

HIT is the descriptive name of the syndrome heralded by the occurrence of a decreasing platelet count. The devastating and potentially life-threatening aspect of this disorder relates to the thrombotic complications owing to the induction of antiplatelet antibodies caused by exposure to heparin. It is estimated that HIT with possible thrombosis occurs in 1% to 3% of cardiac surgical patients.

Two distinct forms of HIT have been described. Type I HIT is a nonimmunologic response to heparin that leads to an early (48–72 hours) thrombocytopenia that is mediated by a direct interaction between heparin with circulating platelets. This reaction can occur in up to 10% of patients and causes platelet clumping or sequestration. This thrombocytopenia is mild and transient with returned to normal platelet count within 4 days after stopping heparin. This form of HIT is not associated with thrombotic complications.

Type II HIT is an immunologic disorder and associated with venous or arterial thrombosis. Heparin combines with platelet factor 4 and this interaction leads to an immunoglobulin G antibody that activates platelets. The subsequent release of prothrombotic particles from the platelets results in an excessive thrombin formation, platelet aggregation, and thrombus formation. Prior exposure to heparin can stimulate earlier manifestations of HIT, but this typically occurs 5 to 10 days after exposure to heparin. Major surgery resets the clock and type II HIT almost never occurs within the first 5 days after surgery.[83]

The incidence of type II HIT is low but the morbid consequences make consideration of this disorder an important decision point. The scoring system called the 4T's can be useful[84] (Table 35.3). This system uses four criteria to give weight to the probability of HIT and has a good negative predictive value when combined with the overly sensitive HIT antibody. A low score has a 1% likelihood of antibody positivity. Because the antibody is so sensitive there are false-positive results and a serotonin release assay may need to be obtained for confirmation.

Two agents have been approved for treatment of HIT: the direct thrombin inhibitor argatroban, which is available in the United States, and the anti–thrombin-dependent factor Xa inhibitor danaparoid (Canada, European Union, and Australia).[85] Argatroban can be used in patients with impaired renal function and has a short half-life. However, argatroban can prolong the prothrombin time and international normalized ratio, which makes institution and monitoring of warfarin effect difficult. The short half-life of argatroban allows it to be discontinued for a couple of hours to determine the prothrombin time/international normalized ratio when a patient is taking warfarin in order to separate the individual drug effects. Warfarin should not be initiated until the platelet count has returned to normal when anticoagulation is necessary in patients with HIT. Finally, platelet transfusion should be avoided unless the patient is actively bleeding as additional platelets may further fuel the thrombotic effect.[86]

TABLE 35.3 The 4T's Assessment for Patients With Suspected Heparin-Induced Thrombocytopenia

T	2 Points	1 Point	0 Points
Thrombocytopenia	<20,000 or >50% from baseline	<10,000–19,000 or 30%–50% from baseline	<10,000 or <30% from baseline
Timing of fall	Day 5–10 from exposure or <1 day if heparin exposure in <30 days	>10 days from exposure <1 day and exposure in past 30–100 days	<1 day with no recent heparin exposure
Thrombosis	Proven thrombosis, systemic reaction after heparin skin necrosis	Erythema "silent" recurrent or progressive thrombosis	None
Other cause for thrombocytopenia	None	Possible	Definite
	6–8 points = high likelihood	4–5 points = intermediate likelihood	0–3 points = low risk of heparin-induced thrombocytopenia

HIT, Heparin-induced thrombocytopenia.

Anemia

Blood loss anemia is by far the most common reason for transfusion in this population. The issue comes about because multiple studies have shown that transfusion in cardiac surgery is associated with increased morbidity and mortality.[87,88] Iron replacement therapy and tolerance of lower thresholds for transfusion should be initiated to avoid this complication. The use of recombinant erythropoietin has a theoretic complication of a prothrombotic effect and is used when there is an advantageous risk-benefit ratio.[89]

Hemolysis can occur in this postoperative population and can be related to cardiopulmonary bypass, shearing across mechanical valves, and transfusion reactions. Less commonly it can be seen in thrombotic thrombocytopenic purpura, which also results in thrombocytopenia, but there is nothing associated with cardiac surgery that increases the risk of thrombotic thrombocytopenic purpura.

Treatment of patients who are Jehovah's Witnesses needs to be considered, and their religious-based refusal of blood products makes anemia a particularly important issue. The management of this population is best begun preoperatively when possible. Optimization should occur before surgery with iron administration and when acceptable, erythropoietin. Emergent surgery does not always make this possible. Postoperatively these patients may need continued erythropoietin with iron administration, and judicious phlebotomy is advisable.

Gastrointestinal[90]

GI complications can develop in about 1% to 3% of cardiac surgical patients. The GI tract is sensitive to hypoxia and hypoperfusion, and as a result these complications are common in all critically ill patients. The common thread in the pathophysiologic mechanism is sympathetic vasoconstriction, with resultant hypoperfusion and hypoxia of the splanchnic bed. The three strongest predictive factors for GI complications are (1) prolonged mechanical ventilation, (2) sepsis, and (3) acute kidney injury, all of which may contribute to splanchnic hypoperfusion.

Intestinal Ischemia

Intestinal ischemia is a rare but highly lethal complication of cardiac surgery. In a study from Massachusetts General Hospital, 8700 patients were reviewed and although GI complications were rare (<1%), mesenteric ischemia was the most common with mortality of 67%.[91] This increased mortality was seen whether patients had surgery or were treated conservatively.

The diagnosis was entertained by the findings of pain disproportionate to physical findings, lactic acidosis, and leukocytosis. A CT angiogram may reveal pneumatosis intestinalis, bowel wall thickening, and possible thrombosis. Endoscopy may reveal a dusky, ischemic colon. It is at that time that operative intervention may be successful, before bowel rupture and peritoneal contamination. When peritoneal signs are present on physical examination, surgery is much less successful.

Pancreatitis

Hyperamylasemia is very common in the early postoperative phase but clinical pancreatitis is rare and seen in only about 1% to 3% of cardiac surgical patients. True symptomatic pancreatitis is rare in this population but carries a high mortality because of its association with multiple organ system failure. Amylase levels are not always helpful, and isolated hyperamylasemia will be associated with a normal lipase and abdominal complaints are not usually present. CT scan or ultrasonography of the abdomen should be obtained when the diagnosis is in question. Treatment of pancreatitis begins and ends with bowel rest and nasogastric drainage. Antibiotics remain a source of controversy as indiscriminate dosing can lead to selection of more resistant organisms, whereas this exuberant inflammatory state can be difficult to distinguish from sepsis. The decision remains at the clinical discretion of the treating physician.

Gastrointestinal Bleeding

The GI tract and especially the large and small intestine are sensitive to hypoperfusion and hypoxemia. The mucosal sloughing and disruption can be seen after cardiopulmonary bypass. The low incidence of obvious GI bleeding suggests that postoperative care has been successful. The use of GI prophylaxis with histamine H_2 blockers and proton pump inhibitors has improved the rate of upper GI bleeding. These agents should be discontinued when the patient leaves the ICU and is taking a full diet because of evidence of gastric bacterial overgrowth with increased incidence of gram-negative infections in those with decreased gastric acidity.

Hypoperfusion is not the only cause for upper GI bleeding. The intraoperative monitoring with transesophageal echocardiogram may lead to trauma to the esophagus. Although Mallory-Weiss tears are infrequent, esophageal erosions especially in combination with anticoagulants and antiplatelet agents can be a source of GI blood loss. Aspirin, in addition to antiplatelet actions, may have a localized, topical effect on the gastric mucosa. This is much less of a concern with enteric-coated formulations of aspirin.

Lower GI bleeding can be catastrophic when it is due to an ischemic-mediated process; however, a lower GI bleed usually is self-limited. Arterial venous malformations are unpredictable and can be corrected with interventional colonoscopy if they appear to be the source of recurrent blood loss. Diverticular disease and hemorrhoids may be an issue because of straining with bowel movements. Constipation is not uncommon for multiple reasons in the postoperative arena. Anesthesia, narcotic administration, psychological inhibition, and immobility contribute to the lack of regular bowel habits. Stool softeners and fiber are used immediately postoperatively but over the next few days laxatives may be necessary to avoid straining.

Elevated Liver Function Test Results

Evidence of hepatic dysfunction is not uncommon after open-heart surgery. It is estimated that approximately 25% of patients will develop a transient hyperbilirubinemia but few progress to frank liver failure. There are also low-grade elevations in transaminases and alkaline phosphatase. These are generally short-lived and multifactorial. Anesthetic agents, cardiopulmonary bypass, and hypoperfusion may give rise to elevations that resolve once these insults have been removed. Individuals with preexisting liver disease or congestive hepatopathy as the result of right-sided heart failure may require a longer time to correction.

Drugs are also a source of elevated liver function test results. Amiodarone, clopidogrel, and statins may contribute to this increase. Once the cause is identified, dosing of acetaminophen should be limited because of an increased susceptibility to toxicity in patients with liver impairment. In addition, several other factors should be considered. Cholecystitis is a rare occurrence in postoperative cardiac surgical patients but should be considered in individuals with fever, right upper quadrant tenderness, and leukocytosis. These symptoms should warrant an investigation with an ultrasound or CT scan of the abdomen. Hemolysis, especially in valve replacement surgery and patients who require recurrent transfusion, should be considered. A peripheral smear, haptoglobin, and lactate dehydrogenase are the initial screening laboratory tests necessary in this workup.

These elevations usually are limited and the liver can recover. The emphasis is avoidance of agents that may perpetuate or prolonged insult and injury, which can result in a delayed recovery.

Miscellaneous

Many GI issues that occur postoperatively do not rise to the level of complication, but providers need to be aware of these.

Pharyngeal dysfunction is not uncommon after intubation. This is usually time related, in that it is more common with longer intubation and usually resolves quickly after extubation. There may be pain on swallowing or inability to swallow. If there is a question, then speech evaluation with fiberoptic endoscopic evaluation of swallowing or modified barium swallow may be necessary. A nasogastric feeding tube may be a temporary means for medication administration and nutritional support.

Anorexia or nausea is frequently seen in those emerging from anesthesia and usually resolves after 24 to 36 hours. Narcotic analgesia may prolong the symptoms and patients respond to antiemetics or promotility agents. Patients require a more thorough workup after that initial time period if symptoms persist.

Diarrhea is usually a late finding postoperatively (3–5 days). This may be related to watery feces passing around an impaction because constipation is more common immediately after surgery. Medications should be reviewed. Stool softeners, laxatives, and promotility agents may be overlooked as they may be a part of the postoperative order set. Magnesium oxide is a common cause for increasingly frequent loose bowel movements because low magnesium is aggressively corrected owing to the concern for arrhythmias. Patients receiving tube feeds may benefit from a less hyperosmolar concentrated formula or by administration of water with the feeds to dilute the osmolarity of these feeds. *Clostridium difficile* colitis should be ruled out in those individuals with an elevated white blood cell count who have received antibiotics because without treatment these patients may progress to frank sepsis or develop a toxic megacolon.

Conclusion

As with critical care more generally, postoperative care of cardiothoracic patients is becoming increasingly complex and specialized. A wider range of bedside diagnostic tools is now available, which can allow clinicians to be more nuanced in their responses to the rapidly changing clinical status of a patient. Best practices are anticipatory instead of reactive, with an understanding of the common complications to be expected. As the practice continues to evolve, cardiothoracic intensivists from a surgical, medical, or anesthesia background will play a larger role in the postoperative care provided to patients.

Key Points

- Handoff from the OR team to ICU staff is an important component to the transfer of information necessary for care of this patient population.
- Meticulous attention to lines, tubes, and medication can help to avoid iatrogenic misadventures.
- Weaning from mechanical ventilation should be prioritized and some centers are extubating patients in the OR.
- Postoperative cardiac arrest may necessitate emergent reexploration.
- AF is very common and the most costly complication in postoperative cardiac surgical population owing to its frequency. The strategies of rhythm control versus rate control are of equal benefit.
- Increased blood utilization is associated with increased morbidity and mortality.
- Neurologic complications are frequent and can be categorized as focal or global dysfunction.
- Postoperative glucose management is mandatory in both diabetic patients and those without diabetes.
- Acute renal failure in the postoperative period is associated with a greater than 10-fold risk in mortality.
- Heparin-induced thrombocytopenia occurs in 1% to 3% of cardiac surgical patients postoperatively.

Review Questions

1. Each of these factors lead to prolonged intubation times *except*:
a. Long pump runs
b. Coagulopathy
c. Increased age
d. Prior stroke
Answer: d. Prolonged pump runs intraoperatively, coagulopathy, and increased age have all been shown to delay extubation times, but previous stroke has not been shown to affect the ability to wean and extubate patients in a timely manner.

2. Which of the following is true about postoperative atrial fibrillation?
a. It is uncommon and resolves frequently without intervention.
b. It is associated with increased mortality and length of stay.
c. It can be prophylactically treated with digoxin.
d. It requires rhythm control and not rate control.
Answer: b. Postoperative atrial fibrillation is the most common complication in cardiac surgical patients and is associated with increased mortality and morbidity. Rhythm control confers no long-term benefit over rate control. Digitalis has not been shown effective in keeping postoperative patients in sinus rhythm.

3. Each of the following is true of postoperative stroke in cardiac surgery *except:*
a. These strokes are usually hemorrhagic because of the high dose of heparin use in cardiopulmonary bypass.
b. Cross-clamping and cannulating the aorta can lead to atheroemboli.
c. The recognition of carotid disease preoperatively has decreased the risk of stroke.
d. Timing of the stroke occurrence can be difficult after surgery.
Answer: a. The incidence of postoperative stroke has been reduced by investigation, recognition, and treatment of carotid disease but cardiopulmonary bypass with cross-clamping and cannulation of atherosclerotic aorta can lead to embolic stroke. The timing of stroke can be difficult to gauge because anesthesia renders physical/neurologic examination ineffective during the 4- to 6-hour procedure/recovery. Most strokes are embolic in nature, and there is a decrease incidence of hemorrhagic stroke despite the anticoagulation intraoperatively.

Acute Respiratory Failure

DAVID P. GURKA AND ROBERT A. BALK

CHAPTER OUTLINE

Acute Respiratory Failure—Types 1 and 2

Hypoxemic Respiratory Failure
- Basic Mechanisms
- Assessment of Oxygenation

Hypercapnic Respiratory Failure
- Assessment of Ventilation
- Clinical Manifestations

Acute Respiratory Distress Syndrome
- Risk Factors

Incidence and Prevalence
- Clinical Manifestations
- Pathologic Manifestations
- Pathophysiology
- Management Strategies
- Drug Therapy for Prevention of ARDS
- Fibroproliferative Phase and Steroid Treatment
- Multiple-Organ Dysfunction/Failure
- Lung-Protection Strategy for Prevention of ARDS
- Prognosis

Future Considerations

Summary

Acute Respiratory Failure—Types 1 and 2

Acute respiratory failure is defined as the inability of the respiratory system to meet the oxygenation, ventilation, or metabolic requirements of the patient.[1] Although the main function of the lungs appears to be related to gas exchange (i.e., oxygenation and ventilation), it should be remembered that the lung is also a metabolically active organ.[1,2] Respiratory failure has been divided into two main types. Type 1 is hypoxemic respiratory failure (oxygenation failure), and type 2 is hypercapnic failure (ventilatory failure) with or without hypoxemic respiratory failure.[2] Operationally, type 1 respiratory failure is defined by a partial pressure of oxygen in arterial blood (Pao_2) less than 60 mm Hg, and type 2 respiratory failure is defined by a partial pressure of carbon dioxide (CO_2) in arterial blood ($PaCO_2$) greater than 50 mm Hg. The respiratory failure can be acute or chronic in nature, related to the onset and duration of the failure.[2,3] Some patients may present with an acute deterioration or worsening of their chronic respiratory dysfunction termed *acute-on-chronic respiratory failure.*[4]

Acute respiratory failure is commonly encountered in the intensive care unit (ICU) setting and may be the primary reason for the admission or a complication of the patient's medical condition(s) or treatment. Respiratory failure may be the result of a variety of causes, some of which may not directly involve the lungs or the respiratory muscles.[2] Like a chain composed of individual links representing the brain, peripheral nervous system, upper airway, lower airway, respiratory muscles, cardiovascular system, and lungs (Fig. 36.1),[2] respiratory failure may result when any of the links become sufficiently dysfunctional or weak. Like a chain, the body is only as strong as its weakest link, and respiratory failure may result when there is significant compromise. Common causes of hypoxemic and hypercapnic respiratory failure are listed in Box 36.1. This chapter reviews the basic mechanisms and clinical manifestations of type 1 and 2 respiratory failure and concludes with a more in-depth discussion of acute respiratory distress syndrome (ARDS); ventilator management is addressed in more depth in other chapters.

Hypoxemic Respiratory Failure

Basic Mechanisms

The five basic mechanisms of hypoxemia are listed in Box 36.2. Ventilation-perfusion abnormality is the most common.[2,3] Multiple mechanisms may be instrumental in the development of respiratory failure. Most of the abnormalities improve with the administration of supplemental oxygen, except for a shunt abnormality in which the Pao_2 continues to be low despite the administration of high levels of supplemental oxygen. The shunt may be either intracardiac (such as a right-to-left shunt through a patent foramen ovale) or intrapulmonary (as seen with pulmonary arteriovenous malformations, pneumonia, or ARDS).[5,6] A diffusion abnormality is infrequently the cause of hypoxemia in clinical practice and typically is clinically significant only in the setting of tachycardia, high cardiac outputs, and when the diffusion capacity is below 25% of predicted.[3]

Assessment of Oxygenation

The hallmark of type 1 respiratory failure is hypoxemia, which is primarily assessed by the Pao_2 with an arterial blood gas (ABG) analysis. Estimates of the patient's oxygenation status can be obtained by measuring the oxygen saturation using a pulse oximeter. An appreciation of the sigmoid shape of the oxyhemoglobin dissociation curve allows for a rough estimation of the Pao_2 (Fig. 36.2). The curve shifts rightward or leftward in relation to changes in the

• **Fig. 36.2** Oxyhemoglobin dissociation curve. *P_{aO_2},* Partial pressure of oxygen in arterial blood.

pH, P_{aCO_2}, temperature, and phosphate ion (PO_4^{-3}) concentration.[7] Determination of the ABG and knowledge of the exact fraction of inspired (F_{IO_2}) allows for the calculation of the alveolar-arterial oxygen gradient[3] (A-a gradient) using the formula $P_{AO_2} - P_{aO_2} =$ A-a gradient, according to the following:

$$P_{AO_2} = F_{IO_2}(P_B - P_{H_2O}) - P_{aCO_2}/R$$

where

P_{AO_2}	Partial pressure of oxygen in the alveolus
P_{aO_2}	Partial pressure of oxygen in the arterial blood
F_{IO_2}	Fraction of inspired oxygen
P_B	Barometric pressure
P_{H_2O}	Water vapor pressure at standard temperature and pressure
P_{aCO_2}	Partial pressure of carbon dioxide in the arterial blood
R	Respiratory quotient (R = 0.8)

The A-a gradient is F_{IO_2} dependent and increases as the F_{IO_2} increases. Because of the F_{IO_2} dependency, some have preferred to evaluate oxygenation abnormalities by calculating the P_{aO_2}/P_{AO_2} ratio, which is independent of the F_{IO_2}.[3] For simplicity's sake, many individuals use the P_{aO_2}/F_{IO_2} ratio as a measure of oxygenation abnormality. This value is used in the definition of ARDS and has gained wide-scale acceptance as a measure of abnormal oxygenation.[8] The shunt fraction or venous admixture can also be calculated while a patient breathes 100% oxygen and has reached steady state.

Hypercapnic Respiratory Failure

Hypercapnic respiratory failure can result from a variety of disorders as listed in Box 36.1.[9] Acute hypercapnic respiratory failure, also termed *acute ventilatory failure*, occurs when a patient has acute respiratory acidemia (pH <7.35) with a P_{aCO_2} greater than 50 mm Hg. This definition is not generally applicable to patients with severe chronic obstructive lung disease or neuromuscular disorders who have developed a compensatory metabolic alkalemia in response to their chronic hypercapnia. However, these patients may have acute exacerbations or comorbid conditions that cause them to decompensate into *acute-on-chronic respiratory failure*.

In steady-state conditions the rate of carbon dioxide (CO_2) production ($\dot{V}CO_2$) equals the rate of CO_2 elimination. CO_2 elimination ($\dot{V}CO_2$) is equal to the alveolar ventilation (VA) multiplied by the partial pressure of CO_2 in the alveolar gas (P_{ACO_2}). Thus the equation for CO_2 production is $\dot{V}CO_2 = VA \times P_{ACO_2}$. In the pulmonary capillary, CO_2 is readily diffusible through the endothelial and epithelial cell membranes down a substantial concentration gradient of approximately 45 to 50 mm Hg (normal pulmonary arterial CO_2 [P_{aCO_2}] versus essentially zero for the partial pressure of inspired CO_2 in room air [P_{ICO_2}]) so that the alveolar and capillary blood partial pressures of CO_2 are equal ($P_{ACO_2} = P_{aCO_2}$).

Not all respired air is effective alveolar ventilation because some of the total tidal ventilation (V_t) ventilates nonperfused areas or dead space (VD) (both anatomic and pathologic). This relationship between V_t, VD volume, and alveolar volume can be expressed as[3]:

$$V_t = VA + VD \text{ or } VA = V_t - VD$$

The minute ventilation (VE) is equal to the sum of the dead-space ventilation (VD) and the alveolar ventilation (VA): VE = VD + VA. Combining and rearranging terms from these various equations yields the following relationship of CO_2 production and alveolar ventilation with the P_{aCO_2}:[3]

$$P_{aCO_2} = \frac{\dot{V}CO_2}{V_t - V_D}$$

Therefore elevated P_{aCO_2} can result from a combination of any of three clinical alterations: increased CO_2 production, decreased V_t, or increased VD ventilation.[9] Increased CO_2 production arises from hypermetabolic states such as exercise, fever, sepsis, burns, trauma, excessive carbohydrate intake, and hyperthyroidism.[9] In isolation, these relatively common conditions rarely induce hypercapnic respiratory failure because the normal physiologic response to an elevated P_{aCO_2} is to increase minute (and therefore alveolar) ventilation to maintain eucapnia and a normal pH. Only those patients who are unable to increase their effective alveolar ventilation as a result of neuromuscular disorders affecting the muscles of respiration, the presence of excessive ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatching, or increased VD ventilation develop

hypercapnic respiratory failure as a consequence of elevated CO_2 production.

Ventilatory deficiencies, decreased V_t ventilation, and increased VD ventilation that result in hypercapnic respiratory failure can be differentiated by using the A-a gradient equation. The $PAO_2 - PaO_2$ difference breathing room air is normally less than 10 to 15 mm Hg when simple alveolar hypoventilation is responsible for the hypoxemia. An increased $PAO_2 - PaO_2$ difference suggests a parenchymal lung process, usually associated with $\dot{V}/\dot{Q}$ abnormalities, to account for the additional hypoxemia in these patients with hypercapnic respiratory failure.

Decreased V_t hypoventilation can be caused by disorders affecting any component of the "neuromuscular sequence," starting in the central nervous system and ending at the muscles of respiration (see Fig. 36.1). Among the more common causes are CNS depressants such as narcotics and sedatives, which diminish respiratory drive; cerebral vascular disorders, especially those that involve the brainstem, which impair the efferent signals to breathe; and disorders of neuromuscular transmission such as myasthenia gravis and the paraneoplastic Eaton-Lambert myasthenic syndrome (Box 36.3).[10,11] Abnormal respiratory mechanics can result from airflow obstruction, chest wall deformities, and loss of lung volume. Disorders that increase the respiratory load (such as a circumferential chest burn eschar or flail chest) or impair function of the respiratory muscles (such as kyphoscoliosis) also lead to hypoventilation.

Assessment of Ventilation

The hallmark feature of inadequate ventilation is the presence of an elevated $PaCO_2$ with or without hypoxemia.[3,9] In the adult population the best method to detect an elevated $PaCO_2$ is with an ABG measurement. Noninvasive evaluation of ventilation in the critically ill adult, using capnometry or end-tidal CO_2 ($PETCO_2$) measurements is gaining in use.[7] Transcutaneous CO_2 ($PtCO_2$) determinations in adults are not as reliable as in the neonate.[7]

Clinical Manifestations

The risk factors for developing acute respiratory failure include the postoperative state, preexisting chronic illness, malnutrition, advanced age, morbid obesity, chronic bronchitis, and cigarette smoking. The clinical manifestations of respiratory distress may be subtle and nonspecific or may be obvious to even the untrained observer. The patient with respiratory distress may have an abnormal respiratory rate (too high or low) or display an irregular pattern of breathing. The patient with respiratory distress may manifest gasping ventilation, nasal flaring, or use of the accessory muscles of respiration. Intercostal retractions may be seen, and the patient may exhibit paradoxical respiratory movement. Typically patients with acute respiratory failure, whether type 1 or type 2, have altered heart rate and blood pressure. The majority demonstrate a sympathetic response with tachycardia and hypertension, but patients may be hypotensive and bradycardic. Cardiac arrhythmias may be seen in both type 1 and type 2 respiratory failure. Patients with acute respiratory failure are usually in distress and often appear apprehensive.[2,9] Many are diaphoretic and have altered mental status or level of consciousness. Hypercapnic patients may demonstrate signs of a respiratory encephalopathy, including somnolence, coma, asterixis, seizures, tremors, or myoclonic jerks. Papilledema and congested conjunctivae may be present. Patients with type 1 respiratory failure may appear cyanotic. Although the management of acute respiratory failure is complex and reviewed elsewhere in this textbook, a great deal of effort has targeted the use of noninvasive ventilation or high-flow nasal cannula to avoid the use of intubation and invasive ventilatory support.[12–14]

Acute Respiratory Distress Syndrome

Since the initial 1967 description of acute catastrophic respiratory failure in 12 patients who were subsequently declared to have the acute respiratory distress syndrome, there has been a great deal of research and clinical study attempting to understand the mechanism of injury and improve the outcome of these critically ill patients.[8,15–19] The hallmark of this disorder was the rapid onset of acute hypoxemic respiratory failure that was characterized by refractory hypoxemia despite the administration of high concentrations of supplemental oxygen; decreased pulmonary compliance; bilateral pulmonary infiltrates; the absence of left-sided heart failure; and histologic evidence of alveolar damage with early hyaline membrane formation, which was followed by fibrosis of the lung.[8,15] The subsequent 10 to 20 years of ARDS management were associated with extremely high mortality rates, at times approaching 90%, despite the provision of extremely aggressive supportive care.[15–20] Some of the initial clinical and basic investigations that attempted to improve the outcome of patients with ARDS were hampered by the lack of a uniformly accepted definition.[21–25] In 1994 an American-European Consensus Conference (AECC) defined acute lung injury (ALI) and ARDS in an attempt to eliminate confusion related to terminology for these conditions.[21,22] The definitions were clinically based and regard ALI as a continuum with the more severe oxygenation abnormalities reflective of ARDS. Among the main benefits of the uniform definition would be improved communication and enhanced clinical trial design.

The AECC definition of ALI and ARDS was challenged related to discrepancies between the clinical and pathologic findings in individuals who died with ARDS.[25] Esteban and colleagues[25] found that one-third of the people who died with a clinical diagnosis of ARDS did not have histologic evidence of diffuse alveolar damage on postmortem examination. In addition, diffuse alveolar damage, the hallmark pathologic finding of ARDS, was evident in 10% of patients who died without a clinical diagnosis of ARDS. Since its introduction, the AECC definition has been used by the vast majority of clinical trials evaluating new treatment strategies for patients with ARDS, particularly those conducted by the ARDS Network investigators, supported by the U.S. National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health.[26,27] In 2011 experts from the European Society of Intensive

Care Medicine, the American Thoracic Society, and the Society of Critical Care Medicine met in Berlin and proposed a new definition for ARDS that also provides a staging as mild, moderate, or severe, based on the oxygenation impairment measured on a minimum of 5 cm H_2O positive end-expiratory pressure (PEEP) (10 cm H_2O for severe).[28] The Berlin definition of ARDS does not drastically differ from the AECC definition but clarifies several important concepts:

1. Timing—patients with ARDS should be identified within 72 hours of a recognized risk factor and nearly all patients should be identified within 7 days.
2. Chest imaging—bilateral opacities consistent with pulmonary edema are seen on chest radiograph or chest computed tomography (CT) scan.
3. Origin of pulmonary edema—ARDS may be present in the setting of coexisting cardiogenic edema or volume overload if in the opinion of the treating physicians the respiratory failure is not fully explained by these conditions and there is a recognized risk factor for ARDS. In the absence of a recognized risk factor for ARDS, there should be some objective assessment of cardiac function such as echocardiography or pulmonary capillary wedge pressure measurement.
4. Oxygenation—because PEEP can affect the Pao_2/FIO_2 ratio there should be a minimum of 5 cm H_2O PEEP and 10 cm H_2O in those patients with severe ARDS ($Pao_2/FIO_2 < 100$).[28]

The Berlin definition for ARDS eliminates the use of the term "acute lung injury" and classifies the severity as mild ARDS ($Pao_2/FIO_2 \leq 300$ but >200), moderate ARDS ($Pao_2/FIO_2 \leq 200$, but >100), and severe ARDS ($Pao_2/FIO_2 \leq 100$), with associated morality rates of 27%, 32%, and 45%, respectively.[28]

To date there is no specific diagnostic laboratory test for the diagnosis of ARDS.[8,21,26] All of the current definitions for ARDS require the presence of bilateral pulmonary infiltrates on chest imaging, but interpretation is not always straightforward, with experts disagreeing up to 50% of the time in some studies.[21,27,29]

Risk Factors

It has been recognized that ARDS may arise in association with a number of clinical conditions or risk factors, with sepsis the most common (Box 36.4).[8,20,21,28,30–34] Various studies report that ARDS develops in approximately 5% to 40% of patients with sepsis.[8,31,33,34] Shock (prolonged hypotension) and the systemic inflammatory response syndrome (SIRS) are also common risk factors. Other frequently encountered clinical risk factors include multiple emergency transfusions; aspiration injury; near-drowning; pancreatitis; trauma (e.g., DIC lung contusion, fat emboli from long bone fractures); burns; cardiopulmonary bypass; and disseminated intravascular coagulation. These clinical risk factors are synergistic, and when more than one of the clinical risk factors is present, the likelihood of ARDS is greater than just the sum of the collective risk factors.[8,20] The clinical risk factors associated with the development of ARDS appear to greatly influence the expected outcome. Whether ARDS arises from a direct pulmonary insult or from an extrapulmonary cause affects the subsequent response to PEEP and ventilatory support (Box 36.5).[20] Age also has an impact on the likelihood for ARDS development.[34] Older individuals have a greater likelihood of developing ARDS from most of the risk factors noted earlier. In the setting of trauma the risk for ARDS seems to peak in the sixth and seventh decades and then declines.[34]

Negative-pressure (postobstructive) pulmonary edema (NPPE or POPE) is a type of noncardiogenic pulmonary edema that can manifest as ARDS.[35] It is rare (five cases reported from a large tertiary medical ICU in 4 years),[36] can range in severity from mild hypoxemia treated with low-flow supplemental oxygen to profound hypoxemia requiring mechanical ventilation, and may even present as alveolar hemorrhage.[37–41] It is believed to be caused by increased vascular permeability resulting in alveolar and capillary damage from large levels of negative intrathoracic pressure generated by attempting to inspire against an occluded airway or airway obstruction.[42,43] This leads to a protein-rich alveolar exudate impairing gas exchange in mild to moderate cases and leaking of capillary blood into the alveoli in more severe circumstances. Most of the reported cases are related to surgical procedures: thyroidectomy,[44] septorhinoplasty,[45] tonsillectomy/adenoidectomy,[46] mandibular open reduction and internal fixation,[47] or cryosurgery for a tracheal obstruction.[48] Nonoperative conditions leading to NPPE have included laryngospasm,[49,50] occlusion of an endotracheal tube,[51,52] excessive tube thoracostomy suction pressure,[53] nonlethal hanging,[54] and even hiccups.[55,56] The common element is the rapid relief of a large airway occlusion. Patients often have no underlying cardiopulmonary disorders. NPPE may account for a small percentage of immediate postoperative extubation failures, particularly if an unrecognized mainstem intubation is present in an awake and spontaneously breathing patient. Clinical manifestations of hypoxemia and respiratory distress may be delayed up to 6 hours.[43]

• BOX 36.4 Common Clinical Risk Factors for ARDS

• BOX 36.5 Common Pulmonary and Extrapulmonary Causes of ARDS

Direct Pulmonary Causes

Pneumonia
Acid aspiration
Inhalational lung injury
Lung contusion
Chest trauma
Near-drowning

Extrapulmonary Causes

Sepsis—systemic inflammatory response syndrome
Shock—hypotension
Pancreatitis
Trauma (fat embolism)
After cardiopulmonary bypass
Massive transfusion therapy
Burns
Elevated intracranial pressure (traumatic brain injury, intracerebral hemorrhage)

Therapy is supportive with supplemental oxygen and, if needed, positive-pressure ventilation (invasive or noninvasive).

Elevated intracranial pressures, either from traumatic brain injury, intracerebral hemorrhage, or status epilepticus can induce an ARDS-like clinical syndrome termed neurogenic pulmonary edema.[57,58] Although the exact mechanisms are not clear, an abrupt and massive release of catecholamines from injured neuronal tissues is thought to act directly on the pulmonary vasculature to promote a "capillary leak" of a protein-rich exudate and an increase in pulmonary vascular resistance.[59] In addition, there may be a neurohumoral (takotsubo) cardiomyopathy, which has the distinctive echocardiographic feature of ventricular apical ballooning that can persist for months.[60–63]

Incidence and Prevalence

The exact incidence and prevalence of ARDS has been variable and influenced by the definition used (Box 36.6).[8,34] Early reports suggested that there were 150,000 patients with ARDS each year in the United States.[8,30,64] This statistic led to an estimated incidence of 75 cases per 100,000 population. Proposed estimates have suggested that the incidence of ARDS ranges from 1.5 to 64 cases per 100,000 population.[34,64,65] The authors noted that increasing age was associated with an increased incidence and mortality rate in ARDS. A recent Spanish prospective observational study (the ALIEN) using the AECC definition and treatment with lung protective ventilatory support strategies reported an ARDS incidence of 7.2 per 100,000 population per year with an ICU and hospital mortality rate of 42.7% and 47.8%, respectively.[66]

Clinical Manifestations

When ARDS becomes clinically apparent, the patient is usually noted to be in significant respiratory distress manifesting dyspnea, tachypnea, accessory muscle use, and increased work of breathing.[8,23,30] ARDS typically presents as an acute catastrophic complication in a patient who has one or more of the clinical risk factors. The precipitating injury need not directly involve the pulmonary system.[8,20] Past definitions have emphasized the need to exclude patients with previous or known chronic pulmonary or cardiovascular diseases.[20,21,26] The AECC definition excluded patients with elevated left-sided heart filling pressures and chronic infiltrative lung disease as the cause of the radiographic or physiologic alterations, but the Berlin definition allows for the concomitant presence of ARDS and cardiac edema/volume overload as long as the predominant process is thought to be ARDS.[21,28]

The physiologic hallmark of ARDS is the presence of hypoxemia despite high concentrations of inspired oxygen, evidence of an increased shunt fraction, decreased pulmonary compliance, and increased V_D ventilation.[8,24,28] The chest radiographic manifestation of ARDS is the presence of bilateral pulmonary infiltrates with a normal cardiac silhouette. Recent reports have cautioned that even among trained experts there is often disagreement concerning the interpretation of the chest radiograph.[27,29,64,67] Chest CT has also demonstrated that the radiographic injury is not homogeneous and has a predominance in the dependent portions of the lung.[8,67] It is important to remember that ARDS is a clinical syndrome and the diagnosis is made clinically, not on the basis of a single radiograph, ABG analysis, or laboratory test.

Pathologic Manifestations

Type 1 alveolar epithelial cells compose the major gas exchange surface of the alveolus and are integral to the maintenance of the permeability barrier function of the alveolar membrane.[8] Type 2 pneumocytes are the progenitors of type 1 cells and are responsible for surfactant production and maintaining homeostasis.[8] During ARDS there is damage to both capillary endothelial and alveolar epithelial cells.[8] Cellular injury and alteration of the normal barrier function results in a permeability defect that gives way to flooding of the alveoli with protein-rich fluid and inflammatory cells.[8,30,68] This results in the alteration of pulmonary mechanics, physiology, and gas exchange.[8,69] There is alteration of surfactant that results from damage to the type 2 pneumocyte and from the inactivation and dilution of alveolar surfactant from the protein and fluid that have entered into the alveolar space, respectively.[70,71] Surfactant dysfunction can lead to atelectasis and a further reduction in pulmonary compliance.[8,70–73] In addition, dysfunction of the alveolar epithelial cells can impair the resorption of fluid from the alveolar space, which augments the parenchymal injury process and gas exchange abnormalities.[8,74]

The observed pathologic findings in ARDS depend on the timing of the tissue sampling. During the initial stages of clinically evident lung injury there is histologic evidence of diffuse alveolar damage.[8] Histologic features of the injury include microthrombi composed of platelets and white blood cells within the capillary lumen, denudation of the alveolar epithelial lining cells, swelling of the capillary endothelial cells, interstitial and alveolar infiltration by polymorphonuclear leukocytes (PMNLs), and hyaline membrane formation within the alveoli.[8] Grossly, the lungs appear heavy and wet. Later, areas of type 3 collagen deposition with fibrosis will be present.[74] An intense inflammatory reaction involving PMNLs, activated monocytes, macrophages, and endothelial cells is present in the fibroproliferative phase of lung injury.[68,71,75] Proinflammatory and antiinflammatory molecules produced by these activated cells may be found in the circulating blood and bronchoalveolar lavage fluid.[75–77] This phase may be followed by fibrosis, but this fibrosis does not appear to have the same permanence as typical fibrosis would have and may actually resolve over time in some survivors of the injury.[78]

Pathophysiology

ARDS may develop as a result of epithelial or endothelial cell injury.[8,79,80] Both sites of injury and cells are important for maintenance of normal barrier function and are capable of initiating an inflammatory response. In the majority of clinical settings the

initial site of the ARDS involves the capillary endothelial cell, which may be the initial manifestation of a "panendothelial cell injury" resulting from SIRS.[77] Endothelial cell injury compromises the integrity of the vascular barrier and results in transudation of fluid and inflammatory mediators into the interstitial tissues and ultimately into the alveoli.[8] The frequent occurrence and early involvement of lung dysfunction as a component of multiple organ dysfunction/failure lends support to the hypothesis of a panendothelial cell injury as one of the target injuries in the setting of sepsis or SIRS.[81]

The complex pathophysiologic processes that culminate in the production of ARDS involve a delicate balance between the body's proinflammatory and antiinflammatory responses to the inciting clinical event.[77,81] The balance that exists between the various inflammatory molecules or mediators and the endogenous compensatory responses evoked by the inflammatory response dictates whether or not lung injury and other forms of organ dysfunction will develop.[75] The ensuing interaction between SIRS and the compensatory antiinflammatory response syndrome (CARS), coupled with activation of the clotting cascade and with inactivation of the normal fibrinolytic pathway, thus determines whether a patient successfully deals with an injury or is predisposed to develop organ dysfunction (excessive SIRS response) or immunosuppression and infectious complications (excessive CARS response).[77,81] This mixed antagonistic response syndrome has tremendous impact on the fate of the critically ill patient.[81]

Management Strategies

Basic management strategies for patients with ARDS are listed in Box 36.7.[8,21,23,30,82] Initial attention must be directed to providing lung-protective ventilator support along with identification and treatment of the predisposing underlying clinical risk factor(s) or condition(s).[8,21–23] The recognition of sepsis and infection as frequent causes of ARDS should prompt an aggressive search for undiagnosed foci of infection and the administration of appropriate antimicrobial treatment and source control as indicated.[20,83]

• BOX 36.7 Basic Management Strategies for Patients With ARDS

Identify and treat underlying/predisposing cause of ARDS
Ventilatory support
- Lung-protective ventilatory support strategy
- Application of PEEP (per ARDS Network protocol)

Restore and maintain hemodynamic function
- Conservative fluid replacement strategy using goal-oriented approach
- Vasopressor and inotropic support as needed to meet goals

Prevent complications of critical illness
- Stress ulcer (stress-related mucosal disease) prophylaxis
- Preventive strategies for pulmonary embolism and deep venous thrombosis
- Prevent infections such as ventilator-associated pneumonia
- Control glucose and metabolic function

Prevent development of multiple-organ dysfunction/failure
Ensure adequate nutrition
Avoid oversedation and medication errors
Use of weaning protocol with spontaneous breathing trials when ready to wean
Cautious use of steroids for fibroproliferative phase (avoid if patient has received neuromuscular blocking drugs)

ARDS, *Acute respiratory distress syndrome;* PEEP, *positive end-expiratory pressure.*

Both experimental and clinical data report significant survival benefit from the use of lung-protective ventilatory support strategies in the management of ARDS.[84,85] The primary goal of this support is to maintain adequate oxygenation and ensure that the lung is allowed to heal and avoid further injury. Use of nonprotective ventilatory support strategies may have a role in the persistent proinflammatory response and the development of multiple-organ dysfunction syndrome (MODS) and multiple-organ failure (MOF).[84–87]

Mechanical Ventilation

See Chapter 11 for a more detailed discussion of mechanical ventilatory support in the management of patients with ARDS. Over the past 20 years there has been increasing recognition that the ventilatory support strategy used in the management of patients with ARDS may produce or augment lung injury or impair the healing process (Box 36.8).[86–91] Results of experimental animal studies demonstrated clinical, physiologic, and histologic abnormalities similar to those observed in patients with ARDS when animals with normal lungs were ventilated with large V_ts or were given high inflation pressures.[90,91] The alveolar overdistention produced by these ventilatory modes was considered the critical element in production of the lung injury.[90,91] Lung injury could result from the administration of large V_ts or the administration of positive-pressure or negative-pressure breaths that were sufficient to produce alveolar overdistention (termed *volutrauma*).[91–94]

Other mechanisms that could potentially result in lung injury were the repetitive recruitment-derecruitment of distal airways (termed *atelectotrauma*) and alveoli or the disruption of alveoli resulting in translocation of organisms or air emboli.[90,91] Alveolar overdistention can also give rise to bioactive molecules that may contribute to the SIRS response and drive the development of MODS/MOF.[86,91] This has been termed *biotrauma*.[91] Interestingly, the lung injury produced by high inflation pressures or large V_ts in these experimental models could be ameliorated by the addition of therapeutic amounts of PEEP.[91] Subsequent human studies have used chest CT scanning to evaluate the distribution of the radiographic injury in ARDS and have noted the dependent nature of the injury.[67,95] The injury to the lungs was not diffuse and homogeneous as once believed. These dependent areas of injury consist of regions of alveolar flooding from the gravitational accumulation of lung water, areas of lung injury, and normal lung regions. The relatively normal ventral (nondependent) lung has been referred to as the "baby lung," and the injured (dependent) lung has been called the "sponge lung."[95] With the use of higher V_ts, PEEP, or high distending pressures, there was evidence of alveolar overdistention, particularly in the areas of normal lung. A multicenter trial of low versus traditional V_t ventilation in patients with ARDS demonstrated increased proinflammatory cytokines in the serum and bronchoalveolar lavage fluid of patients ventilated with the larger traditional V_ts, supporting the concept of biotrauma from alveolar overdistention.[86] Pulmonary barotrauma (pneumomediastinum, pneumopericardium, pneumoperitoneum, pneumothorax, subcutaneous

emphysema, pulmonary interstitial emphysema, and air embolism) is a well-recognized complication of ventilatory support that has been reported in 7% to 15% of patients with ARDS.[96]

The landmark study by NHLBI ARDS Network compared low V_ts (6 mL/kg of ideal body weight) against conventional V_ts (12 mL/kg of ideal body weight).[88] A protocol governed the use of PEEP according to the FIO_2 required to meet the oxygenation goals. A weaning protocol was used once the patient was receiving a reduced amount of ventilatory support. The trial was terminated after 861 patients were enrolled after the determination of a significant (22% relative reduction) decrease in mortality rate associated with the use of low V_ts (39.8% vs. 31%; $P = 0.007$). A significant difference occurred between the low- and high-V_t groups in length of stay, ventilator days, and development of MODS.[88] No difference occurred in the development of barotrauma between the two ventilator support strategies. On further analysis, this survival benefit was present irrespective of the patient's body mass index.[97] The ARDS Network (ARDSnet) lung-protective protocol strove to keep the end-inspiratory plateau pressure (P_{plt}) ≤30 cm H_2O to avoid alveolar overdistention and the potential production of ventilator-induced lung injury (VILI).[91] The transalveolar pressure [(P alveolar pressure (P_{ao}) − P pleural (P_{pl})] likely governs the production of VILI, but some have evaluated the driving pressure (P_{plt} − PEEP) as a more readily identifiable variable associated with poor outcome.[98,99] Using an administrative dataset from past studies of lung protective ventilatory support an increase in driving pressure was associated with increased mortality, whereas a decrease was associated with decreased mortality in patients with ARDS.[98]

The use of lower V_ts typically results in controlled hypoventilation or permissive hypercapnia and can lead to hypercapnic acidosis.[100] Some experimental animal models of lung injury suggest that hypercapnic acidosis may be beneficial to the lung and produce less lung injury as measured by extravascular lung water (Box 36.9).[101] Other reports have detailed potentially harmful effects of hypercapnia on epithelial and endothelial barrier function, lung edema, edema clearance, innate immunity, and host defenses and have reported increased mortality as the hypercapnia worsens.[101,102]

PEEP is a major component of the ventilatory support strategy and may actually have a direct therapeutic role in the prevention of VILI, as noted in some experimental models.[8,90,103–105] PEEP is beneficial in the recruitment of atelectatic lung units and prevention of recruitment-derecruitment, and it increases the functional residual capacity, decreases the shunt fraction, and allows for a reduction to a less toxic FIO_2 while still maintaining adequate oxygen saturation and tissue oxygen delivery.[105–109] The application of the "right amount" of PEEP has been the topic of investigation and controversy over the past few decades (Fig. 36.3).[110–115]

PEEP has the potential to have profound hemodynamic consequences in selected patients and clinical circumstances, and it is important to closely monitor patients with hemodynamic, echocardiographic, or other sophisticated monitors if there is a question of the adequacy of cardiac function when PEEP is applied.[6,104,109] Right-to-left shunting through a patent foramen ovale can occur in up to a third of patients with severe ARDS, and increasing PEEP may not produce the expected oxygenation benefits in these individuals.[116] The effect of PEEP may not be the same in the supine and prone positions. There is an enhanced ability to recruit alveoli when the patient is in the prone position compared with the supine position related to stabilization of the anterior chest wall.[117] There may be a different responsiveness to the use of PEEP depending on whether the ARDS results from a direct pulmonary injury or a nonpulmonary process.[20]

A multicenter French study has reported that the use of neuromuscular blockade with cisatracurium during the initial 48 hours of severe ARDS was associated with improved 90-day survival and longer time off ventilatory support in contrast to conventional ventilator management.[118] A prior study by these investigators noted decreased inflammatory response associated with the use of neuromuscular blockade in patients with ARDS.[119] Although there is always a risk for prolonged neuromuscular weakness associated with the use of neuromuscular blocking drugs, as well as in critical illness, there are many potential benefits in support of using neuromuscular blocking agents early in severe ARDS.[120] Some of these potential benefits include better patient-ventilator synchrony and interaction, less VILI as a result of better control of driving pressure and transpulmonary pressure, better recruitment effect from administered PEEP, and decreased oxygen consumption.[118,120,121]

Noninvasive ventilation (NIV) is increasingly used in patients with ARDS, although the evidence supporting its use remains sparse. A substudy of the observational LUNG SAFE (Large Observational Study to Understand the Global Impact of Severe Acute Respiratory Failure) study examined the current practice of NIV use in ARDS, the utility of the PaO_2/FIO_2 ratio in classifying patients receiving NIV, and the impact of NIV on outcome.[122] Data suggested an association between mortality and the use of NIV in the setting of moderate to severe ARDS (PaO_2/FIO_2 < 150 mm Hg). It is possible that if this association is cause and effect that it could be related to delayed implementation of lung-protective ventilatory support.

Fluid Management and Vasoactive Support

Patients with ARDS, like other critically ill patients, need adequate oxygen delivery to tissues, which implies an adequate oxygen saturation and hemodynamic function. The past controversy concerning optimal fluid management in patients with ARDS[123–125] has been addressed by the ARDSnet Fluid and Catheter Treatment Trial (FACTT) study.[126] This study compared a liberal versus conservative fluid replacement strategy and also evaluated the utility and safety of using a pulmonary artery (PA) catheter to guide volume replacement as opposed to a central venous catheter.[126,127] The safety and potential benefits of using PA catheters in the critically ill has been an area of controversy since the 1990s.[128–130] The trial evaluated liberal versus conservative fluid management on the basis of the central venous catheter data (central venous pressure [CVP] versus PA catheter [PA occlusion pressure]) data in 1000 patients with established ARDS.[127,128] There was no difference between the groups in lung or renal function, use of vasopressors, renal replacement therapy, or hypotension. The PA catheter group did have twice as many catheter-related complications, predominantly in the form of arrhythmias, compared with the central venous catheter group. The liberal fluid management arm of the FACTT study had an average net gain of almost 7 L over the first 7 days, whereas the conservative fluid management group averaged a loss of 136 mL over 7 days.[126] The use of the conservative fluid management strategy was associated with a significant improvement in oxygenation index and lung injury score and increased the number of ventilator-free days compared with the more liberal strategy. There was no difference in the development of shock or the need for renal replacement therapy between the two fluid management strategies.[126] As a result of this trial the use of conservative fluid management without the use of a PA catheter is the recommended strategy for patients with ARDS.

Prevention of Complications of Critical Illness

Patients with ARDS are at risk for the expected complications of critical illness, which are largely preventable. Prophylactic strategies should be used whenever possible. Common complications include deep venous thrombosis and pulmonary embolism, stress-related gastrointestinal hemorrhage, ventilator-associated pneumonia (VAP) and hospital-acquired infections, metabolic abnormalities, critical illness polymyoneuropathy, pressure ulcers, delirium, and malnutrition.[131–139] Anticipation and prevention of these complications are vitally important. Prophylactic strategies to prevent stress-related mucosal disease and gastrointestinal bleeding using H_2-blockers, proton pump inhibitors, or possibly early enteral nutrition should occur in all patients unless otherwise contraindicated.[135,136] Deep vein thrombosis and pulmonary embolism prophylaxis should also be administered unless there are contraindications.[136] The use of enteral nutrition may be valuable in an attempt to prevent stress-related gastrointestinal bleeding and prevent translocation when normal barrier function of the gastrointestinal mucosa is compromised.[135–140] Nutritional support may also be important to maintain the proper level of immune function and potentially to prevent the development of malnutrition in the catabolic critically ill patient. The use of special enteral formulas designed to enhance the immune response remains controversial, but recent trials have failed to demonstrate a survival benefit with their use.[141–143] The ARDS Network found that the use of twice-daily enteral supplementation with ω-3 fatty acids, γ-linolenic acid, and antioxidants did not improve clinical outcome and was associated with a greater amount of diarrhea.[142] A subsequent (EDEN) randomized trial by the same investigators found that ARDS patients who received trophic (minimal enteral) feeding did just as well and had less gastric residual volume, vomiting, and constipation and a lower blood sugar and insulin requirement than the patients who received full enteral feeding over the first 6 days.[143] For patients who did not tolerate enteral nutrition, waiting to provide parenteral nutritional support for up to 8 days was found to be well tolerated, had fewer complications, and was associated with a faster recovery in critically ill adult patients.[144]

A major goal of management should be the prevention of hospital-acquired infections/sepsis and multiple-organ dysfunction/failure because these two conditions are currently responsible for the high mortality rate seen in patients with ARDS.[135,140] VAP is a frequent complication in critically ill ventilated patients. As previously mentioned, prevention of VAP should be a primary management goal for patients with ARDS. Detection of a complicating VAP can be difficult in the setting of the pulmonary infiltrates seen in patients with ARDS. Diagnosis of VAP and identification of the offending pathogen often requires the use of bronchoscopy with bronchoalveolar lavage or protected specimen brushes coupled with semiquantitative culture techniques.[131,133] Some advocate the use of biomarkers for bacterial infection (e.g., soluble triggering receptor expressed on myeloid cells, procalcitonin, and so on) may be beneficial in the detection of VAP but does not identify the specific etiologic organism.[145] Ventilator management bundles that include keeping the head of the bed elevated above 30 degrees, not routinely changing ventilator tubing, and daily oral mouth care have been shown to be effective at preventing VAP.[146] Additional measures designed to decrease the development of VAP include continuous subglottic suction, coated endotracheal tubes, closed suction systems, and kinetic therapy.[136] Most centers use a ventilator management bundle to decrease ventilator-associated complications and now attention is directed toward early reduction in sedation and analgesia, timely extubation, and increased mobility.[147] It is important to wean patients who no longer require ventilatory support in a timely fashion using guideline-based protocols that speed the separation process and decrease the risk for reintubation.[148,149] Recent consensus guidelines have been published to facilitate the weaning process.[148,149] Use of strategies to decrease the risk of complications in the critically ill has been associated with decreased morbidity, length of stay, cost of care, and possibly mortality rate compared with those patients in whom complications do develop.[135,136]

Strategies to Improve Oxygenation and Rescue Strategies

In patients with severe ARDS and persistent hypoxemia various rescue strategies have been used in an attempt to improve oxygenation, lessen F_{IO_2} requirements, and improve outcome. Included in these strategies are neuromuscular blockade, recruitment maneuvers, prone positioning, inhaled vasodilators, sophisticated modes of ventilatory support (airway pressure release ventilation, high-frequency oscillation, and so on) and extracorporeal membrane oxygenation (ECMO) support.[117,118,150–162] The proposed benefits of early neuromuscular blockade in severe ARDS have been described earlier in this chapter. The efficacy of some of these techniques remains controversial at this time and should be subjected to rigorous evaluation to adequately determine their ability to improve outcome for patients with ARDS. It should be remembered that the use of higher V_ts (12 mL/kg ideal body weight) in the ARDS Network trial was associated with an improvement in oxygenation, but significantly decreased survival in patients with ARDS.[88]

Recruitment maneuvers represent an attempt to open the atelectatic distal airways and alveoli on the border of the collapsed flooded alveoli that compose the dependent area of radiographic lung injury.[91] Some experts believe that this maneuver should precede the application of directed PEEP and ventilator support in the early phases of ARDS.[163] The maneuver is accomplished by increasing the PEEP to 35 to 50 cm H_2O and holding that level of pressure for 30 to 40 seconds. The ARDS Network attempted to define the value of a recruitment maneuver in 43 patients with ARDS by randomly assigning them to a recruitment maneuver with 35 to 40 cm H_2O for 30 seconds versus a sham recruitment maneuver.[151] The efficacy of the recruitment maneuver was assessed based on a sustained improvement in oxygenation as judged by the ability to titrate PEEP/FIO_2 on the basis of the network algorithm and changes in lung compliance. There was no significant difference in the magnitude or duration of the oxygenation effect, compliance, or change in PEEP/FIO_2 titration. The group that received a recruitment maneuver did have a greater decrease in blood pressure during the maneuver. It should be noted that the recruitment maneuver was not followed by PEEP setting to compliance or by increase in PEEP, which some believe is necessary to maintain any improvement in oxygenation that occurs with a recruitment maneuver. The Alveolar Recruitment for Acute Respiratory Distress Syndrome Trial (ART) attempted to address this factor.[164]

More than a thousand patients with moderate to severe ARDS (PaO_2/FIO_2 ratio <200) were randomly assigned to receive either PEEP as indicated on the ARDSnet low PEEP table (control) versus a lung recruitment maneuver followed by PEEP titration according to best respiratory system compliance (experimental group). Mortality was greater in the experimental group. The worse outcome in the experimental group was potentially due to an unfavorable balance between the potentially positive effect of decreasing driving pressure and negative effects of increasing overdistention and hemodynamic impairment. Other studies have reported that recruitment maneuvers are well tolerated from a hemodynamic standpoint and are not associated with increased cytokine release as may be expected with alveolar overdistention.[165]

Patients with ARDS may improve their oxygenation abnormalities when they are placed in the prone position.[145,166–173] This position may be more physiologic for most mammals and results in improved secretion removal, better ventilation-perfusion matching, and enhanced aeration of the dorsal lung units.[145] The prone position may also prevent the heart from collapsing the left lower lobe and augment the recruitment effects of PEEP by stabilizing the more flexible ventral chest wall.[145] Prone positioning may also unload the right ventricle in the setting of severe ARDS.[145] A number of trials have demonstrated an improvement in oxygenation during and after being placed in a prone position, but have failed to demonstrate a survival advantage.[145,167–170] After a meta-analysis detected a possible survival benefit for patients with severe ARDS managed with prone positioning,[174] a subsequent multicenter clinical trial demonstrated improved survival with prone positioning for patients with a PaO_2/FIO_2 ratio <150.[175] However, there are potential complications that can result from the process of changing the patient from a supine to a prone position.[171,172] The potential complications include tube/catheter malposition/problems, pressure sores, blindness, and difficulty with patient assessment and resuscitation.[171,172] Most experts now agree that prone positioning should be considered in patients with severe ARDS who require high FIO_2 and PEEP despite optimization with a lung-protective ventilatory support strategy.

Inhaled Vasodilator Therapy

Inhaled vasodilators, like nitric oxide or prostacyclin, are bronchial and vascular smooth muscle dilators that also decrease platelet adherence and aggregation.[153,176] Inhaled vasodilator therapy has been shown to improve oxygenation by improving ventilation-perfusion relationships in the lung.[153,176,177] A reduction in PA pressure and pulmonary vascular resistance also occurs. These beneficial pulmonary effects of nitric oxide are associated with minimal systemic effect because it is rapidly inactivated when the nitric oxide enters the circulation and is taken up by red blood cells. However, multiple prospective, randomized, placebo-controlled clinical trials failed to demonstrate an improvement in survival despite the early improvement in oxygenation associated with the administration of inhaled nitric oxide.[154,155,178,179] This therapy is not approved by the U.S. Food and Drug Administration, is costly, may affect platelet function, and may be associated with an increase incidence of acute kidney injury.[154,178,179] Some centers are using inhaled epoprostenol as an alternative inhaled vasodilator for rescue therapy (i.e., other more accepted therapies have failed to achieve the PaO_2/FIO_2 target), but there are no data to support an improved outcome from this treatment.[180]

Surfactant Replacement Therapy

Surfactant abnormalities are present in patients with ARDS related to decreased production, inactivation by alveolar proteins and proteolytic enzymes, and dilution by the alveolar fluid.[181] Theoretically, surfactant replacement should produce a survival benefit, just as it does in the infant respiratory distress syndrome.[181–183] However, multiple trials have failed to demonstrate significant survival benefit using surfactant replacement therapy in adults with ARDS.[181–183]

Extracorporeal Life Support

Since the 2009 H1N1 influenza A pandemics we have seen a dramatic rise in the use of extracorporeal life support, particularly ECMO, in patients with severe ARDS.[184,185] The use of ECMO support was in part driven by the CESAR (Conventional ventilatory support vs extracorporeal membrane oxygenation for severe adult respiratory failure) trial, which demonstrated a 31% decrease in death or severe disability in U.K. patients who were transferred to the ECMO center for care as opposed to standard care provided at the other referring hospitals.[186] Although there were several criticisms of the trial, particularly related to the use of lung-protective ventilatory support strategy in only 63% of the non-ECMO centers, the improvement in composite endpoint associated with ECMO center management likely fueled the resurrection of ECMO use for adults with ARDS. Extracorporeal life support can be provided to remove CO_2 (extracorporeal CO_2 removal [ECCOR]), to provide oxygenation support (venovenous [VV] ECMO), or to provide additional cardiac support using venoarterial (VA) ECMO or venoveno-arterial (VVA) ECMO.[159]

The most common form of ECMO support for patients with ARDS and adequate cardiac function involves the use of VV ECMO. Blood is drawn from a large-bore venous catheter (typically placed in the femoral vein or a bicaval catheter placed in the internal jugular vein) and then passed through an oxygenator where oxygen is added and CO_2 is removed from the blood. The oxygenated blood is then returned to the patient via a catheter in the right side of the heart or the PA. For patients with high cardiac output needs, adequate flow can be ensured by using large-bore catheters or central cannulation techniques. Indeed, ECMO may be the

paramount means of lung-protective ventilatory support during ARDS because it can provide all of the needed gas exchange and oxygenation support without the need for invasive mechanical ventilatory support.[159,186] Without the use of positive-pressure ventilation there should not be further lung injury and the lungs will be allowed to rest and heal.[187–189] In addition, the patient managed by ECMO and off ventilatory support may require less sedation and analgesia and thus be more able to participate in early rehabilitation and mobilization, which could translate into improved postrecovery status from the ARDS injury state and may have less potential for delirium, which is associated with worse postrecovery outcome from critical illness.[189,190] Our center uses lung-protective ventilatory support with ECMO runs and typically starts with a pressure control mode of 20 cm H_2O, PEEP of 10 cm H_2O, FIO_2 of 1.0, and respiratory rate of 10 breaths/min and then titrates as necessary. Our goal is to work toward early extubation, if possible, so that we can reduce sedation and allow the patient to participate in rehabilitation and mobilization.

Experimental and Antiinflammatory Therapies

In an attempt to reduce the high mortality rate associated with ARDS, a number of experimental and innovative therapeutic approaches have been evaluated. A majority of these approaches target abnormalities that either produce or result from the systemic inflammatory response that is considered central to the pathogenesis of the injury. To date, none of these approaches has been demonstrated to offer significant benefit in well-conducted, prospective, randomized controlled, multicenter clinical trials. These approaches have included the early administration of high-dose corticosteroids, prostaglandin E_1, nonsteroidal antiinflammatory drugs, antiendotoxin, and anticytokine therapy.[191–208]

Many investigations in experimental animal models of ARDS have demonstrated benefit from pretreatment and early treatment with high-dose corticosteroids.[209] To further complicate this clinical situation, it has been demonstrated that a significant proportion of patients with septic shock and other critical illnesses have relative adrenal insufficiency as defined by the inability to elevate the plasma cortisol level more than 9 μg/dL after adrenocorticotropic hormone stimulation.[210] This relative adrenocortical deficiency has been implicated as a potential cause of the persistent shock state and impaired perfusion. However, these patients have not always been responsive to the administration of steroids, and the adrenergic hyporesponsiveness may be related to sepsis-induced nitric oxide production, desensitization, or downregulation of α- and β-adrenergic receptors.[210] Lower-dose, more physiologic steroid replacement may restore the α- and β-adrenergic responsiveness and potentially turn off the inflammatory reaction to allow for better healing and less injury.[211] Attempts to prevent the development of ARDS in high-risk patients with severe sepsis and septic shock with high-dose corticosteroids have not been shown to prevent the development of ARDS, improve the reversal of ARDS, or improve the outcome from ARDS.[193] There are a number of potential beneficial effects of steroids for patients with ARDS, such as suppression of systemic inflammatory response.[212,213] In addition, a recent meta-analysis of steroids in the treatment of severe community-acquired pneumonia has demonstrated a decrease in ARDS development in those patients treated with corticosteroids.[214]

Steroid therapy has been shown to be beneficial in patients with severe *Pneumocystis jiroveci* (*carinii*) pneumonia and ARDS and possibly in patients with fat embolism.[215,216] In the patient with adrenal insufficiency, stress dose steroids should be administered. There was an increase in mortality seen in those patients with viral-induced ARDS (H1N1 influenza A) treated with steroids compared with controls.[217,218] The use of corticosteroids to treat patients with established ARDS is controversial and is discussed later. Ibuprofen, a nonsteroidal antiinflammatory drug, failed to significantly improve the outcome of patients with severe sepsis or septic shock and failed to prevent the development of ARDS in a prospective, randomized, placebo-controlled, multicenter clinical trial.[219]

Additionally, several investigative clinical trials have evaluated "antimediator therapy" in sepsis and ARDS and failed to demonstrate a significant survival benefit.[8,193,198,199,201] Attempts to change the inflammatory response by changing the ratio of ω-3/ω-6 fatty acids have evaluated the potential benefit of an enteral nutritional formula rich in eicosapentaenoic acid and γ-linoleic acid.[220]

Pentoxifylline and lisofylline are xanthine derivatives that were believed to have utility in the management of sepsis and ARDS.[221] Pentoxifylline is a rheologic agent with the ability to inhibit toxic oxygen radical release, decrease platelet aggregation, decrease phagocytosis, diminish the response to platelet-activating factor stimulation, and inhibit the release of tumor necrosis factor into the systemic circulation. Clinical evaluation of this treatment strategy by the National Institutes of Health (NIH) ARDS Network found no significant benefit.[221]

ARDS may be produced or worsened by the elaboration of toxic oxygen radicals from the activated inflammatory cells.[8] The abundant production of toxic oxygen radicals may overwhelm the ability of the endogenous oxygen radical scavengers, superoxide dismutase, catalase, and the glutathione redux cycle. The administration of antioxidants, such as N-acetylcysteine, procysteine, vitamin E, β-carotene, and vitamin C, has been evaluated in the prevention and management of patients with ARDS.[207,222,223] No survival benefit was seen associated with the administration of N-acetylcysteine or procysteine versus control in patients with ARDS.[207]

Drug Therapy for Prevention of ARDS

The ability to prevent the development of ARDS would be a welcome achievement that to date has been elusive. Two older trials demonstrated a significant reduction in the development of ARDS in surgical patients when ketoconazole, an imidazole thromboxane A_2 synthetase inhibitor, was administered to an at-risk population of patients.[224,225] However, when ketoconazole was evaluated by the ARDS Network in the treatment of patients with ARDS there was no benefit on survival.[226] The use of 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors (statins) as a prevention for ARDS was evaluated in an observational study of a large cohort of patients at risk for developing ARDS and was not found to decrease the development of ARDS or improve mortality rates, organ failure–free days, or ventilator-free days.[227] It has been suggested that aspirin may help prevent the development of ARDS in at-risk patients.[228] Research is under way evaluating the use of mesenchymal stem cells to improve outcome and lung repair in ARDS patients. Preliminary studies have suggested that microparticles released from mesenchymal stem cells may be instrumental in lung protection and repair that may be responsible for this beneficial effect.[229] The current emphasis of the NHLBI in ARDS management has focused on *p*revention and *e*arly *t*reatment of *a*cute *l*ung injury (PETAL) projects. The first two projects are ROSE (Reevaluation of Systemic Early neuromuscular blockade) and VIOLET (Vitamin D to Improve Outcomes by Leveraging Early Treatment).[230,231]

Fibroproliferative Phase and Steroid Treatment

An improved understanding of the injury and repair phase of ARDS has resulted in the recognition of the late fibroproliferative phase.[8,75–78,232,233] This stage of the injury/repair process is characterized by replacement of damaged epithelial cells and accumulation of mesenchymal cells and connective tissue products in the airspaces and the intraacinar microvessels.[68,74,75] Clinical manifestations include fever, leukocytosis, diffuse alveolar infiltrates on the chest radiograph, and persistent inflammatory mediators in the serum.[68,74,75] Physiologic manifestations include the worsening of static pulmonary compliance, abnormal gas exchange, increased V_D ventilation, pulmonary hypertension, and lack of PEEP response.[232,233] This picture of persistent inflammation requires a dedicated approach to ensure that there is not an ongoing uncontrolled infectious process that has not been adequately addressed.[232] Once it is determined that this state is not the result of inadequately treated infection, therapy with corticosteroids is used by some experts.[232] Several anecdotal reports have suggested that this therapy may have potential efficacy in patients with a persistent inflammatory response.[215,232] A small, single-center, prospective, randomized, placebo-controlled, double-blind clinical trial in 24 patients with the fibroproliferative phase of ARDS demonstrated an improvement in survival, lung function, and organ system dysfunction.[233] This study has been criticized because it included the crossover of patients at day 10 and had a smaller study population than a previously reported uncontrolled trial from the same center.[233]

The use of steroid rescue for the patient with persistent ARDS or the fibroproliferative phase of ARDS was evaluated by the NIH-sponsored ARDS Network.[234] The study prospectively randomly assigned 180 patients with ARDS for 7 days or longer to a placebo-controlled trial of methylprednisolone versus placebo. The primary efficacy outcome was being alive at home at 60 days. Patients with septic shock, a defined need for corticosteroid therapy, disseminated fungal infection, or undrained abscess were excluded. The trial was conducted over 6 years and included a modification of the study protocol that included a reduction in the number of subjects from 400 to 180 and an increase in the inclusion P_{AO_2}/F_{IO_2} ratio. The use of methylprednisolone was associated with an early improvement in mortality rate, P_{AO_2}/F_{IO_2} ratio, blood pressure, ventilator, and ICU-free days. An increase in the white blood cell count and glucose level related to steroid administration occurred, along with a decrease in body temperature. No difference was measured in the primary efficacy endpoint 60-day mortality rate, and no significant difference in 180-day outcome occurred between the two groups. The steroid treatment was not associated with an increase in serious infections. In fact, there was more pneumonia and septic shock in the placebo group than in the steroid-treated group. Unfortunately, the use of steroids was associated with more neuropathy and myopathy, but it is important to note that 30% of the steroid-treated patients were receiving neuromuscular blocking drugs.[234]

Meduri and colleagues evaluated a low-dose prolonged methylprednisolone infusion in patients with early severe ARDS and noted a significant decrease in lung injury score and C-reactive protein level along with a decrease in ICU mortality rates, duration of mechanical ventilation, and multiple-organ dysfunction scores.[235] The steroid infusion decreased levels of inflammatory biomarkers and coagulation.[236] The prolonged infusion strategy appeared to be safe and well tolerated, but this was a small study of 91 patients and the topic of steroid treatment in ARDS remains controversial; we eagerly await more definitive studies. With the recent benefit of steroid treatment in severe community-acquired infection, some argue that steroids are likely beneficial in ARDS that results from sepsis, as long as the infection is not viral in etiology.[214] A recent multispecialty task force of the Society of Critical Care Medicine and the European Society of Intensive Care Medicine has critically reviewed the evidence related to steroid use in patients with ARDS and has suggested the use of methylprednisolone treatment (1 mg/kg per day for early ARDS up to day 6; 2 mg/kg per day after day 6) of patients with early moderate to severe ARDS (P_{aO_2}/F_{iO_2} < 200) and then slow tapering over 13 days.[237]

Macrolide antibiotics have been reported to have important immunomodulatory properties that could prove beneficial in patients with ARDS. The ARDS Network has reviewed initial antibiotic data on 235 patients enrolled in the LARMA (Lisofylline and Respiratory Management of Acute Lung Injury) trial and found that 20% received a macrolide antibiotic within the first 24 hours of the trial.[238] These patients were more likely to have a pulmonary infection as a cause of ARDS. Of interest was the observation that the macrolide-treated patients had a 23% mortality rate compared with a 36% mortality rate for nonmacrolide antibiotic regimens.[238] This interesting observation may warrant additional study.

Multiple-Organ Dysfunction/Failure

A frequent complication of an exaggerated proinflammatory state in the setting of sepsis, SIRS, and ARDS is the development of organ system dysfunction.[83,140,239,240] This dysfunction may involve single or multiple organs.[140,239] A recent consensus conference has suggested that the dysfunction of two or more organs such that normal homeostasis cannot be maintained in the setting of a systemic inflammatory response to a variety of insults is considered MODS.[241] This dysfunction may be partial or complete, reversible, or irreversible.[140] A continuum of abnormalities ranging from dysfunction to failure for each organ is probable.[140] Unfortunately, to date there has been no consensus on the threshold that separates these two phenomena or the threshold between reversible and irreversible organ system dysfunction.[140]

MODS and MOF are the most common causes of death in the noncoronary ICU.[239,242] Many authorities consider ARDS the earliest manifestation of an uncompensated systemic inflammatory process with excessive proinflammatory component.[81,145] One hypothesis for this injury suggests that in the absence of a direct injury to a specific organ, there must be multiple inflammatory insults to produce the clinically apparent MODS/MOF.[140] This hypothesis, called the "two-hit hypothesis,"[140] suggests that an initial sensitizing insult is followed within a specific period of time by a second insult that is capable of initiating a more profound proinflammatory response because the target cells have been upregulated or primed by the initial insult.[140] Multiple combinations of direct injury, ischemic injury, circulating humoral or inflammatory mediators, translocation of endotoxin or colonic bacteria, altered rheologic properties of the blood cells, or iatrogenic effects of the therapy administered may interact in the eventual production of MODS/MOF.[140]

Lung-Protection Strategy for Prevention of ARDS

There are now several well-conducted studies and systematic meta-analyses that support the benefit of lung-protective ventilatory support in the emergency department operating room, and for non-ARDS patients in the ICU, as a way to improve outcome and even prevent the development of ARDS.[243–246] Neto and colleagues conducted a meta-analysis of lung-protective ventilation with lower

V_ts in patients who did not have ARDS and found that this technique was associated with decreased lung injury, decreased mortality, and reduced pulmonary infections compared with conventional V_t ventilatory support.[243] Using lung-protective ventilatory support strategies in the operating room was noted to decrease postoperative pulmonary complications.[244] Fuller and colleagues conducted the LOV-ED (Lung-Protective Ventilation Initiated in the Emergency Department) trial comparing lung-protective ventilatory support initiated in the emergency department and noted a decrease in the composite primary endpoint of mortality and ventilatory days compared with ventilatory support with conventional V_ts.[245] These studies suggest that prevention of ARDS by using lung-protective ventilatory support from the beginning of invasive mechanical ventilation may be the most effective way to deal with ARDS.

Prognosis

Recent studies report a significant reduction in the mortality rate from ARDS using lung protective ventilatory support and proper levels of PEEP.[8,77,88,247,248] Current trials report mortality rates in the range of 30% to 60% compared with 60% to 90% of the past.[8,88,161,249] The 30-day mortality rate seen in patients enrolled in the NIH-sponsored ECMO trial of the 1970s was 91% with both conventional and ECMO treatment.[161] Older reports from large tertiary referral centers documented mortality rates of 90% for patients with gram-negative septic shock and ARDS.[249] A large multicenter trial of inhaled surfactant in 725 patients with sepsis-induced ARDS demonstrated survival rates of 60% at 28 days in both the treatment and the control groups.[182] Today the mortality rate from ARDS appears to depend on the cause of the injury, the patient's underlying disease status, patient age, and institutional factors.[8,34,240] This improvement in the mortality rate mandates the use of a concomitant control group as opposed to using historical control subjects in the assessment of new innovative therapeutic strategies.

The most common causes of death in patients with ARDS continues to be from MOF and recurrent sepsis.[8,185,250] Fewer than 20% of patients die because of the inability to adequately oxygenate or ventilate them.[250] When infection is present, the lung is a frequent site for the process and may be extremely difficult to diagnose.[32,83,131,132] Patients with pulmonary infections were found to typically have a septic clinical picture without definitive positive culture results.[32] On the other hand, in patients who were found to have positive blood cultures without antemortem identification of a specific site, the site of occult infection was commonly found to be in the abdomen at postmortem examination.[32] Predictors of high mortality rates from ARDS include the development of multiple-organ dysfunction/failure, development of secondary sepsis, concomitant cancer, and the presence of cirrhosis or hepatic dysfunction.[8,251] A clinical study in ARDS patients receiving lung protective ventilatory support reported that the oxygenation index (mean airway pressure $\times$ F_{IO_2} $\times$ 100 $\div$ P_{aO_2}) was an independent predictor of mortality rate.[251]

Survivors of ARDS may be subject to persistent pulmonary function abnormalities, quality-of-life disruption, and neurocognitive dysfunction. A long-term follow-up study found that 80% of ARDS survivors who were discharged from the ICU were still alive 5 years later.[252,253] Although most ARDS survivors have initial abnormalities in pulmonary function, the majority return to near their baseline pulmonary function status within 3 to 6 months.[254,255] The major residual abnormality in pulmonary function is a restrictive pulmonary defect and a reduction in the carbon monoxide diffusion capacity.[254–256] These alterations may result in exercise desaturation in some patients or, more commonly, a decrease in timed walked distance.[254–256] When observed over the next 5 years, their pulmonary function did not improve a great deal after this initial improvement.[252,256] However, most patients continue to experience exercise limitation at 5 years, despite the fact that 65% have returned to work.[252,256]

Survivors of ARDS have been found to have a decreased health-related quality of life, increased respiratory symptoms, insomnia, depression, anxiety, and posttraumatic stress disorder.[257–262] They also have been found to have a clinically significant reduction in their physical function and increased pulmonary symptoms compared with matched survivors of critical illness.[257–265] Survivors of ARDS have also been found to have long-term cognitive impairment, problems coping with their disability, and relationship strains.[260,261,263] Elderly patients (>70 years of age) seem to have worse outcomes with an increase in mortality rate compared with ARDS patients who are younger than 70 years of age.[259]

Future Considerations

The growing knowledge of molecular biology and the elaborate mechanisms that govern a person's response to injury, repair, and cell death will likely have a major role in the management of patients with ARDS. Individuals with increased risk for ARDS development will no doubt be identified on the basis of their genetic profiles. This knowledge will likely affect and direct future management as we move further along the path of precision management of clinical conditions. In years to come, scientists may potentially modify the genetic makeup or the biologic response of a susceptible individual by inserting selected genes or modifying the transcription or function of various regulatory proteins. Studies with mesenchymal stem cells have been conducted in rodents with lung injury and demonstrate potential promise for future therapy.[266]

Summary

Acute respiratory failure is the inability of the respiratory system to meet the oxygenation (type 1 or hypoxemic failure) or ventilation (type 2 or hypercapnic failure) requirements of the patient. Hypoxemic respiratory failure is defined as a P_{AO_2} of less than 60 mm Hg and is the result of one of six potential mechanisms: low inspired F_{IO_2}, hypoventilation, ventilation-perfusion mismatching, shunt, low pulmonary arterial oxygenation, or diffusion impairment. The exact cause may be elucidated by analysis of the alveolar-arterial oxygen gradient, response to the administration of supplemental oxygen, and the clinical context. Hypercapnic or ventilatory failure is defined as a P_{ACO_2} of greater than 50 mm Hg, generally with acidemia; it can be acute, chronic, or acute-on-chronic and is the result of one of three potential mechanisms: hypoventilation, increased V_D ventilation, or increased CO_2 production. Clinical manifestations can range from adrenergic sympathetic hyperactivity (tachycardia and hypertension) to tachypnea and respiratory distress to encephalopathy with somnolence. Therapy is with supplemental oxygen, assisted ventilation with or without high levels of PEEP, or both.

ARDS continues to have a significant morbidity and mortality rate despite the advances in understanding and management that have occurred over the past 5 decades. Major advances have

occurred in our understanding of the pathogenesis and in our ability to adequately provide the required ventilatory support while the injury is allowed to heal. Attention has been directed toward lung-protective ventilatory support, the use of local and systemic therapies, and prevention of injury in high-risk patient populations. Despite recent improvements in management and knowledge of the pathophysiologic alterations likely involved, the mortality rate continues to be unacceptably high. Recent improvements in prognosis have occurred, primarily in those patients younger than age 60 years. Remembering the systemic nature of the injury and developing effective preventive and reparative strategies are important as we look to the future of ARDS management. Repair of the acutely injured lung, whether from the initial event, the ventilator, or complicating infection, is an important target and may be more achievable than attempting to prevent the initial injury or intervening early enough to prevent the development of ARDS.

Key Points

- Both type 1 and type 2 acute respiratory failure are common problems in the ICU and may represent the primary reason for ICU admission or be a complication arising in the critically ill patient.
- The ABG value is the cornerstone for the diagnosis and management of the patient with acute respiratory failure.
- The American-European Consensus Conference definition of ARDS has now been replaced by the Berlin Definition, which does not include ALI, just ARDS. The Berlin definition suggests that the degree of oxygenation abnormality when assessed on appropriate F_{IO_2} and PEEP has prognostic importance and defines mild, moderate, and severe ARDS.
- The most common clinical risk factors for the development of ARDS include sepsis, SIRS, hypotension, shock, trauma, near-drowning, and aspiration injury.
- The pathophysiology of ARDS represents a complex interrelationship of antiinflammatory and proinflammatory responses, activation of the coagulation system, abnormal function of the microcirculation, and altered surfactant function. Alterations affect both the capillary endothelium and the epithelial lining cells.
- At this time the management of patients with ARDS is primarily supportive, but it is important to (1) provide specific treatment directed at the underlying predisposing cause, (2) use lung-protective ventilation, and (3) prevent complications of critical illness.
- The concept of VILI has now been supported by the results of recent clinical trials demonstrating a survival benefit associated with the use of lower V_ts to avoid alveolar overdistention.
- The proper amount of PEEP therapy is important in the management of patients with ARDS to avoid alveolar overdistention and the repetitive collapse and recruitment-derecruitment of alveoli and small airspaces.
- The use of steroids to treat the fibroproliferative phase of ARDS remains a controversial area. If there is no active untreated infectious process and there is a persistent inflammatory process in the lung, there may be a benefit associated with corticosteroid therapy; however, a trial conducted by the ARDS Network did not find a survival benefit at 60 days. Current recommendations favoring steroid treatment of severe community-acquired ARDS may sway the clinician to use steroids in the management of septic patients with ARDS.
- Although the overall prognosis in ARDS has been improving, the mortality rate still ranges from 30% to 60% and decreased overall health status and function persist for as long as 5 years after recovery.

Review Questions

1. Which one of the following causes of hypoxemia would be expected to have a normal alveolar-arterial oxygen (A-a) gradient?
   a. 25-year-old man with heroin overdose
   b. 32-year-old woman with near-drowning
   c. 40-year-old man with an acute asthma attack
   d. 60-year-old with a pulmonary embolus
   Answer: a. Hypoventilation alone (as occurs with respiratory drive suppression with heroin overdose) can be a cause of hypoxemia but there is a normal A-a gradient because there is no abnormality at the oxygen exchange interface. All of the other conditions are associated with some degree of ventilation-perfusion mismatch, which will be associated with an increase in A-a gradient as a contributing mechanism for the hypoxemia (alveolar flooding with water, bronchospasm, and release of mediators owing to clot in pulmonary arterial vessels respectively).
2. Which one of the following disorders is least likely to result in a good outcome when noninvasive ventilatory support is used for management?
   a. Acute respiratory distress syndrome (ARDS) secondary to pneumonia
   b. Chronic obstructive pulmonary disorder (COPD) with hypercapnia
   c. Obesity with hypoventilation
   d. Congestive heart failure (CHF) with hypoxemia
   Answer: a. There has been a growing interest in the use of noninvasive ventilatory support in treating COPD exacerbation, CHF, and hypoventilation associated with neuromuscular disease, but noninvasive ventilation has not proved as universally beneficial in the setting of pneumonia and in moderate to severe ARDS. In fact, recent data suggest higher mortality with the use of noninvasive ventilation in the setting of moderate to severe ARDS, likely related to delayed implementation of lung-protective ventilatory support.
3. The Berlin definition of ARDS includes which one of the following components?
   a. Bilateral pulmonary infiltrates
   b. Progression from acute lung injury
   c. Evidence of elevated pulmonary artery occlusion pressure (PCWP)
   d. Elevated serum brain natriuretic peptide (BNP)
   Answer: a. The Berlin definition of ARDS includes (1) an onset with 1 week of a known clinical insult or new or worsening respiratory symptoms, (2) bilateral pulmonary opacities (not pleural effusions), (3) respiratory failure not fully explained by cardiac failure and/or fluid overload, and (d) abnormal oxygenation with a Pao_2/FIO_2 ratio of 300 or lower. The oxygenation abnormality on PEEP therapy defines the severity of the ARDS as mild (Pao_2/FIO_2 ratio ≤300, but >200), moderate (Pao_2/FIO_2 ratio ≤200, but >100), or severe (Pao_2/FIO_2 ratio ≤100).
4. Lung-protective ventilatory support is a ventilator management strategy that incorporates which one of the following:
   a. Tidal volumes of 4 to 6 mL/kg ideal body weight
   b. Keeping positive end-expiratory (PEEP) levels continuously above 10 cm H_2O
   c. Maintaining a peak inspiratory pressure below 40 cm H_2O
   d. Maintaining the fraction of inspired oxygen (FIO_2) less than or equal to 0.6 to avoid oxygen toxicity
   Answer: a. Lung-protective ventilatory support is designed to limit the development of ventilator-induced lung injury and in ARDS patients to allow the injured lung to heal. The constituents of lung-protective ventilatory support include using a tidal volume of 4 to 6 mL/Kg based on predicted body weight (at least 6 mL/kg and lower if end-expiratory plateau pressure is not ≤30 cm H_2O), using adequate PEEP to maintain open airways and prevent atelectrauma, which occurs when PEEP is set too low such that the lung collapses at end expiration and then reopens with the next breath, producing shear force injury with reopening. PEEP is often dosed based on a high or low PEEP strategy nomogram with higher PEEP use in more severe ARDS. The least toxic FIO_2 should be used to maintain a Pao_2 of 55 to 80 mm Hg.
5. Neuromuscular blocking drugs may be beneficial in the management of a patient with ARDS because of which one of the following?
   a. Decreased transalveolar pressure
   b. Increased ventilator dyssynchrony
   c. Increased sedation requirements
   d. Decreased venous return
   Answer: a. Neuromuscular blocking drugs in early ARDS may be beneficial and lead to improved outcome by decreasing the transalveolar pressure and improving patient-ventilator synchrony. Reducing the intrathoracic pressure by lessening the positive pressure required for delivering the tidal breath and possibly reducing PEEP requirements improves venous return and cardiac output. Improved patient-ventilator synchrony leads to more consistent application of PEEP, lessens the transalveolar pressure gradient, and lessens end-inspiratory plateau pressure. There are also data to demonstrate less biotrauma (ventilator-induced lung injury [VILI] associated with systemic release of proinflammatory mediators) and the potential for less systemic organ dysfunction. The Reevaluation Of Systemic Early neuromuscular blockade (ROSE) trial of the National Heart, Lung, and Blood Institute PETAL (*p*revention and *e*arly *t*reatment of *a*cute *l*ung injury) Network is currently conducting a large multicenter trial to evaluate the effect of early neuromuscular blockade in the management of moderate to severe ARDS.
6. Which one of the following strategies may improve the outcome of ARDS patients?
   a. Liberal fluid management
   b. Early high-dose steroids
   d. Prone positioning for severe hypoxemia
   d. Immune-enhancing nutritional support
   Answer: c. Prone positioning has been shown to improve survival in patients with moderate to severe ARDS and persistent hypoxemia. Prior trials in all patients with ARDS did not produce a survival benefit. Conservative fluid management was shown to decrease organ dysfunction and increase ventilator-free days compared with liberal fluid administration. High-dose steroids have not been beneficial in ARDS or sepsis, but recent studies and meta-analyses now favor the use of early and/or rescue lower-dose methylprednisolone in the management of patients with moderate to severe ARDS. Recent studies have not demonstrated a benefit associated with the use of immune-enhancing diets for patients with ARDS.

7. The risk of ventilator-induced lung disease is reduced by which one of the following strategies?
a. Increasing the tidal volume to 10 mL/kg PBW
b. Providing PEEP
d. Adding sighs every 10 minutes
d. Performing recruitment maneuvers every shift
Answer: b. Provision of adequate PEEP has been shown to minimize the production of VILI and even prevent VILI in experimental models. Using high tidal volumes (i.e., ≥10 mL/kg PBW), sighs, and recruitment maneuvers may all induce alveolar overdistention, which can result in volutrauma and the production of VILI.

8. Corticosteroid treatment should be considered for use in patients with ARDS secondary to which one of the following?
a. Viral infections
b. Severe pneumonia
c. Acid aspiration injury
d. Multiple blood transfusions
Answer: b. A meta-analysis and systematic review of studies treating patients with severe pneumonia with corticosteroids added to the antibiotic regimen have demonstrated improved survival and decreased development of ARDS. This meta-analysis in large part is responsible for the recent recommendation of the Society of Critical Care Medicine–European Society of Intensive Care Medicine consensus recommendation for the use of corticosteroids either early (onset to day 6) or late (after 6 days) for the treatment of patients with moderate to severe ARDS.

9. Prone positioning is best used in ARDS patients with which one of the following?
a. A history of abdominal surgery
b. Partial pressure of oxygen in arterial blood (Pa_{O_2})/F_{IO_2} ratio <150
c. Obesity hypoventilation syndrome
d. Predominantly upper lobe disease
Answer: b The benefit of prone positioning for ARDS management has been demonstrated in those patients with moderate to severe ARDS or a Pa_{O_2}/F_{IO_2} ratio of 150 or less. Although patients as classified by answers a., c., and d. may benefit from prone positioning based on the degree of oxygenation defect, these specific diagnoses do not in their own right indicate benefit from prone positioning.

10. Which one of the following statements concerning inhaled vasodilator therapy in ARDS is true?
a. Inhaled nitric oxide (NO) has been found to improve survival.
b. Inhaled NO causes systemic hypotension.
c. Inhaled NO will increase the Pa_{O_2}.
d. Inhaled NO is approved by the U.S. Food and Drug Administration (FDA) for use.
Answer: c. Inhaled NO has been shown in multiple trials to produce an early increase in oxygenation in patients with severe ARDS. Unfortunately, the improvement in oxygenation did not translate into an improvement in survival or assist in earlier weaning of the patient from ventilatory support. The NO is rapidly scavenged by the hemoglobin of circulating red blood cells and there is not a systemic effect from the inhaled vasodilator therapy. Inhaled NO is not approved by the FDA for use in ARDS. Inhaled epoprostenol (a less expensive selective inhaled vasodilator), also not FDA-approved, and inhaled NO have been used for "salvage" therapy in patients in whom ARDS net mechanical ventilation protocol, neuromuscular blockade, and prone positioning have failed to achieve an acceptable Pa_{O_2}.

Life-Threatening Asthma

JENNIFER LAROSA

CHAPTER OUTLINE

Epidemiology

Genetics and Pathophysiology

Signs and Symptoms

Inhaled Therapies
- Oxygen
- Inhaled Short-Acting β_2-Selective Agonists: Albuterol, Levalbuterol, and Salmeterol
- Inhaled Anticholinergics: Ipratropium
- Heliox

Systemic Therapies
- Corticosteroids
- Methyxanthines: Theophylline and Aminophylline
- Magnesium Sulfate
- Anti-IgE Antibodies: Omalizumab
- Leukotriene Antagonists: Montelukast
- Alternative and Investigational Agents

Mechanical Ventilation in Patients With Asthma
- Indications for Mechanical Ventilation
- Neuromuscular Blocking Agents
- Noninvasive Positive-Pressure Ventilation

The Future for Those With Life-Threatening Asthma

Summary

Epidemiology

Asthma has been recognized for literally thousands of years. Around 2600 BC, Chinese records reveal a disease of "noisy breathing." Around 400 BC, Hippocrates defined the term asthma as a derivation of the Greek word for wind (ἄνεμος). Similar accounts follow through the ages and early Romans, Jews, and Egyptians used various natural remedies, some of which were valid and effective (smoking stramonium, a herb with anticholinergic properties) and some of which were not (drinking the blood of wild horses).[1]

Since the early 1980s, the prevalence of asthma has continued its relentless climb, affecting more than 25 million individuals (roughly 1 in 12 people) and 8.4% of the population as of 2010. Higher rates of adult disease exist in those of mixed racial background, African American, and Puerto Rican ancestry, females, those living at lower income levels, and those with a genetic predisposition for the disease.[2–5]

Although the overall mortality of asthma has steadily decreased since the turn of the millennium (0.15 per 1000 persons per 2007–2009 data), specific subgroups are continuing to die at alarming rates. Female African American patients older than 65 years of age have a considerably increased likelihood of death at a rate of 0.58 per 1000 persons. Although persons of Puerto Rican ethnicity have the highest rates of asthma exacerbations, African Americans have an almost 200% greater chance of having asthma and of dying from it (Figs. 37.1 and 37.2).

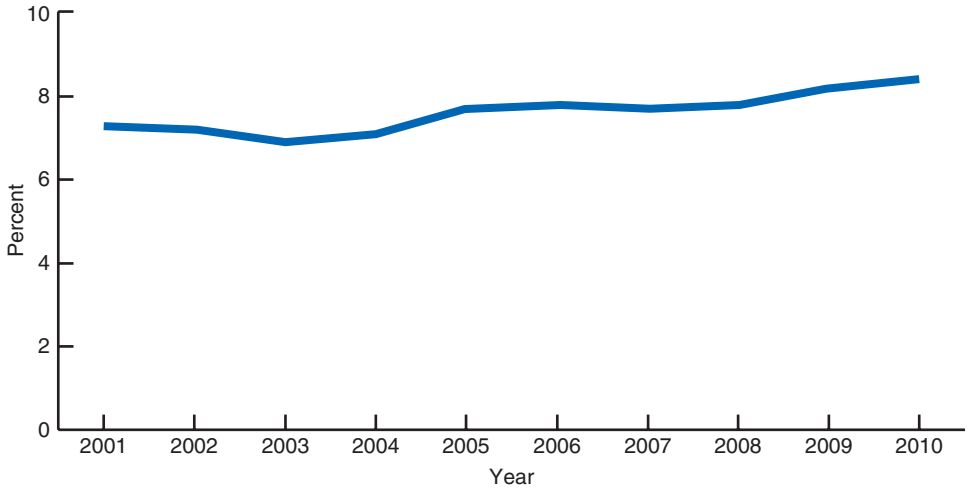
In addition to the costly effects of asthma on morbidity and mortality, it is estimated that the United States spends as much as $56 billion annually on medical care, lost productivity, and mortality for asthmatics. This equates to more than $3000 per person in the United States every year.[6,7]

We are failing to adequately control and manage this disease. As many as 65% of adults with asthma have chronic and persistent symptoms, and up to 50% of adults with asthma meet criteria for uncontrolled asthma at any given time. It is not surprising, then, with increasing rates of disease and increasing disease severity that so many of these patients require critical care services.[8,9]

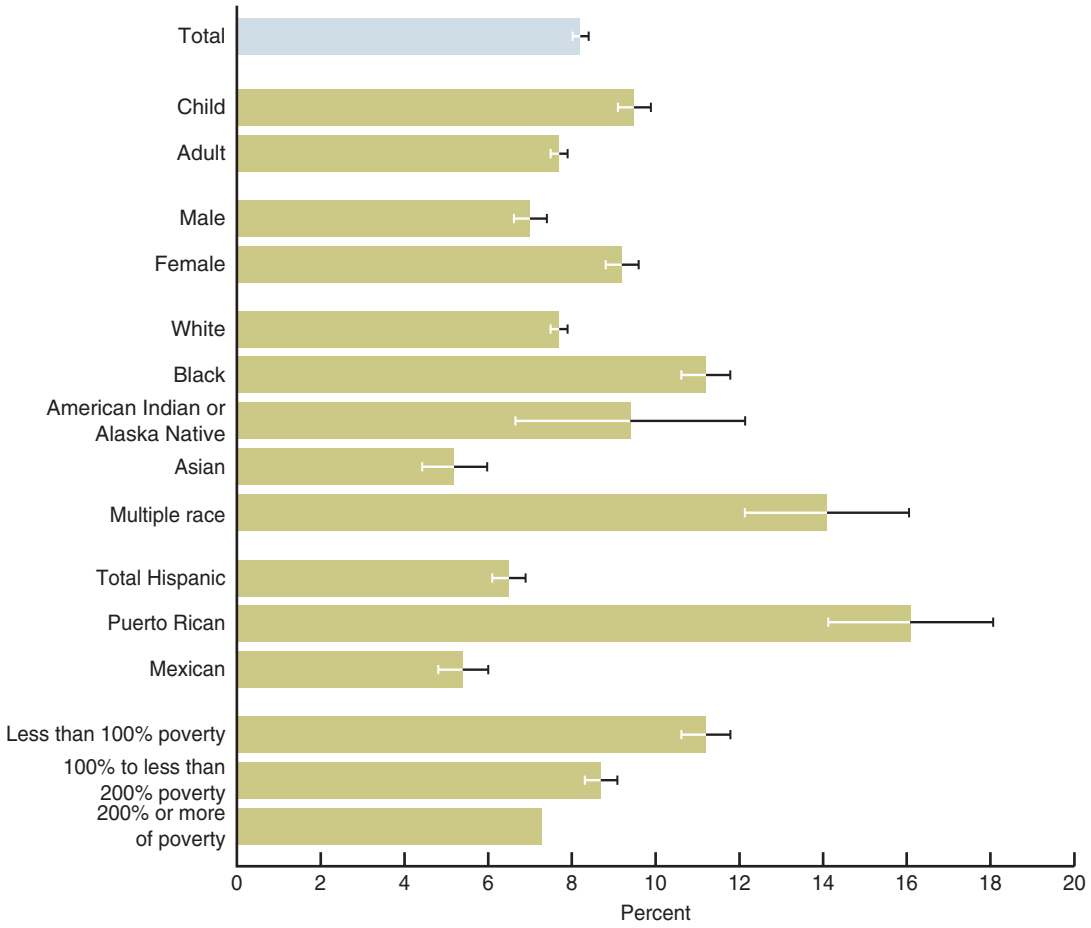
Genetics and Pathophysiology

Asthma is a disease of the distal airways characterized by bronchoconstriction, mucus hypersecretion, and intense cellular infiltration. Although asthma is, by definition, a reversible illness, the disease is poorly controlled in many patients and this chronic disease eventually leads to airway remodeling, which includes increased basement membrane thickness, increase smooth muscle, and metaplasia of goblet cells. Over time, inadequately controlled disease and airway remodeling can lead to a chronic and no longer reversible condition.

The American Thoracic Society defines severe asthma as "asthma which requires treatment with high dose inhaled corticosteroids (ICS)…plus a second controller (and/or systemic CS) to prevent it from becoming 'uncontrolled' or which remains 'uncontrolled' despite this therapy."[10] Louie et al. further subdefine asthma that requires critical intervention as status asthmaticus and near-fatal asthma.[11] Status asthmaticus is a severe asthma attack that does not respond to immediate and consecutive bronchodilator therapy. Near-fatal asthma refers to persistent status asthmaticus that ultimately requires ventilatory support. Pendergraft and colleagues reported that among 29,430 admissions in the United States with a primary diagnosis of asthma, 10.1% were admitted to intensive care units (ICUs) and 2.1% were intubated.[3] The risk of in-hospital death was significantly higher in patients who were intubated and



• **Fig. 37.1** Asthma prevalence in the United States, 2001–2010. Asthma prevalence refers to the percentage of people who have ever been diagnosed with asthma and still have asthma. Data are age-adjusted to the 2000 U.S. standard population. (Data table available at http://www.cdc.gov/nchs/data/databriefs/db94_tables.pdf#1. From Centers for Disease Control and Prevention/National Center for Health Statistics, National Health Interview Survey.)



• **Fig. 37.2** Asthma prevalence by selected demographic characteristics: United States, average annual 2008–2010. Asthma prevalence refers to the percentage of people who have ever been diagnosed with asthma and still have asthma. 95% confidence interval. (Data table available at http://www.cdc.gov/nchs/data/databriefs/db94_tables.pdf#2. From Centers for Disease Control and Prevention/National Center for Health Statistics, Health Data Interactive and National Health Interview Survey.)

who had comorbid conditions. Near-fatal events occur in 2% to 20% of patients admitted to ICUs with acute severe asthma and in 2% to 4% of those intubated for respiratory failure.[3,11] Box 37.1 provides a comprehensive list of factors noted to increase both the likelihood of and the mortality from a severe asthma attack.

Genetic predispositions to asthma are well known. According to the Centers for Disease Control and Prevention, a child with at least one parent with asthma is three to six times more likely to develop asthma than their counterparts with nonasthmatic parents.[2,6] The genes listed in Box 37.2 (and up to 75 others) have been associated with clinical asthma. Discrete genes have been correlated with phenotypic variations in asthma as noted in Box 37.2, but considerable work remains to conclusively associate these factors.[13] Needless to say, the phenotypic manifestations of such genetic predispositions remains highly variable based on exposures to respiratory illnesses, pollution, and various other known and unknown triggers.[13]

Histologically, severe asthma is characterized by smooth muscle hypertrophy, influx of inflammatory cells, excessive mucus production, and, over time, airway remodeling. Cellular host responses are the platform for asthmatic inflammation and, when allowed to persist, for airway remodeling. In response to noxious stimuli (usually allergic or infectious triggers), epithelial and dendritic cells trigger T- and B-cell subsets and lymphoid cells to modulate airway inflammation via various cytokines and chemokines, such as interleukins (ILs) and granulocyte-stimulating factors. Excessive immunoglobulin E (IgE) production is triggered by these cytokines and chemokines, and neutrophils, eosinophils, and mast cells infiltrate the airways and continue the cascade of inflammatory damage. Over time, especially with poorly controlled disease and recurrent or persistent injury, the airways remodel with thickening of the basement membrane, mucus hypersecretion and plugging, goblet cell metaplasia, and smooth muscle hypertrophy. Many, if not all, of the cytokines implicated in asthmatic histopathology have been identified in various concentrations in bronchoalveolar lavage samples of patients with asthma. Although by no means exhaustive, some of the more common offenders include specifically IL-4, -5, -8, -13, and -17; neutrophil chemoattractant; and matrix metalloproteinase. Studies vary as to whether a predominance of neutrophils or eosinophils confers more serious disease, although most investigations favor the former.[11,13–18]

Phenotypically, the most severe form of asthma occurs in roughly 5% of all patients with asthma and presents symptomatically in one of two ways as described by Rodriguez-Trigo and colleagues.[5] The fundamental distinction between the two is based on time and rapidity of inset. In type 1, or "slow onset–late arrival" asthma, the asthmatic patient has chronic moderate to severe airflow obstruction that progresses over a course of days to weeks. Disease is characterized by copious mucus, capillary leak with boggy airways, intense eosinophilic infiltration, and recalcitrant disease when routine treatment is applied. Type 1 asthma is estimated to be responsible for as many as 80% to 85% of deaths in asthmatic patients.[5]

Conversely, type 2, or "sudden asphyxic" asthma is characterized by intense cellular infiltrate and rapidly progressive airflow obstruction with almost immediate responsiveness to conventional therapy when it is applied in a timely fashion. This subtype accounts for 15% to 20% of asthma deaths.[19–21]

• BOX 37.1 Risk Factors for Severe and Fatal Asthma in Adults[11–14]

- History of prior nonfatal asthma attack
- Prior intubation
- Female gender
- Age >65 years
- African American ethnicity
- Obesity
- Tobacco use
- Inhalational drug abuse
- Poorly controlled disease
- Poor recognition of dyspnea and other symptoms
- Steroid dependence
- H1N1 viral infection
- Misuse or lack of proper use of maintenance medications
- Psychiatric illness
- Lack of access to medical care
- Lack of ability to limit triggers (i.e., persistent exposure to pollutants, dust)
- Comorbid heart disease, obesity, and/or diabetes
- Bronchoalveolar lavage predominance of neutrophils, interleukin 8, and matrix metalloproteinase

• BOX 37.2 Genetic and Phenotypic Associations in Asthma

- *ADAM33*: gene bronchoconstriction
- *ORMDL3/GSDMB* locus, chromosome 17q21: childhood onset
- CpG portion of *ACSL3*: associated with maternal exposure to automobile pollution
- *IL33* on chromosome 9
- *IL2RB* on chromosome 22

Signs and Symptoms

Asthma was recognized by the ancient Chinese as "noisy breathing" and is, in fact, often associated with wheezing. However, wheezing lacks sensitivity and may be a manifestation of many other cardiac, pulmonary, and oropharyngeal conditions, such as cardiogenic pulmonary edema, pulmonary embolism, and vocal cord dysfunction syndrome. Furthermore, severe and life-threatening asthma, the topic of primary discussion in this chapter, often represents disease that has progressed beyond the traditional wheeze. A silent chest is a particularly ominous sign as it represents some degree of cessation of any air movement. Other signs of advanced and life-threatening asthma may be seen in Box 37.3.[21–24]

Physiologically, these findings are accompanied by severe ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch with perfusion of poorly ventilated areas leading to derangements in both ventilation, and as disease progresses, oxygenation. Both decreased expiratory time and the physiologic need for additional expiratory time contribute to concomitant air trapping. Trapped air leads to increased intrathoracic pressure with decreased venous return, a reduced effective tidal volume, and increased likelihood of barotrauma, all of which further compound impaired ventilation and oxygenation.[4,22] A patient's inability to markedly improve peak expiratory flow rates with aggressive bronchodilator therapy is the best predictor of asthma-associated morbidity, and a prior near-fatal asthma exacerbation is the best predictor of mortality.[4,11]

1. Ancillary studies have variable utility in predicting morbidity, mortality, and the need for mechanical ventilation in patients

• BOX 37.3 Signs and Symptoms of Severe Asthma

- "Tripoding"—sitting upright and leaning forward
- Diaphoresis
- Use of accessory muscles
- Asynchronous accessory muscle use
- Air trapping and hyperinflation manifesting as decreased inspiratory stroke volume and pulsus paradoxus
- Peak flow <200 L/min and/or <30% predicted[a]
- FEV_1 <1 L/min and/or <20% predicted[a]
- Evidence of barotrauma
  - Unilateral diminution in breath sounds
  - Tracheal deviation
  - Thoracic crepitus
- Signs of impending respiratory arrest
  - Altered mentation
  - Cyanosis
  - Hypoxia
  - Hypercarbia
  - Hemodynamic instability
  - Silent chest

[a]*Note that these values are estimations because both peak expiratory flow rate and forced expiratory volume in 1 second (FEV_1) vary with age, gender, and height.*

with severe asthma. A routine chest x-ray is likely to demonstrate flattened diaphragms as the result of air trapping and, in cases associated with barotrauma, pleural or mediastinal emphysema and tracheal shift.

2. The arterial blood gas (ABG) analysis can be as dangerous as it can be useful. A novice practitioner's finding of "normal" ABG findings in this setting is tantamount to an increased mortality rate in his or her practice. In other words, a normal or near-normal partial pressure of arterial carbon dioxide ($PaCO_2$) level in any patient with tachypnea is an ominous sign and one that requires immediate attention. That said, most patients with this degree of airflow obstruction will also, as noted above, exhibit tripoding (see Box 37.3), tachypnea, tachycardia, anxiety, diaphoresis, and demand attention. As with the ABG analysis, the quiet patient or asthmatic is one who has been left unattended for too long.
3. The electrocardiogram (ECG) and other serum laboratory studies are largely nonspecific in this setting and thus of greatly limited utility. The ECG may demonstrate right heart strain, which resolves with control of airflow obstruction. Muscle enzyme and inflammatory markers, such as creatinine kinase MB fraction, erythrocyte sedimentation rate, and C-reactive protein, may be elevated and bicarbonate levels may be acutely skewed as the body attempts to compensate for acid-base abnormalities. Elevated exhaled nitric oxide levels can be found in severe allergic asthma and may predict future exacerbations and steroid treatment response; however, use of this biomarker is not recommended at this time and needs further evaluation.[25–30]

Inhaled Therapies

Oxygen

As with all respiratory illnesses, clinical effects can be roughly divided into abnormalities of ventilation and derangements in oxygenation or, of course, both. Although ventilator disturbances are typically the earlier and more predominant abnormality seen in severe asthma, hypoxia often follows. Derangements in ventilation are covered in the sections on noninvasive and invasive support.

If ABG analysis or peripheral oximetry confirms the presence of hypoxemia, oxygen should be given to maintain oxygen saturation at greater than 92%. Hypoxemia may initially be further exacerbated by the use of serial bronchodilation secondary to β-adrenergic vasodilation and subsequent increased perfusion of persistently poorly ventilated lung segments. This effect is usually transient and has been observed primarily in children with severe asthma exacerbations using aerosolized salbutamol administration; these effects have been poorly replicated in adults. However, because the benefits of inhaled β-agonists far outweigh the risks in this scenario, they should continue to be used with supplemental oxygen provided as needed. Humidification of oxygen using a heated cascade humidifier is an important adjunct to avoid addition of bronchoconstriction induced by dried air. Although hypoxia is unusual with judicious use of oxygen therapy, it can occur and may, in turn, worsen hypercarbia owing to regional release of hypoxic pulmonary vasoconstriction.[31–36]

Inhaled Short-Acting β_2-Selective Agonists: Albuterol, Levalbuterol, Salmeterol

Inhaled β_2-selective agonists remain the cornerstone of rescue treatment in asthmatic patients with acute severe exacerbations. Initial therapy, as recommended by the National Asthma Education and Prevention Program Update, is 2.5 to 5 mg of albuterol (0.5–1 mL of 0.5% solution in 5 mL of normal saline solution) nebulized every 20 minutes for 3 doses (for optimal delivery, dilute aerosols to a minimum of 3 mL at gas flow of 6–8 L/min), followed by 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg/hr continuously, with the titration based on response and ongoing severity of symptoms. Those with the most severe bronchoconstriction usually require consecutive treatments, which may lead to tachycardia and hypokalemia. β_2-Selective agents delivered parenterally or orally lose much of the β_2 selectivity, which provides the rationale for inhalation treatment as the cornerstone of therapy.[37–41]

β-Agonists delivered by metered-dose inhaler (MDI) have been consistently shown to be equally efficacious and cheaper in cost and resource utilization than the nebulized equivalent. Adequate delivery requires patient cooperation and spacer technique as well as increased dose requirements compared with nebulized therapy. Four puffs of albuterol by MDI with a spacer (0.36 mg) is equipotent to 2.5 mg of nebulized albuterol. In mechanically ventilated patients, drug deposition in the endotracheal tube and ventilator circuit may effectively reduce the delivered dose so that dose doubling is recommended in this scenario.[42–45]

Although long-acting inhaled β-agonists are now recognized as an important adjunctive therapy in the management of obstructive lung disease, they have little role in the treatment of a patient with acute life-threatening asthma.

β-Agonist therapy, in the form of subcutaneous epinephrine or terbutaline, may also be delivered to adult patients at the following doses: epinephrine: 0.3–0.5 mL of a 1:1000 dilution (1 mg/mL) and terbutaline: 0.25 mg. Both may be repeated as needed up to 3 times at 20-minute intervals. However, both medications have undesirable therapeutic-to-toxicity ratios, especially in patients with cardiac disease, and neither drug has demonstrated a superior outcome benefit compared to inhalational therapy.[46,47]

Inhaled Anticholinergics: Ipratropium

Inhaled anticholinergics, most commonly in the form of ipratropium, are effective mainly as an adjunct to inhaled β-agonists as they attenuate bronchodilation. This combination has been demonstrated to accelerate improvements in lung function and to reduce the need for hospitalization in patients with acute asthma. Those patients with severe asthma who require hospitalization do not typically continue to enjoy the benefits of combination therapy after the first 24 hours or so.

Although ipratropium achieves less bronchodilation at peak effect than β-agonists and a less predictable clinical response, the effects of both are additive. Most published evidence supports the addition of ipratropium to inhaled β-agonist therapy for patients with acute asthma. It produces a clinically modest improvement in lung function compared with albuterol alone, especially in those with very severe disease.[35,37,48,49]

Ipratropium is administered at a dose of 0.5 mg by nebulizer every 20 minutes for 3 doses and then every 2 to 4 hours as needed. Nebulization occurs by a handheld nebulizer either simultaneously or after inhalation of β-agonists to maximize the attenuated effect. Nebulization of ipratropium by face mask may be dangerous because contamination of the ocular area with precipitation of narrow-angle glaucoma may occur in susceptible individuals. Ipratropium may be combined with the nebulized albuterol dose as long as a handheld device is used. The onset of action of ipratropium is slow and may occur over 20 to 90 minutes with more rapid results in patients with severe asthma and a slower effect in those with chronic obstructive pulmonary disease.[37,41]

Heliox

Heliox is a mixture of helium and oxygen in varying ratios from 60:40 to 80:20 with helium representing the predominant gas. By transitioning airflow from turbulent to laminar, this low-density mixture reduces airway pressure. Although its utility has historically been in modifying airflow through large stridorous airways, it appears to have some promise in facilitating improved flow through distal bronchioles. The need for intubation and mechanical ventilation as well as mortality were reduced with the use of heliox in patients with chronic obstructive pulmonary disease in an observational study by Gerbeaux and colleagues.[50] The more recent ECHO ICU trial was unable to duplicate these findings.[51]

In patients with severe asthma, heliox has been studied as an adjunct to better distribute bronchodilators in the lower airways, and in one study this combination demonstrated greater peak expiratory flow rate improvements than bronchodilation accompanied by oxygen. The effect was most pronounced in those with the most severe disease.[52] A similar study demonstrated nearly identical improvements in airflow, measured as forced expiratory volume (FEV), with the combination of inhaled heliox and bronchodilators. Again, the effects were most notable in those with the most severe airflow obstruction.[53]

Systemic Therapies

Corticosteroids

Corticosteroids, like bronchodilators, are critical in the management of asthmatic patients with a life-threatening exacerbation. Although long-term outcome differences have failed to be shown between the use of intravenous (IV) versus oral steroids, IV forms have a faster onset of action. Steroids are administered in considerably more temperate doses than in the past; the National Institutes of Health Expert Panel currently recommends IV methylprednisolone, 40 to 80 mg/day in one or two divided doses, until peak expiratory flow reaches 70% of predicted or personal best. Higher doses offer no benefit, IV is not superior to oral therapy (expect for afore-stated more rapid onset of action), and treatment durations of 3 to 10 days without need for taper are considered sufficient. The delay in effect may reflect the time necessary for steroids to induce upregulation of new β_2-receptors and reversal of β_2-receptor desensitization and downregulation. Given this relatively lengthy onset of action, steroids play a role in the hospital course of life-threatening asthma but are not considered immediate rescue therapy as bronchodilators are.

Inhaled corticosteroids play a role in the management of chronic disease but have no role in acute rescue maneuvers. However, it may be beneficial to start inhaled corticosteroids while asthmatic patients are inpatients to teach and reinforce appropriate use techniques.[31,37,54]

Methyxanthines: Theophylline and Aminophylline

Although methylxanthines are effective bronchodilators compared with placebo in patients with acute bronchospasm, inhaled β-agonists are superior agents for acute rescue. Although a few studies have demonstrated some physiologic benefits with methyxanthines between 24 and 48 hours, the availability of safer and more efficacious drugs and the high toxicity side effect profile of methylxanthines makes them a last choice for those who do not otherwise respond.[41,55–58]

Magnesium Sulfate

Magnesium sulfate works by inhibiting calcium channels, thereby reducing smooth muscle bronchoconstriction and reducing airway parasympathetic tone. It can be administered via IV infusion or in inhalational form and is relatively contraindicated in those with renal insufficiency. Onset of action is slower than bronchodilators but faster than corticosteroids. Most studies support its use as adjunctive therapy. A Cochrane meta-analysis concluded that use of IV magnesium sulfate improves pulmonary function and decreases hospital admissions in acute severe asthma, particularly in patients with severe exacerbations. Inhaled magnesium sulfate improves pulmonary function during acute exacerbations of asthma, although it fails to modify clinically important outcomes, such as hospital admissions.[59,60]

Anti-IgE Antibodies: Omalizumab

The use of monoclonal antibodies and other immunologic modulators has exploded over the past several years. Such therapies are now commonly used for immune-mediated arthritis, inflammatory bowel disease, and a host of other diseases in which the immune cascade can be interrupted. For asthma, the most commonly studied agent in this category is the recombinant anti-IgE antibody omalizumab, which is indicated as step-up therapy for severely allergic asthmatic patients with markedly elevated IgE levels. Several studies have demonstrated a reduced number of severe exacerbations,

fewer episodes requiring systemic corticosteroids, and fewer health care visits associated with its use. Each of these benefits has been demonstrated in patients with severe allergic asthma but not at the time of life-threatening exacerbation. Drawbacks include high cost, subcutaneous administration, and unknown optimal duration of treatment. Studies examining the use of such agents in severe acute exacerbations are limited and potential clinical utility is unknown at this time.[61–64]

Leukotriene Antagonists: Montelukast

Leukotriene receptor antagonists (LTRAs), such as montelukast, are another asthma management strategy based on immune modulation. Significant and rapid (about 10 minutes) improvement in lung function (measured as forced expiratory volume in 1 second [FEV_1]) has been noted in patients with severe asthma given IV LTRAs; these drugs appear to have the greatest impact on patients with allergic and exercise-induced asthma. Similar studies in patients with life-threatening asthma have not been undertaken. A 2012 Cochrane review by Watts and Chavasse confirmed improvements in lung function, but this benefit did not translate to reduced hospital admissions and investigators advised against the routine use of LTRAs in acute exacerbations.[65] A 2016 study by Altawalbeh and colleagues actually revealed that the addition of LTRAs in older adults with asthma increased emergency department visits and hospital admissions compared with the addition of long-acting β-agonists.[66] As with omalizumab, any clinical utility of this agent in acute severe asthma is unknown.

Alternative and Investigational Agents

New medications and old medications with historically nonasthma indications are postulated to have potential utility in the treatment of asthma every day. Such agents that have demonstrated early or intermittent promise include methotrexate, antifungal agents, macrolide antibiotics, ketamine, inhaled heparin, furosemide, and anesthetics. None have been studied as acute rescue agents in life-threatening asthma and we are, at best, years away from endorsing any such recommendation.[10]

Immunomodulatory therapy holds promise as future asthma control agents that may reduce steroid use and concomitant side effects, manage disease more seamlessly with fewer overall agents, and reduce the frequency, severity, and mortality associated with life-threatening asthma. Such investigations are directed against various interleukins (specifically IL-4, -5, -8, -13, and -17), chemokine antagonists, Toll receptor agonists, and tyrosine kinase inhibitors.[13]

Also gaining notoriety is bronchial thermoplasty, an endoscopic procedure in which the bronchial smooth muscle is ablated using radiofrequency waves. Although this intervention has historically been performed only in patients who are not having an acute exacerbation, a recent small study by Langton and colleagues in Australia demonstrated that patients with severe chronic asthma had improved lung function and fewer exacerbations even when their disease was poorly controlled before the intervention.[67]

Finally, extracorporeal membrane oxygenation is gaining support as a potential means to rescue patients with very severe asthma exacerbations, especially those with refractory acidosis and/or hypercarbia. However, this therapy remains invasive and controversial and consideration for its use should be reserved for those with appropriate expertise and experience.[68]

Mechanical Ventilation in Patients With Asthma

Indications for Mechanical Ventilation

Medication management in life-threatening asthma is often not enough. Roughly 10% of admitted patients with asthma require critical care services and about 2% require mechanical ventilator support. Although this certainly does not represent the majority of patients with this disease, the attributable mortality remains too high in this ostensibly reversible disease.[3,11]

Signs of impending respiratory failure should trigger endotracheal intubation and mechanical ventilation. Such signs may include central cyanosis, altered mentation, paradoxical breathing, refractory hypercarbia and/or hypoxemia, and a silent chest. An elevated $PaCO_2$ indicates an FEV_1 less than 25% predicted and is an ominous predictor for the need for ventilator support. Not surprisingly, asthmatic patients in whom ventilator support is initiated before formal respiratory arrest have better outcomes.[69] The estimated attributable mortality rate for those with severe asthma who required mechanical ventilation varies between 6.5% and 10.3%.[3,70–73]

Physiologically, life-threatening asthma is characterized by severe airway resistance, which leads to incompletely exhaled tidal volume and subsequent increased dead-space ventilation and trapped air. Plateau pressure is a reliable surrogate for measuring auto–positive end-expiratory pressure (PEEP) and levels of 30 cm H_2O and greater are associated with more barotrauma and more hemodynamic instability related to poor venous return. Mechanical ventilation, in and of itself, is not a curative therapy for the patient with acute asthma. Ventilator support settings should be chosen to maximize expiratory time, reduce air trapping, and avoid barotrauma. Excessive tidal volumes and respiratory rates with insufficient expiratory time may worsen an already tenuous ventilator status.[73,74]

By definition, patients with life-threatening asthma require improved ventilation, manifested, of course, as minute ventilation. Herein lies the dichotomy of too much or too little of a good thing. Too much minute ventilation may lead, as stated earlier, to reduced expiratory time and worsening air trapping. Too little ventilation can be viewed as inadequate management of the very disease being treated. Two investigations by Tuxen and colleagues demonstrated that ventilator strategies aimed at normalizing $PaCO_2$ required such high minute ventilation that risk for barotrauma was unnecessarily invoked.[75,76] Conversely, permissive hypercarbia and associated acidemia can increase intracranial pressure and cerebral blood flow and may further adversely affect those with anoxic brain damage. Current data suggest that the best strategy is to allow mild hypercarbia for brief periods to facilitate reduced air trapping and improved venous return. In extreme cases, alkalinizing agents may be considered as an additional temporizing measure.[77,78]

Recommended initial ventilator settings are a tidal volume of 6 to 8 mL/kg ideal body weight and a frequency of 10 to 14 breaths/min. Minute ventilation of less than 8 to 12 L/min is ideal with increased expiratory time to facilitate avoidance of auto-PEEP and oxygen saturation greater than 90%. Peak inspiratory flow rates should be set at 60 to 80 L/min with a square inspiratory waveform to assist in maximizing expiratory time. In healthy adults, inspiratory:expiratory time ratios are usually 1:2, whereas patients with acute asthma may require ratios of 1:3 to 1:5 or greater. The use of noncompressible tubing also facilitates shorter inspiratory and longer expiratory times.[79]

Controlled mechanical ventilation in patients with acute asthma almost invariably requires heavy sedation and analgesia, or at times, sedation, analgesia, and muscle paralysis. Assisted controlled ventilation without heavy sedation or sedation/paralysis predisposes the patient to hyperinflation if the patient's intrinsic drive to breathe exceeds that of the ventilator. Heavy sedation with or without paralysis reduces carbon dioxide production, facilitates accurate measurement of airway pressures, and reduces dyssynchrony and discomfort. Pressure-control ventilation is discouraged because of fluctuating high airway resistance and intrinsic PEEP. There is no role for synchronized intermittent mechanical ventilation.[78,80,81]

Delivery of inhaled therapies while a patient is supported by mechanical ventilation can be challenging. The length and acute angles of the ventilator circuitry predispose toward deposition of medication in the endotracheal tube and extension tubing and not in the patient's airways. Strategies to facilitate proper delivery include doubling doses and placing the nebulization device as close to the patient as possible.[82]

Neuromuscular Blocking Agents

Neuromuscular blocking agents (NMBAs) are increasingly being studied for their utility as adjunctive agents in severe asthma, acute respiratory distress syndrome, and septic shock with ventilator failure. By achieving complete muscle paralysis, NMBAs are theorized to reduce patient-ventilator dyssynchrony and to reduce the untoward but expected consequences of severe air hunger—air trapping and barotrauma. Most studies focus on the collective muscle weakness and polyneuropathies that occur as a result of their use, particularly in conjunction with corticosteroids, heavy sedation, and the critical care environment. Such neuromuscular derangements are more prevalent in females with renal failure and hypophosphatemia. Concomitant use of corticosteroids and NMBAs typically produces proximal and distal muscle weakness. Creatine kinase may be elevated and myoglobinuria may be present. Steroid myopathy, by contrast, primarily involves proximal muscles and the creatine kinase levels are typically normal.

Ideally, NMBAs should be avoided or used for as brief a time as possible and delivered by intermittent dosing. In the rare patient who needs to be continuously paralyzed, infusions must be stopped every 4 to 6 hours to minimize dosing and accumulation and to facilitate neurologic evaluation. A peripheral nerve stimulator should be used to limit paralysis to no less than a recording of one or two twitches in response to a train-of-four stimulus. In patients with asthma, cisatracurium is the first-choice NMBA because it is eliminated by esterase degradation and spontaneous breakdown in the serum.[31,83–86]

Noninvasive Positive-Pressure Ventilation

The role of noninvasive positive-pressure ventilation (NIPPV) remains controversial. In those with true life-threatening asthma (extremis), it should not be used with preference for endotracheal intubation. The aims of NIPPV are the same as those in patients with invasive mechanical ventilation. The usefulness of NIPPV in improving breathing cycle synchrony and in reducing airway pressures is largely unproven. Several small studies have demonstrated that NIPPV can be safely used in asthmatic patients with acute exacerbations and can even help avoid the need for intubation. A nonrandomized study by Meduri and associates reported a reduction in $PaCO_2$ and improvement in dyspnea with the use of NIPPV in 17 episodes of asthma with acute respiratory failure. Ram and colleagues, however, countered that NIPPV in status asthmaticus, despite some promising preliminary results, remains controversial. A most recent investigation by Stefan and colleagues failed to demonstrate a reduction in the need for invasive ventilation or a mortality benefit, although the hospitals that used NIPPV the most frequently trended toward a shorter length of stay. If NIPPV is used, initial setting should be an expiratory positive airway pressure (continuous positive airway pressure or PEEP) of about 5 cm H_2O and inspiratory pressure (or pressure support) of approximately 8 cm H_2O. If tidal volumes are shallow (<7 mL/kg), inspiratory pressure can be increased gradually by 2 cm H_2O every 15 minutes to a goal to reduce the respiratory rate to less than 25 breaths/min[87–93] (also see Chapter 10).

The Future for Those With Life-Threatening Asthma

As population health efforts shift into high gear, there is increasing recognition of the need for better knowledge of risk factors for severe asthma and what outpatient strategies might ameliorate readmissions, the severity of exacerbations, and mortality. Obesity in the United States has reached epidemic levels and its impact on new adult-onset asthma and the severity of the disease is well known. Koebnick and colleagues demonstrated the following compared with patients with a body mass index (BMI) of 25 kg/m^2 or less. Adult patients with a BMI ranging from 25 to 29.9 kg/m^2 had a 12% increased risk of adult-onset asthma. BMIs in excess of 50 kg/m^2 conferred a 250% increase in adult-onset asthma.[94]

A recent investigation by Pakhale and colleagues revealed that even mild reductions in BMI and waist circumference were associated with reduced asthma severity, improved FEV_1 and forced vital capacity, and improved symptom control and quality of life.[95] Although these findings cannot yet be extrapolated to the critical care experience for patients with severe asthma, we might surmise that the benefit would extend to that population as well.

Concomitant mental illness and gastroesophageal reflux disease have been demonstrated to worsen asthmatic symptoms and to make control more challenging. In addition to other risk factors, such as prior hospitalizations and intubations, gastroesophageal reflux disease and mental illness were associated with increased utilization of health care resources and increased 30-day readmission rates.[96–98]

After a near-fatal episode of asthma exacerbation, strategies can be implemented to reduce the likelihood of another event or the severity of subsequent episodes. Examples include asthma education, follow-up phone calls, assistance and facilitation of primary and specialist follow-up appointments, and more. Gibeon and colleagues developed 11 asthma centers around the United Kingdom that used standardized treatment approaches and reported into a national database. This intervention reduced steroid use and improved quality-of-life scores but, again, the impact on life-threatening asthma remains unknown.[99]

Two recent studies assessed the impact of healthy environments and in-home assistance as mechanisms to control severe asthma in low-income, minority patients with social and economic barriers. Bryant-Stephens and colleagues made home visits and found high-risk dwellings with mite and cockroach infestations, mold, overcrowding, and chronic exposure to tobacco smoke and unhealthy diets.[100] Reddy and colleagues expanded these findings in a study from 2007 to 2011 recently published. Investigators partnered with New York housing administration to identify at-risk patients and to optimize opportunities to maximize modification of risk—dwelling updates and reduction of onsite triggers as examples. Considerable reductions in morbidities were achieved as predicted.

Summary

Asthma is a complex and comprehensive disease and its severity exists along an extensive spectrum. Life-threatening asthma in adult patients is more common in those with previous serious exacerbations, those who are female, obese, and African American. Corticosteroids and inhaled bronchodilators remain the cornerstones of rescue treatment, and invasive mechanical ventilation may be required for those with refractory airflow obstruction. Immune-modulating drugs are increasingly recognized as possible adjunctive or replacement agents. Efforts to modify risk factors such as obesity, mental illness, and comorbidities and efforts to maximize disease management and avoidance of triggers continue to be fundamental to the success of asthma care and the avoidance of life-threatening episodes.

Key Points

- The prevalence of asthma in the United States continues to steadily decrease and mortality is highest in African American women older than 65 years of age.
- Severe asthma may be characterized as type 1 (slow onset) or type 2 (rapid onset) and the majority of mortalities are related to type 1.
- Bronchodilators and corticosteroids remain the cornerstones of severe asthma treatment but are not being supplemented with nontraditional inhaled therapies and immune modulators.
- In a patient with severe asthma, signs of impending respiratory failure requiring invasive mechanical ventilation may include central cyanosis, paradoxical breathing, altered mentation, hemodynamic instability, a silent chest, and a "normal" $PaCO_2$.
- Reducing risk factors, triggers, and comorbidities is likely the most effective strategy to sustainable improvement in mortality from severe asthma.

Review Questions

1. Which of the following is the best predictor for a life-threatening asthma attack?
a. Age >45 years
b. African American heritage
c. A prior near-fatal attack
d. Male gender
Answer: c. Advanced age, female gender, and African American heritage all predispose to adult-onset severe asthma, but the best predictor of mortality is having had a prior near-fatal episode.

2. Which of the following should prompt the practitioner to immediately intubate and provide mechanical ventilation to the severe asthmatic patient?
a. Partial pressure of arterial carbon dioxide ($PaCO_2$) of 45 with respiratory rate of 26 breaths/min
b. Diaphoresis
c. Diffuse bilateral wheezing on auscultation
d. H1N1 infection
Answer. a. All of the symptoms listed are serious and have the potential to lead to mechanical ventilation. However, a patient with an elevated respiratory rate and a simultaneously elevated $PaCO_2$ is demonstrating severely impaired ventilation and an insufficient ability to overcome this derangement.

3. Which of the following treatments has the most clear and undisputed role in the treatment of severe acute asthma?
a. Bronchial thermoplasty
b. Anti–immunoglobulin E antibodies like omalizumab
c. Leukotriene inhibitors
d. β-agonist bronchodilators
Answer: d. Each of the therapies listed shows promise in the management of chronic asthma, but only β-agonists bronchodilators have a well-established role in rescue from acute severe disease.

Terminal Care for the Patient With End-Stage COPD

The most recent 2017 iteration of the Global Initiative on Obstructive Lung Disease (GOLD) guidelines defines chronic obstructive pulmonary disease (COPD) as a preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients.[1] Its pulmonary component is characterized by chronic airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with abnormal inflammatory response of the lungs to noxious particles and gases. The 2017 GOLD classifies COPD based on spirometric staging (1–4) and symptoms/exacerbations (A–D). The new classification predicts mortality more accurately than previous symptoms.[2]

Definitions

Although controversies remain over the definition of exacerbation, how they should be monitored, and their underlying mechanisms, acute exacerbations of COPD (AECOPD) are major and increasingly recognized events in the disease course. They typically occur one to three times per year. Exacerbations are associated with an increase in economic burden[3] and a decline in health-related quality of life.[4] Those patients with more than two exacerbations per year have significantly worse health-related complications and decline in lung function than those with two or fewer exacerbations.[5] As mentioned earlier, there is no general agreement on the definition of AECOPD, but it has been defined according to the presence of specific signs and symptoms, worsening in symptoms, and the need for medical intervention; each of these approaches has positive and negative connotations. It is well recognized, however, that the presence of increased shortness of breath, increased sputum volume, and increased purulence are the three specific symptoms that represent an exacerbation.[6]

Background

COPD affects more than 200 million people worldwide and is the fourth leading cause of death. COPD is a disease that is both preventable and treatable. COPD is a major cause of morbidity and death in the world, with an increasing burden as a result of epidemiologic changes that expose more of the population to COPD risk factors. Although the major environmental risk for COPD is tobacco smoking, only 20% of smokers develop COPD. Indoor air pollution from burning biomass fuel is associated with increased risk of COPD in developing countries. In the United States, COPD is the fourth leading cause of death[7] and is exceeded only by heart attacks, cancer, and stroke. COPD has had a similar effect on health and mortality rate throughout the developed and underdeveloped sectors of the world, and many of the important issues surrounding COPD in the United States apply elsewhere.[8]

The real prevalence is masked by the burden of undiagnosed COPD; a population-based Spanish sample of 4274 adults (age 40–80 years) who answered a questionnaire and underwent prebronchodilator and postbronchodilator spirometry found that the prevalence of COPD was 10.2% (4.4% with GOLD II disease or worse) with only 27% having a prior diagnosis.[9]

Pathophysiology

The main pathophysiologic feature in COPD is the limitation to expiratory flow.[10] Chronic expiratory flow limitation and

hyperinflation are the mechanical hallmarks of COPD.[11] Expiratory airflow limitation results from many factors; among them, narrowing of the peripheral airways,[12] mucus hypersecretion,[13] and impaired ciliary clearance[14] are the most important factors.

Several mechanistic concepts have been implicated in the pathogenesis of COPD. First is the development of exaggerated chronic inflammation in the lung in response to inhalation of cigarette smoke compared with smokers without lung disease.[15] Host factors including genetic susceptibility, epigenetic changes, and oxidative stress contribute by amplifying inflammation induced by cigarette smoke. Second, patients with deficiency of α_1-antitrypsin, the main inhibitor of neutrophil elastase, develop emphysema early in life owing to an increase in proteolytic activity.[16] Third, an imbalance between oxidants and antioxidants in the lungs of patients with COPD, resulting in excessive oxidative stress, not only amplifies airway inflammation in smokers but also induces cell death of structural cells in the lung. Disruption of the balance between cell death and replenishment of structural cells in the lung contributes to the destruction of alveolar septa, leading to emphysema.[17] Autoimmunity has been proposed as a late pathogenic event in the progressive course of the disease.

COPD is characterized by a specific pattern of inflammation involving increased numbers of $CD8^+$ cytotoxic T-cell lymphocytes present only in smokers in whom the disease develops. These cells as well as neutrophils and macrophages release inflammatory mediators and interact with epithelial cells in the airways, lung parenchyma, and pulmonary endothelium; all these relationships and interactions produce structural changes in the lungs by activation of growth factors.[18] Changes in the airway architecture, endothelium, and lung parenchyma lead to the characteristic physiologic abnormalities and symptoms of COPD.

In acute exacerbations there is an increase in sputum neutrophil numbers as well as an increase in neutrophils in bronchial biopsies, which rarely are seen in the stable state.[19] Interestingly, virally induced exacerbations are associated with increased expression of eosinophils in sputum. Viral infections induce the expression of chemokine (C-C motif) ligand 5 (CCL5) in airway epithelial cells,[20] and CCL5 may act synergistically with $CD8^+$ cells to enhance the apoptosis of virally infected cells, thus leading to increased tissue destruction.[21] Also, an increase in the concentration of the elastolytic enzyme matrix metalloproteinase-1 during exacerbations is consistent with evidence of elastolysis, which may provide a causal link between exacerbations and accelerated decline in lung function.[22]

Changes in the microbiome also lead to exacerbations. During these episodes, changes in the taxonomy of the microbiome (i.e., increases in Proteobacteria and decreases in *Acinetobacter,* Clostridia, and Bacteroidia) could contribute to the development of exacerbations. Additionally, treatment with steroids influences the diversity of the microbiome, and antibiotic therapies result in a reduction in the number of colonies.[23]

Data from patients with AECOPD who required mechanical ventilation indicates the presence of increased central drive, dyspnea, tachypnea, reduced tidal volume, and development of hypercapnic respiratory failure, but ventilation-perfusion ($\dot{V}/\dot{Q}$) match remains relatively preserved.[24] AECOPD appears to be characterized by increased central drive, decreased inspiratory capacity, and decreased inspiratory muscle force, perhaps secondary to dynamic hyperinflation. There is an association between increased serum levels of interleukin 6 (IL-6) and leukotriene B4 and the magnitude of dyspnea, respiratory rate, and inspiratory capacity, suggesting that it may be possible to detect serum changes that reflect the inflammatory burden of the exacerbation.[25]

Although hypercapnia depends on the severity of airflow limitation, there is considerable variability in the relationship of partial pressure of arterial carbon dioxide ($PaCO_2$) to forced expiratory volume in 1 second (FEV_1) and total lung resistance, best explained by contribution of dead space and minute ventilation.[26] In stable COPD patients with severe airflow obstruction, shallow breathing is the main factor associated with carbon dioxide (CO_2) retention. In this circumstance the diaphragm is less effective than in normal subjects, and with increasing airflow obstruction and hyperinflation, the contribution of the rib cage muscle to the generation of ventilatory pressure increases.[27] Abdominal muscles are recruited during expiration in patients with severe COPD, and the expiratory rise in gastric pressure is directly related to intrinsic positive end-expiratory pressure (iPEEP). During acute exacerbation, patients with severe airflow obstruction increase the inspiratory recruitment of the rib cage muscles relative to the diaphragm. This recruitment is associated with abdominal muscle contraction and a reduction in abdominal volume at end expiration, which contributes to iPEEP. Dynamic hyperinflation can be overestimated during chronic and acute airway obstruction if abdominal muscle function is not evaluated.[28]

Hypercapnic respiratory failure is associated with a worsening of the lung mechanics, including an increased inspiratory load as indicated by the integral pressure/time of the diaphragm and other respiratory muscles (respiratory load). These factors are related to a worsening of muscle strength and the ability to generate pressure and can translate into an imbalance of capacity/load, resulting in a superficial and rapid respiratory pattern that can lead to acute respiratory failure.[29]

The worsening gas exchange and the deterioration of the arterial blood gas values during acute exacerbations in patients with severe COPD can be explained by several factors. These factors are, in no particular order, respiratory muscle fatigue,[30] increases in dead-space ventilation, and alveolar hypoventilation.[31] Minute ventilation may be normal early in an exacerbation, but the respiratory rate is generally increased. There is an associated increase in physiologic dead space that impairs CO_2 elimination and may result in acidemia.[32] The hypoxemia seen during exacerbations results from the combination of two factors: alveolar hypoventilation and, later, worsening of $\dot{V}/\dot{Q}$ matching. Increases in $\dot{V}/\dot{Q}$ heterogeneity are attributed to (1) a reduction in the effectiveness of hypoxic vasoconstriction as a protective mechanism as pulmonary artery pressure rises and vasodilatory inflammatory mediators are released, and (2) the failure to redirect perfusion away from inadequately ventilated regions because of the reduction in cross-sectional area of the pulmonary vascular bed.

Clinical Manifestations

An exacerbation of COPD is a sustained deterioration of the baseline condition in a patient that begins acutely and requires additional treatment over and above the usual care.[33,34] However, defining the characteristics of the clinical picture is essential. Much effort has been exerted to standardize the diagnosis of "COPD exacerbation," but because of the variability in the symptoms that characterize each case, reaching a consensus has been challenging. The following symptoms may be present: breathlessness, wheezing, chest tightness, increased cough, fever, and changes in sputum color or volume; these symptoms may be accompanied by malaise, insomnia, fatigue, depression, and confusion. Spirometric variables,

• BOX 38.1 Clinical Signs of Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Increasing cough
Worsening dyspnea
Increased sputum production
Purulent sputum

such as the peak expiratory flow rate (PEFR), FEV_1, and forced vital capacity may worsen (Box 38.1). The symptoms may slowly intensify over several days or appear acutely, partially depending on the severity of the underlying disease. Additionally, patients often have a recent history of an upper respiratory tract infection. The vital signs typically show tachycardia and tachypnea, and blood pressure can be reduced in response to the effect of iPEEP. The use of accessory inspiratory muscles may be observed as the severity of the exacerbation increases. Because of diaphragmatic fatigue, the diaphragm no longer functions as a primary muscle of inspiration, but instead it assists the inspiratory effort of the intercostal muscles by fixing the rib cage. This action is associated with a rise in the diaphragm, and the abdomen moves inward instead of outward as it does in normal inspiration. This sign is called *paradoxical breathing* and is indicative of respiratory muscle fatigue and often imminent ventilatory failure and respiratory arrest.[31,32] Wheezing and other auscultatory signs of obstruction are also often present. Cyanosis is an insensitive manifestation, but its presence indicates severe hypoxemia. Patients with severe acute CO_2 retention may present in a coma. The classic clinical signs of imminent respiratory failure include an inability to speak complete sentences, the use of accessory muscles, the absence of wheezing, a paradoxical pulse, lethargy (common in hypercapnia), cyanosis, and hemodynamic instability.

Precipitating Factors

The most common precipitant factor is respiratory infection, either bacterial or viral.[35,36] Air pollution can also precipitate exacerbations of COPD[37,38]; however, the cause of one-third of AECOPD events cannot be identified. Some other conditions that can either mimic or induce an exacerbation include pneumonia, arrhythmia, pneumothorax, pulmonary embolism,[39] and pleural effusion. Medication failure and lack of compliance have also been shown to lead to exacerbations.

Infections

Bacteria and viruses account for the vast majority of episodes of exacerbation. Respiratory viruses are associated with 30% of exacerbations with or without a superimposed bacterial infection.[40] Another study reported that up to 78% of the patients admitted to the hospital with severe AECOPD had evidence of viral or bacterial infection.[20]

Several studies have been conducted to investigate airway bacterial infections as etiologic factors involved in COPD exacerbations.[41–43] Bronchoscopic sampling of the distal airway has demonstrated the presence of pathogenic bacteria in 50% of exacerbations. Acquisition of new strains of bacterial pathogens has been associated with more than a twofold increase in the risk of AECOPD.[44] At present, there appears to be an agreement that the major pathogens isolated from sputum during acute exacerbation are *Haemophilus influenzae, Streptococcus pneumoniae,* and *Moraxella catarrhalis*[45]; however, all of these bacteria can be isolated in patients during the stable phases of COPD.[46,47] Atypical bacteria, mostly *Chlamydia pneumoniae,* have been implicated in approximately 10% of acute exacerbations.[48,49] Other potential microorganisms that should be considered include other *Streptococcus* species, enteric gram-negative bacilli, and *Legionella.*[50] Bacterial colonization may be a factor increasing airway inflammation.[51] There is an association between bacterial colonization and increased markers of inflammation in sputum and in the frequency of exacerbations.[52]

Approximately 50% of AECOPD events are associated with upper respiratory tract virus infections. Infections with rhinovirus, respiratory syncytial virus, and influenza virus have been associated with AECOPD.[53] COPD patients with a history of frequent exacerbations may be more susceptible to respiratory viral infections. There is increasing recognition that many patients with exacerbations have concomitant viral and bacterial infection. Approximately a quarter of patients admitted to hospital with AECOPD have coinfection with viruses and bacteria, and those patients have more severe exacerbations.[53]

Environmental Factors

Environmental factors are among noninfectious causes of COPD exacerbation that should be investigated as precipitating causes.[37,54,55] Epidemiologic studies have shown that hospital admissions with AECOPD increase slightly with a rise in atmospheric levels of sulfur dioxide, ozone, nitrogen dioxide, and particulates. There is convincing evidence that exposure to particulates with a 50% cutoff aerodynamic diameter of 10 μm is associated with increased hospital admissions for AECOPD.[56] Air pollution is implicated as a trigger of exacerbations[57]; however, a direct cause-and-effect relationship has been difficult to establish.[58] From an epidemiologic viewpoint, definitive evidence exists regarding a role of air pollutants in the increased death rates seen in cities during periods of heavy pollution.[59] The recent dramatic increase in motor vehicle traffic has produced a relative increase in the levels of newer pollutants, such as ozone and fine-particulate air pollution. Elucidation of the mechanisms of the harmful effects of these pollutants should allow improved risk assessment for the patients with airway diseases who are susceptible to the effects of these air pollutants.

Pulmonary Thromboembolism

Pulmonary thromboembolism (PTE) can precipitate acute COPD exacerbations through either impairment of gas exchange or increases in pulmonary vascular pressures.[60,61] Some evidence suggests that deep venous thrombosis occurs in more than 5 million people each year. More than 500,000 people eventually develop PTE, which is the primary cause of death in more than 100,000 patients annually in the United States.[62] The precise incidence of PTE in COPD is unknown. Studies in COPD patients have found pulmonary embolus in up to 50% of autopsies and in patients admitted to the hospital with severe AECOPD of unknown cause; 25% had pulmonary embolism confirmed by spiral computed tomography (CT).[63] PTE risk factors inherent to COPD are sedentary lifestyle, right ventricular failure, right ventricular mural thrombi, and secondary polycythemia.[64] Patients with COPD have also been shown to have increased platelet aggregation and increased plasma β-thromboglobulin.[65]

Up to 30% of patients with untreated thromboembolism die. The necessity of diagnosing PTE as the precipitating factor in acute COPD exacerbation is crucial. However, the diagnosis of PTE is extremely difficult in COPD exacerbation. Nonetheless, the approach to diagnosis is similar to that used with other patients.[66] Unfortunately, most patients with COPD have an indeterminate $\dot{V}/\dot{Q}$ scan, usually making this scan unhelpful in evaluation for PTE.[67] For patients with such indeterminate results (low or intermediate probability), noninvasive testing of the lower extremity should be conducted.[68–70] If positive results for deep venous thrombosis are obtained, anticoagulation therapy must be initiated. It has been proposed that use of newer D-dimer assays may also have a role as a diagnostic tool; however, even with a sensitivity of 98%, specificity is problematic, with a value of 39%.[71] When the diagnosis is still in doubt (intermediate-probability scan and negative leg study or low-probability scan and negative leg study with intermediate clinical probability of PTE), helical CT or conventional pulmonary angiography may be required. Even though the safety of pulmonary angiography in patients with cor pulmonale has been questioned, data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study support both safety and accuracy in patients with COPD.[66] Helical CT has become an increasingly accepted technique and is the method of choice for direct visualization of pulmonary emboli. The quantitative assessment of tissue perfusion may yield more important information for patient management than the direct visualization of emboli by CT alone. Enhanced multislice helical CT with thin collimation can be used to analyze precisely the subsegmental pulmonary arteries and may identify even more distal pulmonary arteries. Recent data suggest that spiral CT may be an alternative to angiography, particularly when results are not discordant with pretest clinical probability of pulmonary emboli and when combined with other tests that support CT findings (D-dimer, leg ultrasound, lung scanning), and may have adequate sensitivity and specificity in the COPD population.[67]

Medication Failure or Noncompliance

Many acute COPD exacerbations can be explained in terms of inadequate pharmacologic therapy or noncompliance with pharmacologic therapy. These factors are likely underestimated causes of exacerbation in COPD patients. It is also possible that patients have toxic drug effects of cardiac, gastrointestinal, or metabolic nature. Certain pharmacologic drug interactions can precipitate toxicity or loss of effect of one drug, and the physician must ascertain whether newer medications for other conditions have recently been added to the patient's therapeutic regimen.[72,73]

Other Causes

Clinical decompensation in patients with stable COPD may also occur as a result of acute congestive heart failure (CHF) or cardiac arrhythmia. One study found that 27% of COPD patients die as a result of coronary disease,[74] likely related to risk factors such as smoking, diabetes mellitus, and vasculopathy. Heart failure may also lead to a symptomatic exacerbation of COPD; however, it may be difficult to differentiate the symptoms of CHF from those of AECOPD.[75]

Other causes of exacerbation include sleep-disordered breathing,[76–78] vocal cord paralysis, tumor or scarring from prior intubations, and the development of spontaneous pneumothorax.[79,80]

• BOX 38.2 General Management of Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Adjust O_2 to Spo_2 goal 88% to 92%
Initiate and maintain β-agonist and anticholinergic agents combined
Start prednisone 50 mg/day for 7 days
Start antibiotics if signs of infection

O_2, *Oxygen;* Spo_2, *oxygen saturation measured by pulse oximetry*

Finally, pleural effusion can also produce respiratory deterioration, especially in patients with poor respiratory reserve.[81]

Initial Management

Because chronic airflow obstruction cannot be reversed, acute management of COPD is directed at reversible pathogenic mechanisms, including pulmonary infection, airway tissue inflammation, bronchoconstriction, and support of failing muscular function. Box 38.2 summarizes initial general management.

Oxygen

Enhancing blood oxygenation by increasing the concentration of inspired oxygen compensates for a major physiologic consequence of COPD with hypoxemia.[82] Oxygen remains the mainstay of initial therapy in most COPD exacerbations. Relief of hypoxemia, and consequently of hypoxemic pulmonary vasoconstriction, decreases pulmonary vascular resistance, with variable effects on the ventilation/perfusion ratio.[83,84] Oxygen delivery may increase as a result of increases in oxygen arterial content and anticipated improved right-sided heart function. However, one study demonstrated that relief of hypoxemia did not increase cardiac output.[85]

Hypercapnia is well tolerated when it is chronic.[86–88] However, oxygen should be administered cautiously in patients who are chronically hypercapnic because it is known to lead to clinically significant rises in $PaCO_2$ in select patients with COPD as a result of changes in the physiologic dead space and perhaps suppression of the respiratory drive.[89,90] Acute increases in $PaCO_2$ are more likely to occur in patients with elevated baseline $PaCO_2$. A randomized study has shown that, although oxygen administration worsened hypercapnia and respiratory acidosis, these changes were well tolerated in most patients.[91] Oxygen therapy should not be withheld in acutely ill hypoxemic patients because tissue hypoxia can lead to acute organ dysfunction. However, oxygen should be initiated at a low fraction of inspired oxygen (FIO_2) and slowly titrated up as necessary with vigilant monitoring to document improvement and stabilization in the partial pressure of arterial oxygen (PaO_2), with special attention paid to maintaining the oxyhemoglobin between 88% and 92% or greater without producing dangerous falls in pH as a result of rises in CO_2. These dangerous rises in $PaCO_2$ are typically associated with worsening mental status. Nasal cannulas or Venturi masks can be used to initiate a low FIO_2. Either nasal cannula at a flow rate of 1 L/min or a Venturi mask initially at the lowest setting (25%) is appropriate for initiating oxygen in patients known or suspected to be chronic CO_2 retainers. However, in the presence of acute severe hypoxemia in patients with impending respiratory failure, high-flow oxygen therapy may be in the patient's best interest regardless of the risk for CO_2 retention.[92]

Drug Treatment

Bronchodilators

Bronchodilator therapy has important roles in both the prevention and treatment of AECOPD. Bronchodilators are the primary treatment to alleviate patient symptoms, improve physiologic state, and prevent or reverse respiratory failure; however, their use has not been shown to improve survival. Systematic reviews have demonstrated that inhaled delivery of short-acting β_2-selective agonists and anticholinergic agents has greater effect on spirometry and is the therapy of choice for AECOPD over parenteral bronchodilators.[93] Bronchodilator treatment in acutely ill COPD patients has been shown to decrease inspiratory muscle loading, with an increase in FEV_1 and a decrease in functional residual capacity and dynamic hyperinflation.[94] In mechanically ventilated patients, a reduction in expiratory resistance and dynamic hyperinflation (measured as a decrease in iPEEP) has been described.[95]

There is no evidence supporting the use of one inhaled β_2-selective agonist over another. There is no difference in outcome between β_2-agonist compared with ipratropium bromide and no evidence that the combination of these two drugs is any more effective in AECOPD; these results are in contrast with the greater efficacy of these combinations in stable COPD.[93] The widespread use of inhaled β-agonists has been accompanied by clinical concern of cardiac complications in elderly patients and those with coronary artery disease. However, in a study performed with clinically stable COPD or asthmatic patients with a history of myocardial ischemia, no ischemic events or dysrhythmias were observed when commonly used doses of salbutamol were administered.[96] To date, no clinical studies have evaluated the use of inhaled long-acting bronchodilators (either β_2-agonist or anticholinergic agents) with or without inhaled corticosteroids during AECOPD.

Several studies have suggested that the combination of β_2-agonists and anticholinergic agents, particularly long-acting agents, prevent exacerbations.[97–101] It is possible that these agents reduce exacerbation frequency as a result of the effect on reduction of dynamic hyperinflation at rest and exercise,[102] as well as nonbronchodilator mechanisms such as antiinflammatory effect.[103]

Intravenous methylxanthines (theophylline or aminophylline) are considered second-line therapy, to be used only in selected cases when there is insufficient response to short-acting bronchodilators. Side effects of methylxanthines are significant and the clinical response is inconsistent.

Corticosteroids

COPD is recognized as an inflammatory disorder, and the severity of airway inflammation correlates with the severity of the underlying COPD. During exacerbations, there is a large increase in concentration of proinflammatory cells, including neutrophils. Systemic corticosteroids improve lung function significantly, shorten hospital stay, and reduce the risk for relapses compared with placebo in patients with AECOPD.[104] In the Inhaled Steroids in Obstructive Lung Disease (ISOLDE) trial, the median exacerbation rate was reduced by 25%, and there was also a reduction in the health status deterioration.[105] In the Reduction in the Use of Corticosteroids in Exacerbated COPD (REDUCE) trial, treatment with prednisone administered at 40 mg/day for 5 days[105] was not inferior to the administration of prednisolone 30 mg/day for 14 days in terms of the length of hospitalization, improved FEV_1 by 60 mL/day, and accelerated recovery from symptoms.[106] The use of oral steroids has not been shown to be different from the use of intravenous steroids.[107] Corticosteroids halve the chance of treatment failure compared with placebo.[108] A meta-analysis demonstrated that the use of systemic corticosteroids was associated with significant reduction in treatment failure, defined as either clinical deterioration, withdrawal from the study owing to unsatisfactory clinical improvement, or relapse of exacerbation symptoms during the follow-up period.[109] It also showed beneficial effects in reducing the length of hospitalization by a weighted mean of 1.42 days.

Oral corticosteroids have beneficial effects in the management of AECOPD. Prednisolone, administered at 30 mg/day for 14 days, shortened the length of hospitalization by 2 days, improved FEV_1 by 60 mL/day, and accelerated recovery from symptoms.[110] The majority of patients with COPD probably require only 2 weeks with oral corticosteroids and therapy for 8 weeks produced no incremental benefits above those achieved at 2 weeks.[111] One of the most important concerns regarding the use of corticosteroids in AECOPD is the possibility of confusing it with community-acquired pneumonia. Nevertheless, there is no evidence that corticosteroid use worsened the prognosis of community-acquired pneumonia if appropriate antibiotics are used; moreover, systemic corticosteroids may reduce morbidity and mortality rates in community-acquired pneumonia.[112]

The use of inhaled corticosteroids is associated with a decrease in exacerbation events by 12% to 25%.[113] Studies involving inhaled corticosteroids and a long-acting β_2-agonist showed reduction in exacerbation frequency to a greater extent than using either corticosteroid or a long-acting β_2-agonist alone.[114,115] There is also a trend toward mortality rate reduction over 3 years of 17.5%, although without statistical significance.[116] There is no evidence that the addition of inhaled corticosteroids to systemic corticosteroids in AECOPD has any impact on either recovery or mortality rate.

Antibiotics

Use of antibiotics in AECOPD remains a controversial topic, with some authors recommending antibiotic therapy and others not, maybe in part because of the heterogeneity of the population studied.[117,118] Compared with placebo, antibiotic use during AECOPD reduced treatment failures by 46%; failures were defined as requiring additional antibiotics within the first 7 days or unchanged or deteriorated symptoms within 21 days. Antibiotics reduced treatment failures, particularly in those patients who were hospitalized, but not when they were used in ambulatory patients.[119] Three clinical trials involving 181 patients demonstrated that the in-hospital mortality rate can be reduced by 78% with the use of antibiotics during AECOPD.[120,121] Patients who present with dyspnea and increased sputum volume or purulence or patients who require mechanical ventilation benefit from a 3- to 7-day course of oral or parenteral antibiotics.[122]

Although routine sputum cultures are recommended in all patients with AECOPD, invasive techniques (transtracheal aspirates,[123,124] bronchoscopic aspirates, or protected specimen brushing[6,125–129]) are not indicated. Exceptions include culture-negative community-acquired pneumonia not responsive to therapy and ventilator-associated pneumonia.[130,131] Because many patients with COPD have airways colonized by bacteria, without clinical signs of infection and exacerbation, there is no clear significance of a positive culture result in a patient with COPD; however, in the presence of exacerbation associated with an alteration in sputum character or quantity, potentially pathogenic organisms grown from sputum should be covered with an appropriate antibiotic.[132] Thus the selection of empiric antibiotics to treat AECOPD should depend on the severity of underlying disease and severity of COPD exacerbation. Therapy for more severe exacerbations should include

coverage for antibiotic-resistant bacteria, such as *Pseudomonas* or methicillin-resistant *Staphylococcus aureus*.

Hemodynamic Support

Fluid Management

Patients with COPD often have chronic pulmonary hypertension, which may worsen with COPD exacerbation because of hypoxic vasoconstriction, dynamic lung hyperinflation, and in mechanically ventilated patients, iPEEP. This may lead to acute or worsening right ventricular failure. In one study, the prevalence of right ventricular failure in patients with terminal COPD was 66% and the prevalence of left ventricular failure was only 6%.[133] As in other patients with right ventricular failure, hemodynamic stability is related to maintenance of mean arterial pressure. Mean systemic pressure can potentially be increased in these patients by increasing intravascular volume or by selectively improving compliance of the pulmonary vascular bed.[134] Intravenous fluid challenge is the initial step in hemodynamic support in the presence of hemodynamic compromise. Despite the presence of peripheral edema, diuretics should be avoided, given the potential to induce loss of intravascular volume, decreased venous return, decreased cardiac output, and hypotension.

Likewise, because pulmonary hypertension produces chronically elevated right ventricular pressures, fluid challenge could potentially worsen the hemodynamic status of patients with cor pulmonale. Overzealous fluid administration may raise right ventricular pressure to the point that it produces a shift in the interventricular septum and a reduction in left ventricular compliance and filling. The central venous pressure (CVP) is no longer used to assess COPD patients; currently the global end-diastolic index has been proposed to achieve accurate measurements.[135] Currently no consensus or guidelines exist concerning invasive pulmonary artery catheterization in this group of patients; however, in patients who remain hypotensive after initial volume challenge or in patients with organ perfusion abnormalities and biventricular failure, invasive monitoring may be clinically useful.

Inotropes and Vasodilators

In patients who remain hemodynamically unstable despite fluid therapy, adrenergic therapy is advised. Although some literature recommends adrenergic therapy for right ventricular failure using norepinephrine or dobutamine,[136–138] we could find no controlled trials of adrenergic drug therapy in hemodynamically unstable COPD patients. However, patients with pulmonary embolism have a hemodynamic derangement similar to that of COPD patients with right ventricular failure, and as such, dobutamine seems a reasonable choice in attempts to increase right ventricular function and increase cardiac output in the normotensive patient with decreased tissue perfusion. In the presence of hypotension, dobutamine would be used in combination with a combined inotrope vasopressor such as norepinephrine or dopamine. Nitroglycerin has been shown in one study to enhance right ventricular performance when added to dobutamine.[139] Nitroglycerin should be administered cautiously in patients who may have suboptimal right ventricle filling. Digoxin has no anticipated clinical utility in right ventricular failure, unless it is associated with left ventricular failure or arrhythmias that respond to digoxin.[140–142]

Although vasodilators have been used in clinical trials of COPD with right ventricular failure,[143–150] there is no consistent evidence of clinical outcome benefit. Inhaled nitric oxide, a selective pulmonary vasodilator with a short half-life and no systemic vasodilator properties, has shown variable results in patients with AECOPD.[151–155]

Nutritional Support

Malnutrition has been recognized as a factor that increases mortality rate[156,157] in COPD. Weight gain has been associated with decreased mortality rate.[158] Nutritional status tends to decline markedly during acute illness in patients with COPD,[159–161] and they may not recover to their previous nutritional state during convalescence, with recurrent exacerbations leading to a stepwise decline in nutritional status over time.[162] Recent studies have shown that skeletal muscle mass is directly related to muscle dysfunction in patients with COPD.[163] Nutritional status has been correlated with weaning outcome.[164] Short-term studies of oral supplemental feeding or enteral feeding have demonstrated increases in body weight and improvement in immunologic markers and respiratory muscle function.[165–167] Nutritional support has been demonstrated to produce improvement in lung function in hospitalized patients with an acute exacerbation of COPD.[168]

Special care must be taken to avoid overfeeding patients with COPD exacerbation because excess calories, particularly if carbohydrate-rich, elevate total oxygen consumption and CO_2 production, which may complicate management in patients with hypercapnia.[169] In one study of mechanically ventilated patients, enteral nutrition was administered with a fixed carbohydrate content and an association between total caloric intake and CO_2 production when providing nutritional support to the COPD patient with acute respiratory failure (ARF) was noted. It has been recommended that enteral alimentation provide total calories from 1.25 to 1.3 times the resting energy expenditure of the patient with a respiratory quotient target of 0.7 to 0.8 and that carbohydrate calories be limited to 40% of total calories.[170]

Noninvasive Mechanical Ventilation

ARF in the setting of AECOPD is characterized by the worsening of hypoxemia and a variable degree of carbon dioxide retention and acidemia. Worsening in $\dot{V}/\dot{Q}$ ratio mismatching is probably the leading mechanism in the occurrence of the hypoxemia by the enlargement of physiologic dead space and the rise of wasted ventilation.[171] The increase in airway resistance and the need of a higher minute ventilation may result in expiratory flow limitation, dynamic hyperinflation, and related iPEEP with subsequent increased inspiratory threshold load and dysfunction of the respiratory muscles, which may lead to their fatigue.[172] Dyspnea, right ventricular failure, and encephalopathy characterize severe AECOPD complicated by ARF. Arterial pH reflects the acute worsening of the alveolar ventilation, and, regardless of the chronic level of $PaCO_2$, it represents the best marker of the ARF severity.[173]

Those patients with severe AECOPD develop ARF requiring ventilatory support. The frequency of this support varies among series, being as high as 74%.[174] Ventilatory support may be of two types: invasive and noninvasive. Noninvasive ventilation (NIV) using nasal masks or face masks has proved efficacious in ARF caused by COPD in several clinical studies, with success rates as high as 65% in some series.[175–177] As with invasive mechanical ventilation, the goals of NIV include respiratory muscle rest, ventilatory support during treatment of reversible conditions, and the correction of severe hypoxemia and hypercarbia.

Several prospective, randomized, controlled studies confirmed the clinical efficacy of NIV in the treatment of the ARF during AECOPD. Compared with standard medical therapy alone the application of NIV improves survival, reduces the need for endotracheal intubation and the rate of complications, and shortens length of stay in the hospital and intensive care unit (ICU).[174,177,178]

Indications

Although there are recommendations regarding the physiologic variables necessitating NIV or invasive ventilation in patients with respiratory failure, no studies have verified the efficiency of using these variables in the initiation of ventilatory support criteria. Patients with mild exacerbation, with normal or mildly reduced pH (pH > 7.35) and without clinical signs of respiratory failure, do not appear to benefit from a trial of NIV.[179]

In patients with moderate ARF, characterized by pH levels between 7.25 and 7.30, NIV is indicated for a few hours per day (<12 hours/day) to prevent endotracheal intubation, with low failure rates (15%–20%), and appears to have the greater benefit.[180]

In more severely ill patients (pH < 7.25), the rate of NIV failures is inversely related to respiratory acidosis. In this population, the use of NIV as an alternative to invasive ventilation does not affect the mortality rate or the duration of ventilatory support, but it is associated with a lower rate of complications (ventilator-associated pneumonia, difficult weaning). Despite the elevated rate of failure, it is worth a short trial of NIV if no contraindication is present (decreased level of consciousness, cardiac or respiratory arrest, severe gastrointestinal bleeding, severe hemodynamic instability, facial surgery or trauma, upper airway obstruction, inability to clear secretions).[181]

Implementation of Noninvasive Positive-Pressure Ventilation

NIV is usually delivered in assisted ventilation modality, but no differences in success rate were found when applied in controlled ventilatory modality.[182] Leak is a constant feature of NIV and may affect triggering of the ventilator, delivered FIO_2, and air humidification. As such, the choice of the interface is one of the crucial issues affecting NIV outcome; although a face mask is the standard interface to deliver NIV in patients with ARF, poor mask tolerance, skin lesions, and leaks are reported among factors causing NIV failure and intubation requirement.[183]

The nasal mask has less dead space, causes less claustrophobia, minimizes potential complications in case of vomiting, and allows both expectoration and oral intake of fluids without the need to remove the mask. However, face masks are preferable in severely dyspneic patients because the nasal resistance to breathing is decreased with combined nose and mouth air entry. Also, opening of the mouth during nasal noninvasive positive-pressure ventilation produces loss of tidal volume, which decreases effectiveness. In our opinion, the face mask is optimal for initial use in most patients with severe respiratory distress.

The use of pressure support ventilation (PSV) is the most common mode of ventilation for application of NIV. Nonetheless, bilevel positive airway pressure has become the preferred mode of NIV administration in COPD patients because it is generally as comfortable as PSV but produces greater improvement in gas exchange and reduces the work of breathing more effectively than PSV alone.[184–186] Specifically designed noninvasive bilevel ventilators have a better leak tolerance and adjust trigger and cycle sensitivity to improve patient-ventilator synchrony.[187]

The goal of NIV is to provide ventilatory support to rest fatigued respiratory muscles while the underlying illness is treated. The use of adequate ventilatory support is important regardless of the ventilator and modality chosen to deliver NIV. When using pressure-cycled modes, the recommended approach is to start at low pressures for patient comfort and titrate the pressure support or inspiratory positive airway pressure to achieve a tidal volume of at least 6 mL/kg, improvement in clinical signs (respiratory rate <25 beats/min, reduced accessory muscle use), and patient comfort.[188] In one clinical trial, spontaneous ventilation at higher pressures (inspiratory positive airway pressure >25 and <34 cm H_2O) with a higher ventilation frequency (two breaths more than the patient's frequency) decreased muscular work and asynchrony.[189] External PEEP, referred to as expiratory positive airway pressure in bilevel ventilators, may counteract iPEEP, and thus aid triggering, reducing oxygen consumption, and improving comfort. Although iPEEP can be as high as 15 cm H_2O in patients with severe AECOPD, expiratory positive airway pressure levels higher than 5 cm H_2O are rarely tolerated or necessary. Therefore slow titration to patient comfort is important to maximize the likelihood of NIV success. Improvements in pH, $PaCO_2$, and level of consciousness at 60 minutes are predictors of success in patients on AECOPD who respond to NIV.[185]

The British Thoracic Society recommended that patients with ARF who respond to NIV be maintained as continuously as possible during the first 24 hours. If the respiratory status has stabilized, then the duration of ventilatory support can be reduced on subsequent days. Masks are removed for meals, conversation, comfort, and respiratory treatment as necessary.[190]

The predictors of early failure include the lack of improvement in pH (7.25–7.29 odds ratio [OR] 4.7; <7.25 OR 20.9) and tachycardia (>120 beats/min OR 2.5)[191] An ultrasonographic evaluation of the diaphragmatic thickness during the respiratory cycle can also be used to predict failure of NIV. The following calculation is used where ΔTdi(%) is change in diaphragm thickness from inspiration to expiration as a percentage of end-expiration thickness as follows:

$$\Delta Tdi(\%) = \text{End-inspiration Tdi} - \text{End expiration Tdi} / \text{End-expiration Tdi} \times 100$$

The presence of diaphragmatic dysfunction is defined as a ΔTdi <20%, which is independently correlated with the failure of NIV.[192]

Weaning From Noninvasive Ventilation

Weaning from NIV may be accomplished either by progressively decreasing the levels of inspiratory positive-pressure support or by permitting the patient to be intermittently off NIV for increasing lengths of time. A combination of both strategies can also be used. In general, it is useful to wean patients by progressively increasing the period of spontaneous breathing without NIV. Once the acute process improves, many patients can be weaned relatively quickly. Unlike invasive ventilation, NIV can be reinstituted easily and quickly if the patient shows signs of fatigue or intolerance to spontaneous breathing.[193] The use of nocturnal NIV may be needed during the early weaning period and may be continued at home in some patients.

Some studies have analyzed weaning outcome in intubated patients with AECOPD, comparing NIV with conventional weaning methods. Results showed that NIV reduced weaning time, shortened intensive care days, decreased the incidence of nosocomial pneumonia, and improved 60-day survival rates.[194,195] NIV has also been used successfully in another study of patients with hypercarbia after extubation.[196] A meta-analysis concluded that, notwithstanding these results, the use of NIV to facilitate weaning in mechanically ventilated patients with predominantly COPD is associated with promising, but insufficient, evidence of clinical benefit at present.[197]

Invasive Mechanical Ventilation

Patients requiring immediate admission to the ICU are those (1) who presented with severe dyspnea that responds inadequately to initial emergency therapy, (2) with changes in mental status (confusion, lethargy, coma), (3) unable to clear respiratory secretions, (4) with severe arrhythmias, (5) persistent or worsening hypoxemia (PaO_2 < 40 mm Hg), and/or (6) severe or worsening respiratory acidosis (pH < 7.25) despite supplemental oxygen and NIV, and (7) with hemodynamic instability requiring the use of vasopressors.

Patients with AECOPD requiring invasive mechanical ventilation have a higher ICU mortality rate and in-hospital mortality rate compared with nonventilated patients.[198]

Complications

The main complication in patients with COPD exacerbations is the development of pneumonia associated with mechanical ventilation. The risk factors in COPD patients are similar to the risks in the general population and include age, male gender, the presence of a tracheostomy, hospitalization for more than 48 hours with invasive mechanical intubation or up to 14 to 15 days of intubation, and advanced stages of COPD.

Intubation is a major risk factor for lower respiratory tract colonization. At 72 hours after intubation in patients with COPD, the most commonly isolated organism is *Pseudomonas aeruginosa* (31%), followed by *Acinetobacter baumannii*.[199,200] The main prevention measure to avoid the development of an in-hospital infection in COPD patients is the use of noninvasive mechanical ventilations as an initial treatment option before intubation to reduce invasive mechanical ventilation days.

Intrinsic Positive End-Expiratory Pressure (Video 38.1)

The two primary pathophysiologic changes that contribute to the development of respiratory distress and ARF in patients with obstructive lung disease are increased expiratory airflow resistance and dynamic hyperinflation. In COPD, the alveolar attachments that normally keep the smaller airway open via radial traction are lost. This leads to airway narrowing and collapse, especially during expiration. In AECOPD the already narrowed airways may be further compromised by increased secretions, mucosal swelling, and peribronchial inflammation. The time constant for lung emptying is prolonged, and end-expiratory lung volume is dynamically increased. Therefore the next inspiratory effort occurs before the expiratory phase is completed, leading to air trapping, and the respiratory system is prevented from returning to its resting state at the end of the expiration and thus dynamic hyperinflation develops. Dynamic hyperinflation results in iPEEP.[201] Initially, PEEP is beneficial because it maintains open airways, thereby reducing the airway resistance.

iPEEP is typically not detected on the pressure gauge of the ventilator because it is open to the atmosphere except for a very brief moment at the end of expiration. If the expiration port of the circuit is occluded at end expiration in a relaxed patient with a delay of next inspiration, the pressure inside the lungs and in the circuit will begin to equilibrate; if occlusion is sufficiently prolonged, iPEEP may be recorded.[202]

iPEEP has numerous hemodynamic and mechanical consequences. When iPEEP is excessive, barotrauma may occur. Hemodynamic consequences of iPEEP effect are more common with decreased venous return, decreased stroke volume, and hypotension. iPEEP also increases the work of breathing, which is represented by an increase of workload during spontaneous inspiration and by an increase in the threshold of ventilator triggering. iPEEP is treated by increasing expiratory time and decreasing the minute ventilation, as well as reducing the airflow resistance by bronchodilators and corticosteroids. This effect is achieved by decreasing the respiratory rate and tidal volume.

In the past, PEEP was avoided in patients with AECOPD because of the concern of worsening dynamic hyperinflation. It is now recognized that the application of extrinsic PEEP below 75% to 85% of iPEEP may facilitate ventilator triggering, because alveolar pressure now needs to be decreased to only below the level of the external PEEP, instead of below the level of atmospheric pressure, decreasing the work required to trigger the inspiration.[203,204]

Weaning

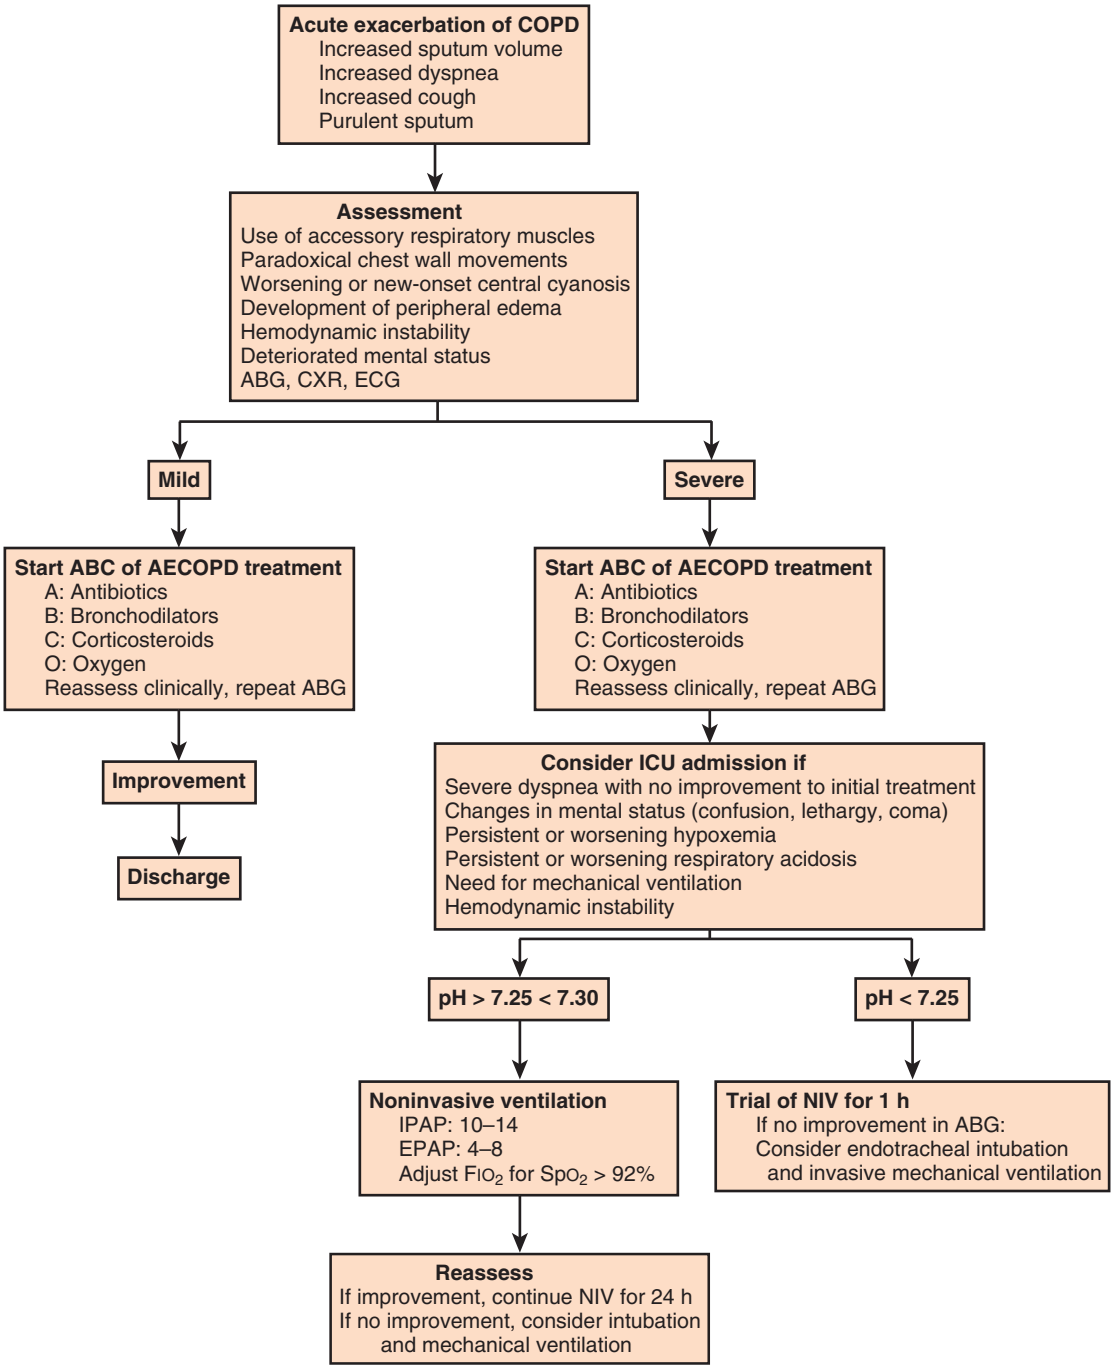
In general, restoration of respiratory muscle function requires approximately 24 to 48 hours of mechanical ventilation.[205–207] Before weaning patients with AECOPD from mechanical ventilation, the premorbid condition that triggered ARF should be corrected and an adequate neuromuscular competency/workload ratio achieved. Therefore the strategy for facilitating weaning from the ventilator should include an increase in inspiratory force and a decrease in the load on the respiratory system. See Chapter 43 for a comparison of various weaning techniques.

Extubation to Noninvasive Ventilation

COPD is classified as a major risk factor for the development of weaning-induced pulmonary edema (OR of 8.7).[208] Earlier studies supported the idea that NIV can facilitate weaning and improve outcomes in difficult-to-wean patients by avoiding the complications of prolonged intubation. There is evidence that the use of NIV as a method of weaning in patients with AECOPD and CHF resulted in shorter periods of intubation, decreased length of hospital and ICU stay, lower rate of nosocomial pneumonia, and improved ICU and 90-day survival. Fig. 38.1 shows a suggested algorithm for the management of AECOPD.

Patients with COPD are predisposed to prolonged weaning with the following risk factors: high $PaCO_2$ and tachycardia during the development of the first spontaneous breathing trial (SBT).[209] In general, studies support the development of noninvasive weaning.

The current proposal relates to the optimal time to withdraw invasive ventilation and develop noninvasive weaning by complying with the basic weaning criteria (i.e., neurologic status, oxygenation, coughing ability, and clinical condition) or choosing the moment



• **Fig. 38.1** Management of acute exacerbations of chronic obstructive pulmonary disease. *AECOPD,* Acute exacerbations of chronic obstructive pulmonary disease; *CXR,* chest x-ray; *ECG,* electrocardiogram; *EPAP,* expiratory positive airway pressure; *FIO_2,* fraction of inspired oxygen; *ICU,* intensive care unit; *IPAP,* inspiratory positive airway pressure; *NIV,* noninvasive ventilation; *SpO_2,* oxygen saturation measured by pulse oximetry.

of infectious control (i.e., temperature corporal, radiographic improvement, decrease in secretions, and normal leucocyte count) as the switching time for intubated COPD patients.

The use of a high-flow nasal cannula after extubation has been proposed as an alternative maneuver to the use of noninvasive mechanic ventilation. We demonstrated noninferiority by comparing noninvasive versus high-flow ventilation for weaning of patients with COPD who passed an SBT and by comparing reintubation and postextubation respiratory failure.[210] Patients at risk for reintubation are considered to have the following risk factors: absence of effective cough and the use of pre-extubation sedatives (OR 8.6).[211]

The British Thoracic Society recommends that patients with ARF who respond to NIV be maintained with NIV as continuously as possible during the first 24 hours. If the respiratory status has

stabilized, the duration of ventilatory support can be reduced on subsequent days. The masks are removed for meals, conversation, comfort, and respiratory treatment as necessary.[193]

Prognosis

The outcome for the patients with AECOPD with ARF depends on the severity of the COPD, the trigger for ARF, and avoidance of ICU complications. In patients who require mechanical ventilation for acute exacerbation, the overall in-hospital mortality rate is greater than 20%.[212] For elderly patients, the mortality rate is greater than 50%.[213] In a multicenter study of patients aged 65 years or older, the mortality rate was 30% at hospital discharge, 41% at 90 days, 47% at 180 days, and 59% at 1 year. The time course and recovery after COPD exacerbation in a cohort of 101 patients with a mean FEV_1 of 41.9% has been reported.[214] Patients recorded daily morning PEFRs after the onset of the exacerbation. Median recovery time for PEFR was 6 days. Recovery of PEFR to baseline values was complete in only 75.2% of exacerbations at 35 days, and 7.1% of patients with exacerbations had still not returned to baseline status at 91 days.[214]

A recently observed factor with a significant correlation with mortality is the presence of anemia at hospital admission, which was maintained for up to 2 years after the exacerbation.[215–217]

Terminal Care for the Patient With End-Stage COPD

All patients with severe end-stage COPD should be well educated about their prognosis and limitations of therapy. Some patients may elect not to be mechanically ventilated when the COPD is in the late stage and the likelihood of extubation is extremely low. Others may choose short-term ventilation only in the hope of a reversible cause. Others may choose long-term ventilation with tracheostomy and home or special facility mechanical ventilation. It is important that emotional and psychological support be given for the end-stage patient and his or her family.

Key Points

- Although hypercapnia depends on the severity of airflow limitation, there is considerable variability in the relationship of $PaCO_2$ to FEV_1 and total lung resistance, best explained by the contribution of dead space and minute ventilation.
- Abdominal muscles are recruited during expiration in patients with severe COPD. Dynamic hyperinflation can be overestimated during chronic and acute airway obstruction if abdominal muscle function is not evaluated.
- Although the precise cause of acute exacerbation is poorly understood, it has been associated with a number of precipitating factors, including infection, either bacterial or viral; environmental factors; pulmonary embolism; medication failure; and patient noncompliance.
- Acute increases in $PaCO_2$ with administration of supplemental oxygen are more likely to occur in patients with elevated baseline $PaCO_2$.
- The cornerstone of treatment of airway flow limitation in AECOPD is based on the ABCs: antibiotics, bronchodilators, and corticosteroids.
- A combination of inhaled short-acting β_2-agonists and inhaled anticholinergics is indicated during exacerbations to alleviate patient symptoms.
- Systemic corticosteroids shorten the recovery time, improve lung function (FEV_1) and arterial hypoxemia, and reduce the risk of relapse, treatment failure, and length of hospital stay. Treatment with corticosteroids should be maintained for 5 days.
- Antibiotics should be given to patients with AECOPD who have an increase in dyspnea, sputum volume, and sputum purulence or who require mechanical ventilation.
- The choice of antibiotics should be based on the local bacterial pattern, and the recommended length of antibiotic therapy is usually 5 to 10 days.
- Nutritional support has been demonstrated to produce improvements in lung function in hospitalized patients with AECOPD.
- NIV reduces the rate of intubation and mortality rate in selected patients with ARF secondary to AECOPD. The highest benefit occurs in patients with moderate ARF with pH between 7.25 and 7.3.
- Potential physiologic benefits of NIV in AECOPD include improvement in tidal volume, gas exchange, respiratory rate, heart rate, oxygenation, and diaphragm activity, as well as a reduction in arterial CO_2 with a concomitant improvement in pH. When these beneficial responses occur, they are typically seen in the first several hours after beginning NIV.
- ICU admission for patients with AECOPD is recommended in patients with severe dyspnea that responds inadequately to initial emergency therapy, changes in mental status, persistent or worsening hypoxemia or persistent or worsening respiratory acidosis despite NIV, the need for mechanical ventilation, and hemodynamic instability.
- If the expiration port of the circuit is occluded at end expiration in a relaxed patient with a delay of next inspiration, the pressure inside the lungs and in the circuit will begin to equilibrate; if occlusion is sufficiently prolonged, iPEEP may be recorded.
- iPEEP has numerous hemodynamic and mechanical consequences.
- To reduce dynamic hyperinflation and iPEEP, provide the longest expiratory time possible, reduce patient ventilatory demand and minute ventilation, and reduce airflow resistance by using bronchodilators and corticosteroids.

Review Questions

1. What is the definition of Acute exacerbation of COPD (AECOPD)?
   Answer:
   - Much effort has been exerted to standardize the diagnosis of AECOPD, but because of the variability in the symptoms that characterize each case, reaching a consensus has been challenging.
   - It has been defined according to the presence and worsening of specific signs and symptoms such as: dyspnea, cough, sputum volume and purulence. It is also important to consider the need for additional treatment over and above the usual care.
   - The vital signs typically show tachycardia and tachypnea. Wheezing and other auscultatory signs of obstruction are also often present.
   - The use of accessory inspiratory muscles may be observed as the severity of the exacerbation increases. Because of diaphragmatic fatigue, the diaphragm no longer functions as a primary muscle of inspiration, but instead it assists the inspiratory effort of the intercostal muscles by fixing the rib cage, therefore producing a sign called paradoxical breathing.
2. Which factors can precipitate an AECOPD?
   Answer:
   - *Infections (bacterial or viral).*
     - Bacteria and viruses account for the vast majority of episodes of exacerbation. Bronchoscopic sampling of the distal airway has demonstrated the presence of pathogenic bacteria in 50% of exacerbations. Approximately 50% of AECOPD events are associated with upper respiratory tract virus infections. Approximately a quarter of patients admitted to hospital with AECOPD have coinfection with viruses and bacteria, and those patients have more severe exacerbations.
   - *Environmental factors*
     - Environmental factors are among noninfectious causes of COPD exacerbation that should be investigated as precipitating cause.
     - Epidemiologic studies have shown that hospital admissions with AECOPD increase slightly with a rise in atmospheric levels of sulfur dioxide, ozone, nitrogen dioxide, and particulates
   - *Pulmonary Thromboembolism*
     - Pulmonary thromboembolism (PTE) can precipitate acute COPD exacerbations through either impairment of gas exchange or increases in pulmonary vascular pressures.
   - *Medication failure or noncompliance*
     - Many acute COPD exacerbations can be explained in terms of inadequate pharmacologic therapy or noncompliance with pharmacologic therapy. These factors are likely underestimated causes of exacerbation in COPD patients
     - Certain pharmacologic drug interactions can precipitate toxicity or loss of effect of one drug, and the physician must ascertain whether newer medications for other conditions have recently been added to the patient's therapeutic regimen
   - *Unknown.*
     - The cause of up to one third of AECOPD events cannot be identified.
3. Studies have shown that in patients admitted to the hospital with severe AECOPD of unknown cause, up to 25% had pulmonary embolism confirmed by spiral computed tomography (CT). What are some of the Pulmonary thromboembolism (PTE) risk factors inherent to patients with COPD?
   Answer:
   - Sedentary lifestyle
   - Right ventricular failure
   - Right ventricular mural thrombi
   - Secondary polycythemia
4. What is the main principle of the initial management of AECOPD?
   Answer:
   Starting **ABCO**
   - Antibiotics
   - Bronchodilators
   - Corticosteroids
   - Oxygen
5. Why is it necessary to be cautious when administering oxygen therapy to a patient with AECOPD?
   Answer:
   - Although oxygen remains the mainstay of initial therapy in most COPD exacerbations, oxygen should be administered cautiously in patients who are chronically hypercapnic because it is known to lead to clinically significant rises in $PaCO_2$ in select patients with COPD as a result of changes in the physiologic dead space and perhaps suppression of the respiratory drive.
   - Oxygen should be initiated at a low fraction of inspired oxygen (FIO_2) and slowly titrated up as necessary with vigilant monitoring to document improvement and stabilization in the partial pressure of arterial oxygen (PaO_2), with special attention paid to maintaining the oxyhemoglobin between 88% and 92% or greater without producing dangerous falls in pH as a result of rises in CO_2.
   - However, in the presence of acute severe hypoxemia in patients with impending respiratory failure, high-flow oxygen therapy may be in the patient's best interest regardless of the risk for CO_2 retention.
6. It is recommended to obtain routine sputum cultures in all patients with AECOPD. Invasive techniques to obtain culture specimen are not generally indicated. What are the two exceptions to this recommendation?
   Answer:
   - Culture negative community acquired-pneumonia not responsive to therapy.
   - Ventilator associated pneumonia.
7. What are the goals of providing ventilatory support in patients with AECOPD who develop Acute Respiratory Failure (ARF)?
   Answer:
   - Provide respiratory muscle rest while the underlying illness is treated.
   - Correction of severe hypoxemia and hypercarbia.
8. What kind of patients with AECOPD and ARF should be considered for Non Invasive Ventilation (NIV)?
   Answer:
   - In patients with moderate ARF, characterized by pH levels between 7.25 and 7.30, NIV is indicated for a few hours per day (<12 hours/day) to prevent endotracheal intubation.

- In more severely ill patients (pH < 7.25), the rate of NIV failures is inversely related to respiratory acidosis. In this population, the use of NIV as an alternative to invasive ventilation does not affect the mortality rate or the duration of ventilatory support, but it is associated with a lower rate of complications (ventilator- associated pneumonia, difficult weaning).
- Despite the elevated rate of failure, it is worth a short trial of NIV if no contraindication is present (*decreased level of consciousness, cardiac or respiratory arrest, severe gastrointestinal bleeding, severe hemodynamic instabil- ity, facial surgery or trauma, upper airway obstruction, inability to clear secretions)*.

9. What are some strategies to reduce dynamic hyperinflation and iPEEP during MV in patient with ARF and AECOPD?
Answer:
- Provide the longest expiratory time possible.
- Reduce patient ventilatory demand and minute ventilation.
- Reduce airflow resistance by using bronchodilators and corticosteroids.

10. Which patients with AECOPD should be considered for admission to the ICU?
Answer:
- Patients with
  - Severe dyspnea that respond inadequately to initial emergency therapy.
  - Changes in mental statu (confusión, lethargy, coma)
  - Persistent or worsening hipoxemia.
  - Persistent or worsening respiratory acidosis despite NIV.
  - Need for mechanical ventilation.
  - Hemodynamic instability.

CHAPTER OUTLINE

Decreased Neuromuscular Capacity
Decreased Respiratory Center Output
Respiratory Muscle Weakness
Respiratory Muscle Fatigue
Increased Load
Increased Mechanical Load
Increased Ventilatory Requirements
Hypercapnia-Induced Hypoventilation
Summary

Hypercapnic respiratory failure is conventionally defined as a state in which ventilation is insufficient to maintain an arterial tension of carbon dioxide ($PaCO_2$) of less than 45 mm Hg for the level of metabolic activity (measured by carbon dioxide [CO_2] production, $\dot{V}CO_2$).[1] Under steady-state conditions, the relationship among $PaCO_2$, alveolar ventilation ($\dot{V}A$), and $\dot{V}CO_2$ is given by the equation:

$$PaCO_2 = (\dot{V}CO_2 / \dot{V}A) \times K,$$

in which K (usually stated as 0.863) is a constant that converts measurement of $\dot{V}CO_2$ from standard conditions to body temperature conditions. The term $\dot{V}_A$ represents the portion of minute ventilation ($\dot{V}_E$) that reaches the terminal gas exchange units and is calculated as

$$\dot{V}A = \dot{V}E - \dot{V}D,$$

where $\dot{V}D$ equals dead-space ventilation. A reduction in $\dot{V}A$ may result from an inadequate $\dot{V}E$ or an increase in $\dot{V}D$ (resulting from an increase in true $\dot{V}_D$ or a functional increase in $\dot{V}D$ secondary to lung regions with high ventilation-perfusion ($\dot{V}A/\dot{Q}$) relationships).[a]

Hypercapnia is synonymous with alveolar hypoventilation for the patient's level of carbon dioxide production. Alveolar hypoventilation can result from decreased neuromuscular capacity and increase respiratory load (Fig. 39.1).[2] Isolated impairments in gas exchange—that is, conditions where the alveolar-arterial O_2 gradient[b] is increased—usually do not cause hypercapnia.[3] When gas exchange is impaired, however, the magnitude of neuromuscular derangements causing hypercapnia or the magnitude of increased respiratory loads causing hypercapnia is less than the corresponding derangements when gas exchange is normal. Conditions where gas exchange contributes to hypercapnia are usually characterized by ventilation-perfusion inequality. When gas exchange is impaired total $\dot{V}E$ may actually be increased despite a concurrent decrease in $\dot{V}A$.

Decreased Neuromuscular Capacity

Disease states that may result in decreased neuromuscular capacity and thus in alveolar hypoventilation include conditions characterized by decreased respiratory center output and conditions characterized by respiratory muscle weakness and respiratory muscle fatigue.

Decreased Respiratory Center Output

Isolated decreases in respiratory drive can produce ventilatory failure without distress. Potential causes include administration of sedatives,[1] hypothyroidism,[4] metabolic alkalosis,[5] semi-starvation,[6] and central alveolar hypoventilation syndrome. The latter can be either idiopathic (i.e., primary alveolar hypoventilation or Ondine curse) or

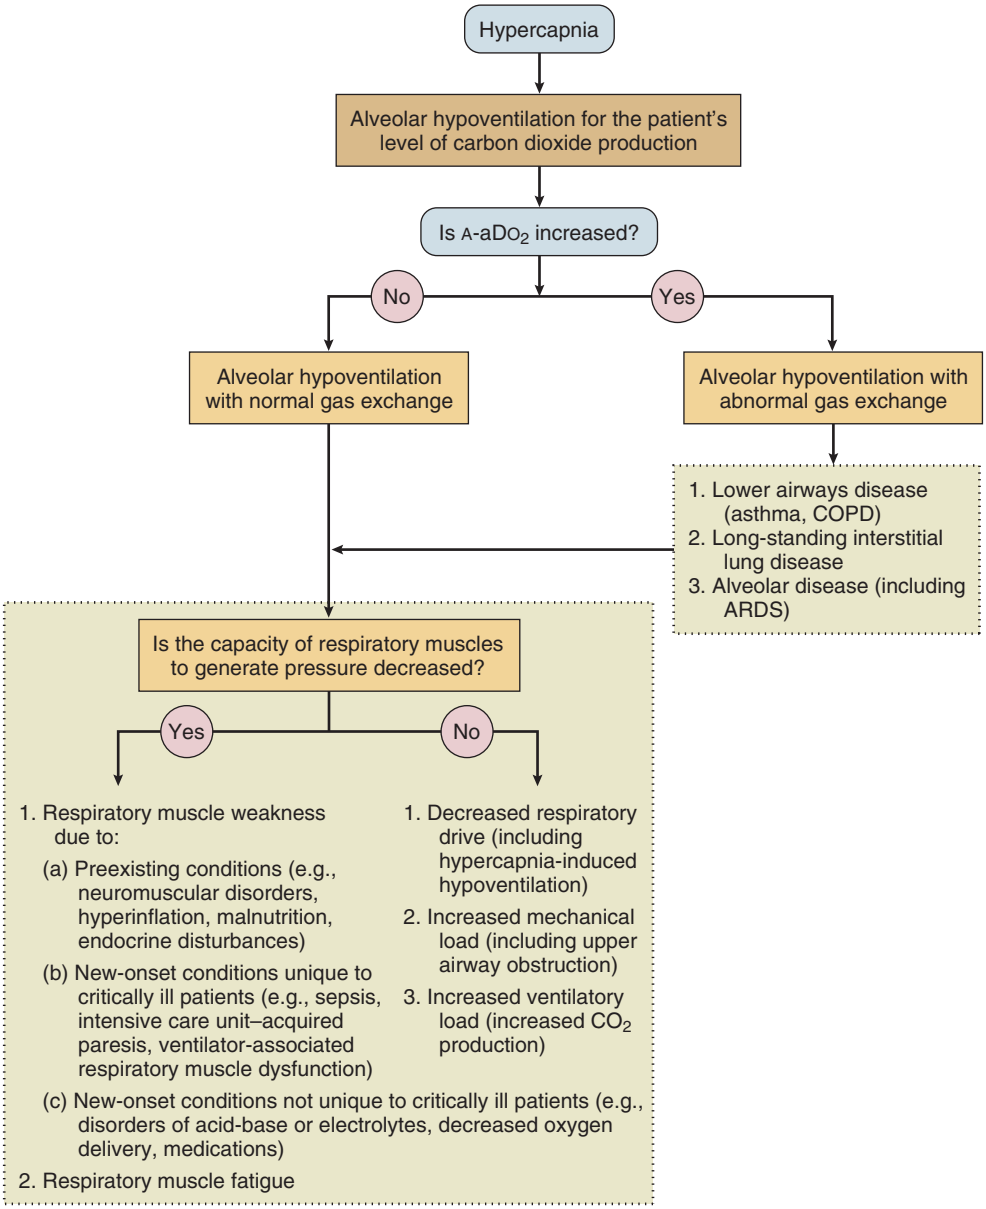
*Supported by a Merit Review Award from the Veterans Administration Research Service 1 I01RX001325-01A2.

[a]Terminology of dead space is confusing. *Anatomic dead space* is made up of the conducting airways (nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles). *Alveolar dead space* is made up of alveoli that receive some or no blood flow, which does not match ventilation (units with very high $\dot{V}A/\dot{Q}$ ratio). *Physiologic dead space* is the sum of anatomic dead space and alveolar dead space.[1]

[b]The alveolar-arterial oxygen (O_2) gradient ($A\text{-}aDO_2$) is calculated as $PAO_2 - PaO_2$, where PAO_2 (alveolar O_2 tension) can be estimated according to the simplified alveolar gas equation:

$$PAO_2 = FIO_2 \times (PB - PH_2O) - PaCO_2 / R,$$

where FIO_2 is the fractional concentration of inspired O_2 (about 0.21 when breathing room air), PB is barometric pressure (about 760 mm Hg at sea level), PH_2O is water vapor pressure (usually taken as 47 mm Hg at 37°C), and R is the respiratory exchange ratio of the whole lung. The respiratory exchange ratio (R) = CO_2 production/O_2 consumption ($\dot{V}CO_2/\dot{V}O_2$). R is normally about 0.8. In steady state, R is determined by the relative proportions of free fatty acids, protein, and carbohydrate consumed by the tissues. In this equation, it is assumed that alveolar PCO_2 and $PaCO_2$ are the same (usually they nearly are). In healthy young subjects (≤30 years of age) breathing air at sea level, $A\text{-}aDO_2$ is usually less than 10 mm Hg, but it increases to as much as 28 mm Hg in healthy 60-year-old subjects.[1]



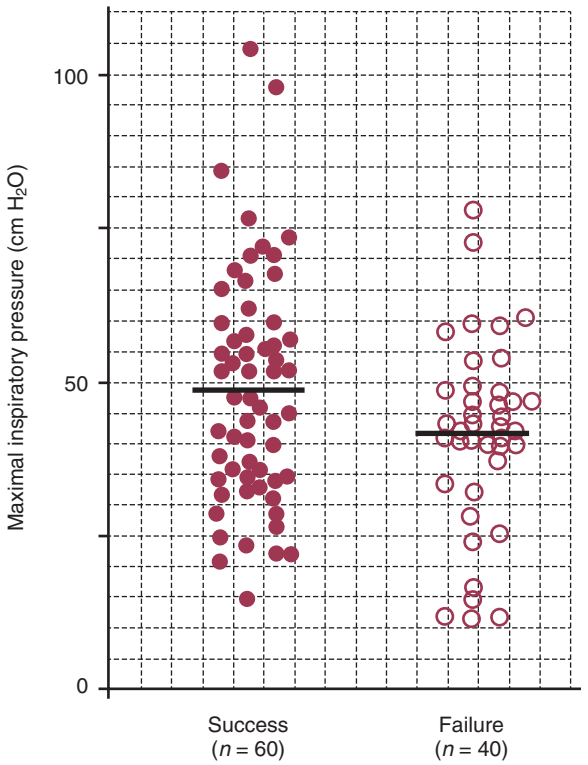
• **Fig. 39.1** Diagnostic approach to critically ill patient with hypercapnia. *A-aDO$_2$,* Alveolar-arterial difference in partial pressure of oxygen; *ARDS,* acute respiratory distress syndrome; *COPD,* chronic obstructive pulmonary disease.

secondary to neurologic lesions, such as trauma, infection (poliomyelitis), infarction, cervical laminectomy with the purported interruption of the reticulospinal fibers innervating the phrenic nerve nuclei,[7] and obesity hypoventilation syndrome.[4] Both hyperoxia and hypoxia can interfere with respiratory center output. Hyperoxia can worsen opiate-induced respiratory depression.[8] Hypoxia can cause respiratory instability by acting on the pre-Bötzinger complex.[9,10] The pre-Bötzinger complex is a neuronal premotor respiratory network located in the ventrolateral medulla of the brainstem that is critical for inspiratory rhythm generation.[9,10] In addition, hypoxia can cause incomplete transmission of inspiratory activity from the respiratory centers to the hypoglossus motor nucleus.[10] These phenomena have been attributed to oxidative stress.[9] Whether sleep deprivation decreases respiratory drive remains controversial.[11,12]

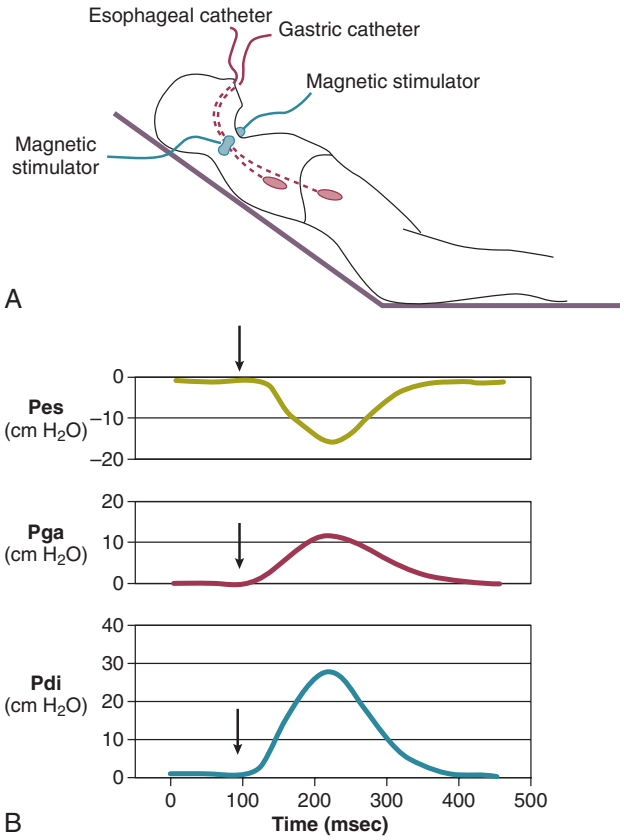
Respiratory Muscle Weakness

Detection of Respiratory Muscle Weakness in Critically Ill Patients

Measurements of airway pressure during maximal voluntary inspiratory efforts are used to evaluate global inspiratory muscle strength.[13] In healthy subjects, maximum inspiratory airway pressure is usually more negative than −80 cm H_2O.[13] In mechanically ventilated patients recovering from an episode of acute respiratory failure, maximum inspiratory airway pressure can range from less negative than −20 cm H_2O to about −100 cm H_2O.[14–16] Values of maximal airway pressure during voluntary maneuvers depend greatly on a level of motivation and comprehension of the maneuver (often not obtainable in critically ill patients).[17] Not surprisingly,



• **Fig. 39.2** Maximal inspiratory pressure recorded before a weaning trial in 60 patients who were successfully weaned *(solid circles)* and 40 patients in whom weaning failed *(open circles).* Maximal inspiratory pressure did not differ significantly between the groups. The *horizontal bars* represent mean values. (Data from Yang KL, Tobin MJ. A prospective study of indexes predicting the outcome of trials of weaning from mechanical ventilation. *N Engl J Med*.1991;324:1445–145, courtesy Martin J. Tobin.)



• **Fig. 39.3** Recording of transdiaphragmatic twitch pressure. A, An esophageal balloon and ca gastric balloon are passed through the nares. Magnetic stimulation of the phrenic nerves elicits diaphragmatic contraction. B, Continuous recordings of esophageal *(Pes)* and gastric pressures *(Pga)* and transdiaphragmatic pressure *(Pdi),* calculated by subtracting Pes from Pga. Phrenic nerve stimulation *(arrows)* results in contraction of the diaphragm with consequent fall in intrathoracic pressure (negative deflection of Pes) and rise in intraabdominal pressure (positive deflection of Pga). These swings in pressure are responsible for the transdiaphragmatic twitch pressure. The smaller the transdiaphragmatic twitch pressure, the smaller the force generation capacity of the diaphragm.

in patients requiring short-term mechanical ventilation, measurements of maximum inspiratory airway pressure commonly do not differentiate between patients with weaning successes and those with weaning failures (Fig. 39.2).[16–18]

In contrast to the voluntary nature of maximal voluntary inspiratory efforts, transdiaphragmatic pressures elicited by single stimulations of the phrenic nerves—or twitch pressure—are independent of patients' motivation and eliminate the influence of the central nervous system.[19] Activation can be achieved with either an electrical stimulator[20] or a magnetic stimulator,[20] although the latter is easier to use in mechanically ventilated patients (Fig. 39.3).[19]

In healthy volunteers, magnetic stimulation elicits twitch pressures that average from 31 to 39 cm H_2O.[13] In patients with severe chronic obstructive pulmonary disease (COPD), twitch pressures average 19 to 20 cm H_2O.[21,22] The value of transdiaphragmatic twitch pressure in patients recovering from an episode of acute respiratory failure is about one-third or even less of that recorded in healthy subjects (Fig. 39.4).[23,24] This marked reduction in twitch pressure[24–26] indicates the presence of respiratory muscle weakness in most of these patients. Respiratory muscle weakness in critically ill patients can result from preexisting conditions or from new-onset conditions.

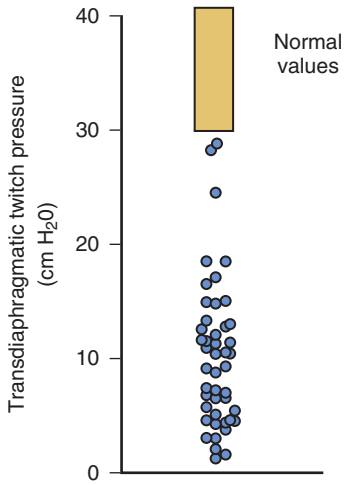
Weakness Caused by Preexisting Conditions

Neuromuscular diseases, malnutrition, endocrine disorders, and hyperinflation are some of the preexisting conditions that can cause respiratory muscle weakness. The existence of preexisting conditions can be recognized before acute ventilatory failure develops, when acute ventilatory failure develops, or when acute ventilatory failure is already established.[13]

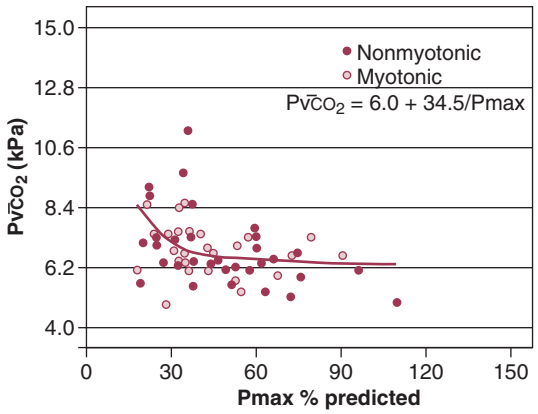
Neuromuscular Disorders

The capacity of the respiratory muscles to generate tension can be decreased in disorders, such as stroke, amyotrophic lateral sclerosis, spinal cord injuries, poliomyelitis, Guillain-Barré syndrome,[13] neuropathies caused by massive intoxications of arsenic or thallium, radiation-induced myopathy,[27] chronic inflammatory demyelinating polyneuropathy, axonopathy of acute intermittent porphyria, myasthenia gravis, acid maltase deficiency,[13] muscular dystrophies such as titin mutations,[28] idiopathic inflammatory myopathies (polymyositis, dermatomyositis, sporadic inclusion body myositis, necrotizing autoimmune myopathy),[29–31] and myotonic dystrophy (i.e., the most frequent adult form of muscular dystrophy).[4]

Hypercapnic respiratory failure usually occurs when respiratory muscle strength falls to 39% of the predicted normal value.[32]

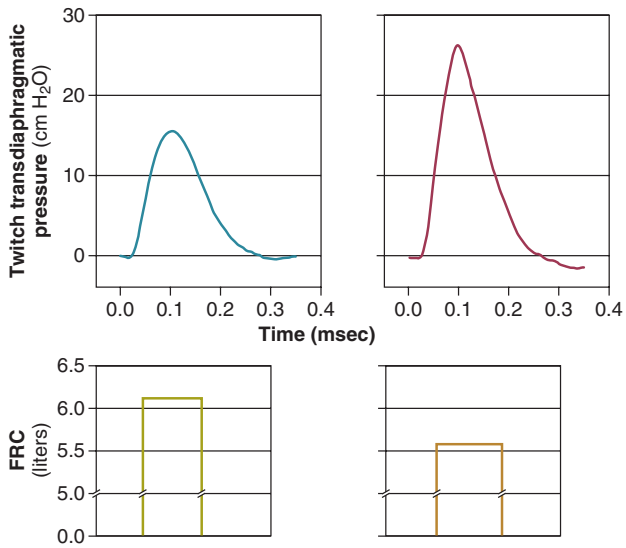


• **Fig. 39.4** Transdiaphragmatic pressure in response to single stimulations (twitch stimulation) of the phrenic nerves recorded in ventilated patients recovering from acute respiratory failure. The boxed area represents the 95% confidence interval of values obtained in healthy subjects. The decreased transdiaphragmatic twitch pressure in patients indicates the presence of diaphragmatic weakness. (From Laghi F. Ventilator-induced diaphragmatic dysfunction: is there a dim light at the end of the tunnel? *Crit Care Med*. 2011;39:903–905.)



• **Fig. 39.5** Relationship between muscle strength and mixed venous partial pressure of CO_2 *($PvCO_2$)* in patients with respiratory muscle weakness. Respiratory muscle strength is the arithmetic sum of maximum static inspiratory and expiratory mouth pressures (Pmax = PImax + PEmax). The *open circles* indicate patients with myotonic dystrophy, and the *solid circles* indicate patients with a variety of nonmyotonic muscle diseases. As respiratory muscle weakness became more severe $PvCO_2$ rose, although considerable variability was observed among patients. The regression lines were similar in the myotonic and nonmyotonic patients. (From Gibson GJ, Gilmartin JJ, Veale D, et al. Respiratory muscle function in neuromuscular disease. In: Jones NL, Killian KJ, eds. *Breathlessness*. The Campbell Symposium. Hamilton, ON: Boehringer-Ingelheim; 1992.)

However, Gibson et al.[33] described several patients with neuromuscular disease who had a normal partial pressure of CO_2 despite decreases in respiratory muscle strength to less than 20% of predicted. Conversely, some patients with only moderate respiratory muscle weakness displayed hypercapnia (Fig. 39.5).[33] In other words, reductions in muscle strength do not consistently predict alveolar hypoventilation in this setting.



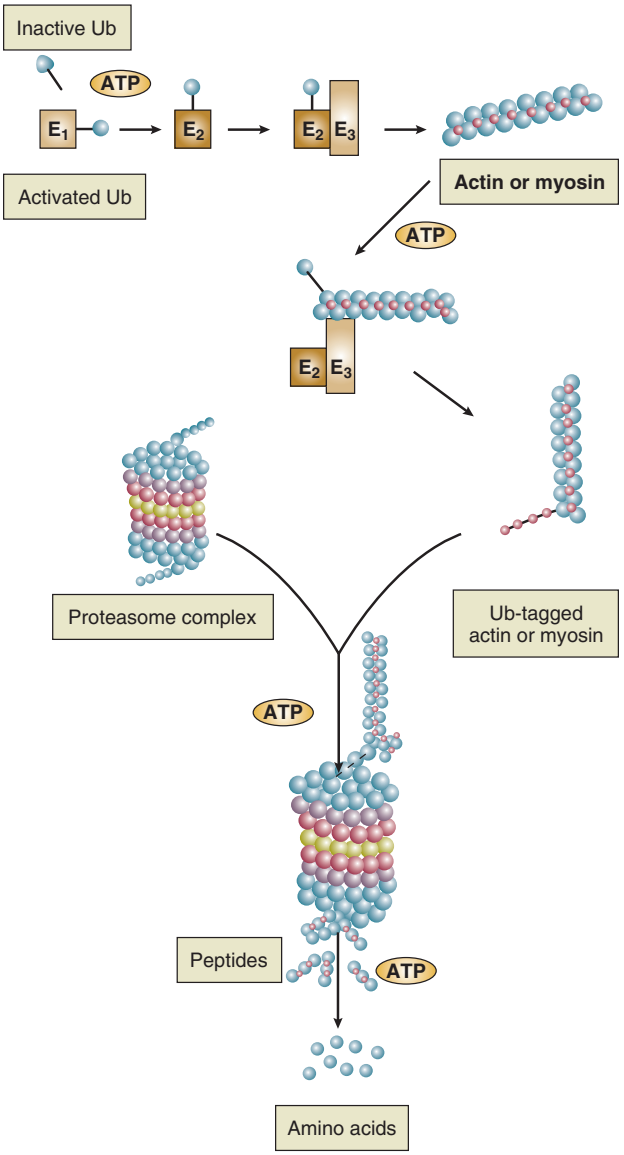
• **Fig. 39.6** Twitch transdiaphragmatic pressure elicited by phrenic nerve stimulation (*upper panel*) and functional residual capacity *(FRC)* (*lower panel*) in a patient with severe emphysema before *(left)* and after *(right)* lung volume reduction surgery. The increase in transdiaphragmatic pressure after surgery was in part due to a decrease in the operating lung volume as demonstrated by the decrease in functional residual capacity. (Data from Laghi F, Jubran A, Topeli A, et al. Effect of lung volume reduction surgery on neuromechanical coupling of the diaphragm. *Am J Respir Crit Care Med* 1998;157:475–483.)

Hyperinflation

Hyperinflation is a common preexisting condition in patients with obstructive lung diseases such as COPD,[4] cystic fibrosis,[34] bronchiolitis,[35] and lymphangioleiomyomatosis.[4] The severity of preexisting hyperinflation commonly worsens in patients experiencing an exacerbation of COPD.[36] Hyperinflation has a number of adverse effects on inspiratory muscle function. The inspiratory muscles operate at an unfavorable position of the length-tension relationship (Fig. 39.6)[37] and flattening of the diaphragm decreases the size of the zone of apposition with the result that diaphragmatic contraction causes less effective rib cage expansion.[4] Hyperinflation also has an adverse effect on the elastic recoil of the thoracic cage.[4] This means that the inspiratory muscles must work not only against the elastic recoil of the lungs but also against that of the thoracic cage. The functional consequences of dynamic hyperinflation are probably the main mechanisms of ventilatory failure in patients with COPD.[38] Hyperinflation can also occur de novo in patients with pneumonia, chest trauma, and acute respiratory distress syndrome (ARDS).[36,39] Impairment of inspiratory muscle function is less likely in patients with ARDS than in patients with obstructive lung disease because patients with ARDS breathe at a low lung volume despite dynamic hyperinflation.[39,40]

Malnutrition

Malnutrition is highly prevalent among critically ill patients requiring mechanical ventilation[41,42] and is associated with poor prognosis.[42] Malnutrition decreases muscle mass and respiratory muscle strength both in humans[43,44] and in laboratory animals.[45–47] Likely mechanisms contributing to decrease in respiratory muscle mass include proteolysis of myofibrillar proteins by the ubiquitin-proteasome proteolytic system (Fig. 39.7) and apoptosis.[4,48] Apoptosis can be triggered by local and circulating



• **Fig. 39.7** Ubiquitin-proteasome degradation of contractile proteins. The first step in degradation of actin and myosin is activation of ubiquitin *(Ub)* by a first enzyme, E_1—a process requiring adenosine triphosphate *(ATP)*. Activated Ub interacts with a second enzyme, E_2, a carrier protein. Ub and E_2 join a third enzyme, E_3. E_3 transfers activated Ub to actin and myosin. The cycle is repeated until a chain of Ub is bound to the contractile proteins. The chain of Ub binds to one end of a proteasome complex in a process requiring ATP. The Ub chain is subsequently removed (allowing reuse of Ub), and actin and myosin are unfolded and pushed into the core of the proteasome. Multiple enzymes within the core degrade actin and myosin into small peptides. The peptides are extruded from the proteasome and degraded to amino acids by peptidases in the cytoplasm. The ubiquitin-proteasome system degrades myofibrillar proteins only after they have been cleaved and released by other proteolytic pathways—that is, the ubiquitin-proteasome pathway cannot degrade intact myofibrillar proteins. (From Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48. Reproduced with permission of the American Thoracic Society. tumor necrosis factor α and by release of cytochrome c from the mitochondria.[49,50]

In patients with COPD, inspiratory muscle strength is about 30% less in poorly nourished patients than in well-nourished patients with equivalent airway obstruction.[51] Similarly, malnourished patients with anorexia nervosa can present with reduced inspiratory muscle strength to 35% to 50% predicted,[44] impaired respiratory muscle endurance,[52] impaired hypercapnic ventilatory response,[52] and, occasionally, with hypercapnia at rest.[44] In malnourished patients, inspiratory weakness,[44,51,52] fatigability,[51] and dyspnea[51] are partially reversible with nutritional support. The process is slow and, in laboratory animals, it can take months of refeeding for muscle mass to return to normal values.[53] To date, it remains unclear whether malnutrition by itself can cause sufficient respiratory muscle weakness to produce hypoventilation. It is more likely for malnutrition to be a contributory factor and not a sole cause of hypercapnic respiratory failure.

Endocrine Disturbances

Endocrine disturbances, such as hypothyroidism, hyperthyroidism, and acromegaly, can adversely affect respiratory muscle function.[54] Proteolysis of myofibrillar proteins by the ubiquitin-proteasome proteolytic system[48] (see Fig. 39.7) is probably responsible for respiratory muscle catabolism and weakness of hyperthyroidism.[50] This mechanism is implicated in muscle wasting associated with acidosis, renal failure, denervation, cancer, diabetes, AIDS, trauma, and burns.[48] In contrast to other endocrine disturbances, respiratory muscle weakness is unusual in patients with Cushing syndrome.[55]

Weakness Caused by New-Onset Conditions

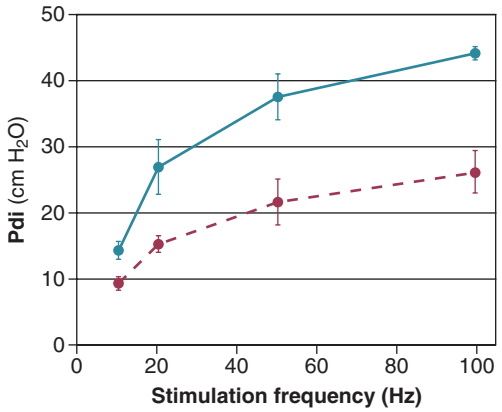
New-onset respiratory muscle weakness in critically ill patients may result from conditions that are unique to these patients. These include ventilator-associated respiratory muscle dysfunction, sepsis-associated myopathy, and intensive care unit (ICU)-acquired paresis. New-onset respiratory muscle weakness can also result from conditions that are not unique to critically ill patients. These include acid-base disorders, electrolyte disturbances, decreased oxygen delivery, and medications. Respiratory muscle weakness owing to conditions unique to critically ill patients are often associated with alterations in respiratory muscle structure, whereas the others are not necessarily associated with alterations in muscle structure. Recovery from respiratory muscle weakness (if it occurs at all) is slow when the weakness is caused by alterations in muscle structure. In contrast, recovery of respiratory muscle weakness in conditions that are not necessarily associated with alterations in muscle structure is usually quick once the underlying triggering factor has been corrected.

Ventilator-Associated Respiratory Muscle Dysfunction

Since the late 1980s, several groups have studied the effect of mechanical ventilation on the muscles of laboratory animals.[56] A seminal study Anzueto et al.[57] showed that 11 days of controlled mechanical ventilation (CMV) together with neuromuscular blocking agents produced a 46% decrease in respiratory muscle strength (Fig. 39.8). Subsequent studies have revealed that complete cessation of diaphragmatic activity with CMV—alone[58] or in combination with neuromuscular blocking agents[59]—results in atrophy and injury of diaphragmatic fibers (Fig. 39.9). Muscle fibers generate less force in response to stimulation, not simply because of a loss of contractile proteins, but also because of dysfunction of the remaining ones.[56,60–62] The decrease in diaphragmatic force ranges from 20% to more than 50%. The alterations in muscle function occur rapidly, within 12 hours of instituting mechanical ventilation,[63] and they appear to increase as ventilator duration is prolonged.[64,65] Of interest, long-term

CMV in rats causes the expected reductions in maximum force and specific force.[62] Paradoxically, however, it also produces an increase in myofiber cross-sectional area. Accordingly, investigators speculate that long-term CMV may trigger an ineffective compensatory hypertrophy of diaphragm myofibers.[62] In these rats, administration of a heat shock protein co-inducer (BGP-15) greatly improves diaphragm muscle fiber function without reversing diaphragm atrophy.[66]

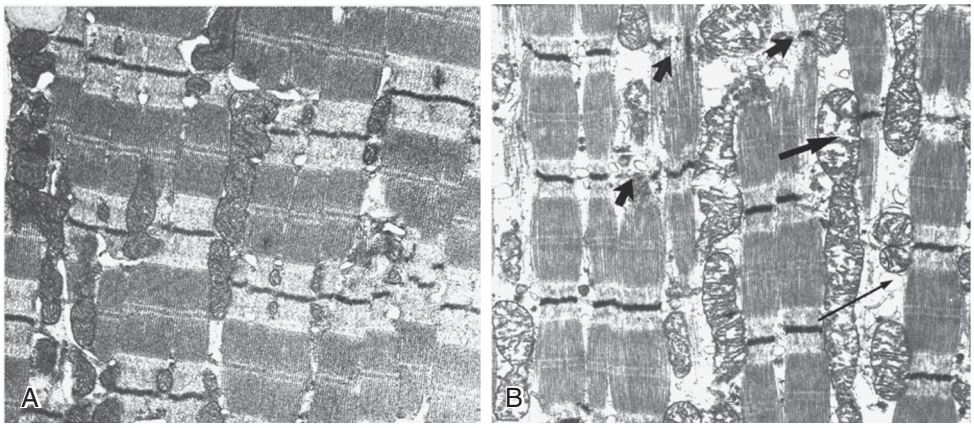
Mechanical ventilation may also harm the respiratory muscles of patients. In 1988, Knisely et al.[67] reported that the cross-sectional area of diaphragmatic fibers in infants who had died after receiving mechanical ventilation for 12 days or longer was much smaller than in infants who had received mechanical ventilation for 7 days or less (Fig. 39.10). Fibers taken from extradiaphragmatic muscles were similar in the two groups. Twenty years later Levine et al.[68] obtained biopsies of the diaphragm from 14 brain-dead organ donors who were maintained on CMV for 18 to 69 hours. They also obtained intraoperative biopsies of the diaphragms of 8 control patients who had received CMV for 2 to 3 hours. Histologic measurements revealed marked diaphragmatic atrophy in the brain-dead patients. Compared with the control group, the mean cross-sectional areas of muscle fibers were decreased by more than 50%. A number of these results have been corroborated by other investigators who also reported a progressive decrease in diaphragmatic contractility of mechanically ventilated patients.[61,65,69–71] The decrease in contractility correlated with the duration of ventilator support (Fig. 39.11).[65,69,70]



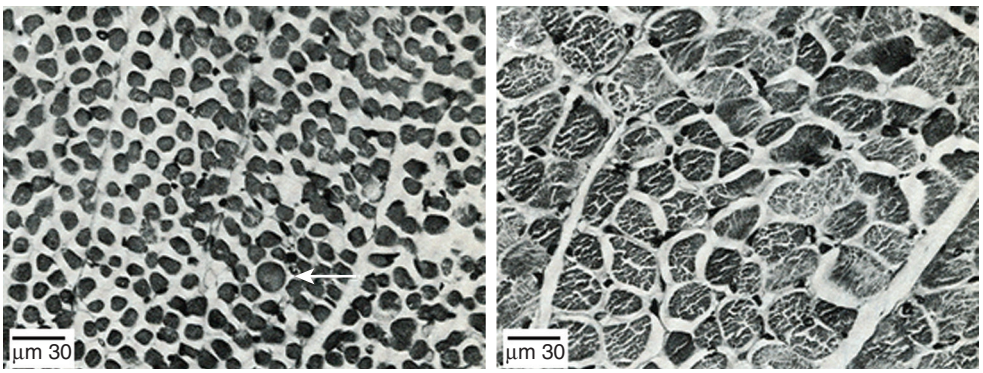
• **Fig. 39.8** Transdiaphragmatic pressure *(Pdi)* response to phrenic nerve stimulation before *(solid line)* and after 11 days *(dashed line)* of mechanical ventilation. That the transdiaphragmatic pressure recorded after 11 days of mechanical ventilation shows a decrease response to all stimulation frequencies is suggestive of ventilator-associated diaphragmatic dysfunction. (Modified from Anzueto A, Peters JI, Tobin MJ, et al. Effects of prolonged controlled mechanical ventilation on diaphragmatic function in healthy adult baboons. *Crit Care Med* 1997;25:1187–1190.)

Biochemical and gene-expression studies in animals and humans[68,72] suggest that oxidative stress is a central factor in the biochemical cascade that leads to ventilator-induced muscle injury.[73] Oxidative stress decreases contractility through protein oxidation, increased proteolysis, and decreased protein synthesis,[73,74] including upregulation of the autophagy-lysosome pathway.[75] Activation of the JAK–STAT pathway (Janus kinase or JAK and signal transducer and activator of transactivation or STAT) is the likely proximal mechanism triggering oxidative stress in the ventilator-induced muscle injury reported in both animals and humans.[76]

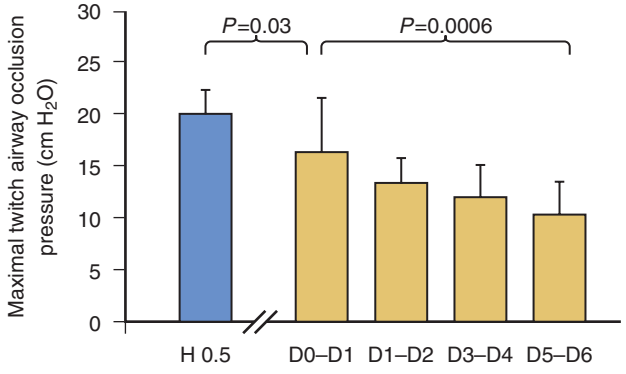
The synergism between ventilator-induced muscle injury and oxidative stress has caused investigators to explore whether early administration of antioxidants might minimize muscle injury.[77–79] In a study of more than 200 critically ill patients—80% of whom required acute ventilator support—duration of mechanical ventilation was nearly 3 days shorter in those who completed a 10-day antioxidant supplementation protocol (vitamin E and vitamin C) than in those who completed a 10-day course of placebo.[80] Similar results have been reported in critically ill surgical patients requiring mechanical ventilation.[81] Whether the decrease in duration of mechanical ventilation was, at least in part, due to the potential positive effects of antioxidants on the respiratory muscles remains



• **Fig. 39.9** Electron microscopy of the diaphragm (longitudinal section) of a rabbit under control conditions (A, specimen processed with 1100-mOsm fixative) and after 3 days of controlled mechanical ventilation (B, specimen processed with 500-mOsm fixative). The control rabbit has an intact ultrastructure. The mechanically ventilated rabbit shows several areas of disrupted myofibrils *(short thick arrows)*, the mitochondria are swollen *(long thick arrow)* and have abnormal cristae, and the intermyofibril space contains lipid droplets *(long thin arrow)*, indicating decreased lipid uptake by the mitochondria. (From Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48. Electron micrographs provided by Dr. Catherine S.H. Sassoon, Long Beach VA Hospital and University of California, Irvine, CA.)



• **Fig. 39.10** Photomicrographs of transverse sections of diaphragm from an infant ventilated from birth until death at day 47 (A) and from an infant ventilated from birth until accidental death at day 3 (B). Prolonged mechanical ventilation was associated with reduction in myofiber cross-sectional area. (The *arrow* indicates a developing myofiber also known as Wohlfart myofiber.) (Modified from Knisely AS, Leal SM, Singer DB. Abnormalities of diaphragmatic muscle in neonates with ventilated lungs. *J Pediatr* 1988;113:1074–1077.)



• **Fig. 39.11** Twitch airway pressure elicited by magnetic stimulation of the phrenic nerves in six patients who received mechanical ventilation (MV) for 30 minutes (short-term MV; *blue bar*) and in six patients who received MV for about six days (long-term MV; *gold bars*). On day 1 twitch airway pressure was already less in the long-term than in the short-term MV group. In addition, long-term MV was associated with a progressive decrease in twitch pressure over time, a mean reduction of 32% ± 6% after 6 days of MV. *D,* Number of days of mechanical ventilation; *H,* number of hours of mechanical ventilation. (From Jaber S, Petrof BJ, Chanques G, et al. Rapidly progressive diaphragmatic weakness and injury during mechanical ventilation in humans. *Am J Respir Crit Care Med*. 2011;183: 364–371.)

to be demonstrated. Of concern, however, is the report that administration of the antioxidant N-acetylcysteine to critically ill patients with severe sepsis worsened sepsis-induced organ failure.[82]

In a study of 10 critically ill patients who had received mechanical ventilation for 28 to 603 hours, Hooijman et al.[60] reported that isolated fast-twitch diaphragm muscle fibers required more calcium to generate force than fibers obtained from 10 patients undergoing elective lung surgery. The investigators were able to restore the force output using CK-2066260, a troponin calcium sensitizer.[60] Despite this encouraging result, another study reported that administration of levosimendan, another troponin calcium sensitizer, to critically ill patients with sepsis was associated with a lower likelihood of successful weaning from mechanical ventilation.[83]

In animal models, ventilator settings can affect the extent of ventilator-associated respiratory muscle dysfunction.[84–87] In rabbits, assist-control mechanical ventilation causes a nonsignificant decrease in diaphragm muscle contractility, which contrasts with the 48% decrease recorded with CMV.[84] Similar results have been obtained when comparing CMV with adaptive support ventilation in piglets,[86] when comparing CMV with pressure support in rats,[74,87] or comparing CMV with intermittent spontaneous breathing in rats as well.[85] These observations raise the important question of whether maintenance of partial diaphragmatic activity or intermittent loading of the diaphragm could prevent the harm done to diaphragmatic function by mechanical ventilation.[88]

Considering that decreases in protein synthesis probably contribute to ventilator-associated respiratory muscle dysfunction,[89] it would seem biologically plausible that administration of anabolic factors—such as growth hormone—might be of benefit in ventilated patients. Unfortunately, when growth hormone has been administered to patients requiring prolonged mechanical ventilation, the duration of mechanical ventilation was not decreased nor was muscle strength increased.[90] Of concern was the report that recombinant growth hormone can increase mortality of critically ill patients.[91]

An even more fundamental point in regard to ventilator-associated respiratory muscle dysfunction has been raised by Hooijman et al.[92] These investigators measured the contractile properties of single diaphragmatic fibers obtained from nine brain-dead organ donors who had received CMV for 26 ± 5 hours (case subjects) and from 9 patients undergoing surgery for localized lung cancer who had received CMV for 1.7 ± 0.1 hour (control subjects). No difference was noted between the muscle fibers of the two groups of patients with respect to cross-sectional area, maximum force per unit area, calcium sensitivity of force generation, and rate constant of redevelopment of force. How to reconcile these results of Hooijman et al.[92] with the reduced calcium sensitivity of force generation reported by the same investigators[60] and with previous data obtained on muscle strips from animal models and by phrenic nerve stimulation in patients remains to be determined.

Finally, it is important to stress two additional points. Healthy rats submitted to CMV for 24 hours, followed by spontaneous

breathing for 1 to 7 hours, develop severe diaphragmatic dysfunction at the conclusion of CMV, yet diaphragm force starts to improve after only 3 hours of spontaneous breathing.[89] Complete recovery occurs by 4 to 7 hours of spontaneous breathing.[89] These findings are associated with increases in diaphragm muscle protein synthesis and type IIx/b fiber dimensions.[89] Such rapid reversibility has never been reported in critically ill patients, arguing that other mechanisms of diaphragm weakness and respiratory failure play a role in critically ill patients.[24] It follows that, in the ICU, ventilator-associated respiratory muscle dysfunction must always be a diagnosis of exclusion.[24]

Sepsis-Associated Myopathy

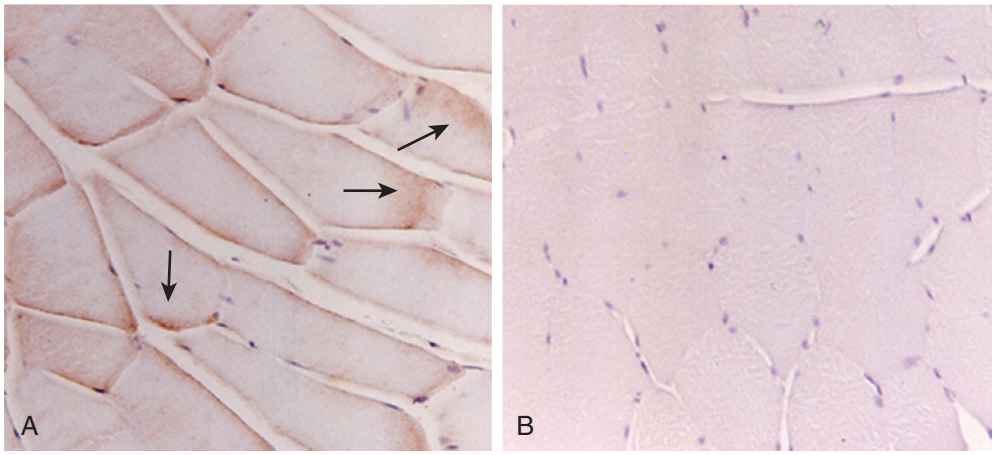
Sepsis, a common occurrence in critically ill patients, can produce ventilatory failure by causing respiratory muscle dysfunction and increased metabolic demands.[93] Septic animals develop failure of neuromuscular transmission (owing to increased sarcolemmal electric potential),[94–96] and failure of excitation-contraction coupling.[93,97] Mechanisms responsible for failure of excitation-contraction coupling include the cytotoxic effect of nitric oxide and its metabolites, free radicals, the activation of proteolytic pathways (including calpains, caspases, and the ubiquitin-proteasome[24]), and, possibly, decrease in nicotinic acetylcholine receptors.[98,99] Local dysregulation of the circulation and Krebs cycle may also contribute.[93] The result is a decrease in diaphragmatic strength by as much as 80% within 24 hours.[100,101]

Nitric oxide, a free radical that has a negative inotropic effect in the heart and skeletal muscle, is produced in large amounts during sepsis by a nitric oxide synthase inducible by lipopolysaccharide and several cytokines (Fig. 39.12).[102] Increased expression of inducible nitric oxide synthase in the diaphragm during sepsis is associated with widespread damage to the myofiber membrane, or sarcolemma (Fig. 39.13).[95] Whereas diaphragmatic contractions enhance this sepsis-induced sarcolemmal injury,[103] early mechanical ventilation decreases sarcolemmal injury and the associated diaphragmatic dysfunction.[104] The beneficial effects of resting the diaphragm with the use of mechanical ventilation are not coupled with a decrease in oxidative stress or with a decrease in the expression of inducible nitric oxide synthase in the muscle.[104] These observations suggest the existence of a detrimental interaction of two independent stressors (oxidative and biomechanical stresses) on the sarcolemma during sepsis.[104]

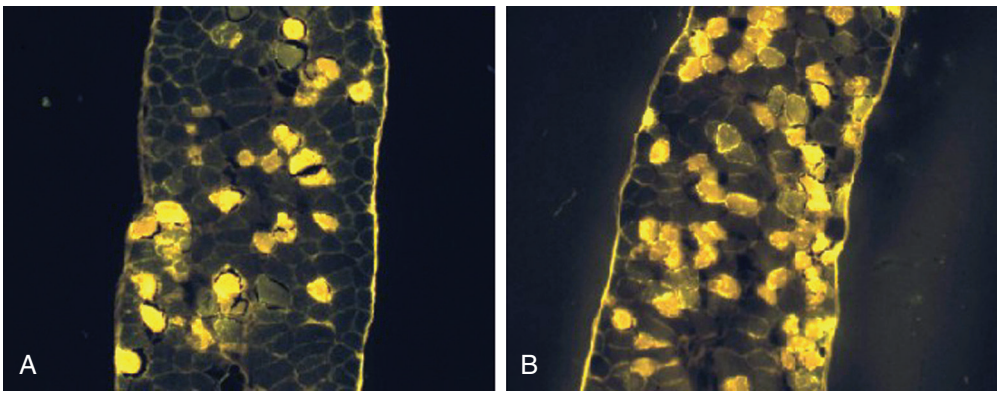
To determine whether the inducible nitric oxide synthase pathway contributes to impaired skeletal muscle contractility in humans, Lanone and coworkers[105] obtained samples of the rectus abdominis in 16 septic patients and 21 control subjects. The muscles of the patients had lower contractile force, and increases in inducible nitric oxide synthase expression (messenger ribonucleic acid and protein) and activity. Immunohistochemical studies revealed the generation of peroxynitrite (a highly reactive oxidant formed by the reaction of nitric oxide with superoxide anion). Exposure of control muscles to the amount of peroxynitrite found in patients caused an irreversible decrease in force generation. These data suggest that sepsis decreases muscle force through the production of nitric oxide and its toxic by-products.

Production of nitric oxide in sepsis may be protective and not solely deleterious.[103,106–108] In mice deficient in inducible[106] or constitutive (neuronal) nitric oxide synthase,[103] endotoxin caused a greater decline in diaphragmatic contractility than in nondeficient mice. This finding contrasts with the observation that nitric oxide synthase inhibitors prevent muscle dysfunction in septic rats.[95,102,109] Although the results may be species-dependent,[103] the data underscore that nitric oxide has both antioxidant and prooxidant actions.[110]

In addition to nitric oxide and its derivatives, several other oxygen-derived free radicals (superoxide anion, hydroxyl radicals, hydrogen peroxide) contribute to the decreased contractility of the diaphragm in sepsis.[108,111–113] This increased expression of oxygen-derived free radicals in sepsis is accompanied by enhanced activity of the antioxidant enzyme superoxide dismutase[111] and increased expression of the heme oxygenase-1 pathway.[113] The heme oxygenase-1 pathway is a powerful cellular system that protects against oxidative stress and contractile fatigue during sepsis.[113] Administration of an inhibitor (zinc protoporphyrin IX) or an



• **Fig. 39.12** A, A sample of gastrocnemius muscle obtained from an adult Sprague-Dawley rat injected 12 hours earlier with *Escherichia coli* endotoxin (20 mg/kg). The section was stained with an antibody to inducible nitric oxide synthase. Positive staining *(brown coloration, arrows)* is evident inside the fibers. B, A sample of gastrocnemius muscle obtained from a rat injected 12 hours earlier with normal saline solution. No positive staining is evident. (From Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48. Photomicrographs provided by Dr. Sabah N. Hussain, Royal Victoria Hospital, Montreal, QC, Canada.)



• **Fig. 39.13** A, A strip of diaphragm obtained from a C57BL/6 mouse injected 12 hours earlier with normal saline solution. The strip was stimulated for 3 minutes (50 Hz, 300-msec duration) and then immersed for 90 minutes in Krebs solution containing a fluorescent probe, Procion orange 14 (0.15, wt/vol). B, A strip of diaphragm obtained from a C57BL/6 mouse injected 12 hours earlier with *Escherichia coli* endotoxin (20 mg/kg). Stimulation and staining were conducted as described in A. Sarcolemmal damage, indicated by *yellow staining*, was increased by endotoxin. (From Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48. Photomicrographs provided by Dr. Sabah N. Hussain, Royal Victoria Hospital, Montreal, QC, Canada.)

inducer (hemin) of heme oxygenase activity, respectively, enhances or reduces the oxidative stress and contractile failure of the diaphragm in a rat model of sepsis.[113] In septic rats, decreased diaphragmatic contractility can also be improved by the administration of specific scavengers of superoxide ions, hydrogen peroxide, and hydroxyl radicals.[111]

According to some,[114,115] but not all, investigators,[70] sepsis is responsible for the development of severe diaphragm weakness in critically ill mechanically ventilated patients. In one study, septic patients had a transdiaphragmatic pressure (Pdi) of only 5.5 cm H_2O whereas nonseptic patients had a median twitch Pdi of 13.0 cm H_2O ($P < 0.001$). In a second study,[115] sepsis was an independent predictor of low twitch tracheal pressure (twitch Ptr) elicited by magnetic stimulation of the phrenic nerves, a surrogate for twitch Pdi (Fig. 39.14).[25,26] However, in a third study of 76 patients undergoing a first spontaneous breathing trial, diaphragmatic weakness was not associated with sepsis but was associated with longer ventilator duration, more frequent weaning failure, and higher mortality.[70] It remains unclear how to reconcile these contrasting reports.[116]

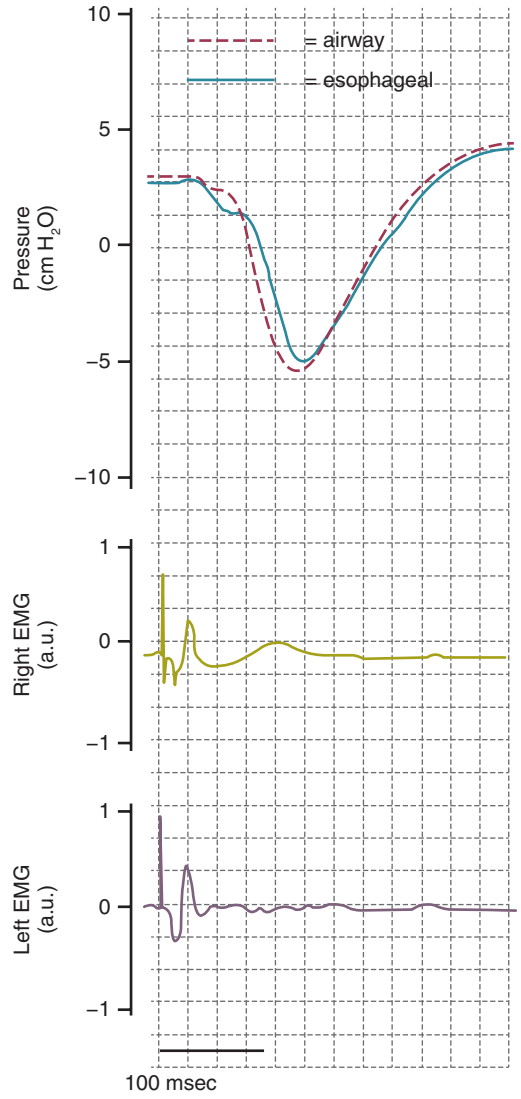
Agents that inhibit deleterious pathways (such as proteolytic pathways) and agents that alter upstream signaling pathways that improve muscle protein synthesis (e.g., mechanistic target of rapamycin [mTOR] activators, anti-myostatin receptor antibodies) are currently being tested in preclinical trials.[24] Clinically, however, aside from prevention and treatment of infections, there are no current available pharmacologic and nonpharmacologic strategies to minimize diaphragm weakness in ICU patients.

Intensive Care Unit–Acquired Paresis

While cared for in the ICU, critically ill patients can develop muscle weakness, reduced or absent deep tendon reflexes, and, occasionally, flaccid tetraparesis or tetraplegia.[117] Some of these patients have evidence for axonal degeneration and denervation atrophy (Fig. 39.15),[4] with nerve dysfunction (abnormal electrophysiologic studies) preceding structural abnormalities.[117] These constellation of findings are known as critical illness polyneuropathy (Table 39.1).[118] Cytokines[119] and low–molecular-weight neurotoxins[120] released during episodes of sepsis or when patients develop multiple organ failure are thought to be responsible for this axonal degeneration. Critical illness polyneuropathy has been considered one of the manifestations of multiple-organ failure syndrome.[117] Sepsis and multiple-organ failure, though, are not essential prerequisites for the development of critical illness polyneuropathy.[121,122] Tight control of hyperglycemia may reduce the risk of polyneuropathy and the duration of mechanical ventilation.[123]

In other patients, rather than axonopathy, there is evidence of isolated myopathy (i.e., critical illness myopathy).[4] Patients in whom isolated myopathy develops often have been treated with steroids and neuromuscular blocking agents (e.g., patients with status asthmaticus).[4] Muscle biopsies demonstrate a general decrease in myofibrillar protein content and a selective loss of thick filaments (myosin) within type I and type II fibers (Table 39.2 and Fig. 39.16). Animal models of critical illness myopathy suggest that medical denervation with paralytic agents cause an upregulation of glucocorticoid receptors in the muscle.[124] If the animal subsequently receives high-dose corticosteroids, it will develop depletion of thick myosin filaments.[124] Although a decrease in thick-filament proteins may be important for prolonged weakness,[125] this decrease is probably not the cause of the acute paralysis,[126] particularly in patients with compound motor action potentials of low amplitude.[127] Impaired muscle membrane excitability is probably more important during the acute stage.[126,128] An additional mechanism at play is an insufficient energy supply to the myocyte caused by insufficient translocation of the glucose transporter-4 (GLUT4) from the perinuclear spaces to the sarcolemma.[129] This, in turn, causes a decreased glucose availability in the cell. Failed activation of p-adenosine monophosphate–activated protein kinase (p-AMPK) is involved in these processes. Of interest, Weber-Carstens et al.[129] were able to prevent muscle-specific AMPK failure, restore GLUT4 disposition, and diminish protein breakdown in 5 critically ill patients by applying neuromuscular electrical stimulation to the quadriceps muscle for 12 consecutive days.

In the past few years it has become increasingly apparent that critical illness neuropathy and myopathy often coexist.[119,122,128,130–132] It has become common to refer to patients who become weak while in the ICU as a result of acquired neuropathy and/or myopathy (not associated with a known disorder) as simply having



• **Fig. 39.14** Airway pressures and electromyographic *(EMG)* signals of the right and left hemidiaphragm in an intubated patient. ICU-acquired paresis.[128,130,132] In patients with ICU-acquired paresis duration of weaning from mechanical ventilation can be two to seven times longer than in patients without ICU-acquired paresis.[133]

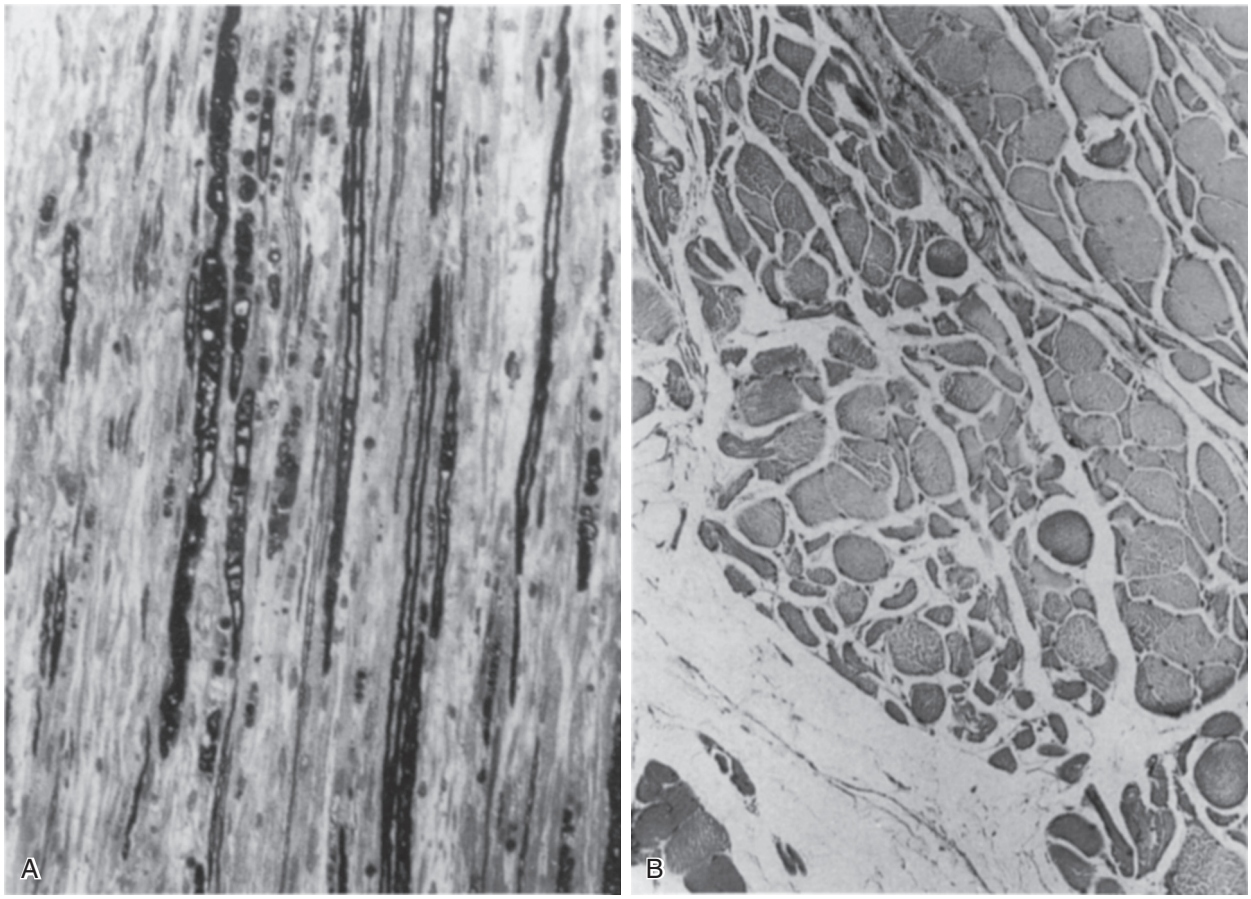
The functional outcome of ICU-acquired paresis is not uniform. Approximately 50% to 60% of patients experience complete recovery (ability to breathe spontaneously and to walk independently) over a period of 2 weeks to 6 months or longer.[125,133,134] About 30% experience severe persistent disability with tetraparesis, tetraplegia, or paraplegia.[133] Other investigators report even worse outcome: only 2 of 10 patients left the hospital in one study.[131] Whether it is possible to prevent ICU-acquired paresis in patients recovering from severe acute illness, and whether that would result in shorter duration of mechanical ventilation, remains unknown.

Acid-Base Disorders

Alkalosis, either metabolic or respiratory, does not affect skeletal muscle strength[135–137] and might improve endurance.[135] Whether acidosis, either metabolic or respiratory, impairs respiratory muscle function remains controversial. Because the contractile response to metabolic and respiratory acidosis is not necessarily the same,[138,139] metabolic acidosis and respiratory acidosis are separately discussed.

Metabolic Acidosis. Until recently, there was little doubt that metabolic acidosis could decrease muscle contractility.[140,141] Purported mechanisms included reduction of actin-myosin cross-bridge activation by hydrogen ion (H^+) competitive inhibition of calcium ion (Ca^{2+}) binding to troponin C, reduced transition of actin-myosin cross-bridges from low- to high-force state, inhibition of myofibrillar adenosine triphosphatase (ATPase), inhibition of glycolytic rate, inhibition of maximal shortening velocity, and inhibition of sarcoplasmic ATPase with reduction of sarcoplasmic Ca^{2+} reuptake, leading to reduced Ca^{2+} release from the sarcoplasmic reticulum.[142] Despite the biological plausibility, investigators have reported no effect[139,143] or marginal effect[144] of metabolic acidosis on respiratory muscle function. Yanos et al.[139] assessed maximal transdiaphragmatic pressure elicited by tetanic stimulation of the phrenic nerves in seven anesthetized dogs during respiratory acidosis (pH 7.1) and during lactic acidosis (pH 7.1). They observed a fall in maximal diaphragm strength with respiratory acidosis (−18%, $P < 0.05$), but not with lactic acidosis (+3%). Similarly, when Coast et al.[144] exposed isolated diaphragm strips of rats to different concentrations of lactic acid, they recorded decreases in force when the pH was lowered to 6.8—but only after the muscles strips were stressed with 75 contractions (25 Hz, 250-ms train duration, one train per second). Contractility was not affected when the pH was decreased to 6.8 to 7.2 at rest, and following the set of 75 contractions when delivered at a pH of 7.1 and 7.2.[144] These negative results are in line with some—but not all[145,146]—investigations questioning the inhibitory role of metabolic acidosis on limb muscle contractility at physiologic temperatures.[147–150] For instance, Nielsen et al.[150] reported that metabolic acidosis (pH 6.80) counteracts the detrimental effects of increased extracellular potassium ion (K^+) concentrations (which occurs with forceful contractions) on the excitability and force generation of the rat soleus muscle. In humans, Degroot et al.[148] measured intracellular H^+ concentration during sustained isometric foot plantar flexion. In contrast to what would be expected if acidosis caused decrease in contractility, Degroot et al.[148] reported a decrease in intracellular H^+ concentration during the first 10 seconds of exercise when force was declining and a rise in intracellular H^+ concentration immediately after exercise, when force partially recovered.[148] Whether severe metabolic acidosis in humans might impair skeletal function by causing a reduced central nervous system drive remains to be demonstrated.[140]

Acute Respiratory Acidosis. There are contrasting reports on the effect of acute respiratory acidosis on respiratory muscle contractility.[136,137,139,151] In anesthetized dogs, diaphragmatic contractility decreases pari passu with the severity of acute respiratory acidosis[136] (but has no effect on gastrocnemius muscle contractility).[139] Similarly, in healthy volunteers, acute increases of arterial carbon dioxide to 54 mm Hg (corresponding to a pH of about 7.29) reduces the capacity of the unfatigued diaphragm to generate pressure by 10% to 30% (Fig. 39.17).[137] Such reduction in pressure generation is even greater when arterial carbon dioxide is increased to 63 mm Hg (corresponding to a pH of about 7.22).[137] Acute respiratory acidosis can decrease respiratory muscle endurance[137,152]



• **Fig. 39.15** Transverse section of a peripheral motor nerve (deep peroneal nerve, A) and of a skeletal muscle (intercostal, B) in patients who developed profound weakness after a prolonged hospital course characterized by sepsis, multiple-organ failure syndrome, and inability to wean from mechanical ventilation. A, The long thin dark structures are myelin sheaths that contain axons. The axons are degenerating and dying; after death, they disintegrate. The myelin surrounding the disintegrating axons collapses around the axonal debris to form ovoids of myelin (seen better on the lateral portions of A). B, Amid muscle fibers that are normal in size and shape are atrophic ones that appear small and that have developed contours with acute angles. These findings are consistent with denervation atrophy secondary to axonal degeneration, so-called critical illness polyneuropathy. (From Zochodne DW, Bolton CF, Wells GA, et al. Critical illness polyneuropathy. A complication of sepsis and multiple organ failure. *Brain.* 1987;110:819–841.)

and it can increase the extent of diaphragmatic fatigue at the conclusion of 2 minutes of maximal voluntary ventilation.[153] Despite greater voluntary activation of the diaphragm,[154] hypercapnic patients with COPD generate lower maximal static inspiratory pressures than patients with normocapnia.[155,156]

A direct inhibitory effect of acute respiratory acidosis[136,137,139,152,153] on respiratory muscle contractility and respiratory muscle endurance could provide a potential mechanism for the rapid clinical deterioration that can occur with severe asthma and during COPD exacerbations.[137] Yet, the human data suggesting a direct deleterious effect of acute respiratory acidosis on respiratory muscle function[137,152,153,155] are not uniform. Some investigators report no change in diaphragmatic contractility[151,153] (but decrease in force of the adductor pollicis)[151] when acute respiratory acidosis causes a decrease in pH to about 7.16 to 7.27,[151,157] no change in the maximum relaxation rate of the diaphragm,[157] and no effect in the extent of diaphragmatic fatigue 20 to 90 minutes after loading.[153]

For several reasons it is difficult to reconcile the conflicting data on the effects of acute respiratory acidosis on respiratory muscle contractility reported in the literature. First, the nonsignificant decrease in diaphragmatic contractility of 12% (twitch pressure) recorded during acute hypercapnia in 12 healthy subjects in one study[151] raises the possibility of type II error. Second, it is impossible to state that more severe acidosis was responsible for the different results in human investigations considering the comparable pHs of the studies with negative[151] and positive[137] findings. Third, it is unlikely that the different frequencies of stimulation used to assess the respiratory muscles[137,151,153] are responsible for the contrasting results because, when present, acidosis-associated decrease in contractility is frequency-independent.[136] Moreover, three additional considerations further cloud our understanding of any interaction (if present) between acute respiratory acidosis and respiratory muscle contractility. Respiratory acidosis (pH 6.50–6.88) may actually enhance and not depress skeletal muscle contractility.[150,158] It is unknown whether comorbidities, which often affect hypercapnic patients such as sepsis, decreased cardiac function, and impaired respiratory mechanics, could act synergistically with acute hypercapnia in worsening respiratory muscle function. Finally, it is unknown whether equivalent levels of pH occurring as a result of acute or

TABLE 39.1 Electromyographic Findings in Respiratory Muscle Weakness

Electromyographic Feature	Axonal Injury	Myelin Injury	Neuromuscular Conduction Defect	Myopathy
Compound muscle action potential (amplitude)[a]	Reduced	Normal to slightly reduced	Normal[b]	Normal
Sensory nerve action potential (amplitude)[c]	Reduced	Normal to reduced	Normal	Normal
Conduction velocity	Normal to slightly reduced	Reduced	Normal	Normal
Spontaneous muscle depolarization[d]	Present	Absent	Absent	None to present
Amplitude of compound muscle action potential with stimulation at 3 Hz[e]	Unchanged	Unchanged	Decreased	Unchanged
Motor unit activation	Decreased	Decreased	Normal	Increased

Examples of injuries and deficits: *axonal injury,* critical illness myopathy; *myasthenia,* prolonged neuromuscular blockade; *myelin injury,* Guillain-Barré; *myopathy,* critical illness myopathy; *neuromuscular conduction defect,* myasthenia, prolonged neuromuscular blockade.
[a]Elicited by motor nerve stimulation.
[b]Decreased in the Lambert-Eaton syndrome.
[c]Elicited by sensory nerve stimulation.
[d]Spontaneous muscle depolarization (caused by denervation) is detected by presence of fibrillation potentials and positive sharp waves.
[e]Repetitive nerve stimulation is performed to exclude neuromuscular transmission defects such as prolonged neuromuscular paralysis.
Although features of myopathy can be recorded by electromyographic studies, electromyography cannot always distinguish critical illness myopathy from critical illness polyneuropathy, and muscle biopsies may be needed.

Glycogen	+	++	++	+++
Capillary supply	+++	+++	++	+
Diameter	+	++	++	+++

[a]Amount of work performed per unit of ATP consumed.
A single myosin heavy chain isoform is typically expressed within an adult skeletal muscle fiber. Fibers classified as type I, IIa, IIx, and IIb express myosin heavy chain isoforms I (or slow), IIa, IIx, and IIb, respectively. Type IIx fibers have been reported in peripheral muscles of humans and animals and in the diaphragm of animals. Type IIx fibers have not been reported in the human diaphragm. More than one myosin heavy chain isoform is expressed in a few fibers (about 14% of adult rat diaphragm coexpresses myosin heavy chain isoforms IIb and IIx, and less than 1% coexpresses myosin heavy chain isoforms I and IIa).[244] Although the velocity of muscle contraction depends primarily on the myosin heavy chain isoform, the velocity of muscle relaxation is mainly determined by troponin C calcium binding and release and by calcium reuptake by the sarco-endoplasmic reticulum calcium-adenosine triphosphatase (SERCA). Several SERCA isoenzymes have been identified. SERCA 1 is expressed in type II fibers (fast calcium reuptake), and SERCA 2a is expressed in Type I (slow calcium reuptake).[245] The density of pumping sites largely accounts for different rates of calcium uptake in fast- and slow-twitch muscle fibers.[245] Despite this separation of tasks, velocity of contraction and velocity of relaxation tend to parallel each other. Type II fibers contract and relax with a greater velocity than type I fibers. Slower velocity of relaxation allows fusion of repetitive twitches at lower frequencies of stimulation as compared with fast relaxations. Impairment of SERCA activity has been implicated in the development of fatigue and in disease states including heart failure and corticosteroid myopathy.

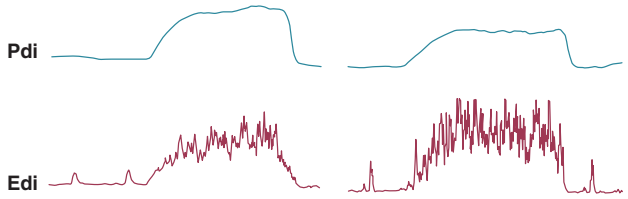
Myopathy with thick filament (myosin) loss following prolonged paralysis with vecuronium during steroid treatment. *Muscle Nerve* 1991;14:1131–1139.)



• **Fig. 39.17** Transdiaphragmatic pressure *(Pdi)* and electrical activity of the diaphragm *(Edi)* during a voluntary isometric contraction in a healthy subject during normocapnia *(left panel)* and during acute hypercapnia (end-tidal CO_2, 7.5%, *right panel*). For a given Edi during hypercapnia, the pressure output of the diaphragm was decreased. (From Juan G, Calverley P, Talamo C, et al. Effect of carbon dioxide on diaphragmatic function in human beings. *N Engl J Med.* 1984;310:874–879.)

acute-on-chronic respiratory acidosis may—or may not—have the same effect on respiratory muscle function.

Electrolyte Disturbances

Respiratory muscle function may be impaired by decreased levels of phosphate,[159] calcium,[160] magnesium,[161] and potassium.[162] Aubier et al.[159] studied the effects of severe hypophosphatemia (0.55 ± 0.18 mmol/L) on twitch Pdi in eight patients with acute respiratory failure who were mechanically ventilated. Correction of hypophosphatemia was accompanied by a significant increase in twitch Pdi—from 9.8 ± 3.8 cm H_2O before phosphate infusion to 17.3 ± 6.5 cm H_2O after phosphate infusion ($P < 0.001$). Changes in serum phosphorus concentration and changes in twitch Pdi were well correlated ($r = 0.73$). These results strongly suggest that hypophosphatemia can impair the contractile properties of the diaphragm during acute respiratory failure.

The same investigators assessed the effects of hypocalcemia on diaphragmatic function in 12 anesthetized dogs.[160] A continuous infusion of the chelating agent ethylene glycol-bis (B aminoethylether)-*N,N′*-tetraacetic acid (EGTA) was used to produce hypocalcemia. Over the 2 hours of observation, a progressive reduction in diaphragmatic force production paralleled the progressive reduction in ionized serum calcium.

Hypomagnesemia, a common occurrence in the ICU, can also cause respiratory muscle weakness. Dhingra et al.[161] reported improvements in maximal inspiratory and expiratory pressures in 17 hypomagnesemic patients after magnesium replacement therapy but not after placebo therapy.

Severe hypokalemia can be caused by several disorders, including posthypercapnic alkalosis,[163] renal tubular acidosis, primary hyperaldosteronism, gastrointestinal potassium losses, use of diuretics, thyrotoxic periodic paralysis, familial hypokalemic paralysis, β_2-adrenergic agonists, and licorice ingestion.[13] When the serum potassium concentration decreases below 2.0 to 2.5 mEq/L, patients may develop muscular weakness (including respiratory muscle weakness) and arrhythmias. Hypokalemia-associated respiratory muscle weakness can result in respiratory failure and death.[162,163]

Decreased Oxygen Delivery

Laboratory animals with cardiogenic shock[164] or with septic shock[93,165] die of respiratory failure. Death is not caused by pulmonary disease per se but by an inability of the respiratory muscles to maintain adequate ventilation. This inability to maintain adequate ventilation is caused by insufficient oxygen delivery to the respiratory muscles.[4]

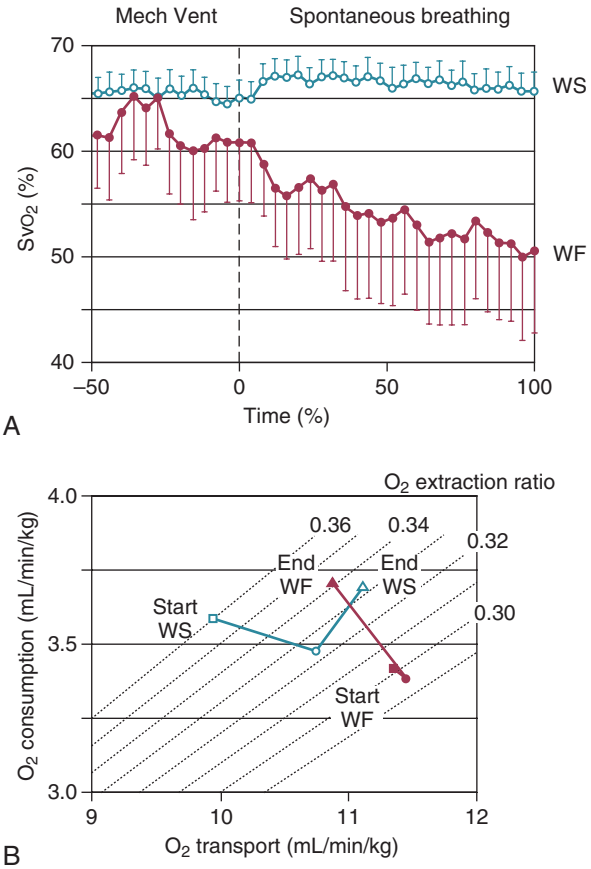
Whether the decrease in oxygen delivery to the respiratory muscles—or the respiratory centers—during shock is sufficient to decrease respiratory muscle performance and cause hypoventilation in patients, although likely,[166] remains to be determined. A nonrandomized study by Kontoyannis et al.[167] in 28 patients with cardiogenic shock supports the view that hemodynamic instability

could decrease respiratory muscle performance in patients with shock. Compared with nonventilated patients, ventilated patients were weaned from an intraaortic balloon pump more often, and their survival was greater.[167] These results are in line with the observation of Viires et al.,[168] who reported decreased metabolic requirements of the diaphragm after institution of mechanical ventilation in dogs with cardiogenic shock.

Hemodynamic situations less extreme than shock, which could still affect respiratory muscle performance, are failed attempts of spontaneous respiration during weaning from mechanical ventilation. Jubran et al.[169] investigated the importance of hemodynamic performance in determining weaning outcome in 8 ventilator-supported patients with a failed trial of spontaneous breathing and 11 patients who tolerated a trial and were successfully extubated. Immediately before the trial, mixed oxygen venous saturation was not different between the two groups. Mixed venous oxygen saturation progressively decreased over the course of the trial in the failure group, whereas it remained unchanged in the success group (Fig. 39.18A). Although the calculated oxygen demand was similar in the two groups, the manner in which it was met differed. In the success group, oxygen transport increased, mainly resulting from an increase in cardiac index; in the failure group, the increase in demand was met by an increase in oxygen extraction, resulting in a decrease in mixed venous oxygen saturation (see Fig. 39.18B). Although increased, the oxygen extraction ratio at the end of the trial in the failure group was close to the ratio reported to signify the onset of anaerobic metabolism (0.60)[170] in only two patients who had ratios of 0.50 and 0.56, respectively.

The ability of the failure group to deal with respiratory muscle energy demands through aerobic pathways is probably related to the capacity of the diaphragm to achieve higher blood flow than most other skeletal muscles.[171] During loading, the diaphragm rapidly increases oxygen extraction to a plateau of about 55% to 65%; further increases in oxygen demand are achieved by increases in blood flow.[172,173] The diaphragmatic musculature appears to be extremely resistant to hypoxic stress, and animals can maintain a ventilation that is sufficient to avoid hypercapnia until phrenic vein partial pressure of oxygen (P_{O_2}) falls to 12 mm Hg.[171] Likewise, investigators have found that an oxygen tension of about 10 mm Hg in the phrenic vein is the threshold associated with the onset of diaphragmatic lactate production[174] and the development of fatigue.[175] The lowest mixed venous oxygen tension recorded by Jubran et al.[169] was 26 mm Hg, which is above the threshold for onset of diaphragmatic lactate production. This association needs to be interpreted with caution, however, because mixed venous blood contains effluents from many tissue beds other than the diaphragm. The investigation of Jubran et al.[169] is the first documentation that when challenged by an increase in mechanical load,[15] the respiratory muscles of critically ill patients do not appear to switch from aerobic to anaerobic metabolism.

High variability in hemodynamic response during failure to wean has been reported by Zakynthinos et al.[18] Similar to Jubran et al.,[169] Zakynthinos et al.[18] recorded a decrease in mixed venous oxygen saturation and an increase in oxygen consumption (met mainly by an increase in oxygen extraction) in 9 of 18 patients in whom weaning failed. In the remaining 9 failures, however, mixed venous oxygen saturation and oxygen consumption were not affected by the weaning trial. It is unclear whether the absent interaction between weaning failure and oxygen consumption was due to depression of the respiratory centers, limited capacity to extract oxygen, or limited cardiac reserve.[176]



• **Fig. 39.18** A, Mixed venous oxygen saturation *(S_{VO_2})* during mechanical ventilation and a trial of spontaneous breathing in patients who were weaned successfully (*WS, open symbols*) and in 8 patients in whom weaning failed (*WF, solid symbols*). During mechanical ventilation, S_{VO_2} was similar in the two groups ($P = 0.28$). Between the onset *(dashed line)* and the end of the trial, S_{VO_2} decreased in the failure group ($P < 0.01$), whereas it remained unchanged in the success group ($P = 0.48$). Over the course of the trial, S_{VO_2} was lower in the failure group than in the success group ($P < 0.02$). The bars indicate the standard error. *B,* Oxygen transport, oxygen consumption, and isopleths of oxygen extraction ratio in the success (WS, *open symbols*) and failure (WF, *closed symbols*) groups during mechanical ventilation *(squares)* and at the onset *(circles)* and end *(triangles)* of a spontaneous breathing trial. See text for details. (Modified from Jubran A, Marthu M, Dries E, et al. Continuous recordings of mixed venous oxygen saturation during weaning from mechanical ventilation and the ramifications thereof. *Am J Respir Crit Care Med.* 1998;158:1763–1769.)

Medications

Weakness can result from medications that have a direct myotoxic effect, such as uncoupling of the oxidative phosphorylation by propofol,[177] blockade of myocyte glycoprotein synthesis, and blockade of the electron transport by inhibitors of the hydroxy-methylglutaryl coenzyme A reductase or nucleoside analogs used in patients with human immunodeficiency virus,[178–181] and purported sarcolemma pore formation by daptomycin, the cyclic lipopeptide with bactericidal activity against gram-positive bacteria.[177] Weakness can also result with neuromuscular blocking agents and aminoglycosides, which interfere with neuromuscular transmission.[182,183]

Paralysis, including the respiratory muscles, can persist after discontinuation of neuromuscular blocking agents.[183–185] Prolonged neuromuscular blockade has been defined as 2,[183] 4,[185] or 6 hours[184]

of paralysis after discontinuation of neuromuscular blocking agents. Prolonged blockade is estimated to occur in 12% to 44% of patients receiving pancuronium or vecuronium for one or more days.[183–185] The risk with vecuronium is increased in patients with renal failure.[183,185] Accumulation of metabolites of the neuromuscular blocking agents is responsible for the prolonged blockade.[183] Recovery from prolonged neuromuscular blockade begins within 2 days of the last dose,[183,184] and this contrasts with the prolonged course of critical illness myopathy or neuropathy.[125,134,186,187] Train-of-four monitoring of the dose of a neuromuscular blocking agent with a peripheral nerve stimulator may hasten recovery.[185]

Acquired Diaphragm Weakness in Critically Ill Patients and Clinical Outcomes

Increasing experimental evidence suggests that, in critically ill patients, acquired diaphragm weakness is associated with excess morbidity and mortality.[70,114,115,188] First, duration of mechanical ventilation is about 6 days for patients without diaphragmatic weakness (twitch Pdi > 10 cm H_2O) and nearly 2 weeks for patients with diaphragmatic weakness (twitch Pdi < 10 H_2O; $P < 0.02$).[114] Second, in the same study, mortality was less than 10% for patients without weakness and it was nearly 50% for patients with diaphragmatic weakness ($P = 0.022$).[114] Third, in mechanically ventilated patients, diaphragm weakness was a far stronger predictor of ICU mortality than comorbidity index, extent of organ failure (including severity of lung functional abnormalities), age, gender, and steroid use.[189] Whether diaphragmatic weakness is a marker of disease severity or is causally related to worse outcomes in critically ill patients remains to be determined.[116]

Limitations in the Current Classification of Respiratory Muscle Weakness

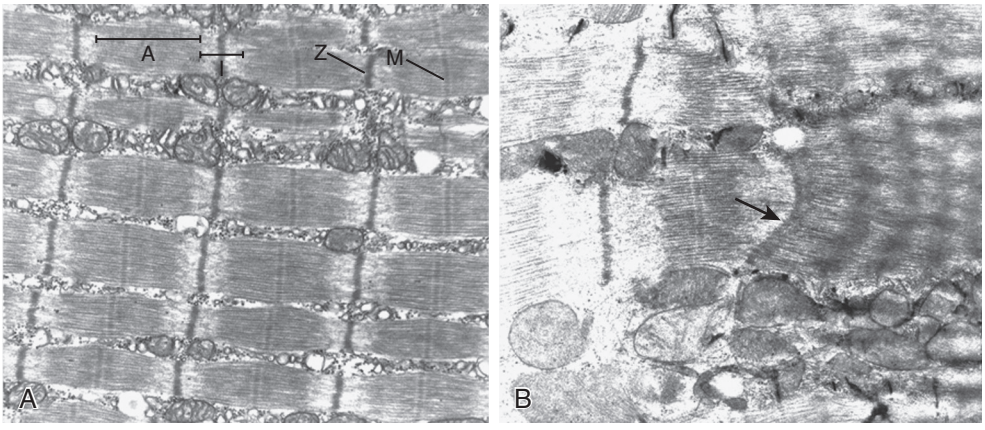
When one is studying respiratory muscle weakness leading to hypoventilation in critically ill patients, it is necessary to bear in mind the current limited understanding of the conditions, as follows:

1. The distinction between preexisting conditions and new-onset conditions can be arbitrary.
2. Conditions that are preexisting (malnutrition and hyperinflation) can worsen during the course of an unrelated critical illness.
3. The nosology is often unsatisfactory—see the nebulous distinction between ICU-acquired paresis and sepsis-associated myopathy or between ICU-acquired paresis and ventilator-associated respiratory muscle dysfunction.
4. Conditions in which respiratory muscle weakness is associated with muscle damage can also display some degree of muscle atrophy—see diaphragmatic atrophy in cases of ventilator-associated respiratory muscle dysfunction.
5. Laboratory specificity to differentiate the different conditions causing weakness in the ICU is limited.
6. In any given patient more than one mechanism may be responsible for respiratory muscle weakness.
7. Respiratory muscle weakness can be combined with depressed drive—for example, in the setting of hypercapnia-induced hypoventilation.

Respiratory Muscle Fatigue

Contractile fatigue occurs when a sufficiently large respiratory load is applied over a sufficiently long period.[20,190–198] Contractile fatigue can be brief or prolonged. Short-lasting fatigue results from accumulation of inorganic phosphate,[149,199,200] failure of the membrane electrical potential to propagate beyond T tubules,[201] and to a much lesser extent intramuscular acidosis.[202–204] Short-lasting fatigue appears to have a protective function, because it can prevent injury to the sarcolemma caused by forceful muscle contractions.[205] Long-lasting fatigue[191] is consistent with the development of, and recovery from, muscle injury (Fig. 39.19).[205,206]

Whether short-lasting or long-lasting contractile fatigue of the respiratory muscles develops in critically ill patients is not clear. Patients who fail a trial of weaning from mechanical ventilation are at particular risk of developing fatigue because they experience marked increases in respiratory load.[14,15,36] The addition of a new injury to the respiratory muscles (secondary to the development of contractile fatigue) might be the ultimate determinant of whether

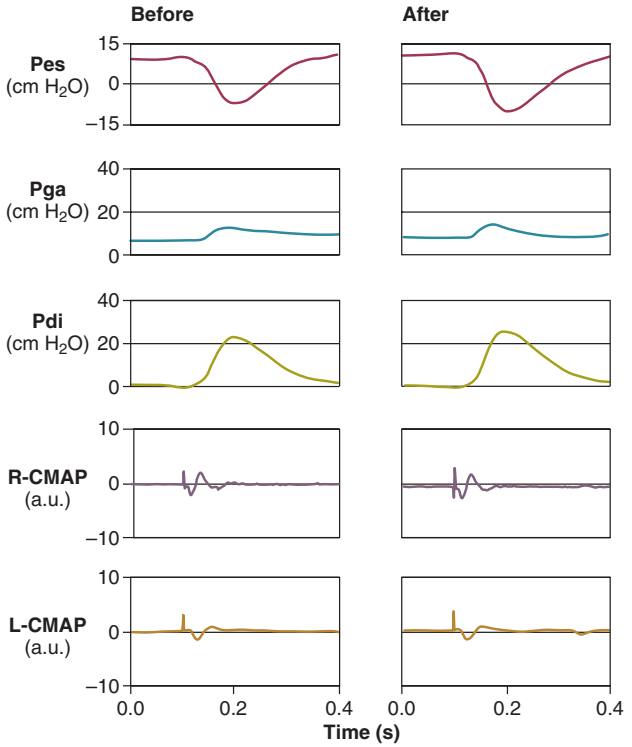


• **Fig. 39.19** Electron micrographs of longitudinal sections from the costal diaphragm of a healthy control hamster (A) and a hamster exposed to 6 days of resistive loading (B). A shows normal sarcomeres with distinct A-bands, I-bands, Z-bands, and M-lines that are aligned between adjacent myofibrils. B shows load-induced damage recognizable by Z-band streaming *(arrow)* and disruption of sarcomeric structure *(right section of B)* with loss of distinct A-bands and I-bands. Z-band streaming is attributed to a loss of cytoskeletal protein elements such as desmin, α-actinin, and vimentin. Magnification for both micrographs: ×16,500. (From Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48. Electron micrographs provided by Drs. David C. Walker and Darlene W. Reid, University of British Columbia, Vancouver, BC, Canada.)

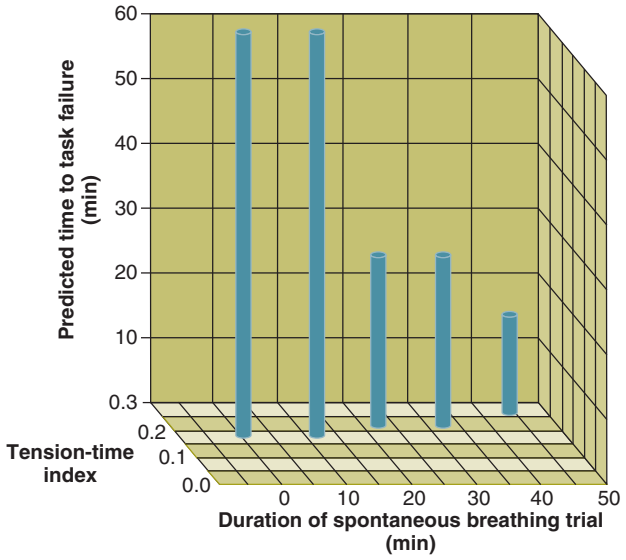
or not some patients ever achieve successful weaning. Circumstantial evidence of contractile fatigue in patients experiencing respiratory distress has been reported.[15,207–209] Because of technical limitations,[207–209] these early data did not provide proof of contractile fatigue.[13,19]

The most direct method for detecting fatigue in patients is to measure twitch Pdi over time (see Fig. 39.3).[20,191] When this technique is used in critically ill patients, it is especially challenging to ensure that successive stimulations are all generated at the same end-expiratory lung volume, that a constant degree of neural depolarization by the stimulator is achieved and that twitch potentiation (the transient increase in pressure that occurs with a recent forceful contraction) does not occur.[20,191] Controlling for these factors, Laghi et al.[17] studied 11 patients in whom weaning failed and 8 patients with weaning success before and after a T-tube trial. Twitch Pdi was 8.9 ± 2.2 H_2O before and 9.4 ± 2.4 H_2O after the trial in the weaning-failure group (Fig. 39.20). The respective values in the weaning-success group were 10.3 ± 1.5 and 11.2 ± 1.8 cm H_2O. Not a single patient developed a decrease in twitch Pdi. The absence of fatigue was surprising because seven of the nine patients in whom weaning failed had a tension-time index (the product of two fractions: [mean pressure per breath/maximum transdiaphragmatic pressure] × [inspiratory time/total time of respiratory cycle]) above the threshold reported to lead to task failure and fatigue (0.15).[210]

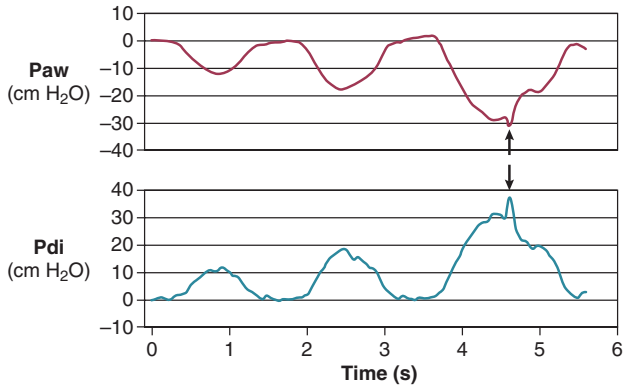
One of the most likely reasons patients did not develop fatigue is because physicians reinstituted mechanical ventilation before there was enough time for its development. The relationship between tension-time index and the length of time that a load can be sustained until task failure follows an inverse-power function. Bellemare and Grassino[210] expressed the relationship as time to task failure = 0.1 (tension-time index)$^{-3.6}$. The increase in the tension-time index over the course of the weaning trial[17] and predicted time to task failure[210] are shown in Fig. 39.21. At the point that the physician reinstituted mechanical ventilation, patients were predicted to be an average of 13 minutes away from task failure. Moreover, the time to task failure was underestimated because diaphragmatic recruitment during maximal voluntary contractions was incomplete (Fig. 39.22).[17] In other words, patients display clinical manifestations of severe respiratory distress for a substantial time before they would develop fatigue. In an intensive care setting, these clinical signs lead attendants to reinstitute mechanical ventilation before fatigue has time to develop. Other factors that might have protected the respiratory muscles from contractile fatigue include development of dynamic hyperinflation (susceptibility to fatigue is greater when fatiguing protocols are conducted at optimum muscle length rather than when a muscle is shortened)[211] and activation of extradiaphragmatic muscles of respiration.[212]



• **Fig. 39.20** Esophageal pressure *(Pes)*, gastric pressure *(Pga)*, transdiaphragmatic pressure *(Pdi)*, and compound motor action potentials *(CMAPs)* of the right and left hemidiaphragms after phrenic nerve stimulation before *(left)* and after *(right)* a failed trial of weaning. The end-expiratory value of Pes and the amplitude of the right and left CMAPs were the same before and after the trial, indicating that the stimulations were delivered at the same lung volume and that the stimulations achieved the same extent of diaphragmatic recruitment. The amplitude of twitch Pdi elicited by phrenic nerve stimulation was the same before and after weaning. *a.u.,* Arbitrary units. (From Laghi F, Cattapan SE, Jubran A, et al. Is weaning failure caused by low-frequency fatigue of the diaphragm? *Am J Respir Crit Care Med.* 2003;167:120–127.)



• **Fig. 39.21** The interrelationship between the duration of a spontaneous breathing trial, tension-time index of the diaphragm, and predicted time to task failure in nine patients who failed a trial of weaning from mechanical ventilation. The patients breathed spontaneously for an average of 44 minutes before a physician terminated the trial. At the start of the trial, tension-time index was 0.17, and the formula of Bellemare and Grassino[210] (see text for details) predicted that patients could sustain spontaneous breathing for another 59 minutes before developing task failure. As the trial progressed, tension-time index increased and predicted time to the development of task failure decreased. At the end of the trial, tension-time index reached 0.26; that patients were predicted to sustain spontaneous breathing for another 13 minutes before developing task failure clarifies why patients did not develop a decrease in diaphragmatic twitch pressure. In other words, physicians interrupted the trial based on clinical manifestations of respiratory distress before patients had sufficient time to develop contractile fatigue. (From Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48.)



• **Fig. 39.22** Continuous recordings of airway pressure *(Paw)* and transdiaphragmatic pressure *(Pdi)* during airway occlusion in a patient with chronic obstructive pulmonary disease after an unsuccessful trial of spontaneous breathing. Phrenic nerve stimulation *(arrow)* during the maximal inspiratory effort resulted in a detectable superimposed twitch. That a twitch could be superimposed during the maximal effort indicates that diaphragmatic activation was incomplete.

Studies in animals[202,213–215] support the finding that patients do not develop long-lasting contractile fatigue of the respiratory muscles. Inspiratory loading in animals causes respiratory failure and acidosis before force output decreases or substrate is depleted in the diaphragm,[202,213–215] suggesting that central[216] and reflex mechanisms[217,218] affect the breathing pattern[203] and α-motoneuron firing rates[219] in response to loading. Two neural pathways may convey information from the respiratory muscles to the central nervous system.[220,221] One pathway transmits information from mechanoreceptors (Golgi tendon organs and muscle spindles)[217,222] in the dorsal column, relaying it to the brainstem and thalamus, before reaching the sensorimotor cortex.[223] This pathway may participate in proprioceptive control of the respiratory muscles, integrating movements originating in the motor cortex.[216] The second pathway consists of vagal[215,222] and possibly phrenic nerve afferents (group IV phrenic afferent fibers)[217] that reach the amygdala after relaying in the brainstem and then projecting to the mesocortex (cingulated gyrus).[222] This pathway may deal with respiratory nociception,[216,224] such as dyspnea (through the relay in the amygdala),[225] and with the ventilatory response to carbon dioxide (through the relay in the brainstem, ventral cerebellum, and limbic system).[216,224,226] In addition to these two pathways projecting to the central nervous system, there is evidence for the existence of a spinal pathway responsible for phrenic-to-phrenic reflex inhibition.[218] An increase in carbon dioxide during loading may also protect the respiratory muscles by decreasing reactive oxygen species production.[227]

In healthy subjects, inspiratory threshold loading to the point of task failure causes hypercapnia without necessarily affecting diaphragmatic force output.[228] Similarly, resistive breathing causes hypercapnia without affecting diaphragmatic force output or aerobic metabolism (assessed by phosphorus 31–nuclear magnetic resonance spectroscopy) in spontaneously breathing piglets.[15,203,229] The hypoxia combined with resistive breathing caused a decrease in diaphragmatic force and inadequate oxidative metabolism, as reflected by accumulation of inorganic phosphorus and decreased phosphocreatine.[203] Force output and oxidative metabolism returned to baseline values with normoxia despite persistent loading.[203] The investigators speculated that loading produces a decrease in central activation (to the point of ventilatory failure), which decreases metabolic demands and prevents peripheral fatigue; additional stress of hypoxia may overwhelm this defense mechanism and cause peripheral fatigue.[203] Hypoxemia can also induce degradation of myofibrillar proteins.[230]

Hypoxia impairs the respiratory centers at a higher oxygen tension than it impairs the respiratory muscles,[175,231] making it difficult to decipher the effects of hypoxemia on the respiratory muscles. Animals develop severe alveolar hypoventilation and respiratory arrest before the tension-generating ability of the diaphragm has begun to decrease.[175,231] As previously stated, in patients with shock[166] it is unknown whether decreases in oxygen delivery to the respiratory muscles[169,232] or respiratory centers can be sufficient to cause hypoventilation.

Increased Load

Increased respiratory load can result from increased mechanical load and/or increased ventilatory requirements.

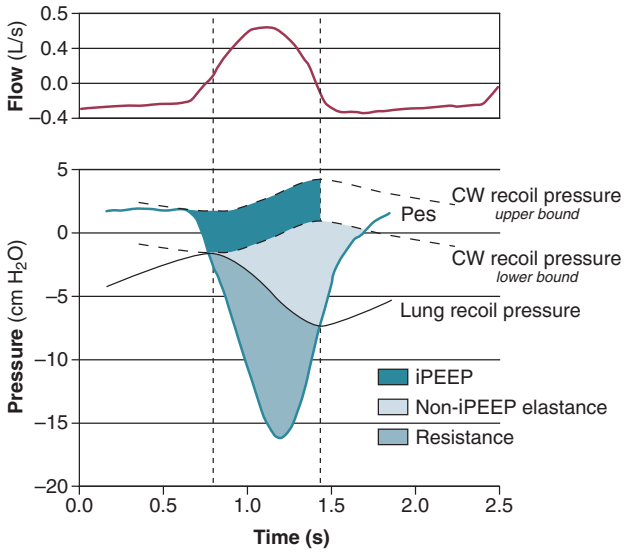
Increased Mechanical Load

Patients in acute respiratory failure usually experience an increased mechanical load.[†] The patients typically have a 30% to 50% greater inspiratory resistance,[15,17,36] 100% greater dynamic elastance,[14,15] and 100% to 200% greater intrinsic positive end-expiratory pressure (PEEP)[14,15,17] than do similar patients who are not in acute respiratory failure. Inspiratory effort—quantified by calculation of the *pressure time product* of the inspiratory muscles—is almost equally divided in offsetting intrinsic PEEP, elastic recoil, and inspiratory resistance (Fig. 39.23).[15,229] Abnormal mechanics arise from bronchoconstriction, bronchial edema, pulmonary edema,[15] and lung inflammation.[233,234] Rapid shallow breathing can aggravate the abnormalities in lung elastance, intrinsic PEEP, and carbon dioxide clearance.[15,36] Expiratory muscle recruitment can also increase intrinsic PEEP and breathing effort.[236] In some patients, increased mechanical load results from upper airway obstruction. The upper airway, which encompasses the passage between the nares and carina, can be obstructed by functional or anatomic causes. Among the first are vocal cord paralysis and laryngospasm. Among the second are trauma, burn, infections, foreign bodies, and tumors. Functional and anatomic obstruction can occur postoperatively in patients with redundant pharyngeal soft tissue (sleep apnea) and loss of muscle tone related to postanesthetic state.[1] Upper airway obstruction is one of the most urgent and potentially lethal medical emergencies.[1] Complete airway obstruction lasting for as little as 4 to 6 minutes can cause irreversible brain damage.[1]

Increased Ventilatory Requirements

Increased ventilatory requirements can result from increased carbon dioxide production, increased dead-space ventilation, and elevated respiratory drive. Carbon dioxide production can increase as a result of sepsis,[93] fever, shivering, drugs (salicylates), lipogenesis,[237,238] and a shift in utilization of fuels from lipids (respiratory quotient [RQ] = 0.7) to carbohydrates (RQ = 1.0).[239] An increase in carbon dioxide production can be only a contributory factor and not a sole cause of hypercapnic respiratory failure.[3]

[†]See references 14, 15, 17, 36, 229, and 233–235.



• **Fig. 39.23** Quantification of inspiratory effort with pressure-time product (PTP) of the inspiratory muscles. Flow (inspiration upward) and pressure tracings during spontaneous breathing. Recoil pressures of the chest wall *(CW)* and lung are calculated from dynamic elastances of the chest wall and lung, respectively, and lung volume. Upper bound inspiratory PTP is calculated using the integral of the difference between esophageal pressure *(Pes)* and upper bound CW recoil pressure from the onset of the rapid decrease in Pes to the transition from inspiratory to expiratory flow. The component of PTP owing to intrinsic positive end-expiratory pressure *(iPEEP)* is computed using the integral of the difference between the upper and lower bound of CW recoil pressure from the onset of rapid decrease in Pes to the transition from inspiratory to expiratory flow. The component of PTP owing to non-iPEEP elastance is computed using the integral of the difference between lung recoil pressure and lower bound CW recoil pressure from the onset of inspiratory flow to the moment of transition from inspiratory to expiratory flow. The resistive fraction of PTP is computed using the integral of the difference between Pes and lung recoil pressure. The *vertical interrupted lines* represent points for zero flow. (From Jubran A, Tobin MJ. Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med.* 1997;155;906–915.)

The ratio of dead space to tidal volume is normally 0.30. The ratio increases up to 0.65 in patients with severe COPD,[240] acute respiratory distress syndrome,[241] and other severe lung diseases.[3] Patients can compensate for such an increase in dead space by doubling $\dot{V}E$.[3] Such an increase in $\dot{V}E$ poses a minor challenge when respiratory mechanics and respiratory muscles are normal; for example, hypercapnia is uncommon with pulmonary vascular disease.[3] Accordingly, an increase in dead-space ventilation should never be considered the primary mechanism responsible for hypercapnic respiratory failure unless there is a concurrent abnormality in the control of breathing, or in the mechanical load of the respiratory muscles or in their contractile performance.[3]

Stimulation of pulmonary irritant or J receptors, neurologic lesions, sepsis, and toxins can inappropriately increase respiratory drive. Whether an inappropriately heightened drive places sufficient stress on the respiratory muscle to cause respiratory muscle fatigue and, consequently, hypoventilation remains to be determined.

Hypercapnia-Induced Hypoventilation

Severe hypercapnia depresses the central nervous system and decreases respiratory motor output.[238] A viscous cycle can arise, whereby hypercapnia causes depressed drive leading to more hypercapnia.[242,243] The possibility of hypercapnia-induced hypoventilation is supported by reports of successful resolution of hypercapnic respiratory failure in some patients after short-term infusion of the respiratory stimulant, doxapram.[242,243]

Summary

A relative or absolute decrease in respiratory muscle output is responsible for alveolar hypoventilation and hypercapnic respiratory failure. The number of distinct clinical entities that result in hypercapnia is vast and often more than one disease process may coexist (e.g., hyperinflation-associated respiratory muscle weakness and ventilation-perfusion inequality in patients with COPD). The relative or absolute decrease in respiratory muscle output in patients with hypercapnia may stem from a decrease in respiratory drive, excess mechanical load on the respiratory muscles and respiratory muscle weakness (see Fig. 39.1). Whether respiratory muscle fatigue is responsible for hypercapnic respiratory failure is an important issue that has yet to be resolved.

Key Points

- Hypercapnia is synonymous with alveolar hypoventilation (for the patient's level of carbon dioxide production).
- A relative or absolute decrease in respiratory muscle output is responsible for alveolar hypoventilation.
- Isolated impairments in gas exchange usually do not cause hypercapnia.
- When gas exchange is impaired the magnitude of neuromuscular impairment or increased respiratory load conducive to hypercapnia can be less than the corresponding derangements when gas exchange is intact.
- Respiratory drive is elevated in many patients with acute ventilatory failure. This finding does not necessarily exclude the possibility that during episodes of ventilatory failure the central nervous system is not fully recruiting the respiratory muscles and may be contributing to carbon dioxide retention.
- In critically ill patients, respiratory muscle weakness is probably responsible for many cases of alveolar hypoventilation.
- Metabolic disturbances, such as hypophosphatemia, hypomagnesemia, hypokalemia, and hypocalcemia, can cause respiratory muscle weakness.

- Hyperinflation, typically described in patients with asthma and COPD, places the respiratory muscles in a mechanical disadvantage to generate the driving pressure of the respiratory system.
- Hyperinflation can occur during episodes of respiratory distress even in patients without a history of airway disease (e.g., pneumonia and chest trauma).
- The role of respiratory muscle fatigue in causing hypercapnic respiratory failure remains to be determined.
- Severe hypercapnia can in itself be conducive to alveolar hypoventilation by depressing respiratory drive.
- It is still unclear whether respiratory or metabolic acidosis has a clinically relevant direct effect on respiratory muscle contractility.

Review Questions

1. A 73-year-old male presented to an outlying hospital after being found on the floor and drowsy at a rehabilitation facility where he was convalescing from uneventful bilateral cervical laminectomy at the C3 to C7 level. In the rehabilitation facility he was ambulating very little and was administered opiates as needed for postoperative back pain. Past medical history included chronic obstructive pulmonary disease (COPD), hypertension, and coronary artery disease requiring bypass surgery, biventricular implantable cardioverter defibrillator, and several lung nodules stable for more than a year.

On presentation to the outlying hospital the patient was reported to be drowsy but arousable and wearing a cervical collar. Periodic breathing with respiratory rate ranged from zero to 24 breaths/min. Remaining vital signs were normal and physical examination also was unremarkable. Oxygen saturatiion was 98% with 2 L/min oxygen administered by nasal cannula. Noteworthy laboratory results included creatinine of 1.85 mg/dL (baseline of 0.9 mg/dL), normal thyroid-stimulating hormone (TSH) concentration, and calcium of 10.8 mg/dL with an albumin of 2.5 gm/dL. A computed tomography (CT) scan of the head without contrast was unremarkable. CT scanning of the of chest without contrast demonstrated multiple stable pulmonary nodules, multiple vertebral lytic lesions, emphysematous changes, and an enlarged pulmonary artery suggestive of chronic pulmonary hypertension.

While at the outlying hospital, the patient has a right frontoparietal acute to subacute ischemic stroke. He is intubated for possible aspiration pneumonia and respiratory failure. He is then transferred to your tertiary center for further evaluation of his respiratory failure.

On arrival to the tertiary center, the patient is alert and awake, follows commands, and moves all four extremities despite mild weakness of the left arm and left leg. On days 2 and 3 of this latest hospital stay, he is disconnected from the ventilation and a T-piece trial is conducted, yet the trial of weaning fails within 10 minutes owing to respiratory distress with tachypnea and use of accessory muscles of respiration. Brain natriuretic peptide levels are normal and there are no signs of obstruction on ventilator mechanics. A repeat chest radiograph shows no infiltrates.

What is the best diagnostic test to perform at this time in evaluating the patient's respiratory failure?

a. Echocardiogram
b. Sniff test
c. Bilateral phrenic nerve electromyography (EMG)
d. Bronchoscopy and biopsy of lung nodules
e. Sural nerve biopsy

Answer: c. Paresis or paralysis of the phrenic nerves was suspected from the clinical presentation. EMG of bilateral phrenic nerves failed to elicit any appreciable motor response at the right and left hemidiaphragms and the same was confirmed with ultrasound of the diaphragm. This might be related to his prior cervical stenosis followed by surgical intervention. It has been hypothesized that patients undergoing cervical laminectomy may experience delayed-onset central apnea caused by interruption of the reticulospinal fibers innervating the phrenic nerve nuclei. Alternatively, the patient's prior coronary artery bypass grafting might have placed him in a compromised state with one phrenic nerve and the recent spine surgery affecting the other phrenic nerve. The multiple lytic vertebral lesions were attributed to multiple myeloma.

An echocardiogram (option a) might help, but brain natriuretic peptide levels are normal and the chest radiograph was negative for infiltrates. Sniff test (option b) might be useful in an outpatient setting to evaluate for an elevated hemidiaphragm but is impractical in an intubated patient. Biopsy of the lung nodules or sural nerve (options d and e) will not shed light on the mechanisms responsible for weaning failure.

2. A 64-year-old obese man is brought to the emergency department by his son for evaluation of altered mental status that has progressed over the past several weeks. The patient has a known history of moderate COPD, type 2 diabetes mellitus, and hypertension. He is a heavy smoker and has active alcohol use disorder. Home medications include lisinopril and glyburide. The patient's son denied that his father had any new rash, fevers, or sick contacts. Within the past few weeks the patient has been housebound, eating and sleeping in bed all day with little to no activity at all. The son thinks that his father has had no chest pain or dyspnea but was gaining weight.

On admission blood pressure was 160/84 mm Hg with a regular hear rate of 60 beats/min, respiratory rate of 10 to 12 breaths/min, oxygen saturation of 96% with 5 L/min of oxygen delivered by nasal cannula. Physical examinations shows an obese male, with a full face, arousable but falling asleep during the interview with no distress. His neck was thick and short with no jugular venous distension, no lymphadenopathy, or thyromegaly. Auscultation revealed distant breath sounds, no active wheezing, and regular heart sounds. Results of the abdominal examination were benign. A neurologic examination was nonfocal except for sluggish reflexes and delayed relaxation phase at the ankle.

Laboratory tests on admission revealed hyponatremia (130 mEq/L), bicarbonate 37 mEq/L, slight transaminitis, and normal bilirubin, international normalized ratio (INR), and ammonia levels. Lipid panel results were as follows: high-density lipoprotein cholesterol 45 mg/dL; low-density lipoprotein cholesterol 203 mg/dL; and triglycerides 356 mg/dL. Urine drug screen results were negative for opiates and benzodiazepines. Brain natriuretic peptide (BNP) levels were normal. Arterial blood gas on one liter oxygen by nasal cannula gas shows pH of 7.28, partial pressure of carbon dioxide (P_{CO_2}) of 80 mm Hg, and arterial partial pressure of oxygen (P_{aO_2}) of 50 mm Hg. Chest radiographic findings were positive for emphysematous changes, and the head CT was unremarkable.

I. What is the cause of hypoxemia in this patient?
- **a.** Alveolar hypoventilation
- **b.** Intracardiac shunt
- **c.** Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch caused by COPD
- **d.** Diffusion limitation as the result of occult interstitial lung disease

II. What testing is most likely to reveal the cause of respiratory failure in this patient?
- **a.** CT angiography to rule out pulmonary embolism
- **b.** Echocardiogram with bubble study for shunt
- **c.** Magnetic resonance imaging (MRI) of the brain to look for brainstem pathology
- **d.** TSH with free triiodothyronine (T_3) and thyroxine (T_4) levels, treat the patient while waiting for results
- **e.** There is no need to do further testing and patient should be intubated

Answers: I: a. The alveolar-arterial (A-a) oxygen gradient is normal. The other choices of shunt, $\dot{V}/\dot{Q}$ mismatch, and diffusion

limitation would result in an elevated A-a gradient and hence are incorrect answers.

II: d. There are several findings suggestive of hypothyroidism and one could argue that the patient is in myxedema coma, a medical emergency. Physical examination findings are key. This patient is not in acute respiratory distress and this is not a COPD exacerbation (option e is incorrect). Arterial blood gas and BNP results are reflective of chronic respiratory acidosis and normal A-a gradient reflecting possibly hypoventilation. Hyponatremia and lipid panel are supportive of hypothyroidism.

3. A 33-year-old woman in her second trimester of pregnancy and with no significant past medical history presented to the emergency department with a 1-month history of dyspnea and proximal limb muscles weakness. She denied any history of skin rash, nausea, vomiting, diarrhea, or recent vaccinations. Her neurologic examination results were normal except for reduced strength in both upper and lower extremities (Medical Research Council [MRC] score, 3 of 5 for the proximal muscles and 4 of 5 for the distal muscles). Reflexes, sensations, cranial nerves, and cerebellar function were intact. Laboratory tests demonstrated elevated serum creatine kinase (2500 U/L; normal value 29–168 U/L) and elevated erythrocyte sedimentation rate (85 mm/h; normal value 0–42 mm/h). Arterial blood gas on room air was suggestive of acute on chronic respiratory acidosis (pH 7.32, $PaCO_2$ 59 mm Hg, PaO_2 78 mm Hg, bicarbonate (HCO_{3-}) 29 mEq/L) for which noninvasive ventilation was started. Further workup excluded any pulmonary infection, pulmonary emboli, and cardiac dysfunction as the underlying cause of her symptoms. Continuous fetal monitoring and obstetrical ultrasound were unremarkable. In the following 24 hours, despite noninvasive ventilation, respiratory acidosis markedly worsened (pH 7.12 and $PaCO_2$ 105 mm Hg), leading to carbon dioxide narcosis. The patient was intubated and mechanically ventilated. With resolution of hypercapnia, her mentation normalized. The following day, maximal inspiratory pressure was recorded at −14 cm H_2O. In addition, bedside needle EMG revealed electrophysiologic evidence of diffuse irritable myopathy including increased insertional activity, spontaneous fibrillation potential, and positive sharp waves, myopathic motor unit potentials, and early recruitment. What is the best testing choice at this time in evaluating the patient's respiratory failure?

a. MRI of the thighs
b. Sural nerve biopsy
c. Deltoid or quadriceps muscle biopsy
d. Bilateral phrenic nerve EMG
e. Lumbar puncture

Answer: c. This patient presents with symmetric proximal muscle weakness, elevated serum muscle enzymes, elevated erythrocyte sedimentation rate, and EMG abnormalities suggestive of a myopathy. The clinical course suggests an acquired myopathy. A muscle biopsy is needed to characterize the myopathy. The lack of skin rash would point away from dermatomyositis. An autoaggressive inflammatory exudate invading nonnecrotic muscle fibers (as was the case in this patient) would indicate polymyositis. A necrotizing pathologic picture would suggest a necrotizing autoimmune myopathy.

MRI of the thighs (option a) might demonstrate muscle edema, yet this finding is insufficient to make any definitive diagnosis. Sural nerve biopsy (option b) and bilateral phrenic nerve EMG (option d) are unlikely to be contributory considering that EMG demonstrated no neuropathic findings. Lumbar puncture (option e) would be a useful test to make a diagnosis of Guillain-Barré syndrome—not uncommon during pregnancy. In this patient, despite the markedly elevated serum creatine kinase, the EMG findings make this an unlikely possibility.

4. A 58-year-old thin alcoholic woman with known COPD was admitted to the medical intensive care unit (ICU) after new-onset grand mal seizure. She ran out of money to buy whiskey after drinking heavily for several days. On physical examination, she was communicative but incoherent, her lungs were clear, and her deep tendon reflexes were 2+ and symmetric. She was cachectic with a body mass index (BMI) of 19. Initial laboratory values included serum sodium 138 mEq/L, potassium 2.6 mEq/L, chloride 90 mEq/L, serum total CO_2 of 15 mmol/L, serum inorganic phosphate of 3.2 mEq/L, albumin 2.4 g/dL, and blood urea nitrogen of 7 mg/100 mL. An arterial blood sample collected while the patient was breathing room air was significant for metabolic acidosis and hypoxemia (pH of 7.24, carbon dioxide tension of 33 mm Hg, and oxygen tension of 55 mm Hg). Head CT was unremarkable and the chest radiograph was free of infiltrates.

Initial management in the ICU unit included intravenous glucose, potassium, thiamine, soluble multivitamins, and phenytoin. The patient was also given aluminum hydroxide, magnesium hydroxide (Maalox) by mouth. During the following day the patient's mentation improved and she started an oral diet. On the fourth hospital day, however, the patient was found to be obtunded. Her respiration was rapid and shallow. An arterial blood sample collected while the patient was using a nonrebreather oxygen mask was significant for mixed metabolic and respiratory acidosis (pH of 7.01, carbon dioxide tension of 71 mm Hg, and oxygen tension of 107 mm Hg). The patient was endotracheally intubated. The postintubation chest radiograph was free of infiltrates. No seizures, focal neurologic deficits, abnormal pupillary reflexes, or arrhythmias were noted. The only change was the presence of generalized areflexia and muscular weakness. A nasogastric feeding tube was placed and the patient was eternally fed. Over the next 2 days she was unable to voluntarily generate a vital capacity greater than 400 mL. Her maximum inspiratory pressure was −12 cm H_2O. She continued invasive ventilation.

What testing should be done next in evaluating the patient's respiratory failure?

a. Head CT
b. Continuous electroencephalographic (EEG) monitoring
c. Quadriceps muscle biopsy
d. Serum electrolytes
e. Lumbar puncture

Answer: d. This patient initially presents with presumed withdrawal seizures. Her admission laboratory test demonstrated hypoxemia and metabolic acidosis, a common finding after generalized tonic-clonic seizures. The clear chest radiograph and the history of COPD suggest that the patient's underlying COPD was responsible for hypoxemia. The patient's clinical course is initially one of neurologic improvement. She quickly starts with oral alimentation. The patient is known to be a heavy drinker and is malnourished. These factors make her at high risk of hypophosphatemia owing to refeeding syndrome. Indeed, on the sixth hospital day when the patient had already been intubated for 48 hours, all laboratory studies were within normal limits except for a serum inorganic phosphate level of 0.5 mEq/L. Potassium phosphate, 60 mEq, was administered intravenously over 16 hours. By the next morning the muscular

weakness was much improved, and forced vital capacity had doubled to 800 mL. Serum inorganic phosphate was 1.2 mEq/L (normal values 1.1–1.5 mEq/L). Later that afternoon, the patient self-extubated and remained extubated thereafter. The rest of the hospital course was uneventful.

A CT scan of the head (option a), continuous EEG monitoring (option b), and lumbar puncture (option e) are wrong choices because this patient has low yield. The patient has no focal neurologic deficit (option a), no evidence of seizure (option b), and no signs suggestive of meningitis (option e). Quadriceps muscle biopsy is not indicated as it would be unlikely for a patient to develop such a severe myopathy leading to hypercapnic respiratory failure within a matter of few days.

5. A 48-year-old woman with a remote history of mastectomy for noninvasive ductal carcinoma in situ of the breast was admitted and emergently intubated for respiratory distress. Arterial blood gas analysis revealed severe hypercapnia ($PaCO_2$ 102 mm Hg). According to family members, for the past 3 weeks the patient had been complaining of progressive dyspnea. In addition, 2 months before admission she started experiencing progressive, symmetric weakness of neck, arms, and leg muscles. One week before admission, she could not walk without support. After intubation, her physical examination revealed neck flexor weakness, mild symmetric proximal arm and leg weakness (MRC score 4 of 5), and weakness of the anterior tibial muscles (MRC grade 3). Deep tendon reflexes and sensation were normal. Her maximal inspiratory pressure was −15 cm H_2O. No skin abnormalities were observed. Creatine kinase was increased (5000 IU/L; upper limit of normal 145 IU/L). Routine blood examination showed no abnormalities. Tensilon test result was negative. EMG exhibited extensive myopathic changes consisting of spontaneous muscle activity and polyphasic motor unit action potentials of small amplitude and short duration in all muscles. CT imaging of the chest and abdomen ruled out overt malignancy and was not suggestive of interstitial lung disease. Repeated weaning trials from mechanical ventilation failed owing to recurrent hypercapnic respiratory failure with respiratory distress.

What is the best testing choice to evaluate the patient's respiratory failure?

a. Head CT
b. Anti–muscle-specific receptor tyrosine kinase (MuSK) antibody titers
c. MRI of the thighs
d. Anti-Hu antibody titers
e. Quadriceps muscle biopsy

Answer: e. This patient is affected by necrotizing autoimmune myopathy (NAM), a rare variant of idiopathic inflammatory myopathies that also include polymyositis, dermatomyositis, and sporadic inclusion body myositis. NAM is characterized pathologically by necrotic muscle fibers with absent or minimal inflammation and with some regeneration. It can be accompanied by statin therapy, connective tissue diseases, cancer, and signal recognition particle (SRP) autoantibodies or 3-hydroxy-3-methylglutaryl–coenzyme A reductase (HMGCR) autoantibodies. Clinically patients usually present with lower extremity weakness (73%). Less often patents experience distal weakness (41%), dysphagia (35%), and dyspnea (37%). Respiratory insufficiency as a presenting symptom of NAM is unusual. Prednisone monotherapy is generally insufficient to control the disease. Accordingly, most patients require a second agent such as azathioprine, methotrexate alone, mycophenolate mofetil, and intravenous immunoglobulins. During immunosuppressant taper or discontinuation, 55% of patients experience a relapse of the disease process.

Options a through d are incorrect because the patient has no focal neurologic deficit (option a), her Tensilon test was negative (option b), CT and abdomen were negative (option c), and thus a workup for malignancy would not be the first diagnostic step to take. MRI of the leg muscles may show hyperintensity, consistent with edema, yet this would not be sufficient to make a diagnosis of NAM.

Hospital-Acquired Pneumonia/Ventilator-Associated Pneumonia
- Etiologies
- Diagnosis
- Management

Pneumonia is the presence of an abnormal collection of microorganisms in the alveolar space that induces a consequent acute systemic host immune response. The recent discovery of a normal lung microbiome has forced reconsideration of prior definitions of pneumonia.[1] Previously the alveolar space was thought to be sterile and pneumonia resulted from invasion and proliferation of microorganisms, which by definition were not "normal." The mere presence of microorganisms was thought to be enough to induce the inflammatory response that characterizes clinical pneumonia. Studies on the lung microbiome document not only that bacteria are normally present at the alveolar level, but also that certain interacting bacterial populations are antiinflammatory and actually prevent progression of chronic lung diseases.

Definitions

A variety of classifications for acute pneumonias have been used. The critical issue for attempts at discriminating between types of pneumonia is the spectrum of usual pathogens. Because most antibiotic therapy currently is empirical, separating cases of pneumonia into those in which the usual spectrum of pathogens, and therefore resultant appropriate empirical antibiotic, are very similar is important for optimizing care.

Community-acquired pneumonia (CAP) is pneumonia with onset that occurs outside an acute medical care setting.[2] Pneumonia that occurs within the first 48 hours of hospital admission is also considered CAP in most studies, with the assumption being that the pneumonia was incubating at the time of hospitalization. Given difficulties in radiographic diagnosis and confusion with other acute illnesses requiring hospitalization, this assumption is usually reasonable.

Advances in medical care have blurred the distinction between CAP pathogens and those usually found in hospital settings. Attempts to identify CAP patients at risk for hospital pathogens resulted in the health care–associated pneumonia (HCAP) classification.[3] Unfortunately, the initial definition used criteria developed for bacteremia. Although the negative predictive value was very high for pathogens resistant to the usual CAP treatment, the criteria were overly sensitive, resulting in excessive antibiotic therapy. This excess was especially driven by use of broad-spectrum antibiotics even when only a single criterion was present, and it was not associated with any clear improvement in outcomes. The HCAP term has therefore been abandoned and specific high-risk profiles for specific pathogens are now more commonly used. Although most important criteria of recent hospitalization—prior colonization or infection with resistant bacteria, recent antibiotic use, and poor functional status—define a high-risk group,[4] the criteria do not discriminate among pathogens.

Hospital-acquired pneumonia (HAP) is pneumonia with onset more than 48 hours after hospital admission or after a period of hospitalization.[5,6] Many patients previously classified with HCAP were in less traditional hospital settings such as long-term acute care facilities (LTACs) or acute inpatient rehabilitation facilities.[7] The risk of HAP pathogens is maintained and possibly even increased in these environments. Patients from more chronic nursing home situations are more difficult to classify. Probably the easiest ways to assess risk for multiple-drug–resistant (MDR) pathogens are to determine whether the patient entered from the community versus a hospital or LTAC, the degree of limitations in normal daily activities, and prior antibiotic exposure.

Ventilator-associated pneumonia (VAP) is a subgroup of HAP, occurring in patients who have been endotracheally intubated for at least 48 hours. Once again, the assumption is that the pneumonia was not incubating at the time of intubation. Aspiration pneumonitis and secondary infectious pneumonia compromise this criterion.[8] Chronically ventilated patients from LTACs or acute rehabilitation hospitals should be considered to have VAP for purposes of empirical

antibiotic therapy. The increasing number of patients with long-term tracheostomy and home ventilatory support are not easily classified; once again, frequency of hospitalization, prior pathogen infection/colonization, and exposure to antibiotics are likely the best criteria.

Pneumonia in the immunocompromised host is a subgroup of both CAP and HAP. The major issue is risk for pathogens rare for CAP and HAP, such as *Pneumocystis jirovecii*, nonendemic fungi such as invasive *Aspergillus* and other molds, cytomegalovirus and other opportunistic viruses, and so on. Infections in the immunocompromised host are covered separately in Chapter 50. However, the separation between immunocompetent and immunosuppressed is somewhat arbitrary. Many patients with pneumonia have some form of immunocompromised state that may not be self-evident. Even 20 mg prednisone equivalent for 30 days or less can increase the risk of sepsis. A variety of immunosuppressive agents are being used for nonmalignant medical problems, most prominently solid organ transplant, but also collagen vascular diseases and other immunologic diseases. Conversely, pneumococcal pneumonia is still the most common pathogen in patients with acute leukemia before induction therapy as well as patients with human immunodeficiency virus (HIV) infection receiving highly active antiretroviral therapy.

Pathogenesis

Prior pathogenesis theories for pneumonia were based on the concept of a sterile alveolar space and acquisition of a foreign pathogen.[1] These concepts generally still apply but are more nuanced with the awareness of a normal alveolar microbiome.

Acquisition of Pathogens

The pathogen's mode of entry into the lower respiratory tract has usually been divided into aspiration, inhalation, hematogenous spread, and contiguous spread.

Inhalation

Inhalation of infectious particles is particularly important for inspection of viruses and tuberculosis. In these situations, pneumonia is not necessarily preceded by upper respiratory tract colonization. Inhalation is the major mechanism for CAP. Rarely, bacteria can be inhaled through aerosols from contaminated respiratory therapy equipment.

Aspiration

Aspiration is the major mechanism for HAP/VAP and for bacterial pneumonia in general. The lower respiratory tract is in constant communication with the upper tract and aspiration likely occurs continuously. When the normal flora in the oropharynx are replaced by bacteria that are not usually present, such as occurs with gram-negative pathogens in HAP/VAP, the new microorganisms can then cause replacement of the normally diverse flora of the lower respiratory tract, especially when under antibiotic pressure.

Hematogenous Spread

Hematogenous spread was thought to be a relatively rare cause of pneumonia, mainly limited to pneumonia resulting from right-sided endocarditis or a septic thrombophlebitis. Recent data from patients with acute respiratory distress syndrome (ARDS) suggest that the microbiota of the gut may translocate into the portal circulation and spread into the pulmonary circulation, from which they can alter the normal alveolar microbiome.[9] Deep sequencing of bronchoalveolar lavage (BAL) specimens from patients with ARDS finds marker pathogens suggesting a gastrointestinal (GI) tract source. This mechanism may also play a role in immunocompromised patients undergoing chemotherapy-related diffuse mucositis.

Contiguous Spread

Contiguous spread of pathogens from an adjacent extrapulmonary infection is an uncommon mechanism for pneumonia. However, primary empyema without pneumonia clearly occurs.[10] If so, then the possibility of secondary pneumonia from the infected pleura is logical but the frequency is somewhat unclear. However, the management is not different than if the pneumonia was primary. Other rare causes include spread from serious neck infections or subdiaphragmatic infections. In each of these cases, infectious invasion through other tissue planes is required before pneumonia occurs, limiting the spectrum of potential pathogens.

Overgrowth of Normal Flora

Discovery of the presence of a normal lung microbiome offers a fifth potential source of pathogens causing pneumonia overgrowth of the normal resident lower respiratory tract flora. Many pathogens associated with pneumonia can be part of the normal lung microbiota, including *Mycoplasma*, the pneumococcus species, and many other *Streptococcus* species.[11] Changes in conditions of the microbiome may result in overgrowth of one of these bacteria. The most obvious example may be an upper respiratory tract viral infection. This possibility may explain the consistent association between low-pathogenicity viruses, such as human rhinovirus, with radiographic pneumonia.[12,13] Further research is clearly needed in this area.

Host Defense

The overwhelming majority of infectious challenges to the lung are handled by the complex, highly effective host defense mechanisms of the upper and lower respiratory tracts.[14] Upper airway mechanisms include the branching anatomy of the conducting airways, mucociliary clearance, cough, and local airway defenses, including antimicrobial peptides such as lysozyme, lactoferrin, and other defensins, as well as secretory immunoglobulin (Ig) A and IgG. Alveolar macrophages are the main cellular component of host defense at the alveolar level, although alveolar epithelial cells also play a role.[15] Multiple antimicrobial peptides and other cells can participate in handling an infectious challenge. For example, surfactant proteins SP-A and SP-D are important for opsonization of bacteria and particles for ingestion by alveolar macrophages.

When local host defenses are inadequate to control an infectious challenge, the innate immune system is activated. This activation results in many other clinical manifestations of pneumonia. Release of endogenous pyrogens, such as tumor necrosis factor and interleukin (IL)-1, cause fever. Granulocyte colony-stimulating factor and IL-8 result in both peripheral and alveolar leukocytosis. A variety of cytokines result in a localized alveolar capillary leak in the area of infection, resulting in radiographic infiltrates and increased secretions. This inmate immune response is often adequate to control infection, even without antibiotic therapy. Microbial antigens are recognized by a variety of pathogen recognition receptors, such as the Toll-like receptors, and transported to regional lymph nodes where they are taken up by specialized dendritic cells and presented to responding lymphocytes to initiate adaptive immune responses. Humoral immunity can prevent development of clinical pneumonia but also facilitate resolution.

Invading microorganisms can overwhelm host defense for several reasons. The patient's immune response may be inadequate from underlying comorbid illness, anatomic abnormalities (endobronchial obstruction, bronchiectasis), disease-associated immune impairment, or therapy-induced dysfunction of the immune system (corticosteroids, endotracheal intubation). Pneumonia in patients with an adequate immune system can result from a large inoculum of bacteria (massive aspiration) or by a particularly virulent organism. Hereditary or acquired deficits in the immune system can be somewhat subtle or be first manifested in a patient who has developed pneumonia.

Antiinfective therapy of pneumonia only partially compensates for problems in the normal host defense mechanisms. Severely immunocompromised patients may still succumb to pneumonia despite provision of optimal antibiotics or other antiinfectives. Conversely, activation of intrinsic host defense mechanisms can cure pneumonia caused by even highly virulent pathogens, even without antibiotic therapy.

Resolution

Resolution of pneumonia is an active process, rather than simply discontinuation of the host immune response. Specific molecules, such as resolvins and protectins,[13] are needed to return the alveolus to its normal structure and function. In addition, antibiotic therapy may induce a significant change in the resident microbiota with long-lasting effects. An overexuberant inflammatory response may result in a persistent inflammatory state despite complete clearance of the original inciting pathogen. This aberrant resolution may result in well-defined syndromes, such as bronchiolitis obliterans organizing pneumonia, or fibroproliferative ARDS. However, a larger adverse effect may be in nonpulmonary organs, including delirium and critical care encephalopathy, increased risk of acute cardiovascular events,[16] and persistent acute kidney injury. These other adverse effects result in excess mortality within a year of hospitalization for pneumonia, compared to matched controls.

Community-Acquired (Community-Onset) Pneumonia

"Severe CAP" is used to define a group of critically ill patients affected with pneumonia, with a disease severe enough that requires hospitalization and most likely a higher level of care in the intensive care unit (ICU). The disease process is better understood as a continuum of complex interactions that go beyond the care delivered in the ICU setting. This continuum of care involves patients with severe CAP that could be initially suspected and recognized at the office, emergency department, or hospital ward and may progress to require ICU level of care. This view is important owing to the impact on poor clinical outcomes associated with severe CAP, such as pneumonia-related complications, longer hospital stay, high health care costs, and death.

CAP and influenza are the leading causes of death from infectious diseases in the United States and accounts for about 50,000 deaths a year.[17] In addition, the World Health Organization considers pneumonia the most relevant of the lower respiratory tract infections and the third leading cause of death globally and the number one cause of death in low-income countries.[18] The incidence of CAP is variable around the globe because of geographic variation, circulating pathogens, and host factors. In Europe the estimated incidence of CAP is 1.1 to 1.7/1000 patient-years and tends to be much higher in the elderly (≥65 years) with an estimate of 8/1000 patient-years. From 10% to 60% (higher rates in the elderly) may require hospitalization owing to CAP and, among the ones hospitalized, 10% to 20% required ICU admission. The main reasons for care in the ICU setting are need for mechanical ventilation (44%–53% of the patients) and vasopressor support for CAP patients with septic shock (50%). These patients with severe CAP tend to stay longer in the hospital compared with ward patients (23 days vs. 6 days) and have higher costs of care ($21,144 for ICU vs. $7500 for ward patients).[19] Despite advances in antimicrobial therapy and supportive measures, the mortality in this group of patients remains unacceptably high (21% to 58%). The main reasons associated with death in patients with severe CAP include refractory hypoxemia, refractory shock, other pneumonia- and cardiovascular-related complications, worsening or exacerbation of comorbid conditions, and multiorgan failure. Early recognition of patients with severe CAP is critical to rapidly institute strategies attempting to minimize the poor clinical outcomes.

Etiologies

The most common etiologic agents causing CAP are bacteria and viruses. Several studies evaluated the etiology of patients with severe CAP but, despite extensive laboratory testing, the causative pathogen is found in only about one-third of the patients, leaving two-thirds of patients without a presumptive etiologic agent.[12] However, ICU patients tend to have higher rates of causative pathogen recognition compared with patients on ward services.[20] This results from more testing in the ICU, the ability to reach the lower respiratory tract in patients requiring invasive mechanical ventilation, and likely higher pathogen loads,[21] making isolation more feasible.

The most common bacterial pathogen causing severe CAP is *S. pneumoniae*. However, many other bacterial pathogens are identified in severe CAP patients (Table 40.1). Mixed infections with typical and atypical pathogens occur in 5% to 40% of cases, and should always be considered to ensure patients are treated with appropriate empiric antimicrobial therapy. In addition, respiratory viral infection or coinfection is important, with involvement documented to be as high as 50%. Over the past decades, outbreaks and case reports of pneumonia caused by less commonly found viruses, such as avian influenza virus, enterovirus, severe acute respiratory distress coronavirus,[22] or Middle East respiratory syndrome coronavirus[23,24] have been increasingly reported.

The most common pathogens implicated with mortality are *S. pneumoniae*, *S. aureus* (particularly community-acquired methicillin resistant strain [CA-MRSA]), *Legionella pneumophila*, and *Pseudomonas aeruginosa*. The severity of pneumonia may be linked to multiple factors, including bacterial burden, virulence factors, geographic exposure, exposure to vectors or infected hosts, impairments of the immune system, and preexisting conditions (Table 40.2). Multiple conditions and patient populations are more vulnerable to acquire severe CAP, such as those with chronic illnesses, including pulmonary, cardiovascular, renal, neurologic, and liver diseases (Table 40.3).

Extensive interest previously focused on CAP cause by drug-resistant *S. pneumoniae* (DRSP). However, multiple studies were unable to confirm an association between drug-resistant *S. pneumoniae* and poor clinical outcomes. Rates of pneumonia owing to *S. aureus* have been increasing in the past 2 decades. CA-MRSA pneumonia has been linked to prior influenza infection.[25]

TABLE 40.1 Pathogens Associated With Severe Community-Acquired Pneumonia

Common	Less Common	Endemic Areas
Gram-Positive Cocci	*Mycoplasma pneumoniae*	*Mycobacterium tuberculosis*
Streptococcus pneumoniae (including DRSP)	*Chlamydia pneumoniae*	Nontuberculous mycobacteria
Staphylococcus aureus (including MRSA)	*Chlamydia psittaci*	*Coccidioides* spp.
Gram-Negative Bacilli	*Coxiella burnettii*	Histoplasmosis
Haemophilus influenzae	*Moraxella catarrhalis*	*Blastomycosis*
Klebsiella spp.	*Bordetella pertusis*	**Bioterrorism/Exposure**
Enterobacteriaceae	*Acinetobacter* spp.	*Francisella tularensis*
Pseudomonas aeruginosa	*Burkholderia pseudomallei*	*Yersinia pestis*
Legionella spp.	Anaerobic bacteria	*Bacillus anthracis*
Influenza virus	Other respiratory viruses	

DRSP, Drug-resistant *S. pneumoniae*; *MRSA,* methicillin-resistant *S. aureus.*

TABLE 40.2 Risk Factors Associated With Selected Pathogens in Patients With Severe Community-Acquired Pneumonia

Pathogens	Risk Factors
Common Pathogens	
Streptococcus pneumoniae	Smoking, COPD, influenza infection, low socioeconomic status, sulfur dioxide air pollution, alcoholism, dementia, seizures, congestive heart failure, CVD, HIV infection
DRSP	Alcoholism, β-lactams within 3 months, presence of more than one coexisting disease, immunosuppressive illness
Staphylococcus aureus	Decreased functional status, CVD, intravenous drug use, diabetes mellitus, renal failure, influenza
CA-MRSA	Skin infections, prior influenza infection
Haemophilus influenzae	COPD, smoking, bronchiectasis
Legionella spp.	Chronic steroid use, hematologic malignancy, humid weather, smoking, diabetes mellitus, cancer, ESRD, HIV infection, epidemic events
Influenza virus	Air pollutants (nitrogen oxide, ozone, and particulate matter), winter season
Anaerobes	High dental plaque index, poor dental hygiene, periodontal disease, alcoholism, aspiration
Less Common Pathogens	
Francisella tularensis	Exposure to rabbits
Coxiella burnetti (Q fever)	Exposure to farm animals or parturient cats
Chlamydia psittaci	Exposure to birds
Histoplasma capsulatum	Exposure to bats, soil contaminated with bird droppings
Coccidioides spp.	Travel to southwestern areas of the United States

CA-MRSA, Community-associated methicillin-resistant *S. aureus; COPD,* chronic obstructive pulmonary disease; *CVD,* cerebrovascular disease; *DRSP,* drug-resistant *S. pneumoniae; ESRD,* end-stage renal disease; *HIV,* human immunodeficiency virus.

P. aeruginosa has been reported in severe CAP patients with specific risk factors, such as chronic or prolonged use of broad-spectrum antibiotic therapy, bronchiectasis, malnutrition, HIV, and immunosuppression.[26]

Diagnosis

Clinical and Radiologic

The most common symptoms are fever, chills, nonproductive or productive cough, pleuritic chest pain, and shortness of breath. Less frequently patients may present with diarrhea; new-onset or worsening confusion, particularly in elderly patients; and headache. On physical examination, patients are hyperthermic or hypothermic, tachypneic, and tachycardic. Lung examination reveals dullness on percussion, increased tactile and vocal fremitus, bronchial breath sounds, and egophony. Auscultation findings include crackles, whispering pectoriloquy, egophony, and pleural friction rub. Distant manifestations of pneumonia include involvement of the joints with arthritis, heart with endocarditis, and meninges with meningeal signs. Infections caused by "atypical pathogens," such as *Mycoplasma pneumoniae* or *Chlamydia pneumoniae,* can lead to complications such as bullous myringitis, skin rash, pericarditis, hepatitis, hemolytic anemia, or meningoencephalitis.

In the elderly or those with comorbid conditions, elevated respiratory rate can be the initial presenting sign of pneumonia, preceding other clinical findings by as much as 1 to 2 days.[27] Respiration rates more than 30 breaths/min indicate an increased pneumonia severity and are usually included in severity of illness scores. Overall, the clinical diagnosis of pneumonia has moderate sensitivity (79%) and specificity (66%). Given this lack of specificity, clinical characteristics suggestive of a pneumonic process require further confirmation by imaging.

TABLE 40.3 Risk Factors Associated With Severe Community-Acquired Pneumonia

Demographics
Age
Genetic polymorphisms
Male gender
Humid weather
Low socioeconomic status
Winter season

Cardiovascular Conditions
Coronary artery disease
Congestive heart failure

Pulmonary Conditions
Asthma
COPD
Chronic systemic or inhaled corticosteroids
Bronchiectasis

Neurologic Conditions
Cerebrovascular disease
Decrease functional status
Dementia
Seizure

Immunosuppressive Conditions
HIV/AIDS
Malignancies
Chemotherapeutic agents
Endocrine conditions
Diabetes mellitus

Renal Conditions
Acute renal failure
Chronic renal failure and ESRD
Need for dialysis

Liver Conditions
Chronic liver disease
Cirrhosis

Exposures
Alcohol
Air pollutants
Intravenous drug use
Prior antibiotic therapy
Smoking
Influenza and other viral infection
Proton pump inhibitors
Skin infections
Prior MRSA colonization
Prior *Pseudomonas aeruginosa* colonization
Severe dental plaque/periodontal disease

COPD, Chronic obstructive pulmonary disease; *ESRD*, end-stage renal disease; *HIV*, human immunodeficiency virus.

The classic imaging includes alveolar filling densities with air bronchograms or peribronchial infiltrates; diffuse ground-glass changes are also common. The chest radiograph may be suboptimal in patients with early infection (especially with volume depletion), severe granulocytopenia, bullous emphysema, and obesity. In those instances, a repeat chest radiograph in 24 to 48 hours is reasonable. CAP severity correlates radiologically with multilobar and bilateral infiltrates, cavitation, or a loculated pleural effusion (suggesting an empyema). Chest radiographic patterns are generally not useful for identifying the cause of CAP, although findings such as pleural effusion (*Pneumococcus, Haemophilus influenzae, M. pneumoniae,* pyogenic streptococci) and cavitation (*P. aeruginosa, S. aureus*, anaerobes, tuberculosis) can suggest certain groups of organisms.

Chest computed tomography (CT) scan has better sensitivity in diagnosing pulmonary infiltrates suggestive of pneumonia, as well as excluding pneumonia in patients with borderline findings.[28,29] In emergency department patients with suspected CAP, chest CT scan results markedly affect diagnosis, treatment, and decision for site of care.[28] However, analysis of cost-effectiveness and actual implementation strategies in different resource settings are clearly needed before routine use.

Use of chest ultrasound for diagnosis of pneumonia has become more common and facilitates the diagnosis of parapneumonic pleural effusions and subsequent sampling of pleural fluid. Point-of-care ultrasound is frequently used in the ICU to avoid unnecessary chest radiographs and decrease radiation. Multiple systematic reviews and meta-analyses confirm that sensitivity and specificity are excellent.[30–33] The most common consolidation pattern on point-of-care lung ultrasound includes a large, compact mass without volume loss. On occasion, a "shred sign" appears at the interface between partially aerated alveoli and completely airless or fluid-filled alveoli from the pneumonic process. Pneumonic infiltrates often contain dynamic air bronchograms—mobile, hyperechoic, punctiform areas due to trapped air bubbles within the bronchi that move with respirations—which are rarely seen in atelectasis. The accuracy of lung ultrasound is limited by some patient factors but mainly the competence of the operator.

Laboratory Testing

A complete blood cell count, chemistry panel, lactic acid, and arterial blood gas analysis are recommended in all patients with severe CAP. Leukopenia and leukocytosis are seen in patients with severe CAP owing to *Pneumococcus* or gram-negative organisms.[34] Several abnormalities observed in the complete blood cell count, such as leukopenia, thrombocytosis, and thrombocytopenia, are associated with poor prognosis in patients with severe CAP.[2] Hyponatremia and hyperglycemia on admission are associated with poor outcome in CAP patients. Increased levels of blood urea nitrogen and creatinine are considered markers of severity in patients with CAP, indicate systemic organ dysfunction, and are associated with poor clinical outcomes. Elevated liver function test results can be seen in a variety of viral and bacterial pneumonias secondary to atypical agents such as *Legionella* spp. and *Mycoplasma* spp., Q fever, tularemia, and psittacosis, as well as in pneumococcal infection. Acidosis, hypoxemia, and alternations of carbon dioxide are frequently overlapping in patients with chronic comorbid conditions and are associated with high mortality.[35–39]

Microbiologic Testing

The American Thoracic Society (ATS)/Infectious Diseases Society of America (ISDA) 2007 guidelines recommend that patients with severe CAP should have two sets of blood cultures.[2] Culture results are more likely to be positive if the patient has not received antibiotics at the time of sampling or has any of the following risk factors: underlying liver disease, systolic blood pressure less than 90 mm Hg, temperature less than 35°C or greater than 40°C, pulse higher than 125 beats/min, blood urea nitrogen greater than 10.7 mmol/L (30 mg/dL), serum sodium less than 130 mmol, and leukocyte count less than 5000 or greater than 20,000 cells/mL.[40] Blood cultures should also be considered in patients with asplenia, cavitary infiltrates, or a history of ongoing alcohol abuse.[34] The presence of bacteremia may not indicate worse prognosis but does allow identification of drug-resistant organisms; most positive blood culture results in CAP reveal *Pneumococcus*.

Respiratory samples, including sputum Gram stain and culture, may assist clinicians in identifying the probable cause of severe CAP, but the results must be assessed carefully to distinguish between normal flora, colonization, or infection. Gram stain can be used to broaden initial empiric therapy to cover pathogens resistant to usual empiric therapy such as MRSA (presence of clusters of gram-positive cocci, particularly during influenza season). A sputum sample that contains less than 10 squamous epithelial cells and more than 25 polymorphonuclear cells per low-power field enhances the value of the sputum culture results in patients with severe CAP. Collection of invasive respiratory samples by bronchoscopic or nonbronchoscopic techniques is highly recommended in patients with severe CAP, who tend to have higher rates of microbial pathogens recovered at the time of pneumonia.[20] Respiratory sampling, including endotracheal aspirates obtained from patients with severe CAP requiring ventilation, assist with the diagnosis, direct changes of empiric antimicrobial therapy according to the culture results, and potentially alter duration of antibiotics. Open lung biopsy is rarely needed to diagnose severe CAP and is reserved principally for highly immunocompromised patients not responding to appropriate standard treatments or in patients with suspected pneumonia mimics, such as inflammatory lung disease, eosinophilic pneumonia, acute interstitial pneumonia, diffuse alveolar hemorrhage, or malignancy. The development of molecular diagnostic tests has largely obviated the need for open lung biopsy for diagnosis of *Aspergillus* spp., cytomegalovirus, *Cryptococcus* spp., *Blastomyces, Histoplasma, Nocardia* spp., and *Toxoplasma gondii* and other fastidious pathogens.

Serologic testing is not routinely recommended in patients with severe CAP. Serologic testing, requiring acute and convalescent collections several weeks apart with a fourfold increase in titers to confirm the diagnosis, is impractical at the site of care. In addition to the questionable value of a single acute result, uncertainty regarding whether the patient will survive to get the diagnosis-confirming convalescent sample and location of the patient at the time convalescent serology is needed create logistic barriers. Therefore routine serologic testing for atypical pathogens such as *C. pneumoniae, Coxiella burnetii* (Q fever), *Chlamydia psittaci*, *Legionella,* and *M. pneumoniae* is reserved for epidemiologic evaluations.

Patients with severe CAP at risk for *Legionella* infection should be tested with *Legionella* urinary antigen, which tends to be positive at the time of admission if the patient is infected with *L. pneumophila* serogroup I infection (which accounts for 70%–80% of legionella cases). A positive *Legionella* urinary antigen test result should be accompanied by culture confirmation on special charcoal-containing agar. Pneumococcal urinary antigen has a sensitivity of 50% to 80% and specificity of more than 90%.[41] False-positive test results are seen in patients who had pneumonia within the previous 3 months.

Polymerase chain reaction (PCR) assays are used for the detection of viruses (as was the case in the H1N1 epidemic) and other agents such as *M. tuberculosis*. They have now become the standard for diagnosis of respiratory viruses, as well as *Mycoplasma* and *Chlamydophila*.[12] PCR assays, usually performed on nasal or oropharyngeal swabs of lower respiratory tract samples, have additional sensitivity and increase the probability that the virus is causative of pneumonia rather than simple persistent shedding from an upper respiratory tract infection. Direct immunofluorescence or enzyme immunoassay can also be used to detect viral antigens such as influenza, parainfluenza, respiratory syncytial virus, and adenovirus. The impact of a positive test result on management of CAP is still unclear, but a negative test result is valuable in directing a focused antibiotic regimen.

Biomarkers

Inflammatory biomarkers such as C-reactive protein (CRP), procalcitonin (PCT), midregional proadrenomedullin, midregional proatrial natriuretic peptide, proarginine-vasopressin, proendothelin-1, and the ILs have been used to distinguish bacterial infection from viral infection. Inflammatory biomarkers such as PCT, CRP, tumor necrosis factor α, and IL-6 levels tend to be higher in patients admitted to the ICU, including those with delayed ICU admission, compared with patients not needing ICU care. CRP is a biomarker that may be of use in patients with less disease to determine site of care. But CRP is nonspecifically elevated with any inflammatory state, such as severe CAP,[42] and therefore lacks discriminating value for complications, such as parapneumonic effusion or empyema. PCT, the peptide precursor of the hormone calcitonin, is a "hormokine" (a hormone with cytokine-like behavior) with a half-life of 25 to 30 hours. PCT is produced in response to bacterial microbial toxins but is inhibited by virus-related cytokines. Serum levels tend to be high in patients with severe bacteremic CAP, and serial measurements help guide the duration of antibiotic therapy.[43] All the other biomarkers remain in the investigational phase and the application in clinical practice is pending.

Management

Traditionally, antimicrobials have been considered the cornerstone of therapy against severe CAP. However, with the understanding of severe CAP as a systemic disease, other non-antimicrobial therapies should be considered for management of this group of patients.

Site-of-Care Decision

The site-of-care decision is critical for patients with CAP because it affects the diagnostic workup, the therapeutic interventions, and the clinical outcomes.[2] Therefore significant interest has been generated in this area of research over the past decades.

Several tools have been developed to predict mortality and determine the site of care for patients with severe CAP.[2] Two extensively studied and validated tools have been recognized and are recommended by the multiple clinical practice guidelines related to CAP (Table 40.4).[44] The Pneumonia Severity of Illness (PSI) score and the CURB-65 are the most frequently cited scores for aiding the decision for hospital admission. The PSI is based on 20 parameters that are evaluated at the time of clinical presentation and consists of three demographic, five comorbid conditions, five physical examination findings, and seven laboratory/imaging variables. The goal of this tool is to identify patients who can be discharged safely and receive home treatment with antibiotic therapy. However, the PSI score is heavily influenced by age, and it does not include certain comorbid conditions frequently found in patients with CAP, such as diabetes and COPD. In contrast, the second score—CURB-65, a six-variable tool that includes *c*onfusion, *u*rea, *r*espiratory rate, *b*lood pressure, and age above *65* years—is less complex.[45] An even simpler tool resulting from withdrawing the only laboratory value needed to calculate the score (blood urea nitrogen), named CRB-65, was validated with similar results. However, the CURB-65 score does not recognize any comorbid conditions previously associated as risk factors for CAP and does not include low oxygen levels as one of the criteria. Therefore these tools have value to designate low-risk patients but are not ideal to recognize patients at high risk of death.

TABLE 40.4 Different Systems Evaluated by the Most Relevant Severe Community-Acquired Pneumonia Severity Scores

Variable	IDSA/ATS 2007 Criteria[a]	PS-CURX080[b]	SMART-COP[c]	CAP-PIRO[d]	qSOFA[e]	SOFA[f]	PSI[g]	CURB-65[h]

Hematologic dysfunction	✓					✓	✓	
Metabolic dysfunction	✓		✓			✓	✓	
Microbiologic				✓				

[a]IDSA/ATS score evaluates two major criteria (need for mechanical ventilation with endotracheal intubation and/or septic shock requiring vasopressors) and nine minor criteria: respiratory rate respiratory rate >30 breaths/min; arterial partial pressure of oxygen/fraction of inspired oxygen (Pa_{O_2}/F_{IO_2}) ratio <250; multilobar infiltrates, confusion/disorientation, uremia with serum blood urea nitrogen >20 mg/dL; leukopenia with white blood cell count <4000 cells/mm^3; thrombocytopenia (platelet count <100,000 cells/mm^3), hypothermia (core temperature <36°C); hypotension requiring agressive fluid resuscitation.

[b]PS-CURX080 predicts the diagnosis of severe community-acquired pneumonia and includes arterial pH < 7.30, *s*ystolic blood pressure <90 mm Hg, *c*onfusion (or altered mental status), blood *u*rea nitrogen >30 mg/dL, *r*espiratory rate >30 breaths/min, multilobar/bilateral lung infiltrates (by *x*-ray), *o*xygen arterial pressure <54 mm Hg or ratio of arterial oxygen tension to fraction of inspired *o*xygen <250 mm Hg, and age ≥*80* years.

[c]SMART-COP measures a low *s*ystolic blood pressure (1 point), *m*ultilobar chest radiography involvement (1 point), low *a*lbumin level (1 point), high *r*espiratory rate (age-adjusted) (1 point), *t*achycardia (1 point), *c*onfusion (1 point), poor *o*xygenation (age-adjusted) (2 points), and low arterial pH (<7.35) (2 points).

[d]CAP-PIRO score measures *Predisposition*: comorbidities (chronic obstructive pulmonary disease or immunocompromised) (1 point), age >70 years (1 point); *Infection:* bacteremia (1 point), multilobar opacities (1 point); *Response*: shock (1 point), severe hypoxemia (1 point); and *Organ dysfunction*: acute respiratory distress syndrome (1 point), acute renal failure (1 point).

[e]Quick Sequential Organ Failure Assessment (qSOFA) measures respiratory rate >22 breaths/min (+1 point); change in mental status (+1 point); systolic blood pressure <100 mm Hg (+1 point).

[f]Sequential Organ Failure Assessment (SOFA) score measure the following variables on a scales from 0 to 4, respiratory: Pa_{O_2}/F_{IO_2} (in mm Hg); coagulation (platelets ×103/μL); liver (bilirubin in mg/dL); cardiovascular hypotension and use of vasopressors (dopamine and norepinephrine at different dosages); central nervous system (Glasgow Coma Scale score); renal (creatinine in mg/dL or urine output, mL/day).

[g]PSI Score measures age (men [points = age in years] and women [points = age in years – 10]); nursing home resident (+10 points); coexistent neoplastic illness (+30 points); coexistent liver disease (+20 points); coexistent congestive heart failure (+10 points); coexistent cerebrovascular disease (+10 points); coexistent renal disease (+10 points); altered mental status (+20 points); respiratory rate ≥30 breaths/min (+20 points); systolic blood pressure <90 mm Hg (+20 points); temperature <35°C or ≥40°C (+15 points); pulse >125 beats/min (+10 points); arterial pH < 7.35 (+30 points); blood urea nitrogen ≥30 mg/dL (+20 points); sodium <130 mmol/L (+20 points); glucose ≥250 mg/dL (+10 points); hematocrit <30% (+10 points); Pa_{O_2} <60 mm Hg or oxygen saturation <90% (+10 points); pleural effusion (+10 points).

[h]CURB-65 is derived from *c*onfusion (altered mental status); serum blood *u*rea nitrogen >19.6 mg/dL; *r*espiratory rate >30 breaths/min; *b*lood pressure (BP) (BP – Systolic BP <90 mm Hg or diastolic BP <60 mm Hg); and age ≧*65* years.

Specific objective tools have been tested to identify patients with severe CAP with increased likelihood of need for ICU care when used in conjunction with clinician experience and clinical judgment. They all have in common the inclusion of parameters that assess organ dysfunction (see Table 40.4). These tools include the IDSA/ATS major and minor criteria,[2] PS-CURXO80,[39] SMART-COP,[37] PIRO-CAP,[46] qSOFA (quick Sequential [sepsis-related] Organ Failure assessment),[47,48] and SOFA scores.[48,49] The IDSA/ATS CAP guidelines in 2007 recommend the need for ICU admission for those patients with one of the major criteria (mechanical ventilation with endotracheal intubation and/or septic shock requiring vasopressors) or for patients with three of the nine minor criteria: hypotension requiring aggressive fluid resuscitation; confusion/disorientation; blood urea nitrogen greater than 20 mg/dL; respiratory rate greater than 30 breaths/min; multilobar lung infiltrates; ratio of arterial oxygen tension to fraction of inspired oxygen (Pa_{O_2}/F_{IO_2}) less than 250 mm Hg; leukopenia (<4000/mm^3); thrombocytopenia (<100,000/mm^3); or hypothermia (<36°C core).[2] Several minor criteria are uncommon and less helpful; conversely, a low pH may have additional discriminating value. Several studies have validated these criteria to admit patients to the ICU[50,51] and also applied them in other groups of patients, including elderly patients and patients infected with HIVs. The PS-CURXO80 predicts the diagnosis of severe CAP and includes these measures arterial pH < 7.30; *s*ystolic blood pressure less than 90 mm Hg; *c*onfusion (or altered mental status); blood *u*rea nitrogen greater than 30 mg/dL; *r*espiratory rate greater than 30 breaths/min; multilobar/bilateral lung infiltrates (by *x*-ray); *o*xygen arterial pressure less than 54 mm Hg or ratio of arterial oxygen tension to fraction of inspired *o*xygen (Pa_{O_2}/F_{IO_2}) less than 250 mm Hg; and age ≧*80* years.[39] The evaluation of severe CAP is based on the presence of one major criterion (PS) or two or more minor criteria (CURXO80). The model showed an area under the curve of 0.92 to accurately predict severe CAP. SMART-COP predicts the need of intensive respiratory and vasopressor support, by measuring low *s*ystolic blood pressure (1 point); *m*ultilobar chest radiography involvement (1 point), low *a*lbumin level (1 point); high *r*espiratory rate (age-adjusted) (1 point); *t*achycardia (1 point); *c*onfusion (1 point); poor *o*xygenation (age-adjusted) (2 points); and low arterial *p*H (<7.35) (2 points).[37] A SMART-COP score of 3 points or higher identified 92% of patients who received intensive respiratory care or vasopressor support, including 84% of patients who did not need immediate admission to the ICU. The CAP-PIRO score is based on the score suggested for the risk of sepsis and evaluates the following variables: *p*redisposition: comorbidities (COPD or immunocompromised) (1 point); age older than 70 years (1 point); *i*nfection: bacteremia

(1 point); multilobar opacities (1 point); *r*esponse: shock (1 point); severe hypoxemia (1 point); *o*rgan dysfunction: ARDS (1 point); and acute renal failure (1 point).[52] Based on the observed mortality with each PIRO score, the patients were stratified in four levels of risk as (1) low (0–2 points; (2) mild (3 points); (3) high (4 points); and (4) very high (5–8 points). Recent validation of qSOFA that includes a respiratory rate above or equal to 22 breaths/min, alteration of mentation, and a systolic blood pressure less than or equal to 100 mm Hg, lack specificity for pneumonia. In patients with pneumonia, qSOFA outperformed the systemic inflammatory response syndrome but was inferior to the PSI score.[53] In addition, a modified SOFA (mSOFA) may assist in predicting mortality and ICU admission, but more information is needed before changing practice. Although all severity criteria scores assess risk of death and the potential need for ICU care, because of the complexities in evaluating each one of them perhaps the most useful in clinical practice remains the IDSA/ATS major and minor criteria for severe CAP.

Empirical Antibiotics

Several professional organizations developed clinical practice guidelines with the objective of standardizing therapy for CAP following an evidence-based medicine approach.[2,54–56] Guidelines include specific recommendations for patients with severe CAP usually managed in the ICU. The guidelines emphasized the importance of appropriate, aggressive, and early management of patients with CAP who are cared for in the ICU. Combination antibiotics should be initiated as early as possible, as is recommended for patients with sepsis or septic shock, to prevent poor clinical outcomes (Table 40.5). Patients should be stratified according to the risk for *P. aeruginosa* infection.[26,57] If a patient has no risk factors for *Pseudomonas* infection, the treatment should always include two antibiotics: one β-lactam (such as cefotaxime, ceftriaxone, ceftaroline, ertapenem, a β-lactam/β-lactamase inhibitor combination) that will cover *Pneumococcus* (including drug-resistant isolates) and other likely respiratory pathogens; and therapy against atypical pathogens, especially *Legionella* spp., such as a macrolide (azithromycin or clarithromycin) or a respiratory fluoroquinolone (levofloxacin at the highest dose of 750 mg/day or moxifloxacin). Ceftaroline, a fifth-generation cephalosporin with anti-MRSA activity, shows higher cure rates and less *Pneumococcus* resistance compared with ceftriaxone.[58]

Severe CAP patients with *P. aeruginosa* risk factors, such as structural lung disease (e.g., bronchiectasis), therapy with broad-spectrum antibiotics for more than 7 days in the past month, use of corticosteroids (>10 mg of prednisone daily), malnutrition, and/or HIV infection should receive antipseudomonal therapy. The treatment should include an initial empiric combination of appropriate anti-pseudomonal coverage with antipneumococcal coverage (with a β-lactam anti-pseudomonal therapy, such as imipenem, meropenem, piperacillin/tazobactam, cefepime, ceftazidime) plus an anti-pseudomonal fluoroquinolone (levofloxacin 750 mg/day or ciprofloxacin 400 mg three times a day). For quinolone-allergic patients, aminoglycosides can be substituted, but lack of atypical pathogen coverage mandates addition of a macrolide or doxycycline. Failure to identify a pathogen has not been associated with a worse outcome particularly in the severely ill, but the empiric regimen should cover *S. pneumoniae* and atypical pathogens. In conclusion, the recommendation is empirical combination therapy with two or more antimicrobial agents according to the risk of *Pseudomonas* infection and the consistent atypical coverage mainly for *Legionella* infection.

Despite a strong recommendation,[2] evidence regarding the use of combination empirical therapy is limited to a few randomized control trials,[59–61] and most data are from observational studies of combination therapy versus monotherapy in large populations that include patients with severe CAP admitted to the ICU.[62–64] Because of the limited data and significant heterogeneity between studies, further randomized control trials have been recommended to clarify these questions. Systematic reviews of observational studies suggest that combination therapy of β-lactam agent plus a macrolide for initial empiric therapy reduces mortality in patients with severe CAP.[65] National practice guidelines strongly recommend that locally adapted guidelines should be implemented to improve process-of-care variables and relevant clinical outcomes. Other publications have consistently found a decrease in mortality with the introduction of guideline-concordant antimicrobial therapy or guideline-based protocols.[61,66] Several of the quality indicators—early administration

TABLE 40.5 Antibiotic Therapy for Management of Patients With Severe Community-Acquired Pneumonia

Pathogen Attempted Coverage	Empiric Antibiotic Recommended Alternatives
Streptococcus pneumoniae (including DRSP), *Legionella* spp., *Haemophilus influenzae,* enteric gram-negative bacilli, methicillin-susceptible *Staphylococcus aureus*	Intravenous β-lactams (cefotaxime, ceftriaxone, ceftaroline, ertapenem, ampicillin/sulbactam) *plus* a macrolide (azithromycin or clarithromycin). Intravenous β-lactams (cefotaxime, ceftriaxone, ceftaroline, ertapenem, ampicillin/sulbactam) *plus* a respiratory fluoroquinolone (levofloxacin with the highest dose of 750 mg/day, or moxifloxacin).
Add or Adjust Therapy if Suspected or Risk Factors Present	**Empiric Antibiotic Recommended Alternatives**
MRSA	Add vancomycin or linezolid
Pseudomonas aeruginosa	Intravenous antipseudomonal β-lactam therapy (imipenem, meropenem, piperacillin/tazobactam, cefepime, ceftazidime) *plus* an antipseudomonal fluoroquinolone (levofloxacin 750 mg/day or ciprofloxacin 400 mg three times a day) Intravenous antipseudomonal β-lactam therapy (imipenem, meropenem, piperacillin/tazobactam, cefepime, ceftazidime) *plus* aminoglycosides (amikacin, tobramycin, or gentamicin). *Add* anti-*Legionella* coverage with a respiratory fluoroquinolone, macrolide, or doxycycline.

DRSP, Drug-resistant *S. pneumoniae*; *MRSA,* methicillin-resistant *Staphylococcus aureus.*

of antibiotics, appropriate antibiotic use following the clinical practice guidelines, use of a critical pathway, switch to oral therapy, and early discharge—have all shown improved clinical outcomes in CAP.

In addition to antibiotic therapy, patients with severe CAP with suspected or confirmed influenza virus infection should receive early treatment with oseltamivir or zanamivir in addition to antibiotic treatment, even if the duration of symptoms is longer than 3 days. Outcome is affected by time to initiation of therapy.[67]

Little information exists on the proper duration of therapy in patients with severe CAP. Even in the presence of pneumococcal bacteremia, short durations of therapy may be possible, with a rapid switch from intravenous to oral therapy in responding patients. Generally, *S. pneumoniae* can be treated for 5 to 7 days if the patient is responding rapidly and has received accurate empiric therapy at the correct dose. The presence of extrapulmonary infection (such as meningitis) and the identification of certain pathogens (such as bacteremic *S. aureus*, and *P. aeruginosa*) may require longer durations of therapy. Identification of *L. pneumophila* pneumonia may require at least 14 days of therapy, depending on severity of illness and host defense impairments. However, quinolone therapy may be the best approach to management and durations as short as 5 days may be effective.[68–70] Biomarkers, especially PCT, can assist in shortening duration of therapy for patients with severe CAP and avoid unnecessarily prolonged use of antibiotics and prevent antibiotic-related adverse events.[43] The switch to oral therapy, even in severely ill patients, may be facilitated by the use of quinolones because of the excellent bioavailability between systemic and oral formulations.

Specific Antibiotics

Patients not responding to initial therapy should raise the concern of antimicrobial-resistant pathogens. Dual therapy including a macrolide has been associated with improved outcomes for severe CAP patients with bacteremic pneumococcal pneumonia. Most experts recommend that CA-MRSA be targeted in patients with severe, necrotizing CAP, including those with empyema, after a viral illness, particularly influenza. Severe CAP patients with prior MRSA infection or colonization can receive empiric or direct therapy with vancomycin or linezolid. However, many adverse manifestations in CAP patients with Panton-Valentine leukocidin (PVL)-toxin–secreting *S. aureus* strains are toxin mediated and addition of agents that inhibit the toxin production such as clindamycin and linezolid are associated with lower mortality compared with β-lactams or vancomycin.[71]

Even with severe CAP, most patients become afebrile by day 3 to 5 and most have an objective clinical response by day 3. Nonresponding patients with CAP should be evaluated for alternative diagnoses (inflammatory lung disease, atelectasis, heart failure, malignancy, pulmonary hemorrhage, pulmonary embolus, a nonpneumonic infection); a resistant or unusual pathogen (including tuberculosis and fungal infection); a pneumonia complication (empyema, lung abscess, drug fever, antibiotic-induced colitis, bronchopleural fistula); or a secondary site of infection (central line infection, intraabdominal infection).[72] The evaluation of a nonresponding patient should be individualized but may include CT scanning of the chest, pulmonary angiography, bronchoscopy, and occasionally open lung biopsy.

Adjunctive Therapy

With a comprehensive approach, non-antimicrobial therapies focus on early supportive therapy for patients with evidence of severe CAP.

Respiratory Support

Patients with severe CAP may present with different degrees of hypoxemia and impending respiratory failure requiring respiratory support. The respiratory support can be provided by invasive and noninvasive methods. Avoiding the need for invasive mechanical ventilation is preferred, if possible, to prevent risks such as ventilator-induced lung injury, VAP, neurocognitive sequelae, and increased hospital and ICU length of stay. Noninvasive respiratory support when possible could be delivered by low-flow nasal cannula, simple face mask, Venturi mask, nonrebreather mask, noninvasive positive-pressure ventilation (NIPPV), or high-flow nasal cannula. The type of delivery device used depends on severity of the disease, degree of hypoxemia, and cause of acute respiratory failure. A low-flow nasal cannula delivers dry oxygen at 1 to 6 L/min via small prongs placed on the nares. Other oxygen delivery devices, such as nonrebreather masks, can deliver 5 to 15 L/min of oxygen, and some of these devices can add humidification to the oxygen delivery. For patients with hypercarbia and need for tightly controlled oxygen levels, such as those with COPD, Venturi masks can deliver 24% to 60% oxygen at a flow of 2 to 5 L/min.

NIPPV can be used with supplemental oxygen in addition to the support for the mechanical process of ventilation. Studies have shown that patients with cardiogenic pulmonary edema or acute exacerbation of COPD, rather than CAP, are most likely to benefit with this intervention. However, poor tolerance of NIPPV because of gastric distention, patient discomfort, and inability to communicate, expectorate, or achieve nutrition goals is a limitation. NIPPV should be used with caution in patients with severe CAP, particularly if two of the limitations for NIPPV are present. Delaying the decision to intubate and begin invasive mechanical ventilation has been associated with worse outcomes.[73] Because of problems with NIPPV, a high-flow nasal cannula that delivers blended humidified air and oxygen at a prescribed FIO_2 at high flow rates via a wide-bore nasal cannula is gaining acceptance for the management of patients with impending respiratory failure.[74]

Severe CAP is the most common cause of acute lung injury/ARDS. Therefore patients with severe CAP who require invasive mechanical ventilation should receive a low tidal volume strategy with tidal volume (VT) of 6 mL/kg predicted body weight and positive end-expiratory pressure (PEEP) as recommended for ARDS.[75] For severe CAP patients with refractory hypoxemia despite these ventilatory interventions, other refractory ARDS therapies such as prone positioning, neuromuscular blockade, and initiation of extracorporeal membrane oxygenation (ECMO) should be strongly considered.[76] Prone positioning has shown improved survival in patients with severe ARDS with FIO_2 below 100 to 150.[77] ECMO therapy came into more prominence as salvage therapy for severe H1N1 pneumonia despite associated prolonged duration of ventilatory support, ICU length of stay, and high mortality. The beneficial effect of ECMO in all forms of severe CAP is lacking; however, review of an ECMO registry suggests some of the best outcomes are for patients with pneumonia.[78]

Corticosteroids

Many studies show increased pulmonary and systemic inflammatory cytokine levels in patients with severe CAP. Among ICU patients, higher circulating inflammatory cytokine levels correlate with the presence of bilateral pneumonia, bacteremia, need for mechanical ventilation, and multiple-organ dysfunction syndrome.[79] Balance between proinflammatory and antiinflammatory cytokines is critical in the host response. The fact that inflammatory markers, such as IL-6, IL-8, and IL-10, are elevated in patients with severe CAP

and decrease in the first few days of appropriate antibiotic therapy suggests use of immunomodulators and antiinflammatory medications, such as macrolides or corticosteroids, may be a beneficial adjunct to reduce the proinflammatory cytokines. Meta-analysis suggests a benefit of corticosteroids,[80] particularly in patients with severe CAP,[81] with hyperglycemia as the most important adverse consequence. A prospective randomized controlled trial (RCT) also showed a lower rate of late treatment failure when steroids were used as adjunctive therapy in CAP.[42] Adjunctive corticosteroids in patients with severe H1N1 pneumonia with ARDS and severe acute respiratory distress were associated with an increased mortality,[82,83] suggesting harm from their use in severe viral CAP. Given the currently available data, corticosteroids should not be part of routine therapy of severe CAP.[61] In special situations, however, steroids may have value. Patients with *P. jiroveci* pneumonia clearly benefit from corticosteroid therapy if the initial arterial oxygen tension is less than 70 mm Hg, by attenuating some of the inflammation induced by antibiotic killing of the organisms.[84] In patients with pneumonia and refractory shock, some investigators still consider using corticosteroids to treat relative adrenal insufficiency despite no benefit in a large prospective randomized trial of sepsis.[85,86]

Hospital-Acquired Pneumonia/Ventilator-Associated Pneumonia

Etiologies

The bacterial etiology of HAP/VAP varies somewhat by the type of ICU and patient population (Table 40.6). Usual CAP pathogens, such as methicillin-sensitive *S. aureus, Escherichia coli*, and even *Pneumococcus,* can cause pneumonia in the ICU with low acuity and limited use of prior antibiotics. As the patient population increases in severity of illness, duration of prior hospitalization, and exposure to antibiotic therapy, the spectrum of etiologies shifts to more drug-resistant pathogens, with MRSA, *P. aeruginosa*, *Acinetobacter* spp., and MDR Enterobacteriaceae most common. Of the Enterobacteriaceae, *Klebsiella* spp., *Enterobacter* spp., and *E. coli* are most common but a wide spectrum of other bacteria in this family can cause pneumonia. This variable spectrum of pathogens has important implications for empirical antibiotic therapy.

Attempts to clinically define groups of patients at low risk for MDR pathogens have been somewhat frustrating. Recent studies of large academic medical centers have found that only 10% or fewer of patients with suspected pneumonia in the ICU did not have risk factors for drug-resistant pathogens.[87] This may reflect improved prevention practices in the ICU that decrease the risk of early-onset pneumonia while having a lesser effect on HAP/VAP owing to MDR pathogens. An alternative possibility is that antibiotic treatment has become so ubiquitous in the ICU that CAP pathogens are never isolated when a patient develops HAP/VAP.

Unfortunately, risk factors for MDR pathogens have little discriminating value. The risks for MRSA and *Pseudomonas*, pathogens that would require distinct empirical antibiotic choices, overlap substantially with that of Enterobacteriaceae treated with a single β-lactam antibiotic. This lack of discrimination has led professional society guideline committees to recommend empirical triple-drug regimens for a large proportion of patients with suspected HAP/VAP.[5,6]

Anaerobes are the one group of pathogens with a very minor role in HAP/VAP. For ventilated patients, the high oxygen tension is adequate anaerobic coverage. This includes patients who may have an episode of small volume aspiration at the time of intubation. β-Lactams with no anaerobic activity, such as cefipime, have equivalent outcomes to those with anaerobic coverage. The one exception may be nonventilated patients with poor oral hygiene and prone to atelectasis; in this setting, a high anaerobic inoculum and low local oxygen tension may allow anaerobes to play a role, although seldom the dominant role.[8]

Other pathogens are markers of prolonged critical illness with persistent immunologic suppression or immunoparalysis of critical illness.[88] These include *Stenotrophomonas maltophilia*, *Burkholderia cepacia*, and opportunistic fungi, including *Aspergillus* and *Mucor* spp. Reactivation of latent viruses such as cytomegalovirus (CMV) and herpes viruses also occur in this setting. The benefit of treatment for these viruses is inconclusive, suggesting that they may be simply markers of immunosuppression rather than independent pathogens.[89]

TABLE 40.6 Etiologies of Hospital-Acquired Pneumonia/Ventilator-Associated Pneumonia

Without MDR Risk[a]	With MDR Risk	Unusual/Prolonged Course
Streptococcus pneumoniae	*Pseudomonas aeruginosa*	*Stenotrophomonas maltophilia*
Staphylococcus aureus: **methicillin-susceptible**	*S. aureus:* methicillin-resistant	*Burkholderia cepacia*
Enterobacteriaceae ***Highly susceptible***	Enterobacteriaceae ESBL Carbapenem-resistant	*Aspergillus* spp. Mucormycocis
Haemophilus **spp.**		CMV, HSV reactivation
Legionella[b]		
Community respiratory viruses		

[a]MDR risk includes prior antibiotic therapy, hospitalization, and/or colonization; immunocompromise.
[b]In hospitals with known nosocomial risks.
CMV, Cytomegalovirus; *ESBL,* extended-spectrum β-lactamases; *HSV,* herpes simplex virus; *MDR,* multidrug resistance.

The role of community respiratory viruses in nosocomial pneumonia is underappreciated, especially in adult ICUs.[90] Pediatric and neonatal ICUs have longer experience and a more aggressive preventative and diagnostic approach. However, the advent of routinely available molecular batteries of respiratory viruses has demonstrated clear-cut nosocomial acquisition, particularly in overtly immunosuppressed patients.

Diagnosis

Clinical/Radiologic Diagnosis

The diagnosis of HAP in nonventilated patients is substantially different than for VAP or for patients with severe HAP requiring intubation and mechanical ventilation. For nonventilated patients with HAP, clinical diagnosis is similar to that for CAP patients. Access to the lower respiratory tract via the endotracheal tube (ETT) allows substantially better diagnostic testing to be performed for intubated patients, the Achilles heel of nonventilated patient diagnosis. However, the effect of critical illness compromising clinical and radiologic diagnosis and the expanded differential diagnosis still results in substantial overlap.

Clinical signs and symptoms are the hallmarks for suspicion of pneumonia, similar to CAP. Some indication of an active infection including fever and leukocytosis is usually mandatory. However, hospitalized patients, particularly the critically ill, may not mount a significant fever because of the severity of their underlying disease. Leukocytosis is very nonspecific and can result from multiple noninfectious causes. Even PCT may be inaccurate for the decision to initiate empirical antibiotics in the critically ill. Physical signs of pneumonia, such as crackles in the egophony, cannot be easily detected in patients who are mechanically ventilated. Increased secretions are hard to quantify in intubated patients and may reflect inadequacies of airway management and macroaspiration rather than a new pneumonia.

Hypoxemia or any change in the oxygen or PEEP requirements of ventilated patients was considered highly sensitive for new-onset VAP. This theory led to a temporary emphasis on ventilator-associated events and complications defined by changes in oxygenation support as an objective quality improvement metric.[91] Subsequent studies demonstrated that ventilator-associated events and complications were neither specific nor sensitive for pneumonia and subject to ventilator manipulation.[92] However, recent attention to decreasing F_{IO_2} as much as possible, based on an associated mortality benefit, may improve the sensitivity of increased oxygen requirement for the diagnosis of VAP.

Radiologic diagnosis in HAP/VAP is also compromised. Critically ill patients often are unable to perform the deep inspiratory maneuver and breath-hold that are critical for good radiographic technique. In addition, the majority of patients with suspected HAP/VAP undergo a portable posteroanterior film without a corresponding lateral radiograph, significantly compromising interpretation. Many patients with suspected pneumonia already have abnormal chest radiographs from the underlying disease causing their ICU admission and changes associated with a new pneumonia may be subtle; comparison with previous chest radiographs is therefore critical. Adjustments in ventilator support can also cause dramatic changes in the degree of alveolar infiltrates, giving the bedside clinician an advantage over trained radiologists who must interpret without the benefit of clinical information.

Alveolar infiltrates are the most common radiographic pattern associated with HAP/VAP. However, the differential diagnosis of alveolar infiltrates in the critically ill patient is large. More specific signs include air bronchograms, especially if not associated with ARDS, and presence of a fissure sign (sharp demarcation of a fissure by an alveolar infiltrate on only one side). Radiographic suspicion of atelectasis based on volume loss on radiographic studies is inaccurate and actually more common in patients with pneumonia.[18]

Although the issue in radiographic diagnosis of HAP/VAP is usually lack of specificity owing to the almost universal presence of an abnormal radiograph, occasionally patients can have other signs and symptoms of pneumonia with a "normal" or unchanged chest radiograph. This may result from purulent tracheobronchitis but is more likely the result of the subtlety of changes or missed infiltrates. The latter are most likely in the lung bases, which are also the most common site for VAP.

CT scans clearly are superior to portable radiographs but cost, radiation exposure, and logistics prevent routine use. Although superior, CT scans are also nonspecific and cannot distinguish between many of the clinical problems in the differential diagnosis, but they clearly can detect occult infiltrates in patients with suspected "normal" chest radiographs. Abdominal CT scans ordered in the search for other sources of the fever or leukocytosis can often reveal alveolar filling densities in the lower lobes. Additional helpful CT scan information is the presence of cavitation, which is highly suggestive of pneumonia caused by specific pathogens—*Pseudomonas*, exotoxin-producing MRSA, and *Aspergillus.* Abdominal CT scans are also extremely accurate in detecting large pleural effusions that may be mistaken for parenchymal lung disease. However, the atelectasis that commonly accompanies larger pleural effusion may still be confused for pneumonia.

Bedside ultrasound may offer an alternative to chest CT scan to discriminate among the different causes of alveolar infiltrates detected on posteroanterior chest radiographs.[93] Ultrasound is clearly very accurate in detecting pleural effusions and can also pick up occult air bronchograms. Further research is needed in this area.

Microbiologic Diagnosis

Given the nonspecificity of clinical/radiographic diagnosis of HAP/VAP, microbiologic diagnosis becomes critically important. Despite decades of research, the microbiologic diagnosis of pneumonia in suspected HAP/VAP patients remains very controversial.

For nonventilated patients, microbiologic diagnosis is limited to blood cultures and rare positive sputum cultures. For institutions with nosocomial *Legionella,* the Binax *Legionella* urinary antigen enzyme immunoassay (Abbott Diagnostics, Santa Clara, CA) may be helpful. Increasing awareness of nosocomial respiratory viral infection has led to increased use of nasopharyngeal PCR assays.[90] However, the overwhelming majority of HAP cases in nonintubated patients have no defined etiology.

Microbiologic diagnosis in patients with HAP that requires intubation is more straightforward. A positive culture result from almost any respiratory sample from the ETT soon after intubation is highly diagnostic. The greatest problem is a negative culture result. In this situation, the result may be negative because pneumonia is not present or because the pathogen is highly sensitive to the empiric antibiotics often started before or soon after intubation. A negative culture result does have value: MDR pathogens such as MRSA, *Pseudomonas*, and *Acinetobacter* are extremely unlikely to disappear after a very short course of antibiotics[94] and empirical coverage can be adjusted appropriately.

The most controversial issue is microbiologic diagnosis in patients with VAP. The major debate is between an invasive approach with

quantitative cultures and use of semiquantitative cultures of tracheal aspirates. Professional society guidelines differ regarding the recommended approach. The IDSA/ATS HAP/VAP guidelines offer a weak recommendation for noninvasive sampling with semiquantitative cultures,[5] whereas the International ERS/ESICM/ESCMID/ALAT (European Respiratory Society/European Society of Intensive Care Medicine/European Society of Clinical Microbiology and Infectious Diseases/Asociación Latinoamericana del Tórax) HAP/VAP guidelines support a weak recommendation for distal quantitative cultures.[6] Discrepancies between the two guidelines may represent differences in the intended use, with concern in the IDSA/ATS guidelines that recommendation for invasive sampling and quantitative cultures could be used by policy makers to require this for even the smallest hospital.[5] The International HAP/VAP ERS/ESICM/ESCMID/ALAT guidelines placed greater emphasis on antibiotic stewardship and minimizing antibiotic therapy.[6]

Both sets of guidelines emphasized the results of two large multicenter clinical trials but vary on the interpretation. A French multicenter trial comparing invasive diagnosis with quantitative cultures to semiquantitative tracheal aspirates mandated that antibiotic therapy was started based only on a positive Gram stain result from the respective specimens (unless the patient was hypotensive).[95] Only 9% of the patients with treatment based on endotracheal aspirates did not receive initial antibiotic therapy compared with 47.5% for invasive culture-based therapy. Invasive culture results were positive in only 44% compared with 86% tracheal aspirate cultures, with significantly more polymicrobial infections and nearly three times more pathogens on culture for tracheal aspirates. All-cause mortality at 14 days after diagnosis, the a priori primary endpoint, was 9.6% less (95% confidence interval [CI] of the difference −17.4 to −1.8, $P = 0.02$) in the invasive group, while severity-adjusted 28-day mortality was also significantly lower. Antibiotic-free days in the next 28 days were significantly lower with invasive diagnosis, including all classes except carbapenems.

In contrast, the Canadian Critical Care Trials Group found no difference in 20-day mortality or use of antibiotics in an RCT of invasive diagnosis versus tracheal aspirates.[96] Two major differences in trial design may explain the discrepancy from the French multicenter trial. First, because of the 2 × 2 factorial design with monotherapy compared to combination therapy,[97] patients at high risk of MDR pathogens were excluded from the diagnostic trial. An equal number of patients were excluded because they were already taking the study antibiotic (imipenem or ciprofloxacin) or had pathogens known to be resistant to the study drugs. The result is that only 6.4% of patients had *Pseudomonas* infection or colonization compared with 20.3% in the French study, and significantly fewer cultures were polymicrobial. In addition, most analyses were carried out combining results of BAL cultures above and below the diagnostic threshold, the main criterion to distinguish between colonization and infection. To compound this issue, antibiotic therapy was not mandated by results of cultures and therefore antibiotics were continued in a high proportion of patients when the attending physician pretest probability of pneumonia being low and a negative culture result for either technique. Unlinking antibiotic treatment from results of cultures obviates the only beneficial effect of a diagnostic technique, severely compromising any conclusions that can be drawn from the study. Clearly, if antibiotic management is not to be based on results of quantitative cultures from distal specimens, no need to do these procedures exists.

Inclusion of both studies in a meta-analysis, along with three other single-center trials, not surprisingly results in no significant difference in clinically important outcomes, the basis of the IDSA/ATS guideline recommendation.[5] However, differences between the two studies may be illustrated by the appropriate use of each strategy. In ICUs with low risk of MDR pathogens and infrequent use of prior antibiotic therapy, the tracheal aspirate culture may be sufficient. Aggressive discontinuation of pneumonia antibiotics in patients with negative endotracheal aspirate culture results will accomplish many stewardship objectives in these units. For ICUs with patients with more complex conditions, higher risk of MDR pathogens, and the resulting need for combination empirical antibiotic therapy, quantitative cultures of distal secretions may be more appropriate, especially for antibiotic stewardship purposes.[6]

Several alternatives exist to address the real issues of availability and cost of bronchoscopic diagnosis of VAP. Two nonbronchoscopic BAL (NBBAL) catheters are commonly available for clinical use. For both, a respiratory therapist can perform the procedure, minimizing cost and allowing routine availability without a bronchoscopist. The first is the BAL CATH (Halyard Health, Inc., Alpharetta, GA), a mushroom-tipped catheter that can be reliably directed to either lung base.[98] Standard BAL quantitative culture procedures, including wedging into subsegmental bronchus, use of large volumes (120–150 mL), discarding the initial aliquot to minimize contamination/colonization, and a 10^4 CFU/mL threshold, can be used with this catheter. In contrast, the CombiCath (Prodimed, Le Plessis Bouchard, France), is a true mini-BAL; the recommended installation volume is only 10 to 20 mL with usual return volumes much less than 10 mL.[99] Because catheters are placed more distally and have less dilution, the usual threshold for positivity is 10^3 CFU/mL. The low return volumes essentially limit testing to Gram stain and culture, without the option for additional specialized tests such as cell count and differential or amylase. No randomized controlled study of antibiotic management based on NBBAL is available. However, comparison to bronchoscopic cultures suggests equivalent sensitivity with slightly worse specificity for NBBAL. The protected specimen brush has been used in many studies of invasive diagnosis of VAP but has fallen into some disfavor because of the additional cost and lower sensitivity compared with bronchoscopic BAL alone.

Quantitative culture of endotracheal aspirates represents an intermediate position between semiquantitative cultures of tracheal aspirates and quantitative cultures BAL specimens. A 1- to 2-log higher threshold for positive cultures ($>10^5$ or $>10^6$ CFU/mL) is required to exclude colonization.[100] Data overall suggest adequate sensitivity at significantly lower sensitivity and distal samples. In addition, the supplemental testing that assists analysis of BAL fluid is inappropriate or inaccurate on tracheal aspirate samples.

One argument against the use of quantitative cultures for each of these specimens is the extra cost and availability compared with semiquantitative cultures of tracheal aspirates. This is a spurious argument because quantitative cultures are performed daily in almost any microbiology laboratory on urine specimens. The quantitative loop technology used for urine cultures can be applied to BAL cultures with minimal differences compared to serial dilutions.

What has also become very apparent from the multiple studies on BAL diagnostic techniques is that quantitative cultures alone are not adequate to distinguish between patients with pneumonia and colonization. Therefore additional tests can be used to increase diagnostic comfort. The first and best validated is the use of a Giemsa stain to look for intracellular bacteria. The presence of intracellular bacteria in as few as 1% of neutrophils correlates with

positive culture results and may help assess borderline cultures.[101] BAL cell count and differential can easily be performed on a hemocytometer. The results and cell counts can be used to assess the adequacy of the lavage sample. Less than 50% neutrophils has a high negative predictive value for bacterial pneumonia and can increase the comfort level for stopping antibiotics in patients with negative or borderline culture results.[102] Occasionally a surprising finding such as a high proportion of eosinophils, indicative of acute eosinophilic pneumonia, or lymphocytes, suggesting either viral disease or hypersensitivity pneumonitis, can be found. An extremely high amylase level in BAL fluid is likely due to aspiration pneumonitis.[103] The advantage of amylase over pepsinogen, which has been used in other studies as an indication of aspiration,[104] is the routine availability of the serum assay and the fact that amylase can detect both oropharyngeal aspiration as well as aspiration of gastric contents, whereas an elevated pepsinogen level is likely only in the latter.

Currently, pathogen identification and antibiotic susceptibility testing of respiratory samples for the diagnosis of HAP/VAP has relied on standard microbiology techniques. However, molecular diagnostics for rapid diagnostics have improved to the point that they are now nearly ready for clinical use. PCR technology to detect the *mec*A gene for MRSA is available in many centers and represents the easiest and most accurate use of PCR technology.[105] Multiplex PCR to identify potential pathogens is limited by the number of slots available in the diagnostic kits. In addition, the high sensitivity of PCR technology will also need threshold determination to avoid over-diagnosing pneumonia in patients with colonization. More problematic is determination of antibiotics susceptibility based on the absence of specific gene mutations leading to antibiotic resistance. The correlation between the presence of a mutation and actual antibiotic susceptibility is not consistent and the clinical relevance of resistance genes detected by PCR is unknown.[106] Despite reservations, PCR and other molecular diagnostic platforms on the horizon offer great hope for more rapid determination of the etiology and antibiotics susceptibility in patients with HAP/VAP.[107]

Differential Diagnosis

Table 40.7 lists important entities in the differential diagnosis of HAP VAP. They can be divided into two groups: (1) those that cause an abnormal radiographic infiltrate with a separate source of fever and/or leukocytosis or (2) entities that themselves cause fever/leukocytosis and a radiographic infiltrate. Common causes of abnormal radiographic infiltrates without fever include congestive heart failure/pulmonary edema, atelectasis, or pleural effusions. In this setting, fever may be due to central line infections, catheter-associated urinary tract infections, or drugs. Other consistent findings in studies of quantitative culture diagnosis of VAP is that multiple other potential causes of fever can be found in patients with negative quantitative cultures.[95,108] Many of these require either a procedure, such as removal of a central venous line, or alternative antibiotics from those standard for HAP/VAP. Aspiration pneumonitis is the most common entity that can cause both radiographic infiltrate and fever/leukocytosis.[8] For most of these alternative etiologies, additional testing in BAL fluid, such as BAL amylase levels, can help redirect investigation to an alternative etiology.

Management

Management of HAP/VAP is predominantly a two-phase antibiotic algorithm with some ancillary support technologies important in certain cases. Antibiotic management is divided into the initial empirical stage and a definitive management phase. The initial empirical antibiotic therapy is very institution specific and may even vary between different ICUs in the same institution. Conversely, once a specific etiology has been established, treatment regimens are fairly standard between institutions, although still not without controversies. Antibiotics commonly used for HAP/VAP are listed in Table 40.8.

Empirical Antibiotic Therapy

The basis of empirical antibiotic therapy is initiation of therapy likely to cover the overwhelming majority of potential bacterial etiologies based on local antibiograms. The threshold for adequate coverage is debatable but is usually greater than 90% of usual isolates.[5,6] Unfortunately, antibiograms available in many hospitals may provide inadequate direction for empirical treatment of HAP/VAP. Almost all antibiograms are based on "reliable" cultures, which are almost exclusively blood cultures. Analysis of only bacteremia may result in a different spectrum of gram-negative bacteria and antibiotic susceptibilities compared with respiratory cultures. For example, *E. coli* bacteremia is dominated by patients with complicated urinary tract and intraabdominal infections and is disproportionately highly sensitive compared with an *E. coli* respiratory sample in a patient with HAP/VAP who has received prior antibiotics. In addition, if multiple cultures with the same pathogen occur in the same patient, only the first is used to construct antibiograms, potentially missing development of resistance during therapy.

β-Lactams are the backbone of treatment for HAP/VAP.[109] Therefore one of the most critical decisions for empirical HAP/VAP treatment is which β-lactam antibiotic to use. Piperacillin/tazobactam dominates the penicillin class of β lactams; cefepime

TABLE 40.7 Differential Diagnosis of Hospital-Acquired Pneumonia/Ventilator-Associated Pneumonia

No Associated Fever[a]	Associated Fever	
Congestive heart failure	Aspiration pneumonitis	Hypersensitivity pneumonitis
Pulmonary hemorrhage/bleeding	Acute respiratory distress syndrome	Acute eosinophilic pneumonia
Pleural effusion	Transfusion-related	Pulmonary infarction
Atalectasis	Extrapulmonary infection	

[a]Associated fever and leukocytosis from concomitant extrapulmonary infection (e.g., central line, urinary tract, *Clostridium difficile* colitis) or noninfectious (e.g., drug fever, deep venous thrombosis).

TABLE 40.8 Antibiotics Commonly Used for Treatment of Hospital-Acquired Pneumonia/Ventilator-Associated Pneumonia

Class/Antibiotic	Dose	Low Risk for Multidrug Resistance Only	Multidrug Resistance	Extensively Drug Resistant	Combination Only in Multidrug Resistance
Penicillin					
Piperacillin/tazobactam	4.5 g q6h		X		
Ampicillin/sulbactam	3 g q6h	X		X+	
Cephalosporin					
Ceftriaxone	2 g q24h	X			
Ceftazidime	2 g q8h		X		
Cefepime	2 g q8h		X		
Ceftolazone/tazobactam[a]	3 g q8h			X	
Ceftazidime/avibactam[a]	2.5 g q8h			X	
Carbapenem					
Ertapenem	1 g q24h	X			
Imipenem/cilastatin	0.5 g q6h to 1 g q8h		X		
Meropenem	1 g q6–8h		X		
Meropenem/vaborbactam[a]	2 g/2 g q8h			X	
Aminoglycosides					
Gentamicin	7 mg/kg loading dose, then TDM				X
Tobramycin	7 mg/kg loading dose, then TDM				X
Amikacin	20 mg/kg loading dose, then TDM				X
Plazomicin[a]	15 mg/kg q24h				X
Fluoroquinolones					
Ciprofloxacin	400 mg q8h	X			X
Levofloxacin	750 mg q24h	X			X
Polymixins					
Colistin	5 mg/kg IV loading dose, then 2.5 mg × (1.5 × CrCl + 30) IV q12h				X
Polymixin B	2.5–3.0 mg/kg per day in 2 daily IV doses				X
Tetracyclines					
Tigecycline[b]	100 mg, then 50 mg q12h				X
Minocycline	200 mg q12h				X

[a]Not approved by the U.S. Food and Drug Administration (FDA) specifically for pneumonia.
[b]FDA warning for hospital-acquired pneumonia/ventilator-associated pneumonia, + for *Acinetobacter* only.
CrCl, Creatinine clearance; *IV,* intravenous; *q,* every; *TDM,* Therapeutic drug monitoring.

and ceftazidime are the most common cephalosporins. Narrower-spectrum β-lactams, such as amoxicillin/sulbactam, ceftriaxone, and ertapenem, can only be used empirically in patients who were at low risk for MDR pathogens. In essence, this means patients who have not had prior antibiotic therapy during the current hospitalization; use is therefore often limited to postoperative surgical patients. HAP/VAP guidelines recommend that when a β-lactam antibiotic covers more than 90% of usual isolates, monotherapy with the narrowest-spectrum β-lactam available is appropriate.

The importance of the β-lactam backbone is demonstrated in two clinical scenarios.[109] Patients with reported penicillin allergy fare substantially worse than nonallergic patients with equivalent infections, likely owing to the increased use of aztreonam or other alternatives to β-lactams. The second is the substantially increased mortality associated with carbapenem-resistant Enterobacteriaceae (CRE) infections.[110] Even though resistant by standard laboratory susceptibility testing, a carbapenem combined with an agent like polymyxin B or colistin will result in higher cure rates. Given this adverse effect on outcomes and the very low proportion with true serious β-lactam allergies, many centers perform skin testing for penicillin allergy and/or desensitization in critically ill patients with purported penicillin allergies.[111]

The choice of empirical β-lactam is most dependent on prior antibiotic therapy. Most hospitals have a preferred β-lactam for empirical treatment of suspected resistant gram-negative infections—either a penicillin (piperacillin/tazobactam) or a cephalosporin (cefepime or ceftazidime). Unfortunately, many patients with HAP/VAP have already received prior antibiotics, most likely including this preferred β-lactam. Whether switching to a cephalosporin in patients previously exposed to penicillins, or vice versa, leads to less inappropriate initial empirical antibiotic therapy is very

dependent on local antibiograms. Previously, empirical carbapenem therapy was the safest option. However, the emergence of carbapenem resistance in many species, particularly Enterobacteriaceae, has made this class of antibiotics less reliable as empirical therapy. Clearly the safest option is to not use that class of antibiotic to which the patient has previously been exposed, particularly if that exposure was recent or prolonged.

The majority of ICUs in larger hospitals do not have one β-lactam to which more than 90% of gram-negative isolates are susceptible.[5,6] In this situation, combination therapy is recommended; the most common agents are fluoroquinolones and aminoglycosides. The data supporting this recommendation remain controversial. Meta-analyses cannot demonstrate a significant survival advantage to combination therapy.[112] The largest clinical trial of a combination of a β-lactam and fluoroquinolone compared with a β-lactam alone was from the Canadian Critical Care Trials Group.[97] Unfortunately, as noted earlier, patients at risk for MDR pathogens were specifically excluded from this study. In addition, they used a β-lactam that covered more than 90% of the cultured pathogens. Little potential existed to demonstrate benefit from the addition of the fluoroquinolone with this trial design. Despite this, patients who actually did have an MDR pathogen cultured had better outcome with combination therapy. There are many studies of combination versus monotherapy or U.S. Food and Drug Administration (FDA) registration trials in which a novel agent was compared against a different β-lactam combination regimen. None of these studies allowed entry of patients with immunocompromise or at very high risk of death at the time of diagnosis. In contrast, epidemiologic studies of all patients with a specific pathogen (e.g., *Pseudomonas*) demonstrate better outcomes with combination therapy.[113,114] The strongest argument for combination therapy from an inefficacy standpoint can be made for neutropenic patients and those with septic shock.[115]

However, the main reason for combination therapy is to avoid initially inappropriate antibiotic therapy.[113] Initially inappropriate antibiotic therapy is consistently associated with worse outcome including mortality. These adverse outcomes did not appear to be reversed when correct therapy was subsequently initiated.[116] A dose-dependent effect is seen; longer times to appropriate therapy are associated with progressively higher associated mortality and morbidity. For this reason, professional society guidelines all recommend initial combination therapy for use in the ICU in which less than 90% of gram-negative pathogens are susceptible to a single β-lactam antibiotic.[5,6]

The need for empirical MRSA coverage is also evolving. In many ICUs, the rate of MRSA pneumonia is decreasing, possibly because of better prevention methods. Conversely, increasing toxicity with vancomycin, particularly when combined with common gram-negative agents such as piperacillin/tazobactam, is also being detected.[117] How low of a threshold must be present before empirical anti-MRSA therapy is not needed is unknown. Use of clinical risk factors may allow better estimation of need. Probably the best risk factor is presence of MRSA in nasal swabs of patients admitted to high-risk units and ICUs, as mandated by local law in many states.[118] A recent negative nasal swab has high negative predictive value, especially combined with lack of clinical risk factors such as recent antibiotic exposure, hemodialysis, and need for wound care. Management of suspected MRSA pneumonia is likely the first treatment decision that can be affected by routine availability of new rapid diagnostic tests in tracheal aspirates or BAL. Only a single gene and an easily detected mutation are ideal for PCR technology.

Antimicrobial Treatment of Specific Pathogens

Once results of diagnostic testing are returned, a specific antibiotic treatment regimen can be determined for each pathogen. With the increasing resistance in many species, knowledge of actual minimal inhibitory concentrations (MICs) is desirable rather than a simple designation as sensitive, intermediate, or resistant. MICs that approach breakpoints may require choice of an alternative agent, pharmacodynamic optimization, or continued use of combination therapy. Conversely, pathogens with limited treatment options with an MIC just above the breakpoint may allow use of an agent despite the bacteria being technically resistant.

Pseudomonas aeruginosa

P. aeruginosa HAP/VAP is one of the most difficult infections to treat in the critically ill. *Pseudomonas* has multiple resistance mechanisms affecting every one of the clinically available antibiotics.[119] *Pseudomonas* is also classic for developing antibiotic resistance during therapy.[120,121] *Pseudomonas* HAP/VAP often affects patients with compromised immunity, altering the ability of host defense to contribute to eradication. In addition, *Pseudomonas* has multiple exotoxins that can cause cavitation, bloodstream invasion, and overt septic shock.[122] The initial failure rates above 50% and high recurrence rates seen in many studies are therefore not surprising.[123] Interestingly, only half of supposed recurrences are truly recurrence; the other half are new infections with a different strain of *Pseudomonas*, most likely because *Pseudomonas* is ubiquitous in the hospital environment.[124]

Of all nosocomial pneumonias, *Pseudomonas* HAP/VAP is most consistently treated with combination therapy. Support for this practice comes most clearly from epidemiologic studies.[114] Meta-analyses of the *Pseudomonas* subgroups of randomized controlled trials of HAP/VAP do not show a clear-cut benefit,[112] although clinical response rates in all of these studies were only 50% for both monotherapy and combination therapy.[123] A theoretical benefit of preventing emergence of antibiotic resistance during therapy has never been demonstrated.

Given the lack of a clear-cut benefit for combination intravenous therapy, aerosolized antibiotics have often been used for *Pseudomonas* HAP/VAP.[125] This may be particularly advantageous for patients with cavitary pneumonia in which penetration from the vascular space may be compromised. Despite an encouraging preliminary study,[126] results of an RCT of aerosolized antibiotics showed no overall benefit.[127] However, there was a trend toward benefit in patients with highly resistant pathogens such as *Pseudomonas*.

Acinetobacter species

HAP/VAP caused by *Acinetobacter baumannii* and other species has become extremely difficult to treat. The incidence of *Acinetobacter* as a cause of HAP/VAP varies somewhat dramatically among ICUs, varying from never seen in some ICUs to more common than *Pseudomonas* in others.[128] Intrinsically more resistant than other gram-negative pathogens, the fairly rapid emergence of carbapenem resistance has severely limited treatment options. The sulbactam component of Unasyn has activity against carbapenem-resistant *A. baumannii* (CRAB) and can be used in younger trauma patients and others with intact immune systems.[129]

The high frequency of CRAB in some ICUs has led to resurgence in the use of polymyxins such as polymyxin B and colistin. These older agents are clearly associated with increased nephrotoxicity and of questionable efficacy. Use of tetracyclines, including minocycline[130] and tigecycline, for CRAB pneumonia, despite the

FDA black label warning against use of the latter agent in pneumonia, is also associated with significant failure rates. Currently, use of pharmacokinetic (PK)/pharmacodynamic (PD)-optimized carbapenem with a polymyxin appears to have the best outcomes despite in vitro resistance to the carbapenem.[131] Once again, aerosolization of polymyxins or amikacin is often used in intubated patients, given the limitations of intravenous therapy and a desire to avoid nephrotoxicity.[125] Development of new treatment for CRAB is a Centers for Disease Control and Prevention and FDA high-priority agenda for the antibiotic crisis.

Enterobacteriaceae

The Enterobacteriaceae are a large and heterogeneous group of pathogens that are common causes of HAP/VAP. Some are exquisitely sensitive to narrow-spectrum antibiotic such as ceftriaxone and ampicillin. Others are resistant to all β-lactams, including carbapenem, and many other classes of drugs. The very common *E. coli* can represent the entire spectrum of antibiotic resistance in this family. For the overwhelming majority of Enterobacteriaceae, appropriate antibiotic therapy is predominantly dependent on prior exposure.

The emergence of two specific resistance patterns has led to dramatic changes in the management of HAP/VAP caused by Enterobacteriaceae. The first is the emergence of extended-spectrum β-lactamases (ESBLs). Predominantly driven by prior exposure to cephalosporins, ESBLs are very adequately treated with carbapenems.[132] However, increased antibiotic pressure has led to the second major pattern of antibiotic resistance, the emergence of CRE. The most common mutation causing CREs in the United States is the *Klebsiella*-producing carbapenemase. The variety of specific β-lactamase mutations that cause these resistance patterns has recently been classified into four groups.[133] However, coverage of some members of the group with new antibiotics does not necessarily lead to coverage of the entire group.

Although carbapenems were adequate for ESBL pneumonia, treatment of CRE pneumonia initially consisted of polymyxin-based combination therapy.[110] However, development of new β-lactamase inhibitors appears to be an effective strategy to address CREs, although resistance appears quickly.[134] Ceftazidime/avibactam has been FDA approved for complicated urinary tract and intraabdominal infections but has been used clinically in pneumonia.[134] The recently released meropenem/vaborbactam combination demonstrated superior activity over standard-of-care treatment without the new β-lactamase inhibitors. A variety of other β-lactam and novel β-lactamase inhibitor combinations are in development. However, newer resistance mechanisms, such as New Delhi metallo-β-lactamase, continue to develop in this family of bacteria.

Methicillin-Resistant *Staphylococcus aureus*

Although as noted earlier that MRSA HAP/VAP may be decreasing in overall frequency, it remains an important pathogen. Two main treatment options are available for MRSA pneumonia. As the only potential treatment for MRSA for many years, vancomycin had become the legacy de facto standard of care despite no FDA-approved indication for HAP/VAP. However, vancomycin failure rates consistently in the 40% range were seen in most studies of MRSA HAP/VAP.[135,136] Attempts to improve outcome by increasing trough levels and PK optimization were associated with increased incidence of acute kidney injury and no improvement in clinical outcomes.[137]

Linezolid is the first agent to show superiority to vancomycin. Subgroup analysis of MRSA cases in the two original FDA registration trials of gram-positive pneumonia demonstrated improved outcomes.[135] A head-to-head comparison of adjusted-dose vancomycin and linezolid confirmed this superior clinical response rate.[138] A mortality benefit was found in the subgroup analysis of the registration trials when linezolid salvage therapy was not available for vancomycin failures. This mortality difference was not found in the head-to-head comparison with linezolid available for vancomycin failures. Linezolid has no nephrotoxicity and the clear-cut bone marrow toxicity seen with prolonged use was not observed during the shorter treatments used for HAP/VAP.

Other glycopeptides have been released for treatment of MRSA infections; although possibly superior to vancomycin,[139] they have not been demonstrated to be superior to linezolid for pneumonia and also carry a nephrotoxicity risk. Ceftaroline, a cephalosporin with MRSA activity, has been approved for CAP[140] but experience with HAP/VAP is limited. Other oxazolidonones are also in development for MRSA pneumonia.

Antibiotic Stewardship

Antibiotic stewardship should be a core competency of critical care physicians.[141] Critically ill patients are at the highest risk for death from MDR pathogens while the ICUs are the breeding grounds for MDR pathogens. True antibiotic stewardship is not solely restrictions on antibiotic use and discontinuation of unnecessary antibiotics. Instead, the CDC definition of "the right drug for the right patient at the right dose" implies other important decisions in diagnosis and antibiotic management of HAP/VAP.[142]

Antibiotic Streamlining. Professional society HAP/VAP guidelines recommending initial broad-spectrum combination empirical antibiotic are predicated on subsequent antibiotic streamlining or deescalation once culture or other data reveal the etiology. This streamlining is much easier if an accurate diagnosis is made; hence the international HAP/VAP guideline recommendation for routine use of distal lung samples and quantitative cultures.[6] However, antibiotic streamlining can be safely performed based on negative culture results and less accurate samples.[143] Although intubated patients with a negative lower respiratory tract culture result may still have pneumonia, the negative predictive value for etiology for MDR pathogens such as MRSA, *Pseudomomas*, and *Acinetobacter* is sufficiently high that additional or broader empirical coverage started specifically for these pathogens can be discontinued. The other value of a negative culture result is to direct attention away from pneumonia to other potential sources of fever or pulmonary infiltrates.[95]

Duration of Therapy. The majority of patients with HAP/VAP should be adequately treated with a 7- to 8-day course of antibiotics, especially if initial antibiotic therapy was appropriate. No difference in mortality was seen when patients treated with 8 days of therapy compared with 15-day duration in a large multicenter study.[121] Concern has been raised regarding a higher number of recurrences in the shorter therapy group for patients with a nonfermenter *(Pseudomonas*, *Acinetobacter)* etiology. However, the actual recurrence rate was not different owing to differences in the observation time without antibiotics, and the mortality specifically in the nonfermenter pneumonia population was lower in the 8-day duration group.

The real issue with antibiotic duration is the high incidence of failure of the primary antibiotic regimen in patients with *Pseudomonas* and *Acinetobacter* HAP/VAP.[144] Randomized controlled trials of antibiotic duration do not support the idea that longer duration of therapy prevents this failure. So if a duration of antibiotics

longer than 8 days is considered necessary the safer option may be to alter the antibiotic regimen rather than continuing a regimen that may be failing.

Pharmacokinetic/Pharmacodynamic Optimization. Given the high failure rates for antibiotic treatment of HAP/VAP, an important part of antibiotic stewardship is optimization of the antibiotics used for treatment. Basic PD concepts include understanding the principal determinants of successful treatment. The area under the curve of antibiotic levels in serum, particularly that above the MIC, is the primary PD parameter for antibiotics such as aminoglycosides, quinolones, and linezolid with dose-dependent killing. Administration of larger doses less frequently is the logical extension of these data. For example, dosing every 24 hours is the standard for aminoglycosides. Conversely, time-dependent killing, as measured by time above the MIC, is the critical parameter for β-lactams. This has led to calls for prolonged, even continuous, infusions of β-lactams.

Although optimizing PK/PD seems logical, the clinical support for routine use is still lacking. A major argument against PK/PD optimization is a HAP/VAP clinical trial comparing prolonged (3-hour) infusion doripenem with short infusion of imipenem.[144] Doripenem was the more active drug by distribution of MICs. Despite the PK/PD optimization of doripenem, the Data Safety Monitoring Board stopped the study prematurely because of excess deaths in the doripenem arm. The most likely explanation of this finding is selection for a highly resistant subpopulation with an MIC above that attained by the prolonged infusion, especially in high-inoculum infections such as HAP/VAP. No difference in clinical parameters until discontinuation of the study drug is consistent with suppression but not eradication of a subpopulation. Trial design precluded use of combination therapy, which may address this issue in clinical practice.

Other studies of continuous or prolonged infusion have led to equivocal or conflicting results.[145,146] Given the heterogeneity of infections and patients, this finding is not that surprising. Most likely these equivocal results represent three populations: (1) low-inoculum infections with highly sensitive pathogens in which short infusion is highly effective and a difference with prolonged infusion therefore is difficult to detect; (2) an intermediate- or high-inoculum group with higher MICs but a minimal proportion of highly resistant pathogens in which the benefit of PD optimization can be demonstrated; and (3) a high-inoculum infection with a significant highly resistant subpopulation, in which prolonged infusion is beneficial for the dominant group but selects for the subpopulation. Unfortunately, most HAP/VAP cases fit in the latter two populations where PK/PD optimization is necessary but not sufficient for high rates of clinical cure.

Therapeutic drug monitoring (TDM) is also an important component of PK/PD optimization. However, TDM is only routinely available for a few agents—principally, aminoglycosides and vancomycin. In these settings, the emphasis is more on avoiding toxicity than on improving cure. Attempts to push vancomycin trough levels to improve the cure of MRSA HAP/VAP and even bacteremia were found to increase nephrotoxicity without a benefit in infection outcomes.[137]

Altered pharmacokinetic properties have also been increasingly recognized in the critically ill. Occult acute kidney injury is not surprising given the multitude of renal insults to which critically ill patients are subjected. However, certain patient subpopulations have also been demonstrated to have increased renal clearance with resultant underdosing of antibiotics and other medications.[147] Probably most importantly, both renal and hepatic clearance are dynamic processes in the critically ill and can vary day to day, if not hour to hour.

An additional factor is that clinical TDM measures only serum levels, whereas the clinically relevant level may be in the alveolar space. Antibiotics vary in the amount lung penetration (i.e., the ratio of alveolar to serum levels). Unfortunately, aminoglycosides and vancomycin have poor lung penetration such that even pushing serum levels may not result in higher alveolar levels. As part of new drug development, BAL levels of the new agent are often measured. Unfortunately, often this assessment of alveolar levels is only in healthy volunteers and may not accurately represent the situation in critically ill patients with altered PK. The general approach to this issue is to use higher doses of antibiotics for pneumonia than may be effective in other sites of infection.

Aerosolized Antibiotics. Interest in aerosolized antibiotics is a response to the adverse PK/PD, lung penetration, and toxicity of maximally dosed intravenous antibiotics. A reverse gradient of antibiotic concentration now occurs with the highest levels in the lung and lower levels in serum, potentially avoiding toxicity. In addition, the very high levels attainable in the lung with aerosolization can clearly exceed borderline MICs for MDR pathogens.[127] Once again, clinical proof for this theoretical benefit is not definitive. The largest RCT of supplemental aerosolized antibiotic did not demonstrate a survival benefit overall, although certain MDR pathogens may have benefited.[126] Similar to other antibiotic management issues, the optimal patient population (one highly enriched for MDR pathogens) may not have been studied. A major issue with aerosolized antibiotics is synchronization of delivery with the ventilator such that the majority of the dose is not deposited in the ventilator tubing and ETT.

Assessment of Response

Given the emergence of a variety of resistance patterns, an increase in overall resistance rates, and a shift in MIC distribution to higher levels, failure of initial antibiotic therapy for HAP/VAP is not uncommon.[123] However, the diagnosis of failure of treatment for HAP/VAP is compromised in the critically ill. Despite early closure for excess mortality in the doripenem study,[123] the Clinical Pulmonary Infection Score[148] did not distinguish between the two groups for more than 7 days. The Clinical Pulmonary Infection Score is simply a numerical composite of the parameters most clinicians follow to assess response to therapy—fever, leukocytosis, amount of tracheal secretions, oxygenation, and chest radiographic changes.[149] Simple disappearance of the pathogen on culture, particularly when the respiratory tract is sampled while the patient is still receiving antibiotics, is also not definitive. This difficulty in clinically assessing response to therapy has been long recognized and led the FDA to recommend mortality as the endpoint for equivalency in registration trials of new agents for HAP/VAP.[150]

PCT can assist in identifying patients whose antibiotic therapy is effective and can be discontinued safely. Several RCTs have demonstrated the safety, and even a potential mortality benefit, of discontinuing antibiotics when PCT levels fall to less than 20% of the initial level or below 0.5 ng/dL.[151,152] However, a persistently elevated PCT level does not necessarily correlate with the need for ongoing antibiotic therapy and may simply represent ongoing sterile inflammation.

Adjunctive Treatment

Ventilator Management. Pneumonia is the most common form of acute lung injury, and ventilator management in patients with pneumonia may put them at even greater risk of secondary lung

injury than other etiologies of ARDS.[75] The markedly decreased compliance and airway obstruction in pneumonia are even more likely to shift the distribution of large tidal volumes to noninvolved areas, causing overdistention. These lower tidal volumes and careful attention to plateau pressures may therefore be even more critical in patients intubated for pneumonia. Surprisingly, this is significantly less of an issue in VAP.

Occasionally, severe hypoxemia can result from unilateral pneumonia. In this situation, increasing PEEP or tidal volume may actually exacerbate hypoxemia by alveolar overdistention of the good lung, with a resultant increase in pulmonary vascular resistance and greater shunting of blood to the pneumonic lung. Positional therapy with the good lung down can temporize these until antibiotics and secretion clearance restore hypoxemic vasoconstriction and improve alveolar ventilation. However, simple ventilatory techniques may fail, and pneumonia still remains the most common disease leading to use of venovenous ECMO.[153,154]

Secretion Clearance. Secretion clearance can be a critically important component to the management of pneumonia. The most persistent problem after serious HAP/VAP is an inability to handle secretions, leading to repeated need for endotracheal intubation. Inability to handle secretions is often associated with neuromuscular weakness, leading to ineffective cough and expectoration.

The most effective mucolytic therapy for HAP/VAP is ensuring adequate systemic hydration, followed by use of hypertonic saline solution aerosols. Acetylcysteine (Mucomyst) is no better than saline solution aerosol in patients without airway stents and has been linked to an increase in pneumonia. DNAase is also of no benefit in patients without cystic fibrosis.

An effective cough requires both accessory inspiratory and expiratory muscles. The inspiratory muscles are needed to generate a large tidal volume, whereas the expiratory muscles are required to perform the forced expiratory maneuver needed to mobilize secretions. The third component is the ability to totally occlude the vocal cords or glottis during initial exhalation to generate the large pressure gradient needed to move secretions proximally. All three components are compromised in patients with HAP/VAP, particularly those requiring endotracheal intubation. The catabolic state in pneumonia, underfeeding, and both disuse and use atrophy all affect the skeletal muscle forming the diaphragm and accessory respiratory muscles. When mechanical ventilation duration was long enough to require tracheostomy, effective cough and poor secretion clearance are often the limiting factors of tracheostomy removal once successful weaning from mechanical ventilation occurs.

Prevention of HAP/VAP

Although prevention of CAP is generally outside the responsibility of critical care practitioners, prevention of HAP, especially VAP, is clearly an important consideration for intensivists. Most of the research has been directed at prevention of VAP, although only certain aspects are unique to HAP.

The keys to prevention are to intervene in critical aspects of the pathogenesis and can be organized along these lines. General infection control measures are critically important for prevention of HAP/VAP.[155] Careful attention to universal handwashing, appropriate isolation, and careful decontamination of respiratory therapy equipment are well-established principles.

By far, the most important prevention strategy for VAP is shortening the duration of mechanical ventilation. The risk of VAP increases with each increasing day of mechanical ventilation and begins to increase exponentially after 7 days.[156] Therefore strategies to facilitate early discontinuation of mechanical ventilation are critically important. Daily awakening from sedation and daily spontaneous breathing trials have been demonstrated in RCTs to shorten the duration of ventilation.[157–159] A side benefit of this early discontinuation is decreased VAP rates. The only caveat is that reintubation is a significant risk factor for VAP.[160] Therefore appropriate selection of patients for extubation is critically important.

Prevention of Aspiration

Elevation of Head of Bed

One of the simpler HAP/VAP prevention methods is to keep the head of the bed elevated to decrease the frequency and volume of aspiration.[161,162] The actual degree of elevation and contraindications remain debatable but this has become standard practice in most ICUs. The decrease in early-onset VAP observed over the past few years may be a result of this routine practice. A further extension of this concept is getting the patient out of bed into a chair, even if the patient is still endotracheally intubated.[163] Increased emphasis on mobilization, and even ambulation, of mechanically ventilated patients has multiple beneficial effects, including pneumonia prevention.

Maintenance of Tracheal Tube Cuff Pressure

Aspiration into the proximal trachea is almost impossible to prevent in patients who are endotracheally intubated. The presence of an ETT prevents the vocal cords from fully occluding and compromises laryngeal function. The result is near-universal microaspiration in patients with ETTs. Several manipulations have attempted to minimize the degree of microaspiration. Probably the most effective is maintaining the pressure in the ETT cuff adequately to maintain pressure against the lateral tracheal walls. This pressure is usually in the 20- to 25-cm H_2O range, below that needed to avoid pressure necrosis of the tracheal mucosa, with appropriately sized ETTs. Maintaining continuous control of tracheal cuff pressure resulted in a decrease in VAP incidence from 22 to 9.7 confirmed cases/1000 ventilator days.[164]

Modified Endotracheal Tubes

Several modifications of the standard ETT tube have been attempted to prevent the development of VAP. The most overt modification is the use of continuous aspiration of subglottic secretions (CASS) specialized ETTs. For CASS, a separate catheter incorporated into the dorsal surface of the ETT with an opening just above the ETT cuff is used to aspirate secretions that pool above the cuff. CASS is ineffective unless tracheal tube cuff pressures are maintained high enough to cause secretions to pool.[165] Occlusion of the additional port also occurs frequently. When maintained properly, CASS tubes can significantly lower the risk of pneumonia, particularly in certain populations.[166] However, the dramatic difference in price compared with a standard ETT prevents more routine use.

Another strategy is to modify the composition and shape of the ETT. These tubes attempt to address the problem of microaspiration through folds and standard ETT costs resulting from a diameter intentionally larger than that of the trachea. Thinner, more pliable construction material prevents development of these folds. In addition, a tapering shape may prevent a plunger-like effect of ETT movement that occurs frequently with position changes and patient movement. For either strategy to be effective, cuff pressures once again must be maintained adequately to provide a continuous seal. The benefit of these tubes on preventing VAP is less well established.[167] Although less expensive than CASS tubes, routine use of these tubes can significantly increase cost.

Early Tracheostomy

Considerable debate remains regarding the benefits of early tracheostomy on prevention of VAP.[168,169] The obligate microaspiration resulting from ETT separation of the vocal cords and laryngeal dysfunction can be obviated by tracheostomy. A percutaneous dilatational tracheostomy prevents many of the surgical site infections and other complications seen with the larger incision and tracheal ring resection technique for standard tracheostomy.[168] A tracheostomy is also often associated with less agitation and resultant use of sedative medications and increased caregiver comfort with patient mobility. Despite these theoretical benefits, results of studies of early tracheostomy are somewhat equivocal[169] and significant family resistance to this intervention remains.

Prevention of Oropharyngeal Colonization

A second primary focus of prevention of HAP/VAP is maintaining the normal microbiome of both the oropharynx and the lower respiratory tract. Not surprisingly, antibiotic therapy is the greatest threat to maintenance of the normal microbiome. Multiple studies of diagnostic strategies that result in less antibiotic exposure are associated with decreased mortality, and specifically decreased incidence of new superinfection pneumonia, especially with MDR pathogens.[95,148] Therefore careful attention to antibiotic stewardship is a major component of pneumonia prevention.

Maintenance of a normal lung microbiome in ventilated patients is a new frontier.[1] However, the normal variation in the microbiome throughout the lung is clearly affected by metabolic processes, pH, and oxygen tension. Alteration in the lung microbiome may therefore be an explanation for the finding that lower FIO_2 is associated with lower mortality independent of correction of hypoxemia. Tighter glycemic control, enteral rather than parenteral feedings, and permissive hypercapnia may all exert effects on the lung microbiome, but a differential effect remains to be proven.

Prophylaxis of Gastrointestinal Bleeding

In the past, major emphasis has been placed on the role of stress ulcer prophylaxis in predisposition to pneumonia. The original theory suggested that maintenance of a low gastric pH may prevent pneumonia, therefore favoring sucralfate. Unfortunately, sucralfate was consistently found to create a slightly higher risk of stress mucosal ulceration. More recent data have suggested that, although proton pump inhibitors and histamine-2 blockers may increase the risk of pneumonia, the need for prophylaxis of GI bleeding itself may not be necessary, particularly in patients who are adequately hemodynamically resuscitated and/or receiving enteral nutrition.[166,170,171] The fact that some of the most common etiologies of HAP/VAP—*Pseudomonas*, *Acinetobacter*, and MRSA—are not typically found in the GI tract also suggests prevention of oropharyngeal colonization by maintaining a lower gastric pH is not a significant benefit. Conversely, elevation of the head of the bed may exert its greatest benefit for prevention of pneumonia by minimizing reflux of fluids containing enteric pathogens into the posterior oropharynx.

Treatment of Colonization

An alternative strategy, often used in conjunction with prevention of colonization, is active treatment of colonization. This can be separated into treatment of oropharyngeal colonization only versus entire GI tract decontamination.

Simple oral hygiene, such as routine tooth brushing, has some benefit in prevention of pneumonia. Addition of 2% chlorhexidine oropharyngeal rinsing has incremental benefit and is relatively low risk for selecting for antibiotic-resistant pathogens.[172] The major limitation of these simple measures is cost, both in terms of acquisition costs and the time needed to perform hygiene by the bedside nurses.

Active intervention to treat oropharyngeal colonization is not without risk. The importance of the normal flora is illustrated by the adverse effects of iseganan, an antimicrobial peptide active against almost all bacteria. Oropharyngeal application of iseganan did not significantly decrease VAP rates but was associated with a trend for increased mortality.[173]

Selective Digestive Tract Decontamination

By far the most extensively studied and most aggressive form of topical antibiotic strategy to prevent colonization is selective digestive tract decontamination (SDD). The focus of this strategy is on preventing pneumonia by almost sterilizing the entire GI tract, including the large bowel. Therefore the antibiotics used are directed primarily at gram-negative bacilli (usually polymyxin B and an aminoglycoside) and *Candida* (usually amphotericin B). Most regimens include two components—topical antibiotics in the oropharynx and nonabsorbable antibiotics via a gastric tube. Some regimens also include an initial short course of systemic antibiotics. Despite more than 40 RCTs and several meta-analyses,[174,175] the benefit of SDD remains unclear. However, several patterns have emerged. Selective SDD fairly consistently decreases the incidence of VAP when systemic antibiotics are used for the first 48 to 72 hours.[176] However, an equivalent benefit on prevention of VAP has been found with a short course of prophylactic antibiotics alone.[177] Statistical adjustment was required for the only study to demonstrate a lower mortality in the SDD group, despite lower rates of VAP.[178] A major concern with SDD is the potential to promote antibiotic resistance, especially with the increasing frequency of MDR pathogens. SDD has been studied mainly in ICUs with a low baseline incidence of MDR pathogens, and the result of introduction to units with a high baseline frequency of MDR pathogens is unknown.[179] Recent data on the role of possible gut translocation in causing pneumonia in patients with ARDS suggest another potential high-risk population in which SDD may be beneficial. Despite the extensive clinical database, SDD use remains confined to only certain ICUs or types of patient.

Enteral Nutrition Strategies

Malnutrition is clearly associated with an increased risk of pneumonia and increased mortality in the critically ill.[180] In addition to classic effects on cell-mediated immunity, an effect specific to pneumonia is increased binding of gram-negative bacilli, including *Pseudomonas*, to epithelial cells.[181]

Enteral nutrition is the preferred route for treating and preventing malnutrition in the critically ill. The optimal timing, volume, and site of infusion remain controversial. Continuous enteral nutrition infusions into the stomach increase both gastric pH and gastric volume.[162,182] A randomized trial found that early aggressive feedings increased the risk of VAP compared with low-level enteral nutrition.[183] The lower rate (approximately 20% of the goal feeding rate) was chosen to avoid atrophy of the microvilli of the enteric mucosa, a potential source of nosocomial infection. The increased risk of VAP was attributed to an increased risk of aspiration. However, meta-analysis of early versus delayed enteral nutrition suggests a mortality benefit and probable decreased risk of VAP with early feedings.[184] A balance between potential risks would be early initiation of enteral feeding but avoidance of aggressive

infusions that might cause high gastric residuals and gastric distention.

Several strategies to provide enteral feeding without increasing gastric colonization with pathogenic microorganisms have been tried. An RCT found that bolus feedings did not lower VAP while fewer patients achieved their goal feeding rates.[185] Acidification of enteral feedings not only did not improve VAP rates but also caused adverse consequences from the resultant metabolic acidosis.[186]

Maintaining Normal Alveolar Host Defense

Given that all intubated patients and many nonintubated patients have at least microaspiration and most have lost their normal oropharyngeal flora, the fact that only a minority of patients actually develop HAP/VAP is surprising. The causes for overwhelming of the lower respiratory tract defenses is the least studied or understood component of the pathogenesis of HAP/VAP. A major reason may be that causes are multiple, heterogeneous, and patient dependent, rather than the stereotypical steps of colonization and aspiration.

Patients in whom VAP develops have a form of acquired immunosuppression.[88] The frequent occurrence of other nosocomial infections, including multiple separate episodes of VAP,[121] in patients with HAP/VAP supports this concept. Many of the causes of compromised lower respiratory tract defenses are due to the underlying disease or critical illness precipitating ICU admission and need for mechanical ventilation. Some of the more common interventions leading to compromised alveolar host defenses are listed in Table 40.9.

TABLE 40.9 Common Causes of Alveolar Host Defense Compromise in Critically Ill Patients

Prior infections	Concomitant viral infection (e.g., HSV, CMV)
Blood transfusions	Hyperglycemia
Chemotherapy	Protein calorie malnutrition
Immunosuppressants	Acetylcysteine (Mucomyst)
Corticosteroids	Norepinephrine
Proton-pump inhibitors/histamine-2 blockers	

CMV, Cytomegalovirus; *HSV,* herpes simplex virus.

Key Points

- The discovery of a normal lung microbiome has forced reconsideration of the prior definition of pneumonia as invasion of microorganisms into a sterile alveolar space.
- CAP and influenza are the leading causes of death from infectious diseases in the United States and around the world.
- Despite extensive conventional diagnostic testing, the etiology of CAP remains unknown in the majority of cases, including those requiring ICU admission.
- Specific objective decision tools used in conjunction with clinician experience and clinical judgment can identify CAP patients with an increased likelihood of need for ICU care.
- Severe CAP should be routinely treated with a β-lactam–based combination therapy with coverage of atypical bacterial pathogens and consideration of coverage for less common pathogens such as CA-MRSA and *Pseudomonas.*
- Despite decades of research, microbiologic diagnosis in patients with suspected HAP/VAP remains controversial, but quantitative cultures of distal specimens are more likely to improve antibiotic stewardship.
- Unless known local antibiotic susceptibility patterns demonstrate more than 90% susceptibility to a single agent, β-lactam–based combination empirical therapy is recommended for HAP/VAP in the ICU.
- Discontinuation in culture-negative cases of suspected HAP/VAP and optimized PK/PD, shortened duration of therapy, and consideration of aerosolized therapy for MDR pathogens are important antibiotic stewardship practices in the ICU.
- Prevention of HAP/VAP requires a multidimensional approach to decrease microaspiration, preserve normal flora, and avoid compromising alveolar host defenses.

Review Questions

1. A patient is diagnosed with *Pseudomonas* ventilator-associated pneumonia (VAP) and starts antibiotic therapy with piperacillin/tazobactam and amikacin. Combination therapy with amikacin was discontinued after 48 hours when piperacillin/tazobactam susceptibility was confirmed. On day 7 of therapy, the patient is afebrile and normotensive. The patient requires suctioning every 3 to 4 hours but secretions are nonpurulent. Arterial saturation is 93% on fraction of inspired oxygen (FIO_2) of 0.30. The white blood cell count has increased from 9500 cells/mm^3 yesterday to 11,300 cells/mm^3. Procalcitonin has decreased from 3.5 ng/dL at the beginning of therapy to 0.65 ng/dL. What would you do at this point?

- **a.** Continue piperacillin/tazobactam for an additional 7 days
- **b.** Switch to meropenem 1 g infused over 3 hours every 8 hours for an additional 7 days
- **c.** Restart amikacin with a loading dose of 20 mg/kg and follow drug levels for redosing
- **d.** Discontinue piperacillin/tazobactam and monitor closely
- **e.** Continue piperacillin/tazobactam and add aerosolized polymyxin B

Answer: d. The patient appears to have successful therapy manifested by a low FIO_2, is afebrile, and has a procalcitonin level less than 20% of the initial value. The white blood cell count and amount of secretions are notoriously inaccurate in assessing response to therapy. More than 60% of patients with *Pseudomonas* pneumonia are adequately treated with a 7- to 8-day course of antibiotics, particularly when initial therapy is appropriate.[121]

2. Ten days after initiation of intubation and mechanical ventilation a patient develops fever to 101.7°F at midnight. Nursing reports increased purulent secretions. Cefepime and linezolid are started empirically after submission of an endotracheal aspirate for culture. Morning laboratory studies reveal leukocytosis, and a chest radiograph demonstrates a new left lower lobe alveolar filling density with air bronchograms. Amikacin is also started at that time. After 72 hours, the endotracheal aspirate culture remains negative. Which of the following would be the most appropriate management strategy?

- **a.** Continue current triple-antibiotic regimen for 7-day course
- **b.** Discontinue all antibiotics
- **c.** Discontinue linezolid and amikacin and complete 7-day course of cefepime
- **d.** Discontinue linezolid but complete 10-day course of cefepime and amikacin
- **e.** Check a procalcitonin level and discontinue all antibiotics if less than 0.50 ng/dL

Answer: c. Culture-negative suspected VAP represents a difficult decision. However, data are fairly clear that samples obtained before or shortly after initiation of antibiotics are adequate to exclude methicillin-resistant *Staphylococcus aureus* (MRSA) and multidrug-resistant pathogens, such as *Pseudomonas* and *Acinetobacter.* Therefore choices a. and d. are clearly incorrect. A single procalcitonin level 3 days into the course of treatment is difficult to interpret; it may actually represent persistent elevation and therefore discontinuing antibiotics based on this single value has some risk. The clinical scenario in addition to a positive radiograph indicates a greater than 90% probability of the patient having pneumonia. A negative endotracheal aspirate culture may represent disappearance of easy to treat pathogens or sampling of the right lower lobe rather than left lower lobe. Therefore continuing a single antibiotic is reasonable. A bronchoalveolar lavage (BAL) sample from the left lower lobe with less than 50% neutrophils could justify discontinuing all antibiotics.

3. A previously completely healthy, athletic 40-year-old presents with fever, cough, and dyspnea for 24 hours. His cough is occasionally productive of bright red blood. The patient has no periodontal disease. A chest radiograph reveals a right midlung dense infiltrate with a small cavity, patchy infiltrate in the left lower lobe, and a pleural effusion. Initial antibiotic regimen should be which of the following?

- **a.** Metronidazole in addition to ceftriaxone and azithromycin to cover for anaerobes
- **b.** Linezolid in addition to ceftriaxone and azithromycin for suspected community-acquired MRSA (CA-MRSA) pneumonia
- **c.** Clindamycin monotherapy for anaerobic pleuropneumonia
- **d.** Piperacillin/tazobactam and ciprofloxacin for possible *Pseudomonas* pneumonia
- **e.** Isoniazid (INH), rifampin, pyrazinamide, and ethambutol for tuberculosis

Answer. b. The presentation is classic for toxigenic *S. aureus* community-acquired pneumonia, both methicillin-susceptible and methicillin-resistant. Athletic locker room exposure increases the risk of MRSA and therefore clindamycin may not be adequate, although it also suppresses exotoxin production like linezolid. The patient has no risk factors for anaerobic pneumonia, *Pseudomonas* pneumonia, or tuberculosis.

4. A 64-year-old concert pianist presents to the emergency department for fever, very productive cough, and shortness of breath. On examination, she is slightly confused according to her daughter. She is normothermic and normotensive with a heart rate of 110 beats/min. Respiratory rate is 32 breaths/min with mild use of accessory inspiratory muscles. She has crackles with some egophony in the left lower lobe. She appears mildly dehydrated. Her chest radiograph demonstrates a left lower lobe pneumonia with air bronchogram. Arterial saturation is 89% on room air but improves to 96% on 2 L via simple nasal cannula. The white blood cell count is 12,000 cells/mm^3, platelets 110,000/mm^3. Electrolytes are normal with a blood urea nitrogen of 19 mg/dL. What would be your management plan?

- **a.** Start intravenous hydration and admit to the medical intensive care unit (ICU)
- **b.** Initiate noninvasive ventilation
- **c.** Perform an arterial or venous blood gas to assess pH and partial pressure of carbon dioxide (PCO_2)
- **d.** Start intravenous hydration and admit to a medical floor
- **e.** Start intravenous hydration and monitor in the emergency department for 2 hours before assessing transfer to the floor

Answer: a. This patient presents a not uncommon management dilemma, and the correct answer may vary somewhat on the health care system and available resources. She has borderline severity for admission to the ICU but she is at high risk. Confusion is a particularly worrisome symptom in a previously highly functional adult and would warrant ICU or step-down unit admission in highly resourced hospitals. She would only receive 2 CURB-65 points and only has 2 IDSA/ATS minor criteria (confusion, respiratory rate). A low pH or abnormal PCO_2 may warrant either ICU admission or prolonged initial emergency department management before transferred to a floor. The latter is associated with lower risk of emergent ICU transfer from the floor and lower mortality.[50]

Weaning from Mechanical Ventilation

MARTIN J. TOBIN

CHAPTER OUTLINE

Pathophysiology of Weaning Failure
- Control of Breathing
- Respiratory Mechanics
- Patient Effort
- Respiratory Muscles
- Cardiovascular Performance
- Gas Exchange

Weaning-Predictor Testing
- Pitfalls in Use of Weaning-Predictor Tests
- Respiratory Frequency/Tidal Volume Ratio

Weaning Trials
- Multiple T-Tube Trials
- Intermittent Mandatory Ventilation
- Pressure Support
- Once-Daily T-Tube Trials
- Comparison of Weaning Methods
- Weaning by Protocol Versus Usual Care
- Extubation

Conclusion

Mechanical ventilation is often lifesaving but it is associated with numerous complications.[1,2] Accordingly, it is imperative to disconnect patients from the ventilator at the earliest feasible time. Deciding the right time to initiate this disconnection process, usually referred to as *weaning,* is one of the greatest challenges in critical care medicine.[3] If a physician is too conservative and postpones the initiation of weaning, the patient is placed at an increased risk of life-threatening, ventilator-associated complications. Conversely, if weaning is begun prematurely, the patient may experience cardiopulmonary or psychological decompensation of sufficient severity to set back the patient's clinical course.[4]

This chapter reviews the pathophysiology of weaning failure, weaning-predictor testing, different weaning techniques, and extubation.

Pathophysiology of Weaning Failure

After patients have been disconnected from the ventilator, up to 25% experience respiratory distress severe enough to necessitate the reinstitution of mechanical ventilation.[5,6] The pathophysiologic mechanisms of weaning failure can be divided into those occurring at the level of the respiratory control system, mechanics of the lung and chest wall, the respiratory muscles, the cardiovascular system, and gas-exchange properties of the lung.[7]

Control of Breathing

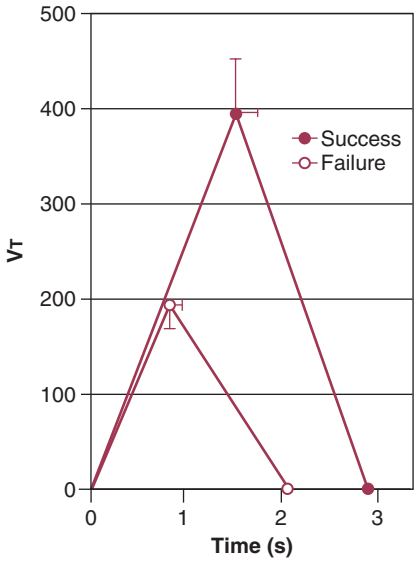
Many patients in whom weaning fails develop hypercapnia. Accordingly, it had been thought that these patients experience an acute decrease in minute ventilation consequent to a decrease in respiratory center output.[3] Measurements of respiratory motor output, using mean inspiratory flow or airway occlusion pressure ($P_{0.1}$), have consistently revealed an increase, not a decrease, in respiratory drive in patients with weaning failure.[4,8,9]

Weaning-failure patients, however, exhibit marked abnormalities in respiratory timing, specifically marked shortening of inspiratory time (T_I), which is coupled with shortening of expiratory time (T_E). The decrease in both T_I and T_E means that respiratory frequency (f) is markedly elevated. The shortening of T_I combined with a normal mean inspiratory flow (V_T/T_I) results in a marked decrease of tidal volume (V_T).[8] This combination (elevated f and decreased V_T) is referred to as rapid shallow breathing—now recognized as the physiologic hallmark of weaning failure (Fig. 41.1).[5]

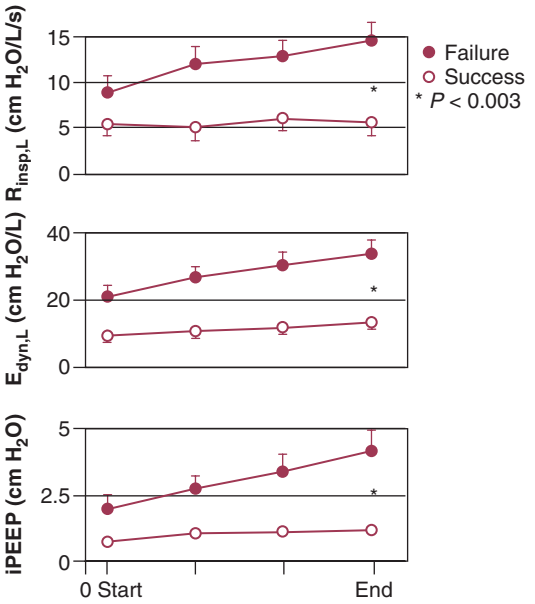
Respiratory Mechanics

The most detailed study of respiratory mechanics during weaning trials was carried out by Jubran and Tobin.[10,11] Immediately before commencement of a trial of spontaneous breathing, patients who went on to tolerate or fail the trial showed little or no difference in detailed measurements of passive respiratory mechanics.[11] Resistance, elastance, and intrinsic positive end-expiratory pressure (iPEEP) were equivalent in the two groups.

Over the course of the trial, all of these variables became more abnormal in the weaning-failure patients than in weaning-success patients (Fig. 41.2).[10] Respiratory resistance increased progressively, reaching about seven times the normal value at the end of the trial. Pulmonary elastance increased, reaching five times the normal value. iPEEP more than doubled over the course of the trial. A similar pattern has been observed by other investigators.[12] The observation that respiratory mechanics were equivalent in patients with weaning success and weaning failure immediately before a weaning trial but deteriorated immediately in the weaning-failure patients as soon as they began to breathe spontaneously indicates that some mechanism associated with the act of spontaneous breathing causes the worsening of respiratory mechanics that leads to weaning failure.



• **Fig. 41.1** The mean respiratory cycle during spontaneous breathing in 7 weaning-failure patients and 10 weaning-success patients. The early termination of inspiratory time in the weaning-failure patients leads to a decrease in tidal volume *(VT).* The decrease in inspiratory time, coupled with a decrease in expiratory time, results in a faster respiratory frequency. Bars represent 1 standard error. (Redrawn from Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis.* 1986;134:1111–1118.)



• **Fig. 41.2** Inspiratory resistance of the lung *(Rinsp,L),* dynamic lung elastance *(Edyn,L),* and intrinsic positive end-expiratory pressure *(iPEEP)* in 17 weaning-failure patients and 14 weaning-success patients. Data displayed were obtained during the second and last minutes of a T-tube trial, and at one-third and two-thirds of the trial duration. Between the onset and end of the trial, the failure group developed increases in Rinsp,L ($P < 0.009$), Edyn,L ($P < 0.0001$), and iPEEP ($P < 0.0001$) and the success group developed increases in Edyn,L ($P < 0.006$) and iPEEP ($P < 0.02$). Over the course of the trial, the failure group had higher values of Rinsp,L ($P < 0.003$), Edyn,L ($P < 0.006$), and iPEEP ($P < 0.009$) than the success group. (Redrawn from Jubran A, Tobin MJ. Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med.* 1997;155:906–915.)

Patient Effort

To compensate for the marked worsening of respiratory mechanics, patients need to make a greater inspiratory effort. It had been thought that weaning-failure patients make weaker inspiratory efforts than do weaning-success patients.[7] On the contrary, direct measurements of work of breathing and pressure-time product[13,14] show that weaning-failure patients consistently make a greater inspiratory effort than do weaning-success patients (Fig. 41.3).[10,15]

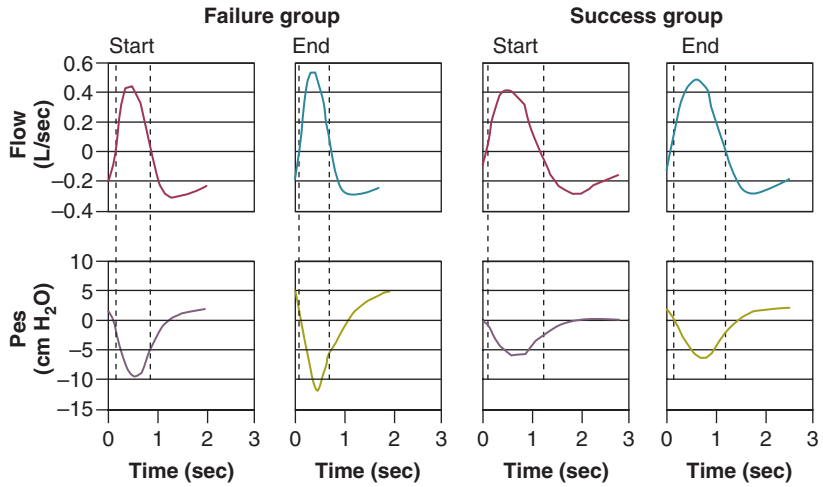
Respiratory Muscles

Numerous research groups have shown that maximal inspiratory pressure (PImax), a measure of respiratory muscle strength, does not discriminate between patients with weaning success and weaning failure.[7] These findings led to the belief that respiratory muscle weakness is not an important determinant of weaning outcome. PImax, however, can misrepresent respiratory muscle strength because the values are heavily influenced by patient motivation and cooperation.[13] A more objective measure of diaphragmatic strength is obtained by stimulation of the phrenic nerves and recording the resulting transdiaphragmatic pressure (Pdi). In weaning-failure patients twitch Pdi values are below 10 cm H_2O, whereas values of 35 to 39 cm H_2O are observed in healthy subjects.[16] These data suggest that weaning-failure patients may have considerable muscle weakness.

Stimulation of the phrenic nerves and recording of the resulting Pdi also provide the most direct measure of diaphragmatic fatigue.[13] Laghi and coworkers[17] used this technique in 11 weaning-failure and 8 weaning-success patients before and after a T-tube trial. No patient in either group exhibited a fall in twitch pressure. This result was surprising. Related analyses disclosed why. Weaning-failure patients became progressively distressed during the trial, leading clinicians to reinstate ventilator support before patients had breathed long enough to develop fatigue (Fig. 41.4).[17,18] In other words, monitoring clinical signs of distress provides sufficient warning to avoid respiratory muscle fatigue.

Cardiovascular Performance

During a weaning trial, patients can experience substantial increases in right and left ventricular afterload.[19,20] These afterload increases most likely result from associated increases in negative swings of intrathoracic pressure. At the completion of a weaning trial, the level of oxygen consumption is equivalent in weaning-success and weaning-failure patients. How the cardiovascular system meets the oxygen demand differs in the two groups of patients. In weaning-success patients, oxygen demand is met through an increase in oxygen delivery, mediated by the expected increase in cardiac output on discontinuation of positive-pressure ventilation.[20] In weaning-failure patients, oxygen demand is met through an increase in oxygen extraction; these patients have a relative decrease in oxygen delivery.[20] The greater oxygen extraction causes a substantial decrease in mixed venous oxygen saturation, contributing to the arterial hypoxemia that occurs in some patients.[20]



• **Fig. 41.3** Ensemble average plots of flow and esophageal pressure *(Pes)* at the start and end of a T-tube trial in 17 weaning-failure patients and 14 weaning-success patients. At the start of the trial, the inspiratory excursion in Pes was greater in the failure patients, and it increased further by the end of the trial. To generate these plots, flow and Pes tracings were divided into 25 equal time intervals over a single respiratory cycle for each of the 5 breaths for each patient in the 2 groups. For a given patient, the five breaths from the start of the trial were then superimposed and aligned with respect to time, and the average at each time point was calculated. The group mean tracings were then generated by ensemble averaging of the individual mean from each patient. The same procedure was performed for breaths at the end of the trial. (Redrawn from Jubran A, Tobin MJ. Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med.* 1997;155:906–915.)

Gas Exchange

Studies using the multiple inert-gas technique have revealed that the ventilation-perfusion maldistribution and acute hypercapnia observed in weaning-failure patients is produced primarily by shallow breathing (low V_T).[7] About half of weaning-failure patients experience an increase in the arterial partial pressure of carbon dioxide ($PaCO_2$) of 10 mm Hg or more over the course of a spontaneous breathing trial.[10] The hypercapnia is not usually a consequence of a decrease in minute ventilation. Instead, it results from rapid, shallow breathing, which causes an increase in dead-space ventilation.

Weaning-Predictor Testing

In randomized controlled trials (RCTs) of different weaning techniques, most patients who had received mechanical ventilation for a week or longer were able to tolerate ventilator discontinuation on the first day that weaning-predictor tests were measured.[5,6] Many of these patients probably would have tolerated extubation a day or so earlier. Much of this delay in ventilator weaning results from clinicians' overconfidence in their intuition that a patient is not ready for a weaning trial.[4] Another source of error is the failure of clinicians to pay close attention to pretest probability—they fail to recognize the importance of Bayesian principles in clinical decision making. When caring for a ventilator-supported patient, physicians should be mindful of these cognitive processes and use compensatory tactics, specifically the use of screening tests, to spot a patient's readiness for weaning. By alerting an unsuspecting physician to a patient's readiness to tolerate unassisted ventilation—hours or days before he or she would otherwise order a spontaneous breathing trial—weaning-predictor tests circumvent the cognitive errors inherent in clinical decision making.[4]

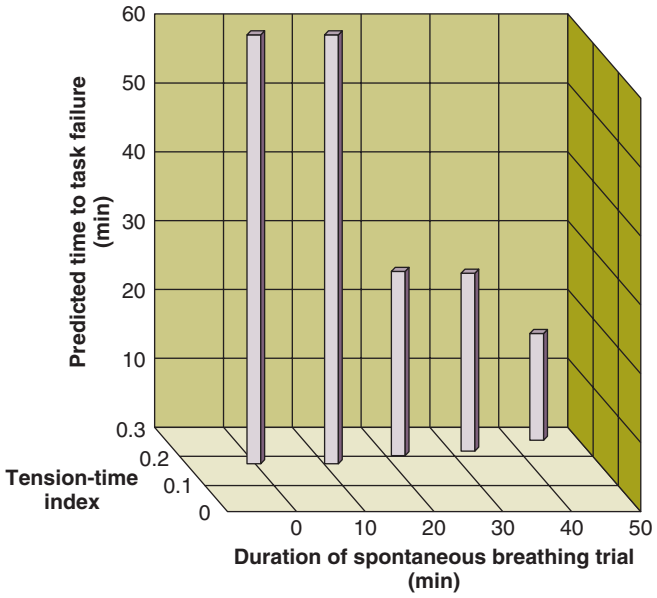
Pitfalls in Use of Weaning-Predictor Tests

Physicians commonly view diagnostic testing in monolithic terms: a test is a test is a test. In reality, diagnostic testing has to satisfy two very different tasks; one is screening, the other is confirmation.[21] The characteristics of these test types differ, and a single diagnostic test rarely fulfills both functions.[21]

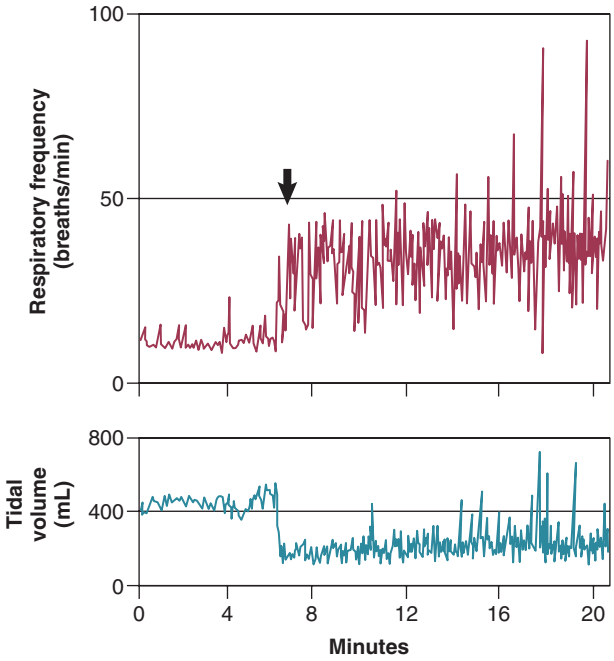
The fundamental job of a weaning-predictor test is screening.[4] Because the goal is to not miss anybody with the condition under consideration, a good screening test has a low rate of false-negative results; to achieve this goal, a higher false-positive rate is acceptable. Thus an ideal screening test has a high sensitivity.[4,21]

Weaning involves the use of three diagnostic tests in sequence: measurement of predictors, a weaning trial, and a trial of extubation.[4] The sequential nature of the testing gives rise to particular problems in studies undertaken to investigate the reliability of a predictor test. One is spectrum bias. This occurs when a new study population contains fewer (or more) sick patients than the population in which a diagnostic test was originally developed.[21,22] A second is test-referral bias. This occurs when the results of a test under evaluation are used to select patients for a reference-standard test, such as use of a weaning-predictor test to select patients for a reference-standard test (passing a weaning trial that leads to extubation).[21,22]

A third factor that affects studies of the reliability of a predictor test is base-rate fallacy.[22,23] Consider a diagnostic test for a disease that has a false-positive rate of 5% and false-negative rate of 0%, and the incidence of the disorder (under consideration) is 1 per 1000 persons. A randomly selected person undergoes diagnostic testing. The result comes back positive. What is the chance this person has the disease? More than 80% of physicians answer 95%. The correct answer is 1.96%.[23] Physicians who answer 95% are failing to take into account the pretest probability of the disorder. Thus they fall into the trap of base-rate fallacy.



• **Fig. 41.4** Interrelationship among the duration of a spontaneous breathing trial, tension-time index of the diaphragm, and predicted time to task failure in nine patients who failed a trial of weaning from mechanical ventilation. The patients breathed spontaneously for an average of 44 minutes before a physician terminated the trial. At the start of the trial, the tension-time index was 0.17, and the formula of Bellemare and Grassino[18] predicted that patients could sustain spontaneous breathing for another 59 minutes before developing task failure. As the trial progressed, the tension-time index increased and the predicted time to development of task failure decreased. At the end of the trial, the tension-time index reached 0.26. That patients were predicted to sustain spontaneous breathing for another 13 minutes before developing task failure clarifies why patients did not develop a decrease in diaphragmatic twitch pressure. In other words, physicians interrupted the trial on the basis of clinical manifestations of respiratory distress before patients had sufficient time to develop contractile fatigue. (Redrawn from Laghi F, Tobin MJ. Disorders of the respiratory muscles. *Am J Respir Crit Care Med.* 2003;168:10–48.)



• **Fig. 41.5** A time-series, breath-by-breath plot of respiratory frequency and tidal volume in a patient who failed a weaning trial. The *arrow* indicates the point of resuming spontaneous breathing. Rapid, shallow breathing developed almost immediately after discontinuation of the ventilator. (Redrawn from Tobin MJ, Perez W, Guenther SM, et al. The pattern of breathing during successful and unsuccessful trials of weaning from mechanical ventilation. *Am Rev Respir Dis.* 1986;134:1111–1118.)

Pretest probability is a physician's estimate of the likelihood of a particular condition (weaning outcome) before a diagnostic test is undertaken.[4] Posttest probability (typically expressed as positive or negative predictive value) is the new likelihood after the test results are obtained. A good diagnostic test achieves a marked increase (or decrease) in the posttest probability (over pretest probability). For every test in every medical subspecialty, the magnitude of change between pretest probability and posttest probability is determined by Bayes' theorem.[22] Three factors (alone) determine the magnitude of the pretest to posttest change: sensitivity, specificity, and pretest probability. Sensitivity and specificity are commonly assumed to remain constant for a test. In truth, test-referral bias, a common occurrence in studies of weaning tests, leads to major changes in sensitivity and specificity.[21] Likewise, major changes in pretest probability arise as a consequence of spectrum bias.[21] All of these factors need to be carefully considered when reading a study that evaluates the reliability of a weaning-predictor test.

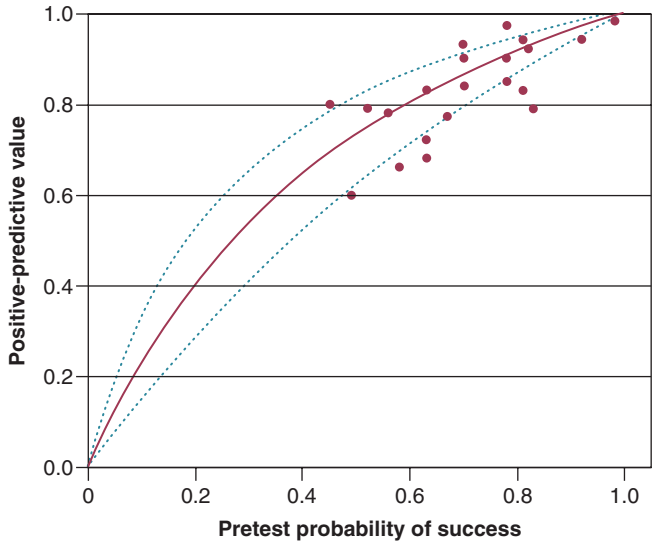
Respiratory Frequency/Tidal Volume Ratio

The ratio of respiratory frequency to tidal volume (f/VT) is measured during 1 minute of spontaneous breathing (Fig. 41.5).[24] Measurements of f/VT in the presence of pressure support or continuous positive airway pressure (CPAP) will result in inaccurate predictions of weaning outcome.[4] The higher the f/VT ratio, the more severe the rapid, shallow breathing and the greater the likelihood of unsuccessful weaning. An f/VT ratio of 100 best discriminates between successful and unsuccessful attempts at weaning.[24]

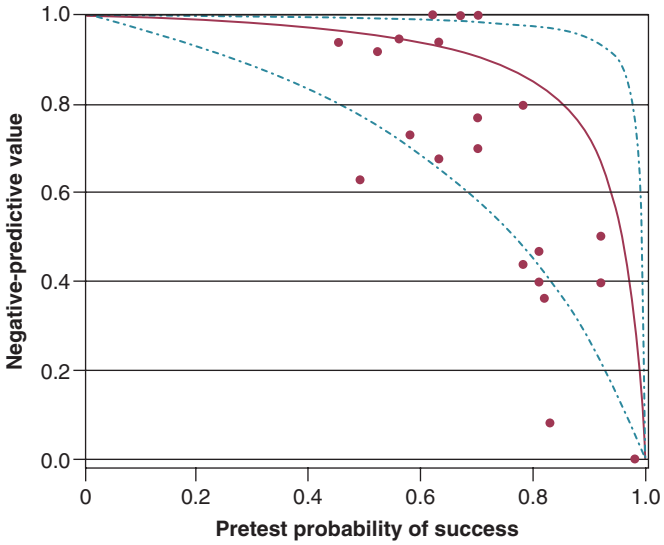
The initial evaluation of f/V_T was reported in 1991.[24] Since then, this test has been evaluated in more than 25 studies. Reported sensitivity ranges from 0.35 to 1.[22] Specificity ranges from 0 to 0.89.[22] At first glance, this wide scatter suggests that f/VT is an unreliable predictor of weaning outcome. This was also the viewpoint of an Evidence-Based Medicine Task Force that undertook a meta-analysis of the studies.[25,26] The Task Force, however, failed to take into account test-referral bias and spectrum bias.[4] As a consequence, the Task Force committed at least 15 major errors—any one of which was sufficient to scupper their conclusions.[27,28] In contrast, when data from the studies (included in the meta-analysis) were compared against the test characteristics in the original 1991 report, taking into account Bayesian pretest probability, the weighted Pearson correlation coefficient was 0.86 ($P < 0.0001$) for positive predictive value and 0.82 ($P < 0.0001$) for negative predictive value (Figs. 41.6 and 41.7).[22]

The primary job of a weaning-predictor test is screening, which requires a high sensitivity.[4,21] The average sensitivity in all of the studies on f/VT was 0.89, and 85% of the studies reveal sensitivities higher than 0.90.[22] This sensitivity compares well with commonly used diagnostic tests.[4]

The whole purpose of diagnostic screening is to perform a simple test at a time when a physician's pretest probability is low (<50%).[4] A screening test should be cheap, easy to perform, pose



• **Fig. 41.6** Positive predictive value (posttest probability of successful outcome) for f/VT plotted against pretest probability of successful outcome. The curve is based on the sensitivity and specificity originally reported by Yang and Tobin[24] and Bayes' formula for 0.01-unit increments in pretest probability between 0.00 and 1.00.[22] The lines represent the upper and lower 95% confidence intervals for the predicted relationship of the positive predictive values against pretest probability. The observed positive predictive value in a study is plotted against the pretest probability of weaning success (prevalence of successful outcome). (Redrawn from Tobin MJ, Jubran A. Variable performance of weaning-predictor tests: role of Bayes' theorem and spectrum and test-referral bias. *Intensive Care Med*. 2006;32:2002–2012.)



• **Fig. 41.7** Negative predictive value (posttest probability of unsuccessful outcome) for f/VT. The curve, its 95% confidence intervals, and placement of a study on the plot are described in the legend of Fig. 41.6. The observed negative predictive value in a study is plotted against the pretest probability of weaning success (prevalence of successful outcome). (Redrawn from Tobin MJ, Jubran A. Variable performance of weaning-predictor tests: role of Bayes' theorem and spectrum and test-referral bias. *Intensive Care Med.* 2006;32:2002–2012.)

minimal risk to patients, and provide a quick answer. A spontaneous breathing trial that involves 30 to 120 minutes of monitored performance is the antithesis of a screening test. Yet the Evidence-Based Medicine Task Force recommends that clinicians should start weaning with a spontaneous breathing trial (a confirmatory test) and use the initial few minutes of the trial as a screening test.[25] This is analogous to saying that when you suspect diabetes, start with a glucose tolerance test and then, as the test gets under way, ask the patient for a urine sample to perform a dipstick measurement.[29]

Weaning Trials

Weaning-predictor tests are not done to forecast a failed weaning trial, but to alert a physician that a patient might tolerate a weaning trial sooner than the physician otherwise thinks and move that weaning trial earlier in time and shorten the overall of duration mechanical ventilation. When a screening test result is positive, the clinician proceeds to a confirmatory test.[21] The goal of a positive result on a confirmatory test is to rule in a condition[19]: the likelihood of a patient tolerating a trial of extubation is high. An ideal confirmatory test has a low rate of false-positive results (i.e., a high specificity).[21] Unfortunately, the specificity of a spontaneous breathing trial is not known. Indeed, its specificity will never be known because its determination would require an unethical experiment: extubating all patients in whom a weaning trial fails and counting how many require reintubation.[4]

Multiple T-Tube Trials

Of the four methods available for conducting a weaning trial, the use of repeated T-tube trials, several times a day, is the oldest method.[3] The patient receives an enriched supply of oxygen through a T-tube circuit. Initially 5 to 10 minutes in duration, T-tube trials are extended and repeated several times a day until the patient can sustain spontaneous ventilation for several hours. This approach has become unpopular because it requires considerable time on the part of intensive care staff.

Intermittent Mandatory Ventilation

For many years, intermittent mandatory ventilation (IMV) was the most popular method of weaning.[3] With IMV, the mandatory rate from the ventilator is reduced in steps of 1 to 3 breaths/min, and an arterial blood gas value is obtained about 30 minutes after each rate change.[30] Unfortunately, titrating the number of breaths from the ventilator in accordance with the results of arterial blood gases can produce a false sense of security. As few as 2 to 3 positive-pressure breaths/min can achieve acceptable blood gas values, but these values provide no information regarding the patient's work of breathing (which may be excessive).[4] At IMV rates of 14 breaths/min or fewer, patient inspiratory efforts are increased to a level likely to cause respiratory muscle fatigue.[31,32] Moreover, this occurs not only with the intervening spontaneous breaths but also with ventilator-assisted breaths. Consequently, use of IMV may actually contribute to the development of respiratory muscle fatigue or prevent its recovery.[7]

Pressure Support

When pressure support is used for weaning, the level of pressure is reduced gradually (decrements of 3–6 cm H_2O) and titrated on

the basis of the patient's respiratory frequency.[33] When a patient breathes without distress at a "minimal level of pressure support," he or she is extubated. The problem with this line of thinking is that pressure support of 5 cm H_2O produces an average decrease in work of breathing of approximately 40% (much more in some patients)[34]; it is difficult to understand how physicians judge this effect to be "minimal."

Once-Daily T-Tube Trials

The fourth method of weaning is to perform a single daily T-tube trial, lasting for 30 to 120 minutes. If this trial is successful, the patient is extubated. If the trial is unsuccessful, the patient is given at least 24 hours of respiratory muscle rest with full ventilator support before another trial is performed.[4]

Comparison of Weaning Methods

Until the early 1990s, it was widely believed that all weaning methods were equally effective, and the physician's judgment was regarded as the critical determinant.[3] The results of RCTs have revealed that the period of weaning is as much as three times as long with IMV as with trials of spontaneous breathing.[5,6] In a study involving patients with respiratory difficulties on weaning, trials of spontaneous breathing halved the weaning time compared with pressure support[6]; in another study, the weaning time was similar with the two methods.[5] Performing trials of spontaneous breathing once a day is as effective as performing such trials several times a day but much simpler.[6]

The most difficult patients to wean are those requiring prolonged ventilation in a long-term acute care hospital. In a randomized trial, Jubran et al.[35] found that intermittent unassisted breathing (using a tracheostomy collar) resulted in 1.43 times faster removal of the ventilator than did pressure support.

Weaning by Protocol Versus Usual Care

Six groups of investigators have undertaken RCTs comparing the use of protocols versus usual care in weaning management. Three groups[36–38] found that protocolized weaning was without benefit. Of the other three studies, two studies[39,40] were marred by major problems of internal validity. The third study[41] revealed no benefit in one of its two intensive care units (ICUs). In summary, only half of one study of six revealed valid support for protocolized weaning, with the remainder providing no evidence of benefit.

Tanios and colleagues[42] undertook an RCT to determine whether the inclusion of f/VT in a weaning protocol influenced weaning time. In the f/VT-protocol group, patients could proceed to a weaning trial (CPAP and pressure support) if—and only if—they had an f/VT of less than 106. In the second study arm, clinicians did not follow the protocolized approach to weaning. The duration of weaning was longer in the f/VT-protocol group than in the nonprotocol group.

The study has two major problems. First, the investigators assume that physicians managing patients in the control group did not calculate f/VT. Physicians, however, are highly aware that respiratory frequency and tidal volume are key variables in deciding whether a patient will tolerate weaning and extubation.[3] Once this knowledge has crept into a physician's brain, it cannot be surgically extirpated at the point of commencing an RCT. To ensure that physicians did not use breathing pattern in the decision making, Tanios and colleagues[42] would have had to have taken steps to hide or occlude the display of frequency and tidal volume on the bedside monitor and ventilator screen.

Second, f/VT was one component in a weaning protocol. It is important to make a distinction between the use of a protocol in conducting a research study and its use in everyday clinical practice. In the research protocol of Tanios and colleagues,[42] patients who had an f/VT of 105 or less progressed to a weaning trial, whereas patients with an f/VT of 106 or higher resumed ventilator support. When conducting research, this is exactly how a protocol must be specified and followed. No flexibility is permitted. A competent clinician, however, would think it daft to slavishly comply with a protocol that decided an entire day of ventilator management on a one-unit difference in a single measurement of f/VT.[43] Rather, intelligent physicians customize knowledge to the particulars of each patient and are expected to outperform the inflexible application of a protocol—as has been shown in numerous studies of weaning protocols.

Extubation

Decisions about weaning and decisions about extubation are commonly combined.[44] When a patient tolerates a weaning trial without distress, a clinician feels reasonably confident that the patient will be able to sustain spontaneous ventilation after extubation. Before removing the endotracheal tube, however, the clinician must also judge whether or not the patient will be able to maintain a patent upper airway after extubation.

Of patients who are expected to tolerate extubation without difficulty, approximately 10% to 20% fail and require reintubation.[5,6] The mortality rate among patients who require reintubation is more than six times as high as the mortality rate among patients who can tolerate extubation.[35] The reason for the higher mortality rate is unknown. It might be related to the development of new problems after extubation or to complications associated with reinsertion of a new tube. A more likely explanation is that the need for reintubation reflects greater severity of the underlying illness.[42]

Many physicians find it convenient to extubate a patient once he or she can breathe comfortably on a pressure support of about 7 cm H_2O and PEEP 5 cm H_2O based on the belief that such "minimal ventilator settings" are simply overcoming the resistance engendered by an endotracheal tube.[45] This claim ignores the inflammation and edema that develop in the upper airways after an endotracheal tube has been in place for a day or more. On removal of the tube, the mucosal swelling produces an increase in upper airway resistance. Straus and associates[46] demonstrated experimentally that the respiratory work dissipated against the supraglottic airway after extubation is almost identical to the work dissipated against an endotracheal tube before extubation. Thus applying any level of pressure support causes physicians to underestimate the respiratory resistance a patient will encounter after extubation. The addition of a small amount of pressure support produces surprisingly large reductions in inspiratory work in ventilated patients: 5 cm H_2O decreases inspiratory work by 31% to 38% and 10 cm H_2O decreases work by 46% to 60%.[34,47] Independently, the addition of 5 cm H_2O of PEEP can decrease the work of breathing by as much as 40% in ventilated patients.[4] In the case of a patient who might experience cardiorespiratory difficulties after extubation, it is incumbent on a physician to ensure that the patient is able to breathe comfortably for about 30 minutes in the complete absence of pressure support or PEEP before removal of the endotracheal tube.[45]

Conclusion

To minimize the likelihood of either delayed weaning or premature extubation, a two-step diagnostic strategy is recommended: measurement of weaning predictors followed by a weaning trial. Because each step constitutes a diagnostic test, clinicians must be mindful of the scientific principles of diagnostic testing when interpreting the information generated by each step. The critical step is for the physician to contemplate the possibility that a patient *just might* be able to tolerate weaning. Such diagnostic triggering is assisted through the use of a screening test, which is the rationale for measurement of weaning-predictor tests. Importantly, one should not postpone this first step by waiting for a more complex diagnostic test, such as a T-tube trial. Many complex facets of pulmonary pathophysiology impinge on weaning management. Thus weaning requires individualized care at a high level of sophistication.

Key Points

- Most patients with an unsuccessful trial of weaning from mechanical ventilation do not succeed because of a markedly increased respiratory load, which, in turn, is secondary to severe worsening of respiratory mechanics over the course of the weaning trial.
- Less common reasons for weaning failure include weakened respiratory muscles or impaired cardiovascular performance; primary abnormalities of the respiratory centers or intrapulmonary shunt are uncommon mechanisms of weaning failure.
- Several studies suggest that most patients weaned successfully could have tolerated the weaning attempts had they been initiated a day or more earlier. Such data emphasize the need for the early use of screening tests.
- The primary goal of a screening test is to not miss anybody with the condition under consideration; thus the test should have a high sensitivity. The ratio of respiratory frequency to tidal volume (f/VT) has been evaluated in more than 25 studies; its average sensitivity is 0.89.
- Weaning involves the undertaking of three diagnostic tests in sequence. The sequential nature of the testing predisposes to the occurrence of test-referral bias and spectrum bias.
- Of the techniques used for a weaning trial, IMV has been repeatedly shown to be inferior to the use of T-tube trials or pressure support.
- Six randomized trials have evaluated the usefulness of protocols in the management of weaning. Three studies observed no benefit with the use of protocols. Two of the remaining three studies had major methodologic problems, leaving only one study supporting the use of protocols.

Review Questions

1. A 62-year-old man with a history of chronic obstructive pulmonary disease (COPD) was admitted to the intensive care unit (ICU) for multilobar pneumonia and COPD exacerbation. He required intubation and mechanical ventilation and was given intravenous broad-spectrum antibiotics and steroids. By day 3, he had improved and was undergoing mechanical ventilation with assist control mode, with tidal volume 400 mL; respiratory rate (RR) 12 breaths/min; positive end-expiratory pressure (PEEP) 5 cm H_2O; fraction of inspired oxygen (FIO_2) 0.40; and oxygen saturation by pulse oximetry (SpO_2) 96%. A weaning trial (spontaneous breathing with T-piece trial) was started but the patient became diaphoretic with an RR of 40 breaths/min, a tidal volume of 250 mL, and an SpO_2 of 88%. Which of the following is the most likely cause of weaning failure?

- **a.** Increased respiratory load and worsening of respiratory mechanics
- **b.** Weaker inspiratory effort resulting in tachypnea
- **c.** A decrease in respiratory drive
- **d.** Hypercapnia owing to a reduction in minute ventilation

Answer 1: a. Patients experiencing weaning failure typically have worsening of respiratory mechanics to include substantial increases in resistance, intrinsic PEEP, and pulmonary elastance. Direct measurements of work of breathing show that weaning-failure patients consistently make greater, not weaker, inspiratory efforts than do weaning-success patients. Similar, respiratory drive is typically increased. Hypercapnia can occur during weaning failure but is typically due to increased dead-space ventilation secondary to shallow breathing or intrinsic PEEP, as opposed to a reduction in minute ventilation. A spontaneous breathing trial also can place substantial work on the myocardium as venous return is increased, left ventricular afterload increased, and if hypoxia, hypercapnia, or intrinsic PEEP occur, and increased right ventricular afterload as well. Given this, clinicians should always also think of cardiac performance as a possible contributor to weaning failure.

2. With respect to weaning methods:

- **a.** All weaning methods are equally effective.
- **b.** Effective weaning involves the gradual withdrawal of support and RR delivered by intermittent mandatory ventilation.
- **c.** A ½-hour trial of spontaneous breathing is as effective as a 2-hour trial.
- **d.** Weaning trials should be performed several times per day, as opposed to one, as evidence supports earlier liberation from the mechanical ventilator.

Answer 2: c. All weaning methods are definitely not equally effective. Weaning with intermittent mandatory ventilation has consistently been proved to be an inferior method. Breathing trials performed once per day are equally as effective as multiple trials per day. The clinician should not automatically condemn a patient to weaning failure for the day after failing a breathing trial. Rather, reasons for failure should be sought and corrected, and another breathing trial should be conducted, knowing the literature supports this.

3. Which one of the following is the least likely cause for reintubation?

- **a.** Inability to tolerate respiratory load
- **b.** Upper airway obstruction
- **c.** Excessive secretions
- **d.** Steroid myopathy

Answer 3: d. Patients who require reintubation have higher severity of illness scores, are older, and have a longer duration of mechanical ventilation than successfully extubated patients. It is not clear whether reintubation per se contributes to mortality rate or is simply a marker of disease severity. Reintubated patients have a much higher mortality rate than successfully extubated patients. Steroid myopathy is an uncommon cause for reintubation. Excessive secretions (16%–28% of reintubations) and inability to tolerate an additional respiratory load (28%–37% of reintubations) are the most common causes of reintubation. Upper airway obstruction is reported to be the reason in 15% of reintubations.

4. Which of the following is true regarding weaning predictor tests and weaning trials?

- **a.** Compared with clinical intuition, weaning predictor tests do not identify a cohort of patients ready to wean from the ventilator.
- **b.** A rapid shallow breathing index (RSBI) or the ratio of respiratory frequency to tidal volume (f/VT) of 100 best discriminates between successful and unsuccessful attempts at weaning.
- **c.** The application of pressure support or continuous positive airway pressure (CPAP) at low levels has no influence in respiratory mechanics or the accuracy of the predictive ability of f/VT.
- **d.** Weaning trials performed as part of a protocol have consistently shown benefit by decreasing mechanical ventilator days.

Answer 4: b. Data have shown that many patients receiving mechanical ventilation tolerate mechanical ventilation discontinuation on the first day they are extubated. This suggests that a big barrier to extubation is lack of clinician recognition of readiness to wean. The RSBI has been studied in a myriad of investigations. Although imperfect, compared with other predictors of readiness to wean (e.g., negative inspiratory pressure, minute ventilation), it has consistently been shown to be the most reliable marker. In the original studies, RSBI was measured in the complete absence of ventilator assistance. The application of low levels of support can markedly reduce work of breathing and overcome resistance. As such, they will alter the values of weaning predictors as compared with no support via a T-piece. Although commonplace, protocolized weaning has not been shown to improve outcome above and beyond usual care. Reasons for failure should be sought and corrected, and the patient should be observed by the treating clinician during a weaning trial; liberation from the ventilator should be customized to the individual patient.

Pulmonary Embolism Response Team

Pulmonary venous thromboembolism (VTE) and deep venous thrombosis (DVT) are different manifestations of the same disease. Despite adequate VTE prophylaxis in the intensive care unit (ICU) the presence of a VTE event is a constant threat to critically ill patients. Although the critical care clinician may encounter the embolization of air, fat, infected clots, amniotic fluid, tumor, and inorganic substances, by far VTE will be the most common pulmonary embolic condition encountered. Critical care clinicians will encounter life-threatening pulmonary embolism (PE) ranging from hemodynamically stable patients with varying degrees of right ventricular dysfunction (RVD) to acute massive PE, defined as hemodynamic shock from acute PE, which represents the most serious manifestation along the spectrum of venous thromboembolic disease.[1–3] According to population-based studies, the annual incidence of VTE in the United States has ranged from 200,000 to a recent estimate of 900,000 cases in which approximately 300,000 people die every year from acute PE.[4,5] More recently (in 2006), 467,000 patients were hospitalized with DVT and 247,000 patients were admitted with acute PE.[6] VTE is associated with significant health care costs. Based on 2004 provider payments, the economic burden of VTE costs ranges between $5.8 billion and $7.8 billion.[7]

The mortality rate can exceed 58% in patients with acute PE presenting with shock, and most of these deaths occur within 1 hour of presentation.[1,2] Acute PE is the third most common cause of death among hospitalized patients, and with an aging population the number of people with VTE is expected to increase. For these reasons, the U.S. Surgeon General issued a "Call to Action" in 2008, identifying VTE as a major public health problem.[8]

The development of DVT occurs largely in the lower extremities and can result in the sequelae of PE, postthrombotic syndrome, and chronic thrombotic pulmonary hypertension.[9] Venous thrombosis is associated with significant morbidity and mortality rates but can be prevented in most patients.[2,3]

In this chapter we review the epidemiology, risk factors, diagnosis, risk assessment, and management of acute PE. In our discussion we review VTE in special adult populations, VTE prophylaxis in the ICU, and long-term prognosis.

Prevalence of Venous Thromboembolism in Intensive Care Unit Patients

ICU patients represent a heterogeneous population. In prospective screening studies for DVT, in the absence of thromboprophylaxis,

[†]Deceased.

the incidence of DVT in a medical-surgical ICU ranges from approximately 13% to 33%.[10–12] In an autopsy review of 6 studies of 436 critically ill patients the incidence of PE ranged from 7% to 27% (mean 13%); PE contributed or directly caused death in 0% to 12% (mean 3%) of the patients. It is important to note that in a majority of the patients there was no antemortem suspicion of fatal PE.[13]

Contemporary prevalence of patients with VTE who are admitted to or VTE that occurs in the ICU setting can be obtained from large VTE clinical trials. Approximately 10% of patients entered into the PIOPED-I (Prospective Investigation of Pulmonary Embolism Diagnosis) study for possible PE were hospitalized in a medical or surgical critical care unit.[14] In the recent international multicenter EINSTEIN PE trial,[15] which randomly assigned 4823 symptomatic patients with PE to rivaroxaban or enoxaparin and a vitamin K antagonist, 600 patients (12.4%) required ICU admission. Finally, in the PROTECT trial (Prophylaxis for Thromboembolism in Critical Care Trial)[16] among 3764 critically ill patients enrolled in which a majority were supported by mechanical ventilation and 40% were receiving vasopressor therapy, dalteparin and unfractionated heparin (UFH) were the agents used for VTE prophylaxis. The primary endpoint was proximal DVT presence. Using compression ultrasonography (CUS), 3.5% of the patients had proximal DVT on admission. The incidence of proximal DVT was 5.1% in the dalteparin group and 5.4% in the UFH group. The proportion of patients with pulmonary emboli was significantly lower with dalteparin (24 patients, 1.3%) than with UFH (43 patients, 2.3%).[16]

There is controversy over routine DVT screening in the ICU. As mentioned earlier, most ICU patients with DVT are asymptomatic and the clinical signs for DVT are nonspecific. CUS is time-consuming and not cost-effective. Efforts must be made to ensure adherence to current DVT prophylaxis guidelines. In ICU patients in whom these guidelines cannot be fully implemented (intracranial, spinal, or leg injuries, or patients at increased bleeding risk) then routine CUS screening may be appropriate.[17–21]

Risk Factors

In the nineteenth century Virchow described stasis, vascular wall abnormalities, and hypercoagulability as general risk factors for the development of DVT.[22]

As illustrated in Table 42.1, patients admitted to the ICU possess multiple preexisting VTE risks factors on admission to the ICU, yet in the International Cooperative Pulmonary Embolism Registry (ICOPER) 20% of the patients had idiopathic or unprovoked PE.[3]

The interaction between patient-related and setting-related risk factors appears to be responsible for the development of the VTE.[23–25] Patient-related risk factors are usually acquired and are long-standing. Examples of patient-related risk factors are age, history of prior VTE, malignancy, neurologic and medical illnesses that result in immobility, cardiopulmonary disorders, collagen vascular disease, and vasculitis. In addition, patient-related factors may include genetic and acquired thrombophilia and hormone replacement therapy and oral contraceptive therapy. Setting-related risk factors are usually temporary. Examples of setting-related risk factors include hospitalizations, nursing home placement, and admission to the ICU.

Virchow has described several risk factors unique to the ICU setting that predispose patients to VTE events. In a prospective observational study of 93 medical-surgical ICU patients, the investigators identified several ICU-related factors associated with increased risk of VTE, including mechanical ventilation, immobility, femoral venous catheters, sedatives and paralytic drugs, and failure to prescribe VTE prophylaxis. Prolonged immobility in the ICU setting is the result of mechanical ventilation, sedative administration, and paralytic agents. These four factors (mechanical ventilation, immobility, sedation, and paralysis) may converge to greatly increase the risk of VTE.[26] Sedation and paralysis also predispose to other ICU complications, including increased duration of mechanical ventilation, and critical illness polyneuropathy.[27,28]

See the online supplement for additional discussion on Risk Factors.

Deep Venous Thrombosis

It is estimated that as many as 95% of clinically significant pulmonary emboli originate from the deep veins of the lower extremity. The proximal deep veins of the leg are the most common sites of origin of clots that embolize to the pulmonary circulation. A general consensus suggests that clinically significant proximal DVTs and risk for PEs originate by proximal extension of calf DVT.[47,48] Venous thrombi are created in the setting of low flow and low shear stress. These thrombi consist of fibrin strands, red blood cells, and platelets. The thrombi form in the valve pockets of calf veins and extend to the proximal veins.[48] After the thrombosis is formed there is raised venous capillary pressure, which increases the transcapillary filtration and the pressure rate, resulting in edema. In approximately 50% of patients, venous outflow obstruction decreases within 3 months by lysis and recanalization.[49] Patients who have early edema are most likely to have residual thrombosis. Clots that continue to propagate have a greater risk to break apart and lead to embolization. This generally occurs more frequently in the first few days

TABLE 42.1 Selected Risk Factors for Venous Thromboembolism

Genetic Risk Factors	Acquired Risk Factors	Triggering Risk Factors	ICU-Acquired Risk Factors
Antithrombin III deficiency	Age	Surgery	Sepsis
Protein S and C deficiency	Previous VTE	Pregnancy	Vasopressor use
Prothrombin gene mutation	Obesity	Estrogens	Central venous line
	Malignancy	Immobility	Platelet transfusions
	Antiphospholipid syndrome		Pharmacologic paralysis
	Collagen vascular disease		Use of recombinant factor VIIa

ICU, Intensive care unit; *VTE,* venous thromboembolism.

VTE events increase with age. In one population-based study, there was a nonlinear, exponential increase in VTE events with age and a significant increase noted after the age of 60 years.[29] In the elderly, rates of PE are rising faster than the rates of DVT; thus a VTE event in an elderly person is more likely to be a PE, with its associated increased mortality.[3,30]

Anderson and Spencer[31] reviewed multiple risk factors associated with a diagnosis of VTE and found that the risk factors were not equal in their impact on VTE occurrence. The strongest risk factors were hip and leg fractures, major general surgery, hip or knee replacement, major trauma, and spinal cord injury. Moderate risk factors included arthroscopic knee surgery, central venous lines, chemotherapy, congestive heart failure, hormonal replacement or oral contraceptives, cancer, pregnancy, thrombophilia, and prior VTE.[31] Heit and associates[32] found that the hospital setting, nursing home, or other chronic facility confinement was an independent risk factor for VTE. This is most likely due to increasing degrees of immobility.

Several acquired and inherited hypercoagulable states have been shown to increase the risk of VTE and are collectively known as thrombophilia. Major acquired hypercoagulable conditions include malignancy, myeloproliferative disorders, and antiphospholipid syndrome (APS).[33] DVT, the most common manifestation of the APS, occurs in 29% to 55% of patients with the syndrome, and about half of these patients have pulmonary emboli.[34–36]

The occurrence of a VTE event in a young adult should alert the clinician to the potential of an underlying inheritable thrombophilic condition. Nearly half the patients with a VTE event before the age of 45 years have an associated inherited disorder.[33] Factor V Leiden mutation causing resistance to activated protein C is the most common inherited risk factor. Factor V Leiden mutation is present in up to 5% of the normal population and is the most common cause of familial thromboembolism.[33] Factor V Leiden mutation appears to be more associated with the development of DVT rather than PE.[37] Primary or acquired deficiencies in protein C, protein S, and antithrombin III are other risk factors and their thrombotic expression is variable.[33]

Several primary disorders are associated with a high risk for fatal VTE. Patients frequently present with massive PE, and ICU admission is required. From the RIETE (Computerized Registry of Patients with Venous Thromboembolism) study, risk factors of immobilization secondary to neurologic disease, cancer, and cardiopulmonary disorders had two- to threefold increased risk for fatal PE.[38] In hospitalized cancer patients, VTE is the second leading cause of death.[39] The risk of VTE in cancer patients undergoing surgery is three to five times greater than that in surgical patients without cancer. Moreover, cancer patients with symptomatic DVT exhibit a high risk of recurrent VTE.[40] Heart failure is a frequent admission diagnosis in the coronary care unit. In patients with severe heart failure (ejection fractions <30%) PE is a major cause of morbidity and mortality.[41,42] Among 198 patients with severe heart failure in the coronary care unit, 9.1% developed PE during their hospitalization, despite a majority receiving thromboprophylaxis.[41] In an autopsy series of cardiac patients nearly a quarter had PE and the diagnosis was unsuspected in 82% of the patients.[43] Acute exacerbation of chronic obstructive pulmonary disease (COPD) is a common reason for admission to the general hospital ward service and the ICU. Increased work of breathing leads to immobility, which is a risk factor of DVT. In a prospective cohort of 196 patients with COPD exacerbation, all patients had ultrasonography of the lower extremities performed. Among the 196 patients, 21 (10.7%) had DVT and the majority of patients were asymptomatic.[44] Moreover, hospitalized patients with unexplained exacerbations of COPD, when routinely evaluated, show demonstrated PE in 25% to 29%.[45,46]

after clot formation. Clots that do not continue to propagate resolve by either fibrinolysis or organization. These processes generally occur within 7 days of clot formation.[49,50]

In general, only 25% of patients with suspected DVT actually have it.[47] The detection of DVT in critically ill patients is hampered by the patient's inability to report symptoms and the unreliability of physical signs of DVT. CUS is noninvasive and highly sensitive and specific for the diagnosis of proximal lower extremity DVT.[51] Full compressibility of either the femoral or popliteal veins excludes proximal DVT[51] when compared to the gold standard demography; CUS has a sensitivity of 97% to 100% and a specificity of 98% to 99% for the detection of proximal thrombosis. Ultrasonography is less accurate in the diagnosis of distal calf vein thrombosis.[51,52] Whether high-risk critically ill patients should be systematically screened for DVT using CUS, given the high incidence of DVT and limitation of clinical examination, is unresolved.[13,17]

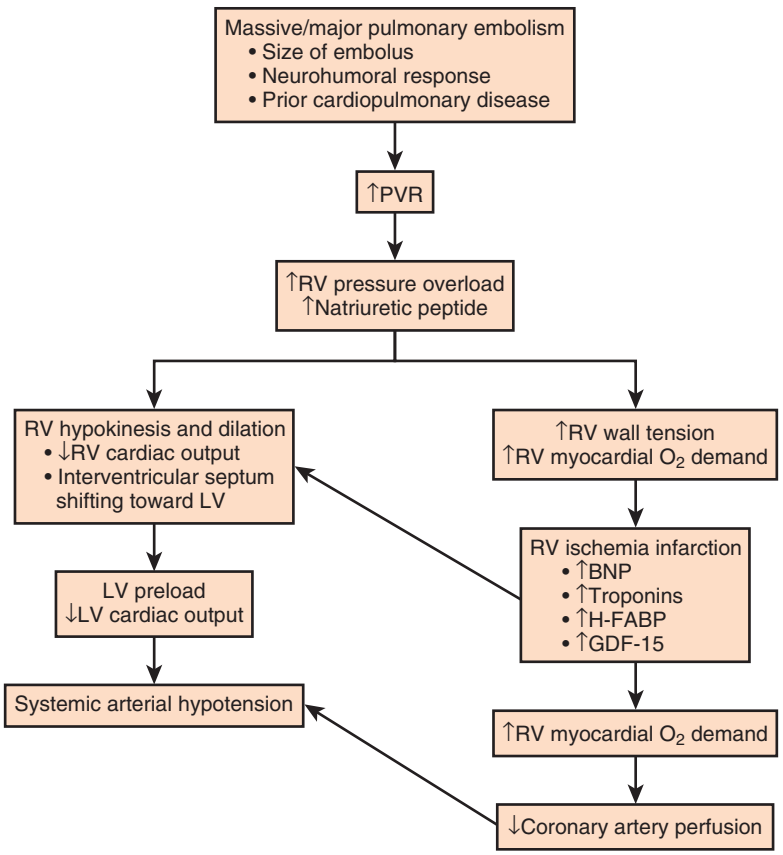
Upper extremity deep venous thrombosis (UEDVT) accounts for approximately 4% of the venous thromboembolic events.[53] Primary UEDVT makes up one-third of all UEDVTs. Primary UEDVTs appear to be associated with inherited thrombophilic conditions, and the risk markedly increased to 14-fold when oral contraceptives were used.[54] Catheter UEDVTs are associated with the placement of a central venous catheter, and these patients are more likely to be inpatients than outpatients, as demonstrated by a large registry.[55] In addition, patients with cancer have an increased occurrence of UEDVT when a central venous catheter is placed in these areas.[55] Catheter-related UEDVT may have a higher pulmonary embolic potential than primary UEDVT.[52]

Pathophysiology

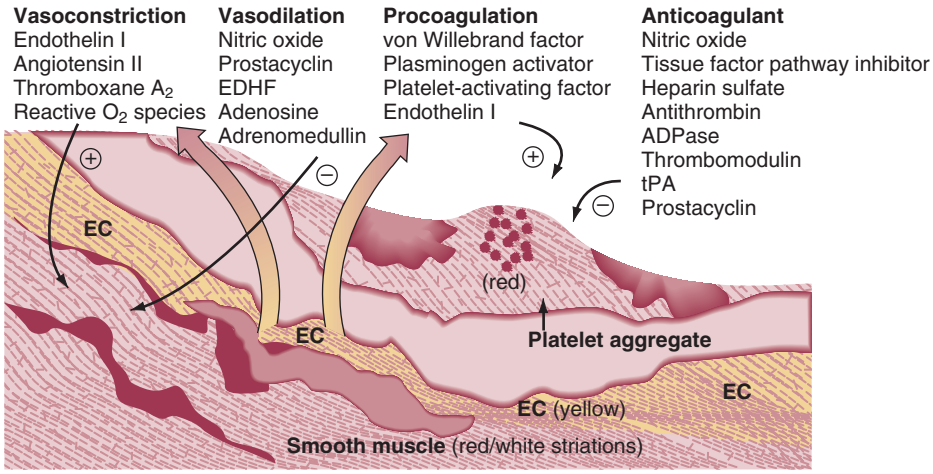
Nearly two-thirds of patients who die from pulmonary thromboembolism die within 1 hour of presentation, but anatomically massive pulmonary emboli (>50% obstruction of the pulmonary circulation) are responsible for only half of the deaths. The term *major pulmonary thromboembolism* has been used to describe any pulmonary thromboembolus that results in a hemodynamically significant event.[1] In patients with pulmonary thromboembolism, hemodynamic presentation is an important predictor of survival. The Urokinase Pulmonary Embolism Trial (UPET) demonstrated that the presence of hemodynamic decompensation was associated with a sevenfold increase in mortality rate.[56] ICOPER confirmed these results by demonstrating a fourfold increase in mortality rate for those patients with hemodynamic instability.[3] Because of the associations between outcome from pulmonary thromboembolism and shock or hypotension, aggressive intervention in patients thought to have pulmonary thromboembolism has given rise to the term *golden hour,* during which timely diagnosis and treatment are paramount.[1]

Hemodynamic Consequences

The principal pathophysiologic effects of pulmonary thromboembolism result from the acute impaction of material into pulmonary circulation and the resulting vascular obstruction and humoral mediator release as depicted in Fig. 42.1.[57] In nonthrombotic obstruction of the pulmonary vasculature, obliteration of 60% to



• **Fig. 42.1** The pathophysiology of acute massive/major pulmonary embolism. *BNP,* Brain natriuretic peptide; *GDF-5,* growth differentiation factor-15; *H-FABP,* heart-type fatty acid–binding protein; *LV,* left ventricle; *O_2,* oxygen; *PVR,* pulmonary vascular resistance; *RV,* right ventricular.



• **Fig. 42.2** Platelet-derived vasoactive factors influencing pulmonary vascular resistance. *ADPase,* Adenosine diphosphatase; *EC,* extracellular; *EDHF,* endothelium-derived hyperpolarizing factor; *O_2,* oxygen; *tPA,* tissue plasminogen activator.

70% of the vascular tree is required to cause an elevation of the pulmonary artery (PA) pressure. In contrast, only 30% of the vascular tree must be obstructed in pulmonary thromboembolism for elevation of the PA pressure to be achieved.[58,59] Therefore factors other than simple mechanical obstruction of the pulmonary vascular system play a role in the elevation of the pressures in the pulmonary vasculature during pulmonary thromboembolism.

The production of platelet-derived vasoconstrictors may play a role in augmenting the increase in pulmonary vascular resistance (PVR) (Fig. 42.2).[57,58,60] Thromboxane A_2 (TxA_2) is a potent vasoconstrictor and is the end product of arachidonic acid metabolism. TxA_2 is produced by endothelial cells, and even in greater quantities by platelets in response to platelet aggregation. It has been demonstrated that there is increased production of TxA_2 in the early phase of PE, which contributes to the PVR elevation and may be attenuated by cyclooxygenase inhibition in animal models.[57] Serotonin (5-hydroxytryptamine) is one of the most potent pulmonary vasoconstrictors. Infusion of serotonin in an animal model can actually simulate the signs and symptoms of PE. Like TxA_2, platelets are the primary source of serotonin production in PE. Serotonin antagonism can reduce PVR.[57,60]

As shown in Fig. 42.1, the degree of mechanical obstruction, the interplay of neurohumoral mediators, and the patient's underlying cardiopulmonary status will dictate the degree of RVD. A rapid rise in the PA resistance produces a significant rise in right ventricular (RV) afterload, thereby causing RV dilatation. The dilation of the right ventricle results in shifting of the interventricular septum into the left ventricle, decreasing left ventricular (LV) preload.[61–63] Moreover, RV dilation potentially promotes an increase in constrictive forces by the pericardium, leading to reduced LV compliance. Decreasing LV preload and compliance subsequently lead to lowering of the cardiac output and systemic hypotension with a resultant decrease in aortic perfusion pressure and decreasing right coronary perfusion pressure.[64,65] A compromised and burdened right ventricle is a direct result of oxygen demand outstripping oxygen supply, creating an ischemic environment for the right ventricle. The functional status of the cardiopulmonary system is very important in the initial hemodynamic presentation and is a major determinant of short- and long-term outcome.[66] In patients without cardiopulmonary disease the anatomic and humoral obstruction must be 75% or greater to cause a mean PA pressure of 40 mm Hg or higher, which is not sustainable; even the previously healthy heart may fail, leading to cardiovascular collapse.[66] Right atrial pressure (RAP) elevation occurs when the mean PA pressure is 30 mm Hg or higher and obstruction exceeds 35% to 40%.[67] Many patients who have a pulmonary embolic event have underlying cardiopulmonary disease. In these patients, cardiopulmonary deterioration (CPD) may occur with a lesser degree of vascular obstruction.[66] This concept is illustrated by the UKEP (Urokinase-Embolie Pulmonaire) Trial in which an initial presentation of shock with acute PE was seen in 56% of patients who had prior cardiopulmonary disease compared with 2% without cardiopulmonary disease. Obstruction of greater than 50% was uncommon.[68]

Respiratory Consequences

Hypoxemia is the most common gas exchange abnormality in patients. However, the Pao_2 and alveolar-arterial (A-a) gradient have been reported to be normal in approximately 30% of patients with PE.[69] Fig. 42.2 summarizes the gas exchange abnormalities as a result of the pulmonary embolic event. Ventilation-perfusion mismatch and low mixed venous oxygen levels are the prevalent causes of hypoxemia.[70,71] As PA pressures increase, right-to-left flow across a patent foramen ovale may occur. Endothelial damage may result from hypoxic exposure and further lead to pulmonary vasoconstriction. Hypoxemia may even promote a prothrombotic and antifibrinolytic effect.[57]

In acute PE an increase in alveolar dead space impairs carbon dioxide (CO_2) elimination; however, the increase in minute ventilation results in hypocapnia. In patients with massive PE there can be a paradoxical elevation of the $PaCO_2$ as a result of a marked increase in dead-space ventilation.[72] In patients with PE because of an increase in alveolar dead space there is a reduction in alveolar CO_2 content, which can be detected by capnography by a reduction in the capnographic waveform area. In one study, patients with PE significantly demonstrated a reduction in the capnographic waveform area compared with patients without PE.[73] There is widening of the partial pressure of end-tidal carbon dioxide ($PETCO_2$)-$PaCO_2$ gradient. Bedside $PETCO_2$ coupled with a Wells score has been shown to have a high negative predictive value.[74]

Clinical Presentation

The signs and symptoms of acute PE are at best nonspecific. The presence of syncope, current DVT, hemoptysis, leg swelling, active cancer, surgery, leg pain, and shock each marginally increases the probability of PE. Further, the absence of dyspnea or tachycardia marginally reduces the probability of PE.[75]

Approximately 50% of patients with acute PE present to the emergency department. In the Emergency Medicine Pulmonary Embolism in the Real World Registry (EMPEROR Registry), among 1880 documented PE patients from 22 U.S. emergency departments, the most common presenting signs and symptoms were dyspnea at rest (50%), pleuritic chest pain (39%), dyspnea with exertion (24%), and syncope, which occurred in 5% as the initial presentation of acute PE. Only 58 patients (3%) had systolic blood pressures of 90 mm Hg or lower on presentation.[76]

Clinical prediction rules have been used in the emergency department setting to determine the pretest probability of acute PE.[77] The most widely known prediction model has been the Wells score and it can allow for a dichotomous classification.[78,79] Other prediction scores have been used, such as the Geneva and the modified Geneva.[77,78] All prediction scores appear to have similar accuracy but are influenced by the local prevalence of PE. The clinical prediction scores are enhanced in identifying the patient with low probability of PE coupled with low D-dimer value.[79]

Clinical Presentation on Admission to the Intensive Care Unit

In patients admitted to the ICU with PE the clinical manifestations may be more demonstrative, as shown in Table 42.2. In the Urokinase Pulmonary Embolism Trial (UPET), the clinical features of massive PE were evaluated. Sudden unexplained onset of dyspnea was the most common symptom and was present in 80% of the patients. A majority of the patients had a well-defined risk factor. Tachypnea and tachycardia were present in 88% and 63% of the patients, respectively. Accentuated second heart sound was noted in 67%, and S_3 or S_4 gallop was present in 47%. Clinical shock was noted in 9%.[80] Syncope can occur. Retrosternal nonpleuritic chest pain may mimic the pain experienced with a myocardial infarction and represent demand ischemia of the right ventricle. The differential diagnosis of pulseless electrical activity (PEA) is massive PE and should be expected when there is a known major risk factor.

The signs and symptoms of submassive PE depend on the degree of RVD. Dyspnea may be progressive over the past 4 to 6 days. Chest pain can be either pleuritic or nonpleuritic in nature. If pulmonary infarction occurs as the result of distal embolization, then hemoptysis may occur. From the PIOPED-II database, 92% of patients with main or lobar pulmonary emboli had dyspnea or tachycardia in contrast to segmental emboli dyspnea and tachycardia, where 65% had these findings.[81,82]

Patients with massive PE and shock manifest systemic hypotension, poor perfusion of the extremities, tachycardia, and tachypnea. In addition, patients appear weak, pale, diaphoretic, oliguric, and develop altered mental status. The patient may be hypoxemic and require high-flow oxygen or urgent intubation and mechanical ventilation. Varying degrees of RVD may be observed. The presence of jugular venous distention, with and without inspiratory collapse, RV heave, summation gallop, accentuated P_2, and presence of tricuspid regurgitation represent the impact the embolus has had on pulmonary vasculature and RV function. If a central line is placed via the subclavian or jugular route, the central venous oxygen saturation ($Scvo_2$) is usually less than 65%.

TABLE 42.2 Clinical Signs and Symptoms of Acute Pulmonary Embolism Potentially Requiring Intensive Care Unit Management

Clinical Variable	Frequency (%) Submassive PE	Frequency (%) Massive PE
Symptoms		
Dyspnea	78	86
Pleuritic CP	85	67
Apprehension	50	70
Altered Mental Status*	5	
Diaphoresis	20	44
Syncope	4	17
Signs		
Tachycardia	42	66
Tachypnea	81	87
Fever	51	50
Deep venous thrombosis	47	39
Cyanosis	3	24
Other Signs		
Jugular venous distention		80
Shock		10
Cardiac arrest (PEA)		28

Recognition of Pulmonary Embolism During Intensive Care Unit Admission

When a patient is admitted to the ICU for a non–PE-related clinical diagnosis, the abrupt and unexplained occurrence of some combination of chest pain, dyspnea, tachypnea, hypotension, and hypoxemia should raise the suspicion of PE. Unexplained fever with and without mild leukocytosis could represent a possible VTE event.[83] Hemoptysis can occur as a result of small distal pulmonary emboli causing alveolar hemorrhage. If PE occurs while the critically ill patient or postoperative patient is using mechanical ventilation, the clinical suspicion and conformation can be difficult. An increase in minute ventilation, dead space, or an increase in supplemental oxygen may be clues to an embolic event. If the patient has end-tidal CO_2 ($PETCO_2$) monitoring, an increase in the $PaCO_2$-$PETCO_2$ gradient may occur.[73]

Diagnostic Testing for Pulmonary Embolism

Arterial Blood Gas Measurement

Hypoxemia and an increased alveolar-arterial gradient are usually seen in PE but can be normal in about 14% and are most likely the result of small embolic events.[84,85] The initial acid-base disturbance is a respiratory alkalosis, which may evolve to a metabolic

(lactic) acidosis as hypotension and shock ensue. A linear relationship between PE severity and Pa_{O_2} in patients without prior cardiopulmonary disease has been described. In the UPET and PIOPED trials 12% and 19% of patients, respectively, had Pa_{O_2} 80 mm Hg or greater.[86] Hypocarbia is usually present with acute PE because of hyperventilation, but hypercapnia can occur with large PEs producing increased dead space.[87,72]

Chest Radiography

The chest radiograph is abnormal in most cases of PE; however, radiographic findings possess inadequate sensitivity to rule out PE. Common radiographic abnormalities include atelectasis, pleural effusion, parenchymal opacities, and elevation of a hemidiaphragm. Radiographic findings of pulmonary infarction often show a wedge-shaped, pleural-based triangular opacity with an apex pointing toward the hilus (Hampton hump). Focal oligemia or decreased vascularity has been known as the Westermark sign. These findings are suggestive of PE but are infrequently prospectively observed.[88,89] Radiographic findings of RVD may include a prominent central PA (knuckle sign) and cardiomegaly. In one large prospective cohort of patients with PE a normal chest radiograph was found in 24% of the patients.[89] A normal-appearing chest radiograph in a patient with severe dyspnea and hypoxemia is suggestive of a pulmonary embolic event.

Electrocardiography

In 1935 McGinn and White first described the association between acute PE and specific electrocardiogram (ECG) changes when they noted the $S_1Q_3T_3$ pattern in seven patients with acute cor pulmonale.[90] A normal ECG can occur with PE in a frequency ranging from 9% to 30%. The most common ECG abnormalities in the setting of PE are tachycardia and nonspecific ST-T wave abnormalities. The classic findings of right-sided heart strain and acute cor pulmonale are tall, peaked P waves in lead II (P pulmonale); right-axis deviation; right bundle branch block; and an $S_1Q_3T_3$ pattern. Only 20% of patients with proven PE have any of these classic ECG abnormalities.[91–93] T-wave inversion in the precordial leads representing subepicardial ischemia may be seen. The presence of this ECG finding is associated with increased degree of vascular obstruction and elevation of the PA pressure.[94] The new onset of atrial fibrillation has been thought to be associated with a pulmonary embolic event. In a recent study the occurrence of atrial fibrillation did not in general increase the probability of PE.[95] However, if chest pain were the only symptom, the presence of atrial fibrillation increases the probability of PE (odds ratio [OR] 2.42, 95% confidence interval [CI] 0.97–6.07).

D-Dimer Assay

The serum D-dimer is a degradation product produced by plasmin-mediated proteases of cross-linked fibrin. D-Dimer is measured by a variety of assays. These assays are categorized as quantitative, semiquantitative, qualitative rapid enzyme-linked immunosorbent assays; quantitative and semiquantitative latex; and whole-blood assays. The quantitative rapid enzyme-linked immunosorbent assays are the best assays to use in terms of sensitivity and likelihood ratio.[96] When clinical prediction scores indicate that the patient has a low or moderate pretest probability of PE, D-dimer testing is useful to further define the likelihood of PE. Negative results on a high-sensitivity D-dimer test in a patient with a low pretest probability of PE (Wells rule) are associated with a low likelihood of VTE and reliably exclude PE.[97] In a large prospective, randomized trial in patients with a low probability of PE who had negative D-dimer results, not performing additional diagnostic testing was not associated with an increased frequency of symptomatic VTE during the subsequent 6 months.[98]

D-Dimer testing loses its ability to predict the likelihood of PE in older patients and in the presence of cancer, pregnancy, and various inflammatory or infectious disorders. If the pretest probability for PE is high, D-Dimer testing should not be performed and objective testing should be done.[96]

Combining D-dimer results with measurement of the exhaled P_{ETCO_2} to the partial pressure of oxygen (P_{O_2}) (P_{ETCO_2}/P_{O_2}) can be useful for diagnosis of PE. Kline and colleagues demonstrated in moderate-risk patients a positive D-dimer result (>499 ng/mL) and a P_{ETCO_2}/P_{O_2} ratio less than 0.28 significantly increased the probability of finding segmental or larger PE on computed tomography (CT) multidetector-row pulmonary angiography.[99] In contrast, a P_{ETCO_2}/P_{O_2} ratio greater than 0.45 predicted the absence of segmental or larger PE.

Duplex Compression Ultrasonography

Currently, DVT is largely diagnosed by duplex CUS. When using CUS, the ultrasonographic transducer pressed against veins shows they are easily compressed, but the muscular arteries are extremely resistant to compression. Where DVT is present, the veins do not collapse completely when pressure is applied using the ultrasonographic probe.[100–102]

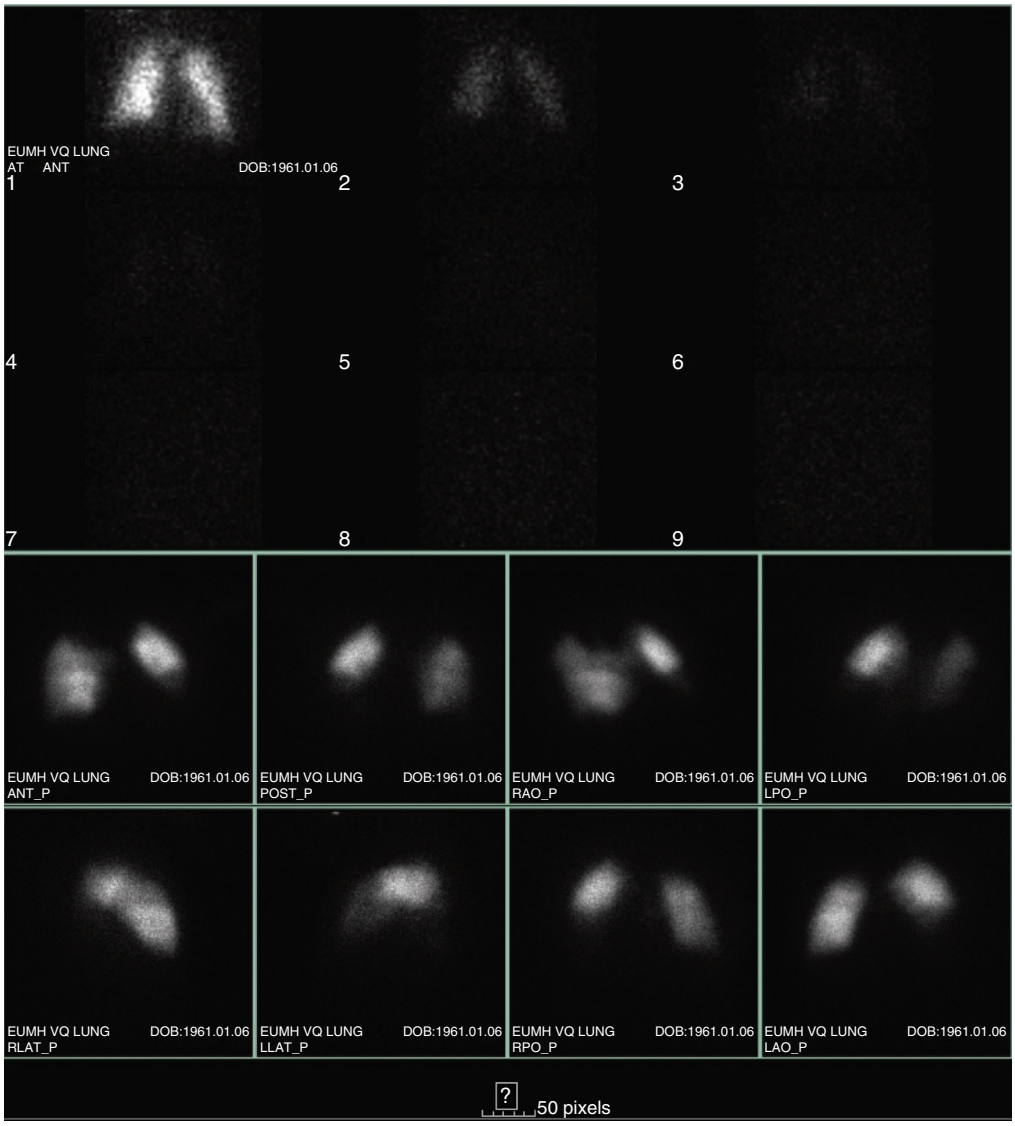
Before an ultrasonographic scan can be considered negative, the entire deep venous system must be examined using centimeter-by-centimeter compression testing of every vessel. The risk of a DVT event after a single whole leg CUS in 3 months is 0.57% (95% CI 0.25–0.89).[103]

CUS is associated with a sensitivity of 97% for proximal DVT, 72% for distal DVT, and a specificity of 94%.[104] In a meta-analysis of the role of CUS in DVT, CUS alone had a sensitivity of 93.8% (92.0%–95.3%) for proximal DVT, 56.8% (49.0%–66.4%) for distal DVT, and specificity of 97.8% (97.0%–98.4%).[105]

Ventilation-Perfusion Nuclear Scans

The ventilation-perfusion ($\dot{V}/\dot{Q}$) scan has a limited role in the diagnosis of acute PE in the ICU, although its diagnostic accuracy is no different from that in non–critically ill populations.[106] Because of the advancing technology of CT scanning, the lung scan is used in critical care units in special circumstances such as renal insufficiency or in the patient who is not intubated and capable of transport from the ICU to the nuclear medicine suite for a full view scan. If the institution has a portable lung scanner, this can be used in the ICU but the number of images is reduced compared with the standard $\dot{V}/\dot{Q}$ scan.

A high-probability scan, as shown in Fig. 42.3, is sufficient diagnostic evidence of PE to begin anticoagulation therapy, and a normal $\dot{V}/\dot{Q}$ scan is considered sufficient evidence to exclude PE. However, the frequency of low- or intermediate-probability scans (indeterminate scans) can be as high as 50% to 70%, with a 10% to 50% probability of PE. Therefore it is impossible to initiate anticoagulation therapy based on this indeterminate lung scan probability. In the first PIOPED study, only 40% of patients with PE had a high-probability $\dot{V}/\dot{Q}$ scan result, whereas another 40% of patients with PE had an indeterminate result and 14%



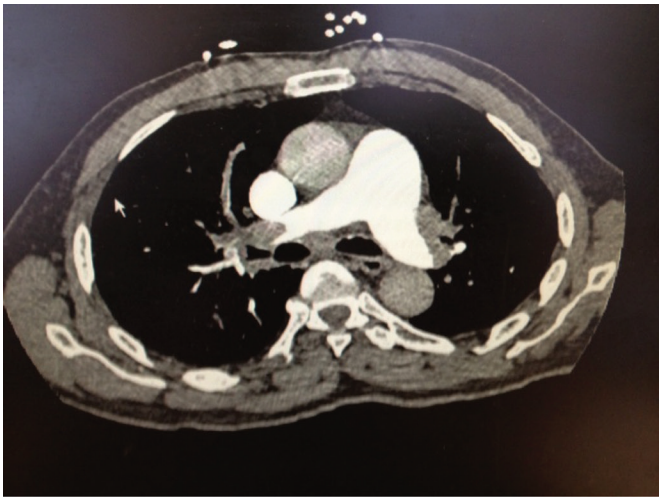
• **Fig. 42.3** High-probability ventilation-perfusion lung scan in a patient with submassive pulmonary embolism and right ventricular strain. Large left lung perfusion defects with a right upper lobe apical perfusion defect are present. Ventilation is normal.

had a low-probability result. A high-probability $\dot{V}/\dot{Q}$ scan result had a positive predictive value of 88% in patients without prior history of PE. The combination of a high clinical probability with the high-probability lung scan resulted in a 96% positive predictive value. The negative predictive value of a low-probability scan result was 88% and improved to 96% when combined with a low clinical probability. Thus a low-probability scan result with a low clinical probability score rules out PE as definitively as a normal scan result. Finally, 39% of the patients had intermediate scan results and 32% of these patients had angiographically proven PE.[14,107]

Preexisting cardiopulmonary disease diminishes the clinical utility of $\dot{V}/\dot{Q}$ scans by increasing the prevalence of nondiagnostic scans. Nondiagnostic scans are more likely to occur in patients with preexisting cardiopulmonary disease. Lung scans are not useful to either establish or rule out the diagnosis of PE in more than 80% of cases. A similar disadvantage of $\dot{V}/\dot{Q}$ lung scans is noted in critically ill patients with prior cardiopulmonary disease. Nevertheless, $\dot{V}/\dot{Q}$ lung scans can be performed in the critically ill, even if patients are receiving mechanical ventilation, and chest radiographic abnormalities can be used as a surrogate of ventilation defects. Despite the limited ventilation component under positive-pressure respiration, the perfusion component is not significantly affected by mechanical ventilation. $\dot{V}/\dot{Q}$ scans remain a useful tool in patients with contraindications to pulmonary angiography or CT angiography.[108,109]

Multidetector Computed Tomography Scan of the Chest

The PIOPED II study firmly established the role of CT pulmonary angiography (CTPA) and largely replaced ventilation-perfusion ($\dot{V}/\dot{Q}$) lung scintigraphy as the main imaging modality in suspected PE.[110] The technology is continually evolving and its use is widespread. As illustrated in Fig. 42.4, CTPA provides direct visualization of emboli throughout the pulmonary arterial vasculature. The advantage of CTPA over pulmonary angiography and lung scan



• **Fig. 42.4** Extensive bilateral lobar pulmonary emboli.

is the discovery of an alternative diagnosis when PE is not found on CTPA. In one study, an alternative diagnosis was established in 57% of patients who did not have a PE.[111] Currently, CTPA is the gold standard for PE diagnosis. A meta-analysis of 23 studies with 4657 patients with a negative CTPA who did not receive anticoagulation showed a 3-month rate of subsequent VTE of 1.4% (95% CI 1.1–1.8) and a 3-month rate of fatal PE of 0.51% (95% CI 0.33–0.76), which compares favorably with the results noted after a normal gold standard invasive contrast pulmonary angiogram.[112] The increased use of CTPA raises concerns about the increased incidence of cancer attributable to radiation.[113] For this reason, combined use of CTPA and CT leg venography should not be performed because the latter adds little to diagnostic utility. In the PIOPED II trial, no patient with PE or DVT would have been undiagnosed if imaging of the pelvic and proximal leg veins had been omitted.[107,110]

Magnetic Resonance Imaging

In the PIOPED II study, as many as 25% of patients had a contraindication to CT angiography of the chest. Preexisting renal failure and pregnancy were the primary conditions that prevented this modality from being used as the primary test for the evaluation of PE.[110] Thus gadolinium-enhanced magnetic resonance pulmonary angiography (MRA) could potentially be used to diagnose PE because it is devoid of radiation. The accuracy of this technique combined with magnetic resonance venography (MRV) has been studied in the prospective, multicenter PIOPED III accuracy study. The proportion of technically inadequate images ranged from 11% to 52% across the seven participating centers. Technically adequate MRA had a sensitivity of 78% and a specificity of 99%, whereas technically adequate MRA and MRV had a sensitivity of 92% and a specificity of 96%. However, 194 (52%) of 370 patients had technically inadequate results, which substantially restricts its clinical use.[114]

Risk Stratification

Death from an embolic event almost always results from hemodynamic deterioration owing to an abrupt rise in PVR overwhelming the contractile power of the right ventricle. The highest-risk individuals present with progressive hemodynamic and respiratory deterioration that characterizes the clinical presentation of major or massive PE and is seen in approximately 5% of patients with PE.[2] Patients who present with relative hemodynamic stability but exhibit varying degrees of RVD can be categorized as having submassive PE. It is important while discussing treatment strategies to identify this group of patients. Risk stratification schemes in normotensive patients center on RV function assessment after an embolic event and identify patients who may be at risk for progressive hemodynamic deterioration. Approximately 50% of patients who are normotensive have varying degrees of RVD and 10% will die. The European Society of Cardiology recommends a classification of PE into high-risk and non–high-risk groups. The high-risk groups represent the massive or major PE presentations. The non-UEDVT high-risk group is further subdivided into intermediate risk in which the mortality rate ranges between 3% and 15% and a low-risk group in which the mortality rate is less than 3%. Initial therapeutic interventions are greatly influenced by risk stratification that includes clinical scoring systems, laboratory data, and imaging.[115–117]

The presence of RVD is a predictor of the increased risk of embolic-related adverse events and mortality rates compared with patients without RVD.[2] Patients who present with circulatory shock usually have severe RVD and have mortality rates up to 65%.[1,2,115] In PE patients with normal hemodynamics and evidence of RVD the mortality rates can range from 8% to 14%. Several registry studies have observed that the frequency of RVD in normotensive patients is approximately 40%.[116,117] In PE patients with initial normal hemodynamics and no RVD the mortality rate is low (0%–3%).

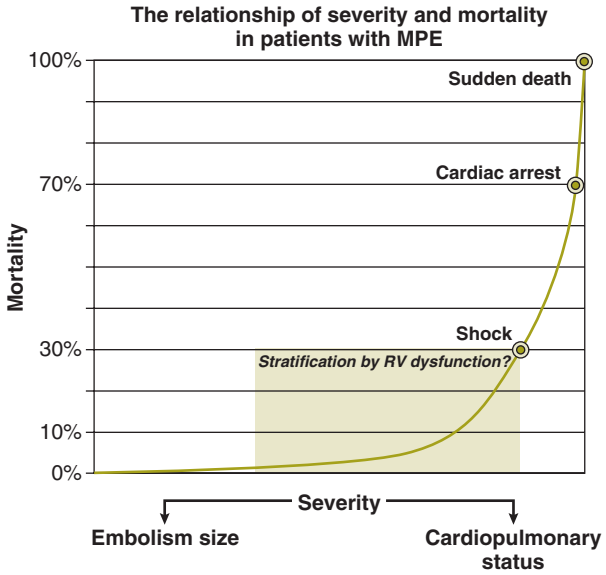
Clinical and Hemodynamic Parameters

The initial hemodynamic presentation of PE is the most powerful predictor of outcome, as illustrated in Fig. 42.5. Arterial hypotension at the time of PE presentation is an early predictor of death. In the 2392 patients from the ICOPER study, the 90-day mortality rates were 52.4% in patients with systolic arterial blood pressures below 90 mm Hg, and 14.7% in those patients who had preserved arterial blood pressures. In addition, comorbid conditions increase the risk of adverse clinical events, even in the presence of anatomically small PE. In the ICOPER findings, age over 70 years, congestive heart failure, cancer, and chronic lung disease were identified as independent predictors of 3-month mortality risk, with approximately twofold increase in the risk of death.[2] In one study, altered mental status at presentation was associated with a sevenfold increase in risk of adverse outcome. Altered mental status most likely reflected decreased cardiac perfusion or hypoxia. In the same study the initial presentation of shock was associated with a threefold increase in risk of 30-day adverse outcome (death, secondary shock, or recurrent PE).[117]

Patients can be clinically risk stratified by the use of a clinical scoring system known as the Pulmonary Embolism Severity Index (PESI), which also has a simplified version.[118,119] This prognostic model was developed by Aujesky and colleagues (Table 42.3) using a large database of hospitalized PE patients from which they derived and validated a prediction rule that identified acute PE patients with low to high risk for fatal PE and adverse events. Using 11 variables of predictors, 5 distribution categories emerged looking at inpatient fatality, 30-day all-cause mortality rate, and the adverse outcomes of nonfatal cardiogenic shock or cardiopulmonary arrest. Class I to class III all-cause mortality rates ranged between 0% and 3.1%, although class IV to class V all-cause mortality rates

were between 10% and 24%. This score has an excellent negative predictive value and readily identifies low-risk patients but suffers in the attempt to predict patients at high risk for adverse events.[119] A more simplified PESI score has been developed and has a high negative prediction value.[120]

In patients with symptomatic acute PE, the presence of DVT may have prognostic significance. In a prospective study by Jiménez and coworkers, among 707 patients diagnosed with acute PE, 51.2% had concomitant DVT and 10.9% had PE-specific fatality at a 3-month follow-up. Patients with PE with the presence of DVT at the time of diagnosis had an adjusted hazard ratio (HR) of 2.05% (95% CI 1.24–3.38) and PE-specific fatality-adjusted HR of 4.25% (95% CI 1.61–11.25). These findings were validated by a large international registry trial (RIETE) that again demonstrated a significant prediction of all-cause mortality rate and PE-specific mortality rate when concomitant DVT was present during the acute embolic event. These results suggest that patients with symptomatic acute PE have an increase in all-cause mortality rate, PE-related death, and recurrent VTE over a 3-month period if at the time of the PE a diagnosis of proximal DVT is also present.[121]



• **Fig. 42.5** Pulmonary embolism mortality rate based on initial hemodynamic presentation. *MPE,* massive pulmonary embolism; *RV,* right ventricular.

Electrocardiogram

Several studies have demonstrated that ECG signs of RV strain correlate with the presence of RVD.[122,123] A study by Punukollu and associates showed that T-wave inversion in leads V_1 to V_3 had a specificity of 88% and diagnostic accuracy of 81% for RVD in acute PE.[124] Daniel and colleagues developed an ECG scoring system based on typical features of acute PE such as presence of right bundle branch block, T-wave inversions, and additional features of right-sided heart strain that predicted severe pulmonary hypertension (systolic PA pressure >50 mm Hg) with a specificity of 97.7% if the patient's "ECG score" is 10 or greater.[125] The ECG may also be a tool for risk stratification of normotensive acute PE patients. In a study by Vanni and coworkers among 306 patients with documented PE, 130 (34%) patients demonstrated ECG findings of right-sided heart strain. In this study ECG findings of right-sided heart strain were defined as incomplete or complete right bundle branch block, $S_1Q_3T_3$, or inverted T waves in the precordial leads

TABLE 42.3 Pulmonary Embolism Severity Index

SCORING	
Predictor	**Points Assigned**
Age	Age, in years
Male gender	+10
Cancer	+30
Heart failure	+10
Chronic lung disease	+10
Pulse >110 beats/min	+20
Systolic blood pressure <100 mm Hg	+30
Respiratory rate >30 breaths/min	+20
Temperature <36°C	+20
Altered mental status	+60
Arterial Sao_2 <90%	+20

RISK CLASSIFICATION				
Class and Distribution	**Score Range**	**Inpatient Mortality Rate (%)**	**30-Day Mortality Rate (%)**	**Nonfatal Cardiogenic Shock or Cardiopulmonary Arrest**
Class I (19.4%)	<65	0.8	1.1	0.4
Class II (21.5%)	65–85	1.8	3.1	1.3
Class III (21.7%)	85–105	4.2	6.5	2.1
Class IV (16.4%)	106–125	5.9	10.4	1.9
Class V (21.0%)	<125	15.8	24.5	4.6

V_1, V_2, and V_3. For this study only one of these ECG patterns had to be present. The investigators demonstrated that the presence of RV strain on the initial ECG was associated with clinical deterioration and death (HR 2.58) in normotensive PE patients.[122]

Cardiac Biomarkers

Biomarkers are important components in the risk stratification of patients with PE. Tests for biomarkers are widely available and there is usually a quick turnaround from the clinical laboratory. Caution must be taken on the interpretation of these biomarkers. It is important for the critical care clinician to understand the clinical issues that affect the interpretation of the biomarkers and understand the negative and positive predictive values.[115] Elevations of brain natriuretic peptide (BNP), troponin, and D-dimer, occur in many patients with PE and correlate with the magnitude of RVD.

See the online supplement for discussion of Brain Natriuretic Peptide, Cardiac Tropinin, and D-Dimer.

Echocardiography

The echocardiogram has become the main imaging modality to assess RV structure and function. In addition, PA pressures can be estimated. Most hospitals in the United States have portable echocardiographic technology allowing for serial assessment of the impact of treatment on RVD. In hemodynamically stable patients with PE, 20% to 40% will have some echocardiographic finding of RVD.[116,117] Box 42.1 illustrates the echocardiographic finding of acute PE. Toosi and colleagues performed a quantitative risk assessment of various echocardiographic measurements of RVD in acute PE. For inpatient mortality rate the positive predictive values range between 11% and 20% and the negative predictive values are between 97% and 100%.[147] The major drawback with the role of the echocardiographic definition of RVD of acute PE is that it lacks standardization. There is no clear agreement on which of the echocardiographic findings predicts adverse outcomes and fatality in normotensive submassive PE. However, an echocardiographic finding of a right ventricle/left ventricle ratio greater than 0.9 was found to be an independent risk factor of in-hospital death (OR 2.7% CI 1.7–6.0) in a large registry trial.[148]

In the ICOPER study that included 1035 PE patients with systolic arterial pressure 90 mm Hg or higher, an echocardiogram was performed within 24 hours of PE diagnosis. The incidence of RVD was 39% (405 patients). The 30-day survival rates were lower in patients with RV hypokinesis (84%) compared with those without RV hypokinesis (91%), HR 1.94 (CI 1.41–3.16; $P \leq 0.001$). The negative predictive value of 30-day mortality rate of echocardiographic confirmation of RVD was 91%. The positive predictive value was 16%.[2]

In the assessment of RVD, if cardiac biomarkers are elevated, how well does this correlate with RVD on transthoracic echocardiography? A study by Logeart and coworkers found that a BNP level less than 100 pg/mL had a negative predictive value of 100% and TnI of less than 0.10 ng/mL had a negative predictive value of 67% for the presence of RVD on echocardiography. Combining a BNP greater than 100 pg/mL and TnI greater than 0.10 ng/mL had a positive predictive value of 80% for the presence of RVD by echocardiography.[149]

The echocardiogram can visualize free-floating right-sided heart thrombi. In the ICOPER study patients with this finding had a mortality rate of 21% compared with 11% in those without right-sided heart thrombi.[150] The detection of a patent foramen ovale or atrial septal defect by echocardiography may be a warning finding for the development of paradoxical embolization, which is associated with a risk of stroke and increased mortality rate.[151]

For the evaluation of circulatory shock transesophageal echocardiography (TEE) is a useful diagnostic modality. In patients with massive PE who cannot undergo CTPA, when TEE is performed, it has a 60% to 80% sensitivity and a 95% to 100% specificity to diagnose acute PE. TEE has a 9% to 95% sensitivity and a 100% specificity in main PA PE.[152] In patients with unexplained cardiac arrest or PEA, TEE has been shown to identify acute massive PE. In a small study of 25 patients with PEA, TEE demonstrated eight (36%) patients with massive PE.[153]

Echocardiography is an important diagnostic and prognostic tool in the management of patients with PE. Echocardiography also influences the therapeutic strategy based on cardiac hemodynamics and RV function. It is simple, quick, noninvasive, accurate, convenient, and safe, while providing critical information on the physiologic effects of PE on cardiac hemodynamics as well as RV size and function.

• BOX 42.1 Echocardiographic Features of Acute Pulmonary Embolism

Global reduction of RV function
RV dilation
RV hypokinesis
McConnell sign (free wall hypokinesis sparing of the apex)
Interventricular septal flattening
"D-shaped" LV resulting from paradoxical septal motion
RV/LV thrombus
Dilated inferior vena cava without inspiratory collapse
Pulmonary hypertension
Tricupid regurgitation with a jet velocity >2.6 m/s
Patent foramen ovale—result of increased pulmonary artery pressures

LV, *Left ventricle;* RV, *right ventricle.*

Computed Tomography Pulmonary Angiography

CT scan findings of right-sided heart dysfunction are illustrated in Figs. 42.6A and B. The detection of RV enlargement by spiral chest CT has recently been evaluated in the risk stratification of patients with acute PE. Using measurements from a reconstructed CT four-chamber view, RV enlargement, defined as a ratio of RV to LV dimension of greater than 0.9, was a significant independent predictor of mortality occurring within 30 days.[153] In a recent multicenter study of 460 consecutive patients with multidetector CT–confirmed PE a majority of the study cohort were hemodynamically stable and 50% had RVD at the time of diagnosis. Again, an RV/LV ratio of 0.9 or greater provided good correlation with RVD demonstrated by echocardiography. In addition, RVD found on multidetector CT was an independent risk factor for death and clinical deterioration. The investigators propose that multidetector CT scan potentially can be the single procedure, not only for diagnosis of PE but also for risk stratification. However, this assumption will require more validation studies.[112]

In hemodynamically stable patients with acute PE, assessing the RV/LV ratio may be important in not only risk stratification but also the location of the emboli. In a recent multicenter study

Brain Natriuretic Peptide

The heart will release natriuretic peptides as result of ventricular volume overload. Ventricular stretch results in cellular production of proBNP. This peptide is subsequently cleaved to the biologically active BNP and the inactive N-terminal fragment (NT-proBNP).[126] Both BNP and NT-proBNP can be measured clinically and have been validated as diagnostic and prognostic markers of ventricular stretch in multiple conditions, including congestive heart failure, pulmonary hypertension, and acute PE.[127] Elevated concentrations of BNP distinguish patients with PE at higher risk for a complicated in-hospital course and death from those with low BNP levels. Both BNP and NT-proBNP have been extensively investigated as prognostic markers in acute PE. In an early study, ten Wolde and colleagues[127] demonstrated in a prospective cohort of normotensive acute PE patients that those who died within 90 days had a significantly increased BNP level at the time of diagnosis compared with those patients who did not die in follow-up (245 pg/mL vs. 30 pg/mL, respectively). In addition, using a cutoff point of 75 pg/mL, these investigators reported that BNP had a positive predictive value of PE-related fatality of 17%, whereas the negative predictive value for death was 99%.[127] As will be seen for most of the prognostic markers for acute PE, the investigators noted that BNP was able to identify those at low risk of adverse outcomes but is a poor discriminator in identifying those who were likely to die from their PE.

Normal levels of BNP or NT-proBNP have a high negative predictive value for short-term fatality and overall short-term complicated clinical outcome in patients with acute PE. This is illustrated by the study by Kucher and colleagues,[128] who investigated the prognostic capabilities of NT-proBNP in a prospective cohort of patients with acute PE. In those who experienced an adverse event (defined as a combined endpoint of in-hospital death or need for escalation of care, including cardiopulmonary resuscitation, mechanical ventilation, vasopressor, or thrombolysis), NT-proBNP was significantly higher compared with those who did not experience an adverse event (median of 4250 pg/mL vs. 121 pg/mL, respectively). An NT-proBNP cutoff point of 500 pg/mL yielded a negative predictive value for adverse outcome of 97% with a corresponding positive predictive value of adverse outcome of 45%.[128] In a meta-analysis of 13 studies by Klok and associates, they indeed demonstrated that both increased BNP and proBNP were risk factors for short-term fatality, adverse clinical events, and a marker for RVD. However, the investigators caution against using this biomarker alone to justify more aggressive medical therapy, such as thrombolytic therapy.[129]

Cardiac Troponin

Serum troponins are widely available for the evaluation of diverse forms of myocardial injury. The assays are rapid and are well suited as a risk stratification tool. A number of studies and meta-analyses have evaluated the prognostic value of cardiac troponin I (TnI) or T (TnT) (determined by conventional assays) in acute PE.[130–132] Overall, the elevation of cardiac troponin levels was associated with an adverse early outcome including fatality.

In hemodynamically (normotensive) stable patients with PE the incidence of elevated troponins can be as high as 40%.[133] As with the management of acute myocardial infarction, in a patient with acute PE, troponin levels must be obtained serially. The first troponin level in patients with PE may be normal, and subsequently levels will increase. This was illustrated in the study by Ferrari and colleagues who investigated the time course of TnT elevation in patients with acute PE. In a prospective cohort, they found that whereas 50% of normotensive patients with acute PE were found to have an elevated TnT, 5% of these patients had an initial normal TnT that became abnormal at the 6-hour analysis; moreover, 25% of those with an elevated TnT (0.01 ng/mL) died during the hospitalization compared with no deaths in patients who had a TnT value less than 0.01 ng/mL.[134]

In a recent meta-analysis, Becattini and colleagues[132] analyzed the prognostic usefulness of cardiac troponins in acute PE. In this meta-analysis of 20 studies, the investigators reported that 20% of patients with elevated troponins died compared with 3.7% of patients with normal troponin levels. A high level of either TnT or TnI was associated with a fivefold increased risk of in- hospital or 30-day death. The investigators noted that a multitude of different troponin assays and selected cutoff points were used in the included reports, although results were generally consistent across studies. Most studies included in the meta-analysis defined an elevated troponin level as any value above the upper limit of normal for the individual troponin assay.[132]

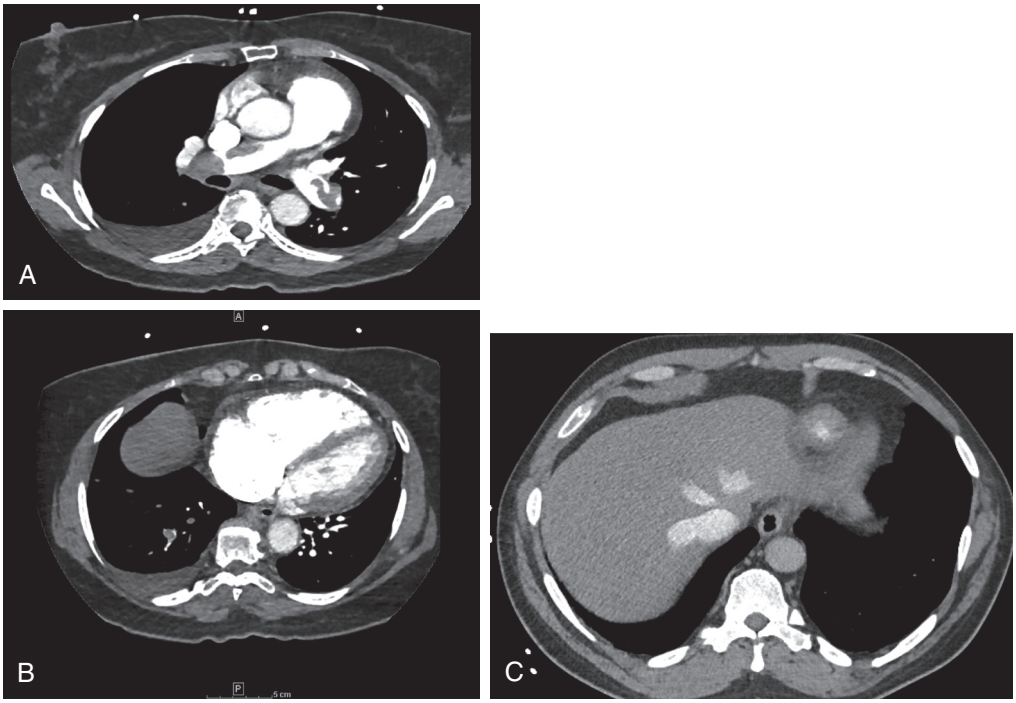
Combining biomarkers with imaging may enhance the prognostication of normotensive patients with acute PE. In one study, the presence of an elevated troponin, echocardiographic evidence of RVD, and the presence of a proximal DVT were associated with an increased 30-day mortality rate.[135]

New generations of highly sensitive troponin assays in patients with acute myocardial infarction have demonstrated excellent diagnostic performance and the potential to improve early risk stratification PE.[136]

Other cardiac biomarkers are released in the systemic circulation when the myocardium is injured. Heart-type fatty acid–binding protein (H-FABP) is a cytosolic protein that is within cardiac myocytes that is released faster than cardiac troponins during injury. Studies have demonstrated that H-FABP has a good negative predictive value for adverse outcomes and, in one study, a 28% positive predictive value in patients with acute PE.[137,138] Growth differentiation factor (GDF)-15 is a distant member of the transforming growth factor-β family. Under normal conditions, myocardium does not produce GDF-15, but its cardiac expression sharply increases after pressure overload and ischemia. The prognostic value of GDF-15 was investigated in a study including 123 patients with acute PE.[23] On multivariate analysis, cardiogenic shock on admission, cardiac TnI, and GDF-15 were independently associated with an adverse outcome at 30-day follow-up.[139] Further studies are needed to confirm these preliminary results.

D-Dimer

The predictive value of D-dimers in the setting of a low pretest probability has been addressed earlier in this chapter. D-Dimer has also been studied as a biomarker for the risk stratification of acute PE.[140–145] As with BNP and troponin, a high negative predictive value has been noted in several studies.[140,141] Elevations of D-dimer in the setting of PE are associated with both 15-day and 3-month mortality.[143,144] Higher levels of D-dimer have also been associated with a more central embolus location, which has been identified as both a mortality and adverse event risk factor.[143,145,146] Although cutoff values vary with each study, D-dimer levels of 3000 ng/mL or their equivalent or more in the setting of PE should be considered significant.



• **Fig. 42.6** A, Computed tomography (CT) scan findings of major pulmonary emboli with right ventricular dysfunction (RVD). B, CT scan findings of RVD (right ventricle/left ventricle ratio >0.09). C, Hepatic reflux of contrast indicated significant RVD.

of 516 hemodynamically stable PE patients, central localization of emboli was found to be an independent mortality risk factor, although distal localization was inversely associated with adverse events. Thus anatomic findings by CT scan may be important in assessing risk in hemodynamically stable patients with pulmonary embolus.[146] Table 42.4 summarizes the various risk modalities used in risk stratification of acute PE.

The Management of Acute Pulmonary Embolism

Pharmacologic Management

The anticoagulation treatment for DVT and acute PE is essentially the same. Anticoagulation therapy does not dissolve the clot but prevents extension. Anticoagulation therapy indirectly decreases clot burden by allowing the natural fibrinolytic system to dissolve thrombus. When PE is suspected, if there is no contraindication, anticoagulation therapy should be started immediately while diagnostic studies are being performed.[154]

Unfractionated and Low–Molecular-Weight Heparin

Heparins act by binding to the natural anticoagulant antithrombin, thereby accelerating the inactivation of thrombin by antithrombin and several other activated coagulation factors This mechanism of action will prevent extension of the thrombus. UFH is usually administered as an initial bolus, followed by a continuous intravenous infusion. Because of a large individual difference in the binding of heparins to plasma proteins, the doses should be adjusted to the results of the activated partial thromboplastin time (aPTT) or the anti–factor Xa (anti-Xa) activity.[155]

TABLE 42.4 Risk Stratification Determination in Acute Pulmonary Embolism

Risk Stratification Test	RV Dysfunction Potentially Present
Compression ultrasonography	Presence of proximal DVT
Natriuretic peptide	BNP >90 pg/mL NT-proBNP >500 pg/mL
Cardiac troponins	TnT >0.1 ng/mL TnI >0.4 ng/mL
Transthoracic echocardiography	Apical four-chamber view: RV/LV ratio >0.9 Qualitative RV systolic dysfunction
Chest computed tomography pulmonary angiogram	Reconstructed four-chamber view: RV/LV ratio >0.9
Electrocardiogram	New complete or incomplete RBBB Anteroseptal ST-segment elevation or depression Anteroseptal T-wave inversion

BNP, Brain natriuretic peptide; *DVT,* deep venous thrombosis; *LV,* left ventricle; *NT-proBNP,* N-terminal fragment proBNP; *RBBB,* right bundle branch block; *RV,* right ventricle; *TnI,* troponin I; *TnT,* troponin T.

The effectiveness of heparin therapy depends largely on achieving a critical therapeutic level of heparin within the first 24 hours of treatment. Nomogram dosing of heparin has been shown to achieve this goal.[156] The critical therapeutic level of heparin is 1.5 times the baseline control value or the upper limit of normal range of

the aPTT. This level of anticoagulation is expected to correspond to a heparin blood level of 0.2 to 0.4 U/mL by the protamine sulfate titration assay and 0.3 to 0.6 by the anti-Xa assay.[157] If intravenous UFH is chosen, an initial bolus of 80 U/kg or 5000 U followed by an infusion of 18 U/kg per hour or 1300 U/h should be given, with the goal of rapidly achieving and maintaining the aPTT at levels that correspond to therapeutic heparin levels. Fixed-dose and monitored regimens of subcutaneous UFH are available and are acceptable alternatives.[154,156]

Low–molecular-weight heparins (LMWHs) have many advantages over UFH. These agents have a greater bioavailability, can be administered by subcutaneous injections once or twice a day, and have a longer duration of anticoagulant effect. There is a lower risk of osteoporosis and immune-mediated thrombocytopenia.[158] A fixed dose of LMWH can be used and laboratory monitoring is not necessary except in clinical circumstances such as morbid obesity, low weight (<40 kg), pregnancy, and renal insufficiency.[159] Comparison trials between LMWH and UFH have demonstrated that LMWH is at least as effective and as safe as UFH, and there are no significant differences in recurrent thromboembolic events, major bleeding, or mortality risk between the two types of heparin.[160] Caution must be used when administering LMWH in patients with renal insufficiency. LMWH is primarily cleared by the kidneys. Therefore monitoring anti-Xa activity should be performed in patients with impaired renal function. If the creatinine clearance is less than 30 mL/min, UFH should be used.[161]

LMWH has a significantly lower incidence of heparin-induced thrombocytopenia (HIT), yet HIT can still occur with exposure to LMWH. Thus LMWH is not an anticoagulant substitute for the patient with HIT requiring VTE prophylaxis or thrombosis treatment.[162]

LMWH can be administered safely in an outpatient setting. This has led to the development of programs in which clinically stable patients with PE are treated at home, at substantial cost savings.[163] An international, open-label, randomized trial compared outpatient and inpatient treatment (both using the LMWH enoxaparin as initial therapy) of low-risk patients with acute PE and concluded that outpatient treatment was not inferior to inpatient treatment.[164]

Fondaparinux

Fondaparinux is a synthetic polysaccharide derived from the antithrombin binding region of heparin. Fondaparinux catalyzes factor Xa inactivation by antithrombin without inhibiting thrombin, and studies have shown that it is effective in the initial treatment and prophylaxis of the VTE. Fondaparinux has been shown to be just as effective and safe as UFH and enoxaparin.[165] Fondaparinux dosing is based on various weight ranges. For patients weighing less than 50 kg, 5 mg once daily is recommended. Patients weighing 50 to 100 kg are given 7.5 mg, and those weighing more than 100 kg receive 10 mg daily. HIT is rare with the use of fondaparinux because of this lack of interaction with platelet factor 4 (PF4).[154]

Warfarin Therapy

The anticoagulant effect of warfarin (Coumadin) is mediated by the inhibition of vitamin K–dependent factors, which are II, VII, IX, and X. Vitamin K antagonists (VKAs) include substances with a short (acenocoumarol), intermediate (warfarin, fluindione), or long (phenprocoumon) half-life. For this reason, and because of genetically induced metabolic variability, the variable vitamin K content of food, a narrow therapeutic index, and interactions with other drugs, the effect on coagulation must be closely monitored. The peak effect does not occur until 36 to 72 hours after drug administration and the dosage is difficult to titrate. Administration of heparins or fondaparinux should overlap during at least 5 days with that of VKAs. After 5 days the parenteral drug can be stopped when the anticoagulant concentration induced by the VKA has achieved international normalized ratio (INR) between 2.0 and 3.0.[154,166]

The current American College of Chest Physicians (ACCP) guidelines for warfarin therapy suggest that the target INR is 2.5 even in high-risk patients (e.g., antiphospholipid syndrome). Because of its lack of validation, the ACCP does recommend pharmacogenetic testing. Warfarin should be started on day 1 or 2 that heparin is started. Usually warfarin 10 mg is administered and INR is adjusted to target INR. There is an increased risk of bleeding when antiplatelet drugs (acetylsalicylic acid, clopidogrel) are administered along with warfarin. In patients with acute coronary syndrome, mechanical valves, or recent coronary artery bypass or coronary stents, there is a likely benefit from the combination. Nonsteroidal antiinflammatory drugs (NSAIDs) also increase the risk of bleeding when taken with warfarin and should be avoided.[166]

New Oral Anticoagulants

A new generation of anticoagulants is emerging with promising advantages over current therapy. These drugs have their effect on specific steps of the coagulation cascade. These agents are taken orally and do not require hematologic monitoring. The direct thrombin inhibitor dabigatran and factor Xa inhibitors rivaroxaban, apixaban, and edoxaban are now approved in the United States to treat DVT or PE. Rivaroxaban has been shown to be as effective as warfarin.[15,167] A major drawback to the factor Xa inhibitors is that there are no specific reversal agents currently available.[168] Idarucizumab, a humanized monoclonal antibody fragment, is now available in the United States as a reversal agent for dabigatran. Andexanet alfa, an anti-Xa decoy agent, is currently under review by the U.S. Food and Drug Administration (FDA).[169]

Duration of Anticoagulation Therapy

A patient with a first thromboembolic event occurring in the setting of reversible risk factors, such as immobilization, surgery, or trauma, should receive warfarin therapy for at least 3 months. No difference in the rate of recurrence was observed in either of two studies comparing 3 versus 6 months of anticoagulant therapy in patients with unprovoked first events.[69,70] The current recommendation is anticoagulation for at least 3 months in these patients; the need for extending the duration of anticoagulation should be reevaluated at that time.[170]

The current ACCP guidelines recommend that all patients with unprovoked PE should undergo a risk-benefit evaluation to determine if long-term therapy is needed (grade 1C).[170] Long-term treatment is recommended for these patients who do not have risk factors for bleeding and in whom accurate anticoagulant monitoring is possible (grade 1A). Patients who have PE and preexisting irreversible risk factors, such as deficiency of antithrombin III, protein S and C, factor V Leiden mutation, or the presence of antiphospholipid antibodies, should undergo long-term anticoagulation.

Heparin-Induced Thrombocytopenia

Thrombocytopenia is common in the ICU setting but rarely is it caused by HIT. Because heparin is a common drug used in the ICU setting, this entity frequently is included in the differential diagnosis of the thrombocytopenia. The downstream consequences

of overdiagnosis can be problematic, especially if it produces breaches in treating patients with VTE or protecting them from VTE.

HIT is a transient prothrombotic disorder initiated by heparin. The main features of HIT are (1) thrombocytopenia resulting from immunoglobulin G–mediated platelet activation and (2) in vivo thrombin generation and increased risk of venous and arterial thrombosis.[171] HIT may manifest clinically as an extension of the thrombus or formation of new arterial thrombosis. HIT should be suspected whenever the patient's platelet count falls to less than 100,000/μL or less than 50% of the baseline value, generally after 5 to 15 days of heparin therapy. However, if a patient has been previously exposed to heparin, falling platelet counts and the clinicopathologic syndrome of HIT can be seen earlier. The pretest probability for HIT can be determined by the application of the "4 Ts": (1) *t*hrombocytopenia, (2) *t*iming, (3) *t*hrombosis, and (4) no o*t*her explanation of thrombocytopenia. At low scores the probability of the presence of platelet-activating HIT antibodies is low; at high scores there is a moderate probability of the presence of the antibodies.[171,172]

The diagnosis of HIT is based on assays that detect the presence of platelet-activating antibodies. The PF4-dependent enzyme immunoassay (EIA) test may lead to overdiagnosis of HIT. However, a negative EIA result essentially rules out HIT. The serotonin release assay is more specific for HIT than the PF4-dependent EIA. EIA is measured in optical density units, and the strength of this measurement is a strong predictor of a positive serotonin release assay result and confirmed HIT. In a patient with thrombocytopenia in whom the optical density units of EIA were less than 1.5 units the thrombocytopenia was not caused by HIT.[171,172]

The treatment of patients in whom HIT develops is to stop all heparin products, including catheter flushes and heparin-coated catheters, and to initiate an alternative, nonheparin anticoagulant, even when thrombosis is not clinically apparent. Preferred agents include direct thrombin inhibitors, such as lepirudin or argatroban. Warfarin therapy should be started while the patient receives an alternative, nonheparin anticoagulant and only when the platelet count has recovered to at least 100,000/μL (preferably to 150,000/μL).[154]

Thrombolytic Therapy

The goal of thrombolytic therapy, by accelerating the conversion of plasminogen to plasmin, is to promote clot lysis and unload the right ventricle by decreasing pulmonary vascular obstruction. Thrombolysis has demonstrated a more rapid resolution of pulmonary vascular obstruction with improvement of RV hemodynamics within 2 hours after initiation of infusion. However, it remains controversial as to whether unloading of the right ventricle with thrombolytic therapy is associated with improved mortality. In the larger original thrombolysis trials, streptokinase and urokinase were compared with heparin alone at infusion rates of 24 and 12 hours, respectively. These studies demonstrated rapid reperfusion of the pulmonary vasculature, reduction in pulmonary resistance, and no difference in mortality rate when compared to heparin.[173,174]

Currently three thrombolytics have FDA approval in the United States for acute PE: streptokinase, urokinase, and alteplase. Streptokinase and urokinase are nonselective agents activating both circulating and clot-bound plasminogen. Both agents have significant limitations; streptokinase is antigenic and may cause hypotension. Alteplase (tissue plasminogen activator [tPA]) is fibrin specific and is the thrombolytic of choice for the management of PE.[175,176]

The current ACCP key recommendations for the use of thrombolytic therapy in acute PE are noted here[170,177]:

1. In patients with acute PE associated with hypotension (e.g., systolic blood pressure <90 mm Hg) who do not have a high bleeding risk, we suggest systemically administered thrombolytic therapy over no such therapy (grade 2B).
2. In most patients with acute PE not associated with hypotension, we recommend against systemically administered thrombolytic therapy (grade 1B).
3. In selected patients with acute PE whose conditions deteriorate after starting anticoagulant therapy but have yet to develop hypotension and who have a low bleeding risk, we suggest systemically administered thrombolytic therapy over no such therapy (grade 2C quality evidence).
4. When a thrombolytic agent is used, we suggest short infusion times (e.g., a 2-hour infusion) (grade 2C—weak recommendation [suggestion]/low-quality or very-low-quality evidence).
5. In patients with acute PE when a thrombolytic agent is used, we suggest administration through a peripheral vein. Central administration is not deemed necessary (grade 2C—weak recommendation [suggestion]/low-quality or very-low-quality evidence). The incidence of major hemorrhage from systemic thrombolytic administration can be as high as 20%, including a 3% to 5% risk of hemorrhagic intracranial complications.

Currently, the thrombolytic that is recommended is tPA at a dose of 100 mg given intravenously over 2 hours. Once the tPA infusion is started, the UFH infusion is stopped. After the 2-hour infusion the heparin is restarted, without a loading dose, when the aPTT is less than 80 seconds after the tPA infusion is complete.

Contraindications to systemic thrombolytic therapy in acute PE include an intracranial neoplasm, recent (i.e., <2 months) intracranial surgery or trauma, active or recent internal bleeding during the prior 6 months, history of a hemorrhagic stroke, bleeding diathesis, severe uncontrolled hypertension (i.e., systolic blood pressure >200 mm Hg or diastolic blood pressure >110 mm Hg), nonhemorrhagic stroke within the prior 2 months, surgery within the previous 10 days, and thrombocytopenia (i.e., <100,000 platelets/mL). Thrombolytic therapy may cause moderate bleeding in menstruating women, but it has not been associated with major hemorrhage. Therefore menstruation is not a contraindication to thrombolytic therapy.[178]

Submassive Pulmonary Embolism With Hemodynamic Stability and Right Ventricular Dysfunction

In patients with acute PE who are normotensive but demonstrate some degree of RVD, the treatment is somewhat controversial and may depend on the degree of RVD present to initiate aggressive steps to protect RV function. There is a spectrum of RVD and RV injury. If RVD is manifested by only RV wall dilation and not injury, then the outcome may be different when injury begins to occur. The normotensive patients with evidence of RV injury will require expedited protection of RV function.

Role of Thrombolytic Therapy in Normotensive Submassive Pulmonary Embolism With Right Ventricular Dysfunction

Patients with known or suspected PE must be treated initially with UFH infusion. It appears that RVD in normotensive PE patients is associated with an increased risk of short-term adverse events

and death than in patients without RVD. A number of studies have suggested that thrombolytic therapy should be considered in these patients. In the Management Strategy and Prognosis of Pulmonary Embolism Registry, of 719 acute PE patients with normal systemic arterial blood pressure and echocardiographic evidence of RVD, 550 were treated with heparin alone and 169 patients received thrombolytic therapy. The subgroup analysis demonstrated that patients undergoing thrombolysis had a significantly lower in-house mortality rate at 4.1% in contrast to anticoagulation alone at 10.5%. PE recurrence was observed in 7.7% in the thrombolysis group and in 18.7% in patients receiving anticoagulation alone.[2] Although this study demonstrated differences in terms of mortality rates and PE recurrence between the two groups, it must be emphasized that this was a registry trial and not a randomized clinical investigation Therefore it was subject to unavoidable selection bias.

An important study that attempted to determine whether normotensive patients with PE-induced RVD should receive thrombolytic therapy produced some very interesting conclusions. In a prospective trial (MAPPET-3 [Management Strategies and Prognosis of Pulmonary Embolism-3 Trial]) of 256 patients with PE, the investigators randomly assigned patients to receive heparin plus either recombinant tPA (rtPA) or placebo. This study used a combined endpoint of in-hospital death or clinical deterioration (escalation of therapy needed). Clinical deterioration was defined as a requirement for either a catecholamine infusion to treat hypotension or shock, secondary or "rescue" thrombolysis, endotracheal intubation, cardiopulmonary resuscitation, or emergency catheter or surgical embolectomy. Initially the study results seem to support the use of thrombolytic therapy. Patients treated with anticoagulation alone were more likely to die or require treatment escalation than those who received rtPA (24.6% vs. 11.0%; $P = 0.006$), and importantly, there was no difference in the incidence of major bleeding or intracranial hemorrhage between the two treatment groups. The difference between the two groups was due to a more frequent need for secondary emergency thrombolysis in the heparin group, although the overall mortality rate was not affected by thrombolysis.[179] One of the major problems with this study was the lack of a consistent definition of RVD. In this study various modalities were used to define RVD and included echocardiography, right-sided heart catheterization, and even ECG signs of RV strain. Nevertheless, this study has been the catalyst for a large multinational European trial currently under way to attempt to resolve the controversy surrounding the role of thrombolytic therapy in patients with PE who are normotensive but have RVD.

Based on the current ACCP guidelines, normotensive PE patients who have RVD (from clinical, biomarker, and echocardiographic findings) and no contraindications to thrombolysis, systemic thrombolysis should be considered (grade 2C recommendation).

Role of Catheter-Directed Therapy in Normotensive Submassive Pulmonary Embolism With Right Ventricular Dysfunction

Catheter-directed therapy (CDT) has the potential to locally reduce clot burden in the PA by mechanically disrupting the clot or locally infusing low-dose thrombolytics or both. In hemodynamically stable patients with RVD who have right and left pulmonary PE or main PA clot, CDT may be considered. However, CDT provides an additional option in the treatment of patients with life-threatening PE and a possible alternative to surgical embolectomy and systemic thrombolysis, especially in patients who are poor surgical candidates and have relative contraindications to systemic thrombolysis. Bleeding risk appears to be lower in CDT administered thrombolysis compared with systemic thrombolysis.[180]

There are no large prospective randomized CDT trials for making evidence-based recommendations. In a meta-analysis of 594 patients with acute massive PE treated with CDT, clinical success was achieved in 86.5%, with success defined as the stabilization of hemodynamics, resolution of hypoxia, and survival to hospital discharge.[181] In the same study, 96% of patients received CDT as the first adjunct to heparin with no previous systemic tPA infusion, and 33% of cases were initiated with mechanical treatment alone without local thrombolytic infusion. When injected locally, the required dose of tPA is likely to be lower compared with a full-dose systemic tPA infusion, and there is less risk for bleeding. Indeed, the rate of major complications from modern CDT has proved to be only 2.4%.

In a recent propensity score–matched cohort study from the National Readmission Database comparing systemic lytics to CDT, CDT demonstrated lower in-house mortality and there was also a lower composite secondary outcome of in-hospital mortality, gastrointestinal bleeding, and intracranial hemorrhage. Interestingly, there was a higher cost of hospitalization in the CDT group even after adjusting for shock and cardiac arrest.[182]

The three types of catheter-based interventions are (1) aspiration thrombectomy, (2) thrombus fragmentation, and (3) rheolytic thrombectomy. Each of these techniques has similar success rates in systematic reviews.[180]

The goal of all these techniques is rapid central clot debulking to relieve life-threatening heart strain and immediately improve pulmonary perfusion. Catheter intervention is important not only for creating an immediate flow channel through the obstruction, but also for exposing a greater surface area of thrombus to the effects of locally infused thrombolytic drug. In patients with overt shock, thrombus fragmentation is usually the first priority of therapy with the goal to expedite reduction in clot burden.

The infusion of tPA can be accomplished unilaterally or bilaterally at a total dose rate of 1.0 to 2.0 mg/h depending on the degree of clot burden. In patients who may be at greater risk for bleeding or may require prolonged infusions greater than 24 hours, fibrinogen levels should be monitored. When the fibrinogen level is decreased below 150 to 200 mg/dL the infusion should be reduced or discontinued.[180] The ACCP currently recommends that CDT be considered in selected highly compromised patients with PE who are unable to receive thrombolytic therapy because of bleeding risk. Although there is a growing body of evidence in favor of CDT, the decision to consider CDT therapy should be multidisciplinary and based on the patient's risk of systemic thrombolysis, his or her status as a surgical candidate, and a case-by-case assessment based on risk stratification findings.

Role of Inferior Vena Cava Filters in Patients With Submassive Pulmonary Embolism With Right Ventricular Dysfunction

The goal of the inferior vena cava (IVC) filter intervention is to prevent further potentially lethal embolic episodes from impact on an already compromised right ventricle. The current IVC filters in use are retrievable and usually placed by interventional radiology. There has been a marked increase in the use of IVC filters for treatment and prevention of the venous thromboembolic disease. Stein and colleagues showed that the use of IVC filters in the United States has increased from 2000 in 1979 to 92,000 in 2006.[183]

IVC filters are usually placed in patients with acute PE or DVT who develop active bleeding during anticoagulation and have an

existing contraindication to anticoagulation. IVC filters should also be considered in the following situations: (1) recurrent thromboembolism despite adequate anticoagulation, (2) the presence of a large free-floating caval thrombus, (3) chronic recurrent PE with pulmonary hypertension, and (4) patients who have had surgical embolectomy or pulmonary endarterectomy.[184]

The Greenfield filter was introduced in 1973, and subsequently many types of permanent IVC filters have been developed; these filters are usually placed under fluoroscopic guidance.[185] Retrievable IVC filters offer an attractive alternative to the standard permanent filters. These retrievable filters are inserted in patients who may have transient contraindications to anticoagulation or patients who have increased bleeding risks (e.g., trauma patients and neurosurgical patients) or in whom the RV hemodynamics normalize. These filters should be removed within 3 months after implantation; unfortunately, these filters are not removed in real-world practice.[184]

The 1998 PREPIC study and its 8-year follow-up suggested that IVC filters reduce the risk of PE while increasing the risk of recurrent DVT, and do not reduce the all-cause mortality rate.[186] Four hundred patients with proximal DVT were randomly assigned to receive IVC filter or no IVC filter and all had received enoxaparin or UFH as a bridge to warfarin therapy, which was continued for at least 3 months. The primary endpoints were recurrent DVT, PE, major bleeding, and death. The patients were followed up at day 12, at 2 years, and then annually up to 8 years after randomization. At day 12, there were fewer PEs in the group that received filters (OR 0.22, 95% CI 0.05–0.90). However, at year 2, there was no significant difference in PE development in the filter group compared with the no-filter group (OR 0.50, 95% CI 0.19–1.33). Additionally, at year 2, the filter group was more likely to develop recurrent DVT (OR 1.87, 95% CI 1.10–3.20). At year 8, there was a significant reduction in the number of PEs in the filter group versus the no-filter group (6.2% vs. 15.1%, $P = 0.008$). However, at 8-year follow-up, IVC filter use was associated with increased DVT (35.7% vs. 27.5%, $P = 0.042$). There was no difference in mortality rate between the two groups. In summary, the use of IVC filters was associated with decreased incidence of PE at 8 years, offset by higher rates of recurrent DVT and no overall mortality benefit.[186,187] Importantly, the indications for IVC filter use in this study differ from the current ACCP guidelines; all patients were given concomitant anticoagulation for at least 3 months, which might not be possible in patients for whom the ACCP recommends IVC filters.

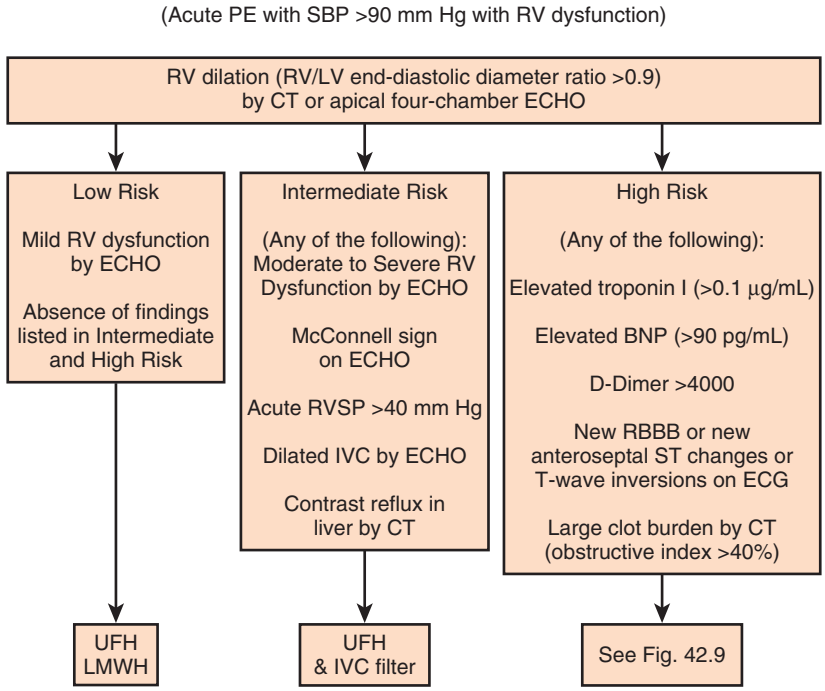
In patients with submassive PE and RVD who are normotensive the role of the retrievable IVC filter to prevent further embolization is controversial. In a small retrospective study adjunctive placement of an IVC filter, especially in patients with RV strain, resulted in no deaths. In patients who did not receive a filter the in-house mortality rate was 10.2%.[188] Prospective studies are needed to further explore the role of retrievable IVC filters in this patient population.

Fig. 42.7 illustrates the therapeutic options available for the management of submassive PE in normotensive patients with RVD. In summary, the goals of these interventions are to reduce clot burden and to prevent further embolic impact on a compromised right ventricle.

Massive Pulmonary Embolism

Respiratory Support

Although mechanical ventilation is often required in massive PE, the hemodynamic effects of mechanical ventilation may further aggravate the vicious circle of RVD and ischemia by augmenting



• **Fig. 42.7** Submassive pulmonary embolus algorithm. *BNP,* Brain natriuretic peptide; *CT,* computed tomography; *ECG,* electrocardiogram; *ECHO,* echocardiogram; *IVC,* inferior vena cava; *LMWH,* low–molecular-weight heparin; *PE,* pulmonary embolism; *RBBB,* right bundle branch block; *RV,* right ventricle; *RV/LV,* right ventricle/left ventricle; *RVSP,* right ventricular systolic pressure; *SBP,* systolic blood pressure; *UFH,* unfractionated heparin.

RV afterload and further decreasing LV preload. Limiting the vasodilating hemodynamic effects of sedation and anesthesia needed for intubation is important. Intubating a patient with massive PE should not be prophylactic, and the risk versus benefit must be weighed carefully for each patient.[189]

Hemodynamic Support in Massive Pulmonary Embolism

Volume Resuscitation

Fluid should be administered in massive PE with caution. Fluid resuscitation may increase RV afterload precipitating RV failure as well as augment septal ballooning into the left ventricle, further decreasing cardiac output and worsening systemic hypotension. It is therefore recommended that small boluses of fluid (250- to 500-mL aliquots) be used initially to evaluate affect.[190,191]

Vasoactive Drugs

There are no randomized controlled studies among different vasoactive agents in massive PE. Norepinephrine (NE), which has both α-adrenergic and β-adrenergic effects, is superior to phenylephrine in a canine model of PE in terms of improving both cardiac output and myocardial perfusion.[192] NE has been shown to increase cardiac contractility and RV perfusion pressure, thus increasing coronary blood flow. Therefore NE has become the most frequently used vasoactive agent for hemodynamic support of massive PE.[192,193] Dopamine, which possesses both β-adrenergic and, at sufficiently high doses, β-adrenergic agonist effects, appears to offer similar benefit. However, its use may be limited by the development of tachycardia.[194]

Inotropic Agents

Dobutamine, in combination with NE in the hypotensive patient, should be considered first-line therapy when treating cardiogenic shock secondary to a massive PE. In 10 patients with massive PE, dobutamine was able to increase cardiac index while reducing right atrial pressure, systemic vascular resistance, and PVR.[195] Although phosphodiesterase inhibitors have been used to support the circulation in cardiogenic shock secondary to massive PE, these agents should be used with caution given the lack of literature support. Their significant vasodilating capabilities could potentially worsen hypoxemia owing to their ameliorating effect on hypoxic vasoconstriction and potentially worsen systemic hypotension.[196]

Pulmonary Vasodilators

RVD contributes to many of the signs and symptoms noted in acute submassive PE. The goal of pulmonary vasodilator therapy is to provide afterload reduction to the RV and thereby ameliorate some or all of this dysfunction. Unfortunately, to date there have been no large randomized controlled studies of either IV or inhaled epoprostenol, or inhaled nitric oxide in acute PE. Although these agents have some theoretical advantages in their ability to unload the RV, they also have some potential disadvantages in altering $\dot{V}/\dot{Q}$ and worsening hypoxemia, as well as contributing to systemic hypotension; therefore as of this writing, they cannot be recommended as routine therapy.[197,198]

Systemic Thrombolysis in Massive Pulmonary Embolism

If there are no contraindications, thrombolytic therapy is the treatment of choice for massive PE resulting in severe hemodynamic and respiratory compromise. This recommendation is sanctioned by the current ACCP guidelines.[170] Several studies have demonstrated the superiority of thrombolytic therapy in improving RV function (24–48 hours) compared with heparin alone. The studies have not demonstrated an improvement in mortality rate with thrombolysis.[173,174,199–201] One reason is that the studies were not large enough for mortality rate to be an outcome measurement. A meta-analysis by Wan and colleagues demonstrated that patients with massive PE had a reduction in mortality rate and PE recurrence and adverse events compared with heparin alone (19.0% to 9.4%; OR 0.45, 95% CI 0.22–0.92).[202] If thrombolytic therapy is given within 48 hours of the pulmonary embolic event there may be greater clinical improvement. However, thrombolysis may continue to be beneficial even in patients who have symptoms up to 2 weeks after their initial PE symptoms.[203]

The thrombolytic agent usually given is tPA in a 2-hour infusion via peripheral venous line. UFH should not be given at the time with thrombolytic therapy. UFH should be restarted after the thrombolytic infusion is completed and when the aPTT is less than twice the normal value.

Massive PE can lead to cardiac arrest and the initial rhythm may include PEA and asystole. When cardiac arrest occurs, the mortality rate is in the range of 66% to 95%. Thrombolytic therapy given in boluses of 50 mg has been shown in case reports to be lifesaving.[204]

Inferior Vena Cava Filters in Massive Pulmonary Embolism

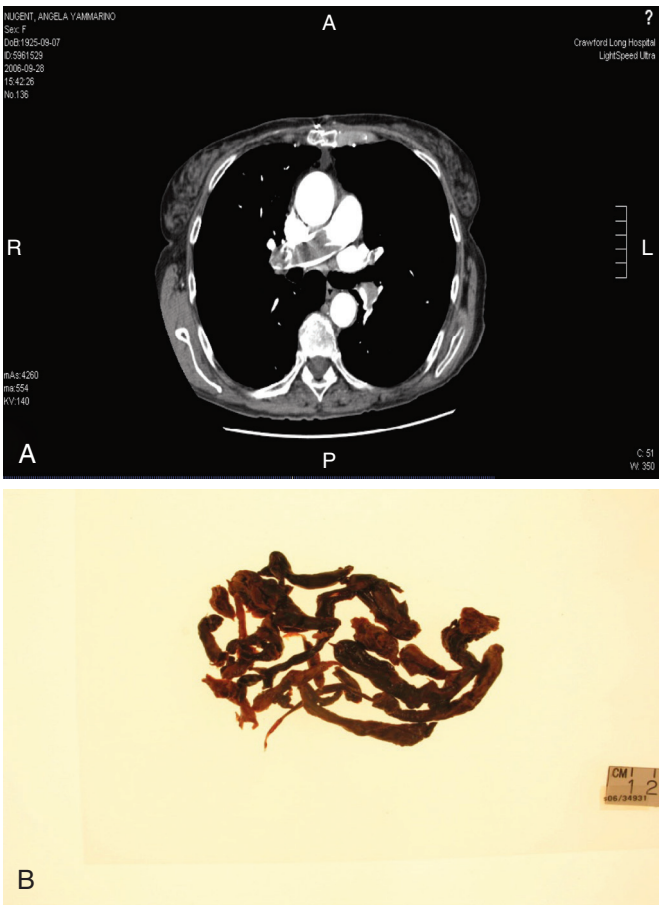
An observational study from an international registry that suggests that IVC filter placement in patients with massive PE (i.e., with hypotension) was associated with a reduction in a combined endpoint of mortality rate and recurrent PE. This study cohort was small; however, it appears to be reasonable that IVC filters should be placed in patients with poor cardiopulmonary reserve.[205]

Unstable PE patients who are treated with standard anticoagulation therapy may benefit further with prophylactic placement of IVC filters. In a recent study by Stein and associates,[206] the mortality rate in 38,000 unstable patients treated with standard anticoagulant therapy alone was 51% compared with 33% in 12,850 who had vena cava filters in addition to anticoagulants. This represents a 35% decrease in the case fatality rate when vena cava filters are combined with standard anticoagulant therapy.

Pulmonary Embolectomy in Massive Pulmonary Embolism

The indications for pulmonary embolectomy are patients with documented massive PE confirmed if possible by angiography (CTPA or pulmonary angiography) with persistent hemodynamic instability despite aggressive medical therapy, including consideration of the local or systemic thrombolysis. Patients with refractory shock in which massive PE is strongly suspected should be transferred to a center where emergent surgical management for PE is performed. These patients must be urgently transferred to the operating room, and on the operating table TEE should be performed to confirm the diagnosis. Despite these efforts, patients who present with cardiac arrest have a high surgical mortality rate.[206,207]

The mortality rate from pulmonary embolectomy ranges from 30% to 40%. There has been concern that medical therapy may delay definitive surgical therapy and may account for the high mortality rate. Among 1047 patients who underwent pulmonary embolectomy from 1961 to 1984 the average in-house mortality rate was 32%. Using the National Inpatient Sample from 1999 to 2008, recently Stein and colleagues showed that the case fatality rates for unstable patients (shock or ventilator-dependent) with PE undergoing pulmonary embolectomy was 40% and in stable patients 24%, with an overall case fatality rate of 28%. The case



• **Fig. 42.8** Large clot burden removed by pulmonary embolectomy.

fatality rates were lower in patients with the primary diagnosis of PE who had few comorbid conditions. It was observed in both groups that patients with IVC filters had a lower case fatality rate than those who did not have filters.[208,209] More recently the surgical mortality rates for pulmonary embolectomy have decreased at specialized centers (Fig. 42.8, pulmonary embolectomy). A multidisciplinary approach appears to be the key to diagnosis, treatment, and postoperative care, translating to reduced mortality and morbidity rates.[210,211]

Endovascular Therapy in Massive Pulmonary Embolism

In patients with massive PE who are not candidates for either pulmonary embolectomy or systemic thrombolysis, if there is institutional expertise for endovascular management, this should be considered. The goal is to convert a massive PE into a submassive PE with resultant improvement in the patient's hemodynamic and respiratory status. Initially, CDT provides mechanical debulking of the clot, and if indicated because of persistent elevation of PA pressures, infusion of low-dose (1 mg/h) tPA directly into the clot over a 12- to 24-hour period. CDT should be considered and the decision should be made quickly as part of a multidisciplinary discussion.[180–215] Complications of CDT are rare, but when they occur they can be serious. They include perforation of the PA or perforation of the atrium or ventricle with pericardial tamponade. These interventions should be performed only by clinicians who are experienced in catheter-based intervention and within institutions that have defined protocols and multidisciplinary teams to manage these critically ill patients.

The management of high-risk submassive PE is summarized in Fig. 42.9. For the normotensive patient with PE it is important to quickly risk stratify and identify the patient with RVD and large clot burden. If patients in this subset manifest signs of RV injury with persistent elevations in troponin and echocardiographic evidence of RV overloading with impending RV failure, then systemic thrombolytic therapy, local thrombolytic therapy, and surgical management are management options to be considered. In the patient with massive PE, as with submassive PE with RVD, there must be multidisciplinary coordination among the critical care physician, interventional cardiology and radiology, and cardiothoracic surgery to quickly determine the best treatment approach. Both respiratory and hemodynamic support will allow some time to consider the various management options.

Special Populations

Pregnancy

The incidence of PE during pregnancy ranges between 0.3 and 1 per 1000 deliveries.[216] PE is the leading cause of pregnancy-related maternal death in developed countries. In the United States, maternal death from PE ranks third after hemorrhage and hypertensive disorders.[217,218] There is a fivefold increased risk of VTE in the pregnant woman because of venous stasis, a prothrombotic state as a result of increased levels of coagulation factors, reduced protein S, and fibrinolytic activity.[219] The two major PE risk factors in pregnancy are a personal history of VTE and heritable thrombophilias.[220] The risk of PE is higher in the postpartum period, particularly after a cesarean section. The clinical features of PE are no different in pregnancy compared with the nonpregnant state. There have been no prospective trials that have validated existing prediction models to exclude PE in pregnancy. It is been shown from a maternal death review that pregnant women who died from PE are older than 35 years, are obese (body mass index >30), and have chronic medical conditions.[221]

Diagnosis of Pulmonary Embolism in Pregnancy

Although D-dimer may be elevated in pregnancy, leading to a high rate of false-positive results, a normal D-dimer value has the same exclusion value for PE in pregnant women as in other patients with suspected PE. Because D-dimer is elevated in pregnancy, it has been suggested that D-dimer testing not be used in the evaluation of suspected VTE in pregnancy or the early postpartum period. However, in view of its negative predictive value, it is reasonable to measure the D-dimer even though the probability of a negative result is lower than in other patients with suspected PE.[219]

An elevated D-dimer assay should be followed by CUS of the lower extremities. If CUS demonstrates DVT, then anticoagulation can occur and thoracic imaging is not necessary. If CUS is negative and the diagnosis is still suspected, then thoracic imaging is warranted. It is important to note that the upper limit of radiation with regard to the danger of injury to the fetus is considered to be 50 mSv (50,000 mGy), and all radiologic tests (CT and $\dot{V}/\dot{Q}$) fall well below this limit.[220] In a pregnant or postpartum woman with suspected PE who has a normal chest radiograph, either a $\dot{V}/\dot{Q}$ scan or a perfusion scan alone will be sufficient. A normal lung scan essentially excludes the diagnosis of PE. Perfusion scanning compares favorably with CT as far as exposure of breast tissue to radiation is concerned.[221] If the chest radiograph is abnormal and the lung scan is nondiagnostic, then CTPA is recommended.

Treatment of Pulmonary Embolism in Pregnancy

The medical treatment of PE in pregnancy is heparin—either UFH or LWMH, neither of which crosses the placenta nor is found in breast milk in any significant amount. As there are no specific data in the setting of pregnancy, treatment should consist of a weight-adjusted dose of LMWH. Adaptation according to anti-Xa monitoring may be considered in women at extremes of body weight or with renal disease. The heparin treatment should be given throughout the entire pregnancy. From limited data fondaparinux appears efficacious in pregnancy, but bleeding risk is not absent, and care is required when used as second-line therapy.[222]

The new oral anticoagulants are not to be used during pregnancy. Teratogenic effects, reduced fetal viability, hemorrhagic changes, and placental abnormalities have been found in both dabigatran and rivaroxaban. Rivaroxaban is secreted in breast milk.[222] VKAs cross the placenta and are associated with a well-defined embryopathy during the first trimester. Administration of VKAs in the third trimester can result in fetal and neonatal hemorrhage as well as in placental abruption. Warfarin may be associated with central nervous system anomalies in any trimester in pregnancy.[220]

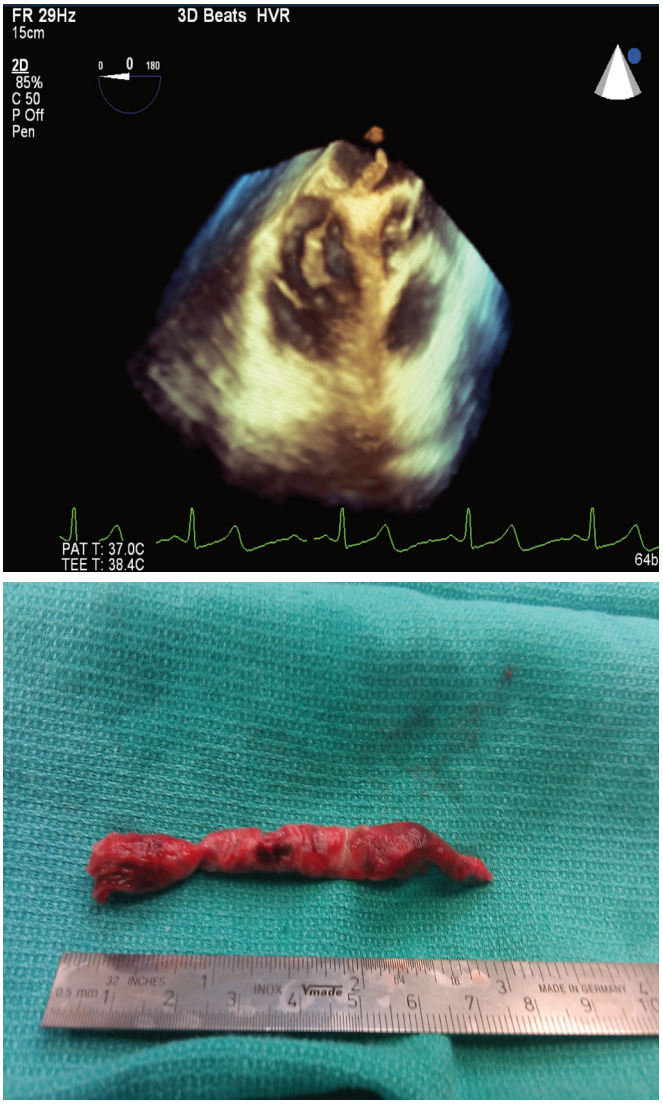
The management of labor and delivery requires particular attention. Epidural analgesia cannot be used unless LMWH is discontinued at least 12 hours before an epidural approach. Treatment can be resumed 12 to 24 hours after withdrawal of the epidural catheter. In any case, close collaboration among obstetrician, anesthetist, and critical care physician is recommended. After delivery, heparin treatment may be replaced by anticoagulation with VKA. Anticoagulant treatment should be administered for at least 3 months after delivery. VKAs can be given even to breastfeeding mothers.[220] Thrombolytic therapy should be used when there is a life-threatening pulmonary embolic event. At the time of delivery, thrombolytic treatment should not be used except in extremely severe cases and if surgical embolectomy is not immediately available. Indications for IVC filters in pregnant women are similar to those in other patients with PE.

In summary, in pregnant women with a clinical suspicion of PE an accurate diagnosis is paramount, as a prolonged course of heparin is required. All diagnostic modalities, including CT scanning, may be used without significant risk to the fetus. LMWHs are recommended in confirmed PE; VKAs are not recommended during the first and third trimesters but could be considered with caution in the second trimester of pregnancy. Anticoagulant treatment should be administered for at least 3 months after delivery.[220]

Right-Sided Heart Thrombi

Echocardiographically documented right-sided heart thrombi occur in approximately 4% of patients with PE.[25,150] These patients have more hemodynamic instability and have a higher mortality rate. In the ICOPER study in patients with acute PE and a free-floating right-sided heart thrombus, the mortality rate was 15% compared with 11% without such thrombi.[150]

In these patients, the treatment of choice is controversial. Both thrombolytic therapy and surgical embolectomy have been used with multiple reports of successful results. In the ICOPER study, thrombolytic treatment was the preferred option, but the 14-day mortality rate was above 20%.[150] In contrast, excellent results with thrombolytic therapy were reported in a series of 16 patients, in which 50%, 75%, and 100% of clots disappeared from the right



• **Fig. 42.10** Embolism in transit through the patent foramen ovale and surgical removal. (Courtesy Dr. Omar Lattouf, Emory University Cardiothoracic Surgery.)

side of the heart within first 2, 12, and 24 hours, respectively, after administration of thrombolytics. All patients survived 30 days.[223] It appears from the literature that treatment with heparin alone is not a treatment option.

For right-sided heart thrombi crossing the interatrial septum (patent foramen ovale) surgical embolectomy is warranted (Fig. 42.10). Whichever therapy is selected, it should be implemented without delay; in the presence of unequivocal echocardiographic visualization of a mobile right-sided heart thrombus, no further diagnostic tests are needed.[25,214,224,225]

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension (CTEPH) is an uncommon but serious sequela of PE.

See the online supplement for additional discussion on CTEPH.

Prophylaxis

The VTE event is a common and recognized complication in critically ill patients. A VTE event can have dire consequences for the critically ill patient with preexisting cardiopulmonary compromise. All critically ill patients have significant risk factors for VTE and also are at higher risk for bleeding. Venous thromboembolic prophylaxis decreases the risk of VTE in ICU patients.[17–21] DVT prophylaxis is effective at reducing the risk of death. In several meta-analyses of surgical patients, prophylactic measures reduced the development of thromboembolic events by more than 50% and also the VTE-attributable mortality rate.[236]

Lack of adherence to evidence-based VTE prophylaxis guidelines has been problematic on a national and international scale.[13,236] With the implementation of electronic medical admission order sets universal VTE prophylaxis can be achieved. Extended post-hospitalization prophylaxis has been recommended in orthopedic surgical and medical patients. The advent of safe and effective prophylaxis strategies makes all critical care patients candidates for some form of preventive therapy on the basis of risk factors present in this population of patients. Several studies suggest that more than 85% of hospitalized patients are receiving some sort of DVT prophylaxis. VTE prophylactic measures are growing in ICUs with quality care initiatives targeting this intervention via bundled care pathways.[237,238]

The administration of prophylactic LMWH (or low-dose UFH) can be administered to the majority of critically ill patients. Critically ill patients at high risk for clinically important bleeding should receive mechanical thromboprophylaxis until the bleeding risk decreases. Renal insufficiency is not a contraindication to the use of LMWH or low-dose UFH.

Long-Term Prognosis

Nearly 25% of patients with PE do not survive the first year after the diagnosis. A majority of these patients succumb to underlying conditions, such as cancer or chronic heart disease, rather than PE. After surviving the first year the patient continues facing bleeding complications from anticoagulation therapy, the risk of recurrent VTE, the development of cancer, and the development of CTEPH.[239]

See the online supplement for additional discussion on long-term prognosis.

Pulmonary Embolism Response Team

Recently, a pulmonary embolism response team model was developed, based in part on the model of the rapid response team.[246] Given the continuum of disease represented by submassive PE and the treatment challenges posed by massive PEs, the goal of the PERT is to rapidly bring together the expertise of a multispecialty team in the field of thromboembolic disease to improve the quality of care and the survival in patients with PE. Not only does the team approach bring expert opinion to the bedside quickly, but it also allows hospital resources to be deployed more efficiently and can be foundational for both local and/or regional research. Although the concept is too new as yet to have efficacy data associated with it, its ability to facilitate care of the PE patient while applying multidisciplinary evidence-based treatments to patients with both submassive and massive PEs may someday make it the standard to which other models are compared.[247]

CTEPH is an uncommon but serious sequela of PE. Certain patients with PE develop an aberrant and incomplete resolution of the thrombotic event, resulting in endothelialized thrombi, which if left unchecked will result in the development of a distal, small vessel vasculopathy. This event results in progressive increases in RV afterload and pulmonary hypertension. When small distal vessel disease develops in patients with CTEPH, the patient no longer is a candidate for surgical management.[226] The reasons are unclear for this divergent pathway in thrombus resolution. Acquired and hereditary risk factors are suspected. For example, 20% of patients with CTEPH have antiphospholipid syndrome, and increased levels of factor VIII are found in CTEPH when compared with non-thrombotic pulmonary hypertension and control groups.[214,224,225] Characteristics of the initial acute embolic event may be associated with subsequent development of CTEPH. Persistent RVD at discharge and persistent elevation of pulmonary artery pressures may play a role.[226,227]

In the past it was estimated that the incidence of CTEPH was only 0.1% to 0.5%.[226] Recent prospective studies have shown that CTEPH is much more common, with an incidence ranging from 1% to 3.8% of patients who survived their acute pulmonary embolic event. It is estimated that in the United States 6000 to 22,000 new cases potentially may occur in each year.[226,228–230]

The $\dot{V}/\dot{Q}$ lung scan plays a central role in the evaluation of patients with pulmonary hypertension. The $\dot{V}/\dot{Q}$ scan in a patient with suspected CTEPH will show the "mottled" appearance of subsegmental and segmental perfusion defects. Larger defects can also be seen.[226] The lung scan is superior to CT angiography in screening patients for CTEPH. A single-center retrospective investigation comparing the lung scan with CT angiography and 227 patients with pulmonary hypertension demonstrated a sensitivity of 97.4% for $\dot{V}/\dot{Q}$ scanning but only 51% for CT angiography in detecting chronic thromboembolic disease.[231]

CT or MRA can be used to plan surgical intervention. Right-sided heart catheterization is required to determine the degree of hemodynamic impairment, and conventional pulmonary angiography can determine the proximal location of the thrombotic obstruction.[226]

Surgical removal of the obstructing material requires a true endarterectomy as opposed to a simple embolectomy. The current approach to pulmonary endarterectomy requires median sternotomy, cardiopulmonary bypass, and periods of hypothermic circulatory arrest to provide adequate visibility. The main pulmonary arteries are incised and the correct endarterectomy level within the wall is defined. Thereafter the plane is followed circumferentially down to the segmental and sometimes subsegmental branches of each lobar artery, a procedure that is performed with the help of special suction dissectors.[229,230]

The perioperative mortality rate is related to the severity of the disease, with a mortality rate of 4% in patients with a preoperative PVR less than 900 dynes/s per centimeter^{-5} and 20% in those with PVR above 1200 dynes/s per centimeter^{-5}. The functional results of a successful pulmonary thromboendarterectomy are excellent and generally are sustained over time, with a 3-year survival rate of about 80%.[231–233]

The major causes of postoperative fatality from pulmonary endarterectomy are RV failure related to persistent pulmonary hypertension and acute lung injury. Lifelong anticoagulation and placement of the IVC filter are recommended. In patients who are deemed inoperable because of distal chronic thromboembolic disease or in whom the surgical mortality risk of endarterectomy is high, medical therapy developed for idiopathic pulmonary arterial hypertension has been studied in patients with CTEPH. It is important to identify patients as early as possible, so they may have the opportunity for pulmonary endarterectomy because the hemodynamic and symptomatic benefits provided by medical therapy are modest.[226,234,235]

Long-term prognosis may depend on whether the pulmonary embolic event was provoked or unprovoked (occurring in the absence of known risk factors). The prognosis of unprovoked PE may be more unfavorable than that for patients who experience provoked PE. Studies have shown that compared with their counterparts with unprovoked PE, patients with provoked PE are at higher risk for recurrent PE, arterial cardiovascular events, the occurrence of cancer, and CTEPH.[240–244]

In a recent study Klok and colleagues investigated the long-term prognosis of acute PE in 308 patients with unprovoked PE, 558 patients with provoked PE, and 334 patients without PE for a median follow-up period of 3.3 years. The mortality rate for the acute embolic event was 5.2%. The adjusted HR for recurrent VTE was increased for patients with unprovoked PE versus provoked PE (HR 2.1, 95% CI 1.3–3.1) and unprovoked PE versus patients without PE (HR 10, 95% CI 4.9–28). Recurrent PE was fatal in 19% of the patients and these fatalities usually occurred after 3 weeks from the initial PE episode. The risk for cancer was higher for the patients after unprovoked PE than for the patients with provoked PE (adjusted HR 4.4, 95% CI 2.0–10) and without PE (adjusted HR 2.5, 95% CI 1.1–2). Patients with unprovoked PE experienced severe cardiovascular disease two to three times more often than the patients from the other two study cohorts (adjusted HR 2.6, 95% CI 1.5–3.8; and HR 2.4, 95% CI 1.2–3.7). There was no difference in the pooled risk for adverse outcome of patients with unprovoked and provoked PE, although the risk on all separate endpoints except for malignancy-related death was markedly higher for the patients with unprovoked PE. From this study, in nearly 4 years after the embolic event, half of the patients diagnosed with acute PE died or were diagnosed with cancer, recurrent VTE, CTEPH, or arterial cardiovascular disease. This study sets forth a clarion call for studies to develop and evaluate accurate prediction strategies for duration of treatment and to provide further insight on clinical surveillance and personal prognostication for the patients who have survived their initial embolic event.[245]

Key Points

- It is important to identify patient-related and setting (ICU)-related risk factors for the development of VTE. ICU risk factors associated with massive PE are malignancy, cardiopulmonary disorders, and immobilization.
- Nearly two-thirds of patients who die from pulmonary thromboembolism die within 1 hour of presentation, giving rise to the concept of the golden hour to accomplish both diagnosis and commence treatment. The principal pathophysiologic effects of pulmonary thromboembolism result from the impaction of clot in the pulmonary circulation with resulting vascular obstruction and humoral mediator release.
- The major clinical presentations of life-threatening PE seen in patients coming to the ICU range from signs and symptoms of RVD to frank shock.
- Risk stratification is useful in the assessment of submassive normotensive PE with RVD. RVD can be identified from clinical findings, ECG, cardiac biomarkers, and imaging modalities (echocardiogram and CTPA). The initial hemodynamic presentation of PE is the most powerful predictor of outcome. Central location of a thrombus is an independent risk factor for death.
- The cornerstone of pharmacologic management of VTE is heparin. Heparin therapy should be initiated, if there is no contraindication, as the diagnostic evaluation is being performed. UFH, LMWH, or fondaparinux followed by warfarin is currently the standard treatment for low-risk PE. New oral agents have been recently approved. Thrombolytic therapy, if there are no contraindications, should be used in patients with massive PE and considered in patients with submassive PE with evidence of severe RVD.
- The management of the normotensive submassive PE patient centers on reducing RV afterload and preventing further insult to the right ventricle. Systemic and endovascular delivery of thrombolytic agents can reduce RV strain. The placement of a retrievable IVC filter can prevent further embolic impact on the RV.
- Supportive therapy for massive PE utilizes judicious use of fluids to avoid further increases in RV strain. NE is the vasopressor of choice to maintain perfusion pressure. Dobutamine should be used to improve contractility. These temporizing measures will allow the critical care team to mobilize thrombolytic, endovascular, and surgical management strategies.
- All diagnostic modalities, including CT scanning, may be used without significant risk to the fetus in the pregnant woman. LMWHs are recommended in confirmed PE. Anticoagulant treatment should be administered for at least 3 months after delivery.
- Thrombolytic therapy or surgical intervention should be considered for right-sided heart thrombi. If a patent foramen ovale is present or right-sided heart thrombi cross the patent foramen ovale, surgery should be performed.
- CTEPH is more common than once thought and is best managed with pulmonary endarterectomy. It is important to identify these patients early.
- VTE prophylaxis strategies are necessary for nearly all critical care patients.
- Four years after PE the majority of patients will have either died or had recurrent PE, cancer diagnosis, arterial cardiovascular disease, or CTEPH. We must do more in follow-up of these post-PE patients.
- Pulmonary embolism response teams can bring a multidisciplinary team together and facilitate the deployment of hospital resources in an expedited fashion to best manage the continuum of submassive and massive PEs.

Acknowledgment

Ken Leeper was renowned and beloved for his incredible dedication to patient care, research, and his tireless devotion to teaching medical students, nurses, medical residents, and fellows with the goal of creating the next generation of bedside practitioners. He co-authored the pulmonary embolism chapter for the 4th edition of Critical Care Medicine. Ken died on April 7, 2016. He will be missed and always remembered as an inspirational man and physician and for his lasting contributions to the art and science of medicine.

Review Questions

1. A 55-year-old man presents to the emergency department (ED) and is diagnosed with a pulmonary embolism (PE) with computed tomography (CT). Which of the following findings are expected changes that this patient may exhibit?

a. An increase in arterial partial pressure of oxygen ($Paco_2$) is a typical finding on arterial blood gas analysis owing to an increase in dead space.

b. Hypoxemia is caused only by a low cardiac output state.

c. Pao_2 and the alveolar-arterial (A-a) gradient are invariably abnormal.

d. The gradient between the end-tidal CO_2 ($etco_2$) and the $Paco_2$ is increased.

Answer: d. Acute PE has a variety of hemodynamic and gas exchange consequences. By occluding the pulmonary vasculature, PE increases ventilation relative to perfusion; it is therefore a dead-space phenomenon. $Paco_2$ is increased in critical illness as a result of either an increase in CO_2 production (Vco_2), a decrease in minute ventilation (VE), or an increase in dead-space ventilation (VD). Using this logic, one would expect PE to cause hypercapnia; typically, however, hypocapnia is present owing to an increase in minute ventilation associated with PE. If a PE is massive enough, especially in patients prone to CO_2 retention (e.g., chronic obstructive pulmonary disease), an increase in CO_2 can occur. This is not the norm, however. Although a problem of dead space, PE typically causes hypoxemia by shunt-type physiology, as local vasoconstriction promotes ventilation-perfusion mismatch. Atelectasis can occur distally to the clot, promoting ventilation-perfusion mismatch as well. Acute increases in right-sided pressures can open a patent foramen ovale, causing intracardiac shunt also. A low cardiac output state can contribute to hypoxemia if mixed venous oxygen saturation falls enough; however, this is not the only cause of hypoxemia, as discussed earlier. Though hypoxemia is common in PE, arterial partial pressure of oxygen (Pao_2) and A-a gradient have been reported to be normal in up to 30% of patients. End-tidal capnography is a useful adjunct in PE. Owing to a drop in cardiac output and an increase in dead space (which will decrease alveolar CO_2), the $etco_2$ waveform area will decrease, widening the gap between $etco_2$ and $Paco_2$.

2. Which one of the following is most correct concerning the diagnosis of PE?

a. D-Dimer has a high positive predictive value and can establish the diagnosis when levels are above 500 ng/mL.

b. Ventilation-perfusion scanning has a very high sensitivity (>90% for the presence of PE) but low specificity.

c. Chest radiographic findings with high sensitivity for PE include pleural-based infiltrates, focal oligemia, and hypovascularity.

d. Pulmonary angiography's high sensitivity as a diagnostic tool is detracted by its lower specificity.

Answer: c. Diagnosing PE has become progressively more sophisticated in recent years. The most important first step is suspicion, and studies have confirmed the usefulness of physicians' pretest clinical suspicion for PE when considering diagnostic testing. Initial evaluation includes chest radiography and blood testing. Pleural-based infiltrates, focal oligemia, and hypovascularity were found to be more common in those diagnosed as having PE but lacked high sensitivity or specificity for this disorder. Similarly, D-dimer testing, which can be positive in many clinical conditions such as recent surgery, trauma, malignancy, severe infection, pregnancy, and liver disease, has been shown to have a very high negative predictive value (94%) and makes PE unlikely if less than 500 ng/mL. Ventilation-perfusion scanning has been the predominant test to help rule in or out disease. Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) data revealed that ventilation-perfusion scans could be diagnostic in two cases: high-probability scans with high pretest probability and normal scans with low pretest probability. However, these two scenarios account for less than 30% of cases and in general, ventilation-perfusion scanning is not diagnostic in up to 80% of patients. Many cardiopulmonary disorders can cause ventilation-perfusion abnormalities, making intermediate- or low-probability scans nondiagnostic. Therefore spiral CT scans of the chest have recently been used more frequently. Specificity for spiral CT scans is better than sensitivity, with much of the difficulty in identifying subsegmental pulmonary emboli. Pulmonary angiogram remains the gold standard, with sensitivity and specificity reaching 95% to 100%.

3. Which of the following is true regarding the hemodynamics and management of the unstable patient with acute PE?

a. An acute increase in pulmonary artery pressures leads to right ventricular (RV) dysfunction and dilatation, causing septal shift into the left ventricular cavity, decreasing left ventricular output, causing shock.

b. Patients with acute PE should be aggressively volume resuscitated to maintain high right-sided pressures and transpulmonary blood flow.

c. Vasoactive medications (i.e., vasopressors) should not be given, as many can increase pulmonary vascular resistance, worsening hemodynamics.

d. Similar to patients with acute respiratory distress syndrome (ARDS), patients with acute RV failure from PE should have their airway pressure limited and allowance for permissive hypercapnia and permissive hypoxemia.

Answer: a. The hemodynamic consequences of acute PE are secondary to RV failure. The RV is accustomed to emptying into a low-pressure circuit—the pulmonary vasculature. Acute embolic obstruction, along with platelet activation and release of humoral mediators (e.g., thromboxane, histamine, serotonin), leads to an acute increase in pulmonary pressures, which the RV cannot overcome. Acute RV failure causes septal shift and progressive decrease in left ventricular cavity size and output (ventricular interdependence).

Preload should be manipulated with caution in acute PE. Volume overloading an acutely pressure overloaded RV will only make things worse. Patients with acute PE still may have recruitable preload, though, and the potential to respond to volume; if volume is given, it should be given judiciously. Management of acute RV failure can be challenging. If arterial hypotension is allowed to go unchecked, coronary perfusion to the RV will fall, worsening RV failure, worsening the entire hemodynamic picture. Knowing this, vasopressors are commonly used in RV failure to maintain arterial pressure and coronary perfusion to the right side. Many vasopressors can increase PVR, but the risk/benefit ratio obviously points to maintaining pressure. Other hemodynamic management decisions that are fairly common include RV afterload reduction with inhaled pulmonary vasodilators and inotropic support with agents such as dobutamine. Finally, an acute failing RV will not tolerate acidosis or hypoxia,

as both will exacerbate acute pulmonary vasoconstriction. Ideally, hypercapnia and hypoxemia could be avoided with as low airway pressures as possible, but priority (at least acutely) should be given to maintaining gas exchange to avoid worsening of RV failure.

4. A 49-year-old woman presents to the ED with chest pain and electrocardiogram (ECG) changes to include a new right bundle branch block and T-wave inversions across the anterior precordium. CT demonstrates acute bilateral proximal PE. Her blood pressure is 120/80 mm Hg and she clinically looks well. Which of the following is true with respect to choices regarding her treatment options?

a. There is a limited role for echocardiography, as the decision to administer thrombolytics is based solely on arterial blood pressure.

b. There is general consensus that normotensive PE patients with RV dysfunction should be administered thrombolytic therapy.

c. An elevation in cardiac biomarkers is associated with concomitant acute coronary syndrome and should be investigated with cardiac catheterization.

d. The decision to administer thrombolyitic therapy should take into consideration not only hemodynamic/blood pressure, but also risk stratification of normotensive patients.

Answer: d. It is generally recommended that patients with acute PE with evidence of hypotension, and no contraindication to thrombolytic therapy, should be given thrombolytics. All other patients should immediately be risk stratified for potential complications. Most importantly, this includes an echocardiogram to assess for RV dysfunction. Normotensive patients with PE without RV dysfunction will overwhelmingly do well and should not be offered thrombolytics. In normotensive patients with RV dysfunction, the decision to administer thrombolytics should be assessed on a case-by-case basis based on risk stratification. This includes how the patient looks clinically, oxygenation and work of breathing, cardiac biomarkers, and ECG and CT scan findings.

- Ventilatory Support
- Mechanical Circulatory Support
- Atrial Septostomy
- Prognosis

Pulmonary hypertension (PH) in critically ill patients admitted to the intensive care unit (ICU) may present with rapid deterioration of right ventricular (RV) function, leading to hemodynamic collapse and death. An understanding of the pathogenesis of RV failure secondary to PH is critical for RV rescue and successful treatment of these patients.

Although PH is defined regardless of mechanism as the presence of a resting mean pulmonary artery pressure (mPAP) greater than 25 mm Hg and a pulmonary vascular resistance (PVR) greater than 240 dynes*second/cm[5] (or >3 Woods units) as determined by right heart catheterization, PH is a pulmonary vascular disorder that encompasses a broad spectrum of pathologies classified on the basis of underlying etiology and pathophysiologic factors (Box 43.1).[1]

When decompensated PH is encountered in the ICU, it is most commonly due to elevated pulmonary venous pressure in the setting of left-sided heart disease (World Health Organization [WHO] group 2) or preexisting vascular disease which could span multiple groups.[2] It is also recognized after cardiothoracic surgery, in part related to endothelial dysfunction seen with cardiopulmonary bypass.[3,4] PH is also associated with sepsis,[5] acute respiratory distress syndrome (ARDS) with associated acute RV failure in 10% to 25% of cases,[6,7] and after massive pulmonary embolism (PE) in up to 60% of patients.[8] PH may also develop as a result of reversible factors that occur in critical illness, leading to an increase in PVR, which often precipitates RV failure. Functional residual capacity is one of these important factors.[9] A decrease in lung volume (atelectasis, endobronchial intubations, effusions, insufficient positive end-expiratory pressure [PEEP], pneumothorax, and pneumonia) will increase PVR, as well as excessive lung volumes (excessive PEEP or tidal volume, air trapping; Fig. 43.1).[10] Other reversible causes of PH include hypoxia, hypercarbia, acidosis (Fig. 43.2),[11] hypothermia, and shivering. Use of alpha-antagonists can increase both SVR and PVR.[10]

Several relatively new developments have led to a greater focus on RV function in critically ill patients. The rapid growth in our understanding of pulmonary vascular biology and the development of several new classes of pulmonary vasodilator medications has led to widespread treatment options for patients with pulmonary arterial hypertension and has enhanced our clinical expertise in managing RV failure, especially toward the end of their disease. Technical advances in the development and use of temporary RV mechanical support for advanced patients with either reversible disease or as a bridge to transplant has provided further insight into the management of otherwise intractable late-stage RV failure.[12]

Pathophysiology of PH and RV Failure

Hemodynamic Classification of PH

The following equation relates the mean pulmonary artery (PA) pressure to the pulmonary venous (PV) pressure, PA blood flow (PBF), and PVR:

$$\text{PBF}\,(\text{L}/\text{min}/\text{m}^2) = \frac{(\text{mPAP} - \text{PV})\ \text{mm Hg}}{\text{PVR units}/\text{m}^2}.$$

The difference between the mPAP and the PV pressure (also referred to as the left atrial pressure [LAP]) is the transpulmonary gradient (TPG). Under normal circumstances, the pulmonary circulation is a low-pressure, low-impedance circuit; despite a fourfold rise in PBF, PAPs increase minimally and PVR falls. Normal hemodynamics are shown in Table 43.1. When PAPs are elevated, the TPG helps determine the site of the elevated PAP (Table 43.2), which corresponds to the location of the underlying pulmonary vasculopathy.

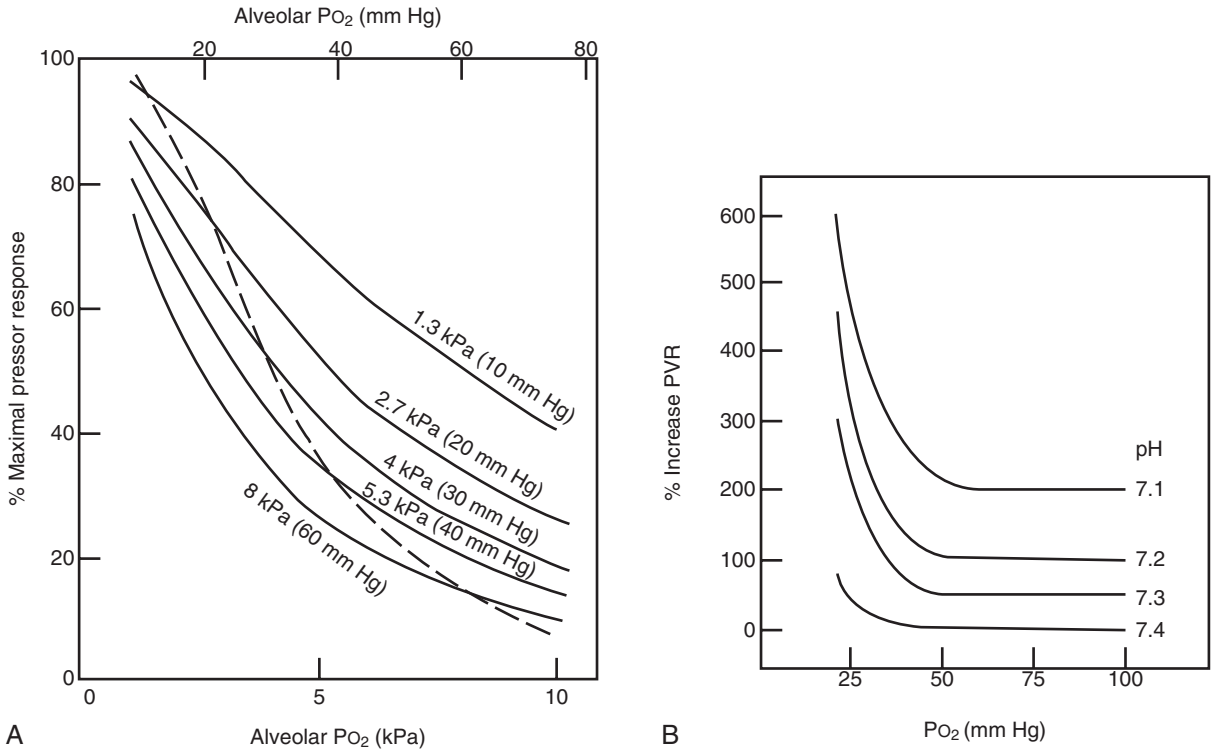
When PAP is normal, the TPG is normally low. In PH, the TPG can be elevated or normal. If the TPG is elevated, there is a precapillary contribution to the PH. If the TPG is normal, then high PAP is due to either high PV pressure or high PBF, and a postcapillary contribution to the PH occurs. With increases in PV pressure and TPG, both postcapillary and precapillary changes are present. In this latter case, combined precapillary and postcapillary PH is present, which may be either fixed or reversible depending on pulmonary vasodilator test results.[13]

In the hemodynamic classification of PH (see Table 43.2) the PV is the LAP and is approximated in clinical practice by the pulmonary capillary wedge pressure (PCWP).

Pathology and Cellular Molecular Physiology of PH

An anatomic overview of precapillary and postcapillary PH is shown in (Fig. 43.3). It is important to recognize that the conditions that raise the postcapillary pressure, such as left-sided heart failure (HF; group 2 PH) differ significantly from conditions that increase the precapillary pressure and primarily affect the pulmonary arteries and arterioles, such as idiopathic pulmonary arterial hypertension (group 1 PH). The former is associated with a relatively small TPG with histopathologic changes in the arterial vessels that consist of mild medial hypertrophy and reversible intimal changes. In the latter, there is an increased TPG or arteriovenous pressure gradient, and histopathologic changes on the pulmonary vasculature are more marked, including significant intimal hypertrophy with fibrosis, marked smooth muscle hypertrophy, vasoconstriction, adventitial proliferation, and thrombosis (Fig. 43.4).[14] These changes cause vascular flow obstruction and eventually lead to abnormal angiogenesis and formation of plexiform arteriopathy. Endothelial dysfunction also develops with imbalances between vasodilation and vasoconstriction and between apoptosis and proliferation, mechanisms that are thought to play the most important role in the development of chronic progressive PH.[15] In patients with combined precapillary and postcapillary PH, marked histopathologic changes may also be present.[13]

In many types of PH, production of endogenous vasodilators (nitric oxide [NO] and prostaglandins) is impaired, and production of vasoconstrictors (endothelin-1, thromboxane A) is increased. The common treatment strategy for PH is to achieve the balance in key molecular pathways by increasing available nitrous oxide (NO) and prostacyclin, and reducing the effects of endothelin-1 (Fig. 43.5).[15] Hypoxic pulmonary vasoconstriction, as occurs in respiratory disorders (World Health Organization group 3), is an important determinant of arterial PH. In ARDS both hypoxemia and the accumulation of intravascular fibrin and cellular debris contribute to subsequent vascular obliteration of PH. RV dysfunction as a complication of ARDS is more gradual than in patients with massive PE and usually



• **Fig. 43.2** Effect of oxygen tension and acidemia on pulmonary vasoconstriction. A, Pulmonary vasoconstriction increases as alveolar oxygen tension (Pa_{O_2}) falls while keeping mixed venous oxygenation constant (mixed venous partial pressure of oxygen *[P_{O_2}]* indicated for each *solid line* from 60 to 10 mm Hg). The combined effect of allowing Pa_{O_2} and mixed venous P_{O_2} to fall is shown by the *dashed line,* where Pa_{O_2} and mixed venous oxygen saturation are the same.[34] Maximal pulmonary vasoconstrictor response was defined as the difference between baseline pulmonary artery pressure when ventilating with a fraction of inspired oxygen (F_{IO_2}) of 0.21 and perfusate F_{IO_2} of 0.06, and the pulmonary artery pressure when both the inspired and the perfusate F_{IO_2} was 0. The pressure response at all other combinations of inspired and perfusate F_{IO_2} was expressed as a percent of the maximum. *B,* Pulmonary vasoconstriction in newborn calves as a function of inspired partial pressure of oxygen under conditions of different levels of arterial blood pH. Hypoxic pulmonary vasoconstriction is increased and occurs as a higher level of inspired oxygen as arterial pH is decreased. *PVR*, Pulmonary vascular resistance. (From Braunwald E. Pathophysiology of heart failure. In: Braunwald E, ed. *Heart disease: a textbook of cardiovascular medicine.* Philadelphia: Saunders; 1980, pp 453–471.)

TABLE 43.1 Normal Hemodynamic Values

Left atrial pressure	8 mm Hg
Systolic pulmonary artery pressure	25 mm Hg
Diastolic pulmonary artery pressure	10 mm Hg
Mean pulmonary artery pressure	15 mm Hg
Transpulmonary gradient	7 mm Hg
Pulmonary vascular resistance	0.9–1.4 Woods units or 90–120 dynes/s/cm^5

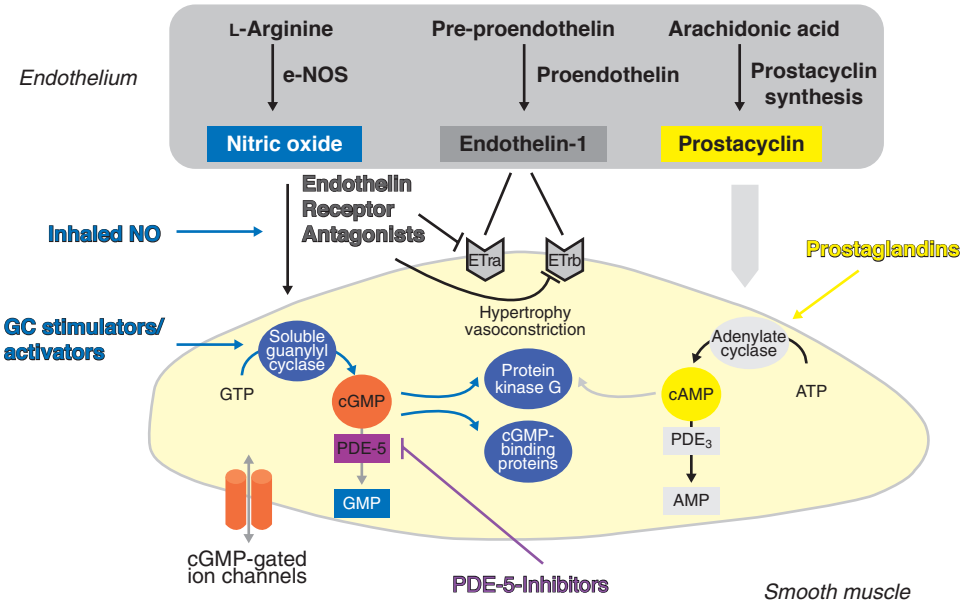
• **Fig. 43.4** Pathogenesis of pulmonary arterial hypertension. In susceptible patients, pulmonary arterial hypertension occurs as the result of an insult to the pulmonary vascular bed. This insult results in an injury that progresses to produce the characteristic pathologic features. *BMPR2* is the bone morphogenetic protein receptor II gene, which is believed to responsible from the inherited form of the disease. *HIV,* Human immunodeficiency virus. (From Gaine S. Pulmonary hypertension. *JAMA.* 2000;284:3160–3168.)

occurs at least 48 hours after the beginning of respiratory support.[7] The mortality rate and incidence of RV failure have been shown to be related to the level of plateau pressure during mechanical ventilation.[16] The implementation of low tidal volume ventilation in patients with ARDS has significantly lowered not only mortality rates but also the incidence of acute RV failure in this patient population.[17] Although sepsis is a major risk factor for developing ARDS, sepsis itself can sometimes lead to severe acute arterial PH.[16]

Endotoxins and vasoconstrictor mediators related to pulmonary vasoconstriction also play significant roles in the development of PH during sepsis. Endotoxins may not only cause systemic hypotension but also pulmonary biphasic hypertension, with a decrease in compliance and increase in resistance of the respiratory system.[5] Endotoxemia is characterized by constriction of the proximal pulmonary arteries during the early phase followed by decreased compliance of the distal pulmonary vasculature.[18]



• **Fig. 43.5** Endothelial and vascular smooth muscle cell pathways involved in the regulation of pulmonary arterial tone and pharmacologic approaches. Vasorelaxation is mediated by increases in cyclic guanosine monophosphate *(cGMP),* antagonism of the endothelin A and B receptors (*ETra* and *ETrb*), or stimulation of adenylate cyclase by prostaglandins, primarily prostacyclin. Intracellular levels of cGMP can be targeted at different levels by exogenous nitric oxide (inhaled nitric oxide), activators/stimulators of soluble guanylate cyclase, or by inhibiting the catabolism of cGMP by phosphodiesterase 5 inhibitors. *AMP,* Adenosine monophosphate; *cAMP,* cyclic adenosine monophosphate; *e-NOS,* endothelial nitric oxide synthase; *GC,* guanylyl cyclase; *GMP,* guanosine monophosphate; *GTP,* guanosine triphosphate; *NO,* nitric oxide; *PDE-5,* phosphodiesterase-5. (From Guazzi M, Borlaug BA. Pulmonary hypertension due to left heart disease. *Circulation.* 2012;126:975–990.)

These endotoxin-dependent hemodynamic and respiratory effects are also mediated by an excessive release of inflammatory mediators and an imbalance in the production of NO, prostacyclin, and endothelin-1 as previously discussed.[5,19] In experimental systems, endotoxin infusion can dramatically affect RV function in the very early phase of septic shock; right ventricular-vascular coupling is preserved by an increase in RV contractility. Later, however, myocardial oxygen consumption and the energy cost of RV contractility are increased, which together with progressive endotoxin-induced PH leads to RV dysfunction and failure.[20]

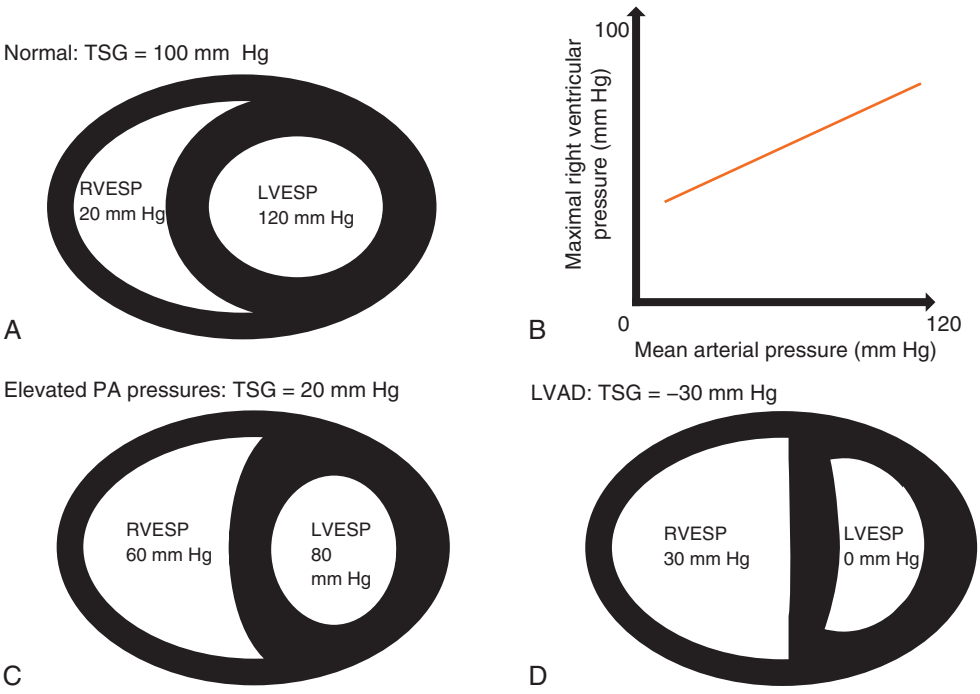
RV Failure

The pump responsible for perfusing the pulmonary circulation is considerably different from its counterpart in the systemic circulation. Unlike the muscular and ellipsoidal left ventricle (LV), which can be considered a four-walled chamber, the RV consists essentially of a thin free wall wrapped around the more muscularized medial wall of the LV.[9] The end diastolic dimension of the RV free wall is 2 to 3 mm in thickness compared with 8 to 11 mm in the LV free wall. Although the smaller mass of the RV produces less contractile force, the RV has a greater end-diastolic volume and surface area per unit of volume of fluid with flattening of the RV free wall during systole. There is a large increase in volume without change in free wall area, allowing the RV stroke volume to match the LV stroke volume with less energy expenditure.[12] The RV bioenergetic requirement is 20% of that of the LV. It is important to mention in this context that forces transmitted from one ventricle to the other through the myocardium and pericardium are termed *ventricular interdependence*. Because of the pericardium, the higher LV pressure is transmitted to the RV through the interventricular septum. This pressure difference, or transseptal gradient (TSG), is present in systole and diastole, and accounts for the normal left-to-right bulge of the septum and creates a scaffold against which the RV free wall contracts (Fig. 43.6A). In a normal heart, 4% to 10% of the LV systolic function depends on the RV, and 20% to 40% of the RV systolic function depends on the LV.[9] Importantly, RV function is dependent on high LV cavity pressure (Fig. 43.6B).[9,12] Coronary perfusion to the RV occurs during both systole and diastole compared with primarily diastolic flow in the LV, making the RV dependent on systolic blood pressure. Therefore right carotid artery (RCA) filling and RV perfusion also depend on a high LV cavity pressure.

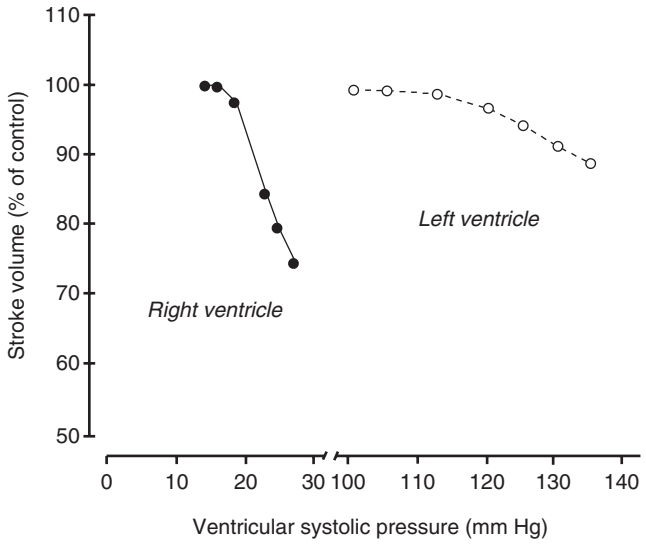
Under normal conditions the RV operates against a low-impedance, high-capacitance, and low-pressure system. Accordingly, and as already described, the RV can accommodate increases in volume overload, but it is exquisitely sensitive to changes in afterload as occurs with an increase in PVR (Fig. 43.7). When there is a chronic increase in PVR (e.g., lung disease, thromboembolic disease, idiopathic pulmonary arterial hypertension), RV hypertrophy occurs. The increased thickness reduces wall stress through Laplace's law[19]:

$$\text{Wall stress} = \text{Pressure} \times \text{Internal radius}/\text{Wall thickness}$$

In acute RV pressure overload, such as that seen in the setting of a massive PE, RV systolic pressure increases to a point where there is no further increase (40 mm Hg) and function begins to decline with decreased cardiac output (CO) and decreased blood pressure (Fig. 43.8). In RV pressure overload, the TSG is decreased (see Fig. 43.6C) and therefore, unlike in the case of volume overload, the septum does not return to its original shape during systole.



• **Fig. 43.6** Relationship between transseptal gradient *(TSG)* and right ventricle (RV) function. A, Normal condition; TSG is 100 mm Hg (normal range 80 mm Hg-120 mm Hg). The shape and position of interventricular septum is maintained. B, Normal physiology; RV pressure development is dependent on left ventricle (LV) pressure. C, Patient with elevated pulmonary artery (*PA*) pressure; TSG is 20 mm Hg. The septum is flattened toward the LV and the RV is dilated. D, Patient with a left ventricular assist device *(LVAD)*; TSG is –30 mm Hg. There is potential for the septum to bulge into the LV or to have a "suction event." *LVESP*, Left ventricular end-systolic pressure; *RVESP*, right ventricular end-systolic pressure. (From Hrymak C, Strumpher J, Jacobsohn E. Acute right ventricle failure in the intensive care unit: assessment and management. *Can J Cardiol.* 2017;33:61–71).



• **Fig. 43.7** Enhanced afterload sensitivity of the right ventricle compared with the left ventricle. Right ventricular stroke volume is impaired to a much greater extent comparison with the left ventricle with comparable acute increases in arterial pressure. (From Lumb AB. The pulmonary circulation. In: *Nunn's applied respiratory physiology.* Woburn: Butterworth-Heinemann; 2000, p 152.)

The RV dilates and the normal helical orientation of the myofibrils is reduced. Mechanical cardiac function is deleteriously affected and RV cardiogenic shock may eventually supervene (Fig. 43.8).[21,22] In this case, acute management then depends on reestablishing the TSG by increasing LV pressure. RV dilatation and failure occur in most conditions that cause an acute decrease in the TSG. In patients with a left ventricular assist device (LVAD), for example, the TSG may become negative as a result of increased LVAD inflow, as with too high a pump speed, leading to further RV dilatation. ("suction events"; see Fig. 43.6D). This situation may be aggravated when hypovolemia is present.

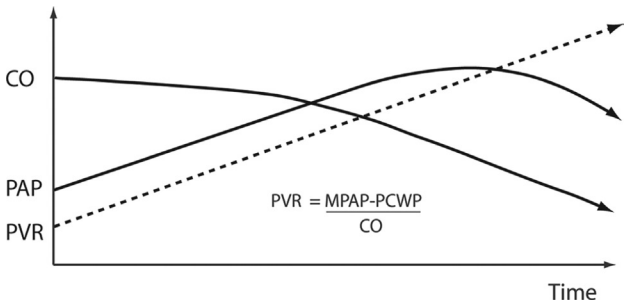
A downstream adverse effect of right-sided HF is the development of systemic venous hypertension that leads to concomitant visceral organ congestion and dysfunction. Regardless of the underlying cause of PH, the final common pathway for hemodynamic deterioration and death is RV failure.

Management of PH and RV Failure in the ICU

General Management Principles

The management of patients with PH associated with RV dysfunction in the ICU is challenging because of the following factors:

1. Multiple etiologies result in similar-appearing clinical scenarios but require subtle differences in approaches to treatment.



• **Fig. 43.8** Right ventricular shock. Relationship between cardiac output *(CO),* pulmonary artery pressure *(PAP),* and pulmonary vascular resistance *(PVR)*. As pulmonary pressures increase, CO will decrease. *MPAP,* mean and pulmonary artery pressure; *PCWP,* pulmonary capillary wedge pressure. (From Haddad F, Doyle R, Murphy DJ, et al. Right ventricular function in cardiovascular disease, part II: pathophysiology, clinical importance, and management of right ventricular failure. *Circulation.* 2008;117:171–131.)

• BOX 43.2 Management Principles of Pulmonary Hypertension With Right Ventricular Failure

1. Maintain SVR and RCA perfusion pressure
2. Optimize preload
   a. Avoid underfilling of RV
   b. Avoid overfilling of RV
   c. Ventilator management to avoid decreased preload
3. Decrease RV afterload and PVR
   a. Pulmonary vasodilators
   b. Reverse metabolic factors
   c. Ventilator settings
4. Augment RV cardiac output
   a. Increase RV contractility
   b. Rate control
   c. Rhythm control, atrioventricular synchronization

PVR, *Peripheral vascular resistance;* RCA, *right carotid artery;* RV, *right ventricle/right ventricular;* SVR, *systemic vascular resistance.*

2. Current guidelines for treatment are based mostly on expert consensus owing to the current lack of evidence-based medicine (i.e., data extrapolated from chronic treatment of PH, animal studies, post–cardiac surgical experience).
3. Treatment requires management of hemodynamics based on knowledge of pathophysiologic principles using a combination of medical and mechanical modalities.
4. The mortality level is high.[2,23]

Therefore patients should be managed at or in conjunction with a center that specializes in PH equipped with all the available specialized medical and mechanical treatment modalities and clinical staff specifically trained to assist in the treatment of these patients.[24–26]

Treatment is hemodynamically directed and has four major goals.

1. Maintenance of SVR and thereby the pressure gradient between aortic and RV pressure in to ensure RCA perfusion and reversal of RV ischemia. This also improves adverse LV conformational changes imposed by a dilated RV via interventricular dependence.[25] In cases of preexisting PH where RV pressures approach or exceed systemic pressures, using drugs that increase contractility before initiating therapies to maintain SVR can lead to an increase in wall tension and increase RV end-diastolic pressure (RVEDP), thus decreasing RV coronary perfusion pressure.[12] Additionally, maintaining perfusion can help mitigate enteric factors that may perpetuate acidemia, which can worsen hypoxic pulmonary vasoconstriction.
2. Optimization of preload, which involves avoiding underfilling of the RV, which leads to low CO via the Frank-Starling mechanism, and avoidance of overfilling to prevent RV overdistention that affects the TSG and myocyte stretch causing suboptimal myofilament placement. With overfilling, increased central venous pressure (CVP) and venous congestion lead to decreased organ perfusion pressure and multiorgan failure.[9]
3. Reduction of RV afterload and PVR.
4. Augmentation of RV cardiac output by improving contractility, rate and rhythm management, and atrioventricular synchronization.[2] This is particularly important in patients with chronic PH when PAP cannot be reversed and management should focus more on optimizing RV function[12] (Box 43.2).

Monitoring

Monitoring of PH and RV pressures, as well as their effects on organ function, is essential in the ICU setting. Close attention to clinical and laboratory markers of organ dysfunction is necessary owing to the deleterious effects of elevated CVP and accompanying venous congestion. Strict recording of fluid intake and output can provide information regarding preload, renal function, or response to diuresis. Laboratory measures such as serum creatinine levels, liver function tests, and lactate levels serve as objective measures of renal and liver impairment and tissue perfusion, respectively, especially when severe RV failure leads to hepatic congestion and decreased end-organ perfusion. Myocardial markers such as natriuretic peptides and troponin can also be used for monitoring.

Although prior studies express concern and controversy about the utility of invasive monitoring,[27,28] the use of PA catheters provides invaluable information on cardiac function in critically ill patients with shock. The ability to readily assess hemodynamic parameters, such as cardiac index (CI), mPAP, PVR, PCWP, and mixed venous oxygen saturation (SvO_2), facilitates the delivery of additional therapies such as vasopressors, inotropes, or vasodilators. The use of serial transthoracic echocardiography (TTE) can lend additional insight into cardiac function by offering a direct glimpse at left and RV filling, interventricular dependence, contractility, and valvular pathology, as well as aid in the assessment of abnormal flow or left-to-right shunting.

Maintaining SVR and RCA Perfusion

Vasopressors

Norepinephrine

Norepinephrine (NE) is widely used in critical care settings to treat hemodynamically unstable patients. Its effects via β_1-receptor agonism are controversial. In animal models there is evidence for increased CO at doses up to 0.5 μg/kg per minute.[29–31] Other studies in patients with septic shock or after cardiac surgery have shown no effect on inotropy and CO.[32–34] NE exerts significant

α_1-receptor–mediated vasoconstriction. Animal studies have shown that α-adrenergic stimulation can cause a disproportionate rise in PVR and worsen PH,[35] with increases in PVR from 2.5 to 3.5 Woods units observed at a dose of 70 μg/min.[34] In a study of patients with septic shock, NE at a dose of 0.7 to 1.2 μg/kg per minute also resulted in increased PVR.[36] However, in patients with chronic PH in whom systemic hypotension developed after induction of anesthesia, it exerted more vasoconstrictive effect in the systemic rather than in the pulmonary circulation, decreasing the PVR/SVR ratio, which is favorable for RCA perfusion pressures and the TSG.[33] Further studies in septic shock showed that NE produced a 26% increase in PVR in contrast to a 35% increase in SVR.[32] Other animal studies have shown that NE causes no increase in pulmonary or renal vasoconstriction.[30] Additionally, in animal models, no increase in PVR was noted at doses less than 0.5 μg/kg per minute.[31] However, in HF patients with pulmonary arterial hypertension (PAH), NE use showed no difference in survival.[37] In post–cardiac surgery patients, NE has been successfully used in combination with prostaglandin for the treatment of patients with acute and chronic PH.[38] Overall, evidence exists for the use of NE in patients with PH and RV dysfunction to increase SVR and RCA perfusion, albeit with care for possible increase in PVR.

Phenylephrine

Phenylephrine is a direct α_1-agonist causing vasoconstriction that can increase SVR.[2] It does not cause tachycardia but may cause reflex bradycardia.[12,39] Phenylephrine has been shown to increase in PVR.[12] In patients with chronic PH with hypotension after induction of anesthesia, phenylephrine was less effective than NE at increasing blood pressure, slightly decreased CI, increased PVR, and had no effect on the PAP/MAP ratio.[33] Thus phenylephrine is not an ideal vasopressor in the setting of PH with RV failure.

Dopamine

Dopamine produces dose-dependent dopaminergic, β-adrenergic, and α-adrenergic effects on cardiac output and vascular tone. In patients with septic shock, dopamine was shown to increase CI without an increase in PVR.[32] Animal studies have shown no increase in PVR up to 10 μg/kg per minute.[2,40] However, dopamine in infants has been shown to increase the PVR/SVR ratio.[2,41] In patients with chronic PH, dopamine infusion led to increases in heart rate, mean pulmonary and systemic pressure, and cardiac index, with a concomitant fall of SVR.[42] Administration of dopamine is associated with an increased risk of supraventricular tachycardia, ventricular tachycardia, and sinus tachycardia with potentially dramatic hemodynamic consequences in patients with severe PH.[39,43] Furthermore, in patients with cardiogenic shock, dopamine was found to increase mortality.[43] Given the evidence, dopamine does not appear to be the ideal agent for treatment of PH with RV dysfunction.

Epinephrine

Epinephrine is a mixed α-/β-receptor agonist. In patients with septic shock, epinephrine at doses of 0.1 to 1.0 μg/kg increased RV ejection fraction but did increase mPAP by 11%.[12,44] In a small animal study of sepsis-induced PH, epinephrine infusion increased SVR and CO and lowered PVR.[45]

Vasopressin

Vasopressin (AVP) is an endogenous hormone with a noradrenergic vasopressor effect on the systemic vasculature and an ability to produce NO-mediated selective pulmonary vasodilation via endothelial V1 receptors.[46] In healthy animals, a linear relationship was observed between vasopressin levels and SVR without significantly affecting PVR.[47] In patients with PH with hypotension postoperatively, a dose of 0.05 to 0.1 U/min increased SVR without affecting PVR or mPAP.[48] However, at a higher dose of 1.16 U/kg per hour, it caused increased PVR and decreased CO with a decrease in RV contractility.[49] Higher doses of 0.08 to 0.4 U/min have also been known to cause pulmonary and coronary artery vasoconstriction.[12] The use of vasopressin at a low dose (0.04 U/min) increased SVR without pulmonary vasoconstriction.[9,50] At lower doses between 0.01 and 0.3 U/min, it can cause pulmonary vasodilation via stimulation of endothelial NO.[12] In animal studies, vasopressin infusion produced significant pulmonary vasodilation and reduction in PVR.[2,51] It can also increase GFR by constricting efferent arterioles. This is in contrast to catecholamine receptor–mediated vasopressors that constrict afferent arterioles and can decrease GFR.[48] This may explain AVP's diuretic effect in vasodilatory shock.[36,52] In patients with vasodilatory shock, AVP in combination with NE was shown to increase CI and SVR without any effect on PVR or mPAP, and the combination also demonstrated a lower incidence of tachyarrhythmias versus NE alone.[52] In contrast, in a different study of patients with sepsis, AVP in combination with NE did not affect CO but decreased mPAP.[53] Overall, the existing literature suggests that low-dose AVP with NE could be a useful combination for the treatment of PH with RV dysfunction.

Optimizing Preload

According to the Frank-Starling law, increasing preload can improve RV stroke volume. However, once the RV is adequately filled, excessive volume loading can be detrimental to the hemodynamics of the RV. In the setting of an elevated PVR, a small increase in preload can cause the right ventricle to dilate, which will increase RV free wall tension. This results in increased myocardial oxygen demand along with a decrease in RV coronary perfusion pressure, which ultimately leads to RV dysfunction and failure. As the right ventricle dilates, the interventricular septum shifts toward the left ventricle, causing impairment in LV diastolic filling and leading to a decline in systemic CO. The tricuspid annulus also begins to stretch as the RV dilates thereby causing tricuspid regurgitation.[9,12,26] Ensuing end-organ damage will result either from poor perfusion, organ congestion, or a combination of the two.

Recognizing RV failure is extremely important. Some classic physical findings are elevated jugular venous distention, hepatomegaly, and peripheral edema. An echocardiogram is useful for assessing size and function of the right ventricle, CO, tricuspid regurgitation, as well as IVC diameter and respiratory collapsibility. The best way to monitor hemodynamics is by inserting a right heart catheter. A rising V wave on a CVP tracing is indicative of increasing RVEDP. Mixed venous oxygen saturation and thermodilution can be used to determine CO while other hemodynamic parameters can also be monitored.

Close monitoring of fluid status is crucial and unmonitored fluid challenges are not advised.[2] In certain cases, RV failure is associated with fluid overload and a negative fluid balance is key to successful therapy.[25] A CVP of approximately 8 to 12 mm Hg is a reasonable preload goal. In the setting of CVP elevation, fluid removal via diuretics or hemodialysis should be the attempted. In contrast, when the CVP is too low, a small fluid bolus of 250 to 500 mL should be administered with careful monitoring of CVP

and markers of systemic perfusion to determine if the right ventricle is fluid-responsive. A modest CVP increase of 2 to 5 mm Hg after a fluid challenge and a resulting improvement in CO indicates that the right ventricle is fluid-responsive, and additional fluid challenges may be attempted. However, if the CVP increases above 20 mm Hg or rises without an improvement in hemodynamic parameters, the right ventricle is not fluid-responsive then further fluid administration should not be attempted.[9,12]

Afterload Reduction

Reversible Metabolic Factors

Proper management of RV failure and PH necessitates identification of reversible factors that incite or perpetuate RV dysfunction. Aside from catheter-assisted or mechanical thrombolysis in the setting of PE, RV afterload reduction in acute RV failure is often challenging because underlying chronic lung or heart disease contributing to increased PVR are not readily reversed by single, definitive treatment modalities. Thus treatment should address ancillary factors that can worsen PVR, such as underlying systemic disease, sepsis, acidosis, and pulmonary hypoxic and hypercapnic vasoconstriction.

Of particular importance is infection, which is a significant predictor of mortality in the ICU setting. In a series of ICU patients with acute right HF and pulmonary arterial hypertension, infection was present in 43% of patients with over a threefold incidence in nonsurvivors compared with survivors.[37] Vasoactive factors such as endothelin are elevated in sepsis and contribute to increased pulmonary arterial hypertension as well as decreased CO.[54,55] In addition, decreased NO synthesis secondary to bacterial endotoxin can lead to an increase in PVR.[12] Low CO after cardiac surgery or in acute decompensated HF is associated with decreased splanchnic perfusion and thus impairment of the intestinal epithelial barrier function. Accompanying changes in pH and gastrointestinal mucosal permeability can lead to increased bacterial translocation and elevated levels of endotoxin and inflammatory cytokines.[56,57] Thus prompt recognition and treatment of infection allows for control of not only source-related pathology, but also management of a critical factor that can affect cardiopulmonary improvement.

Pulmonary Vasodilators

Reduction of RV afterload and PVR is important in the management of patients with PH. Most pulmonary vasodilators can be subdivided according to their action on the pulmonary vasculature via cyclic guanosine monophosphate (cGMP), prostacyclin, or endothelin pathways[17] (see Fig. 43.5). In the chronic setting, most agents are generally only indicated for use in group 1 PH. There is only one agent, riociguat, indicated for use in group 4 PH.[58] Limited data exists for phosphodiesterase-5 (PDE-5) inhibitors in group 2 patients.[59] No agents are indicated for use in group 3 patients because of ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. In trials used as monotherapy or in combination, pulmonary vasodilators were able to improve clinical and hemodynamic outcomes.[60] However, only IV prostacyclin has been shown to improve mortality.[61] Not all of these pulmonary vasodilators can be used in a critical care setting: the route of administration, half-life, and systemic effects significantly affect the choice of the medication. Pulmonary vasodilators with longer half-lives or significant systemic hemodynamic effects can decrease organ perfusion pressure and reduce right coronary artery blood flow with further deterioration of RV performance. Use of pulmonary vasodilators in the ICU setting depends largely on the etiology of PH, as inappropriate use can result in worsening clinical status and hemodynamic deterioration.

Of note, pulmonary vasodilators should be used after optimization of RV perfusion and CO as lowering of SVR may worsen RV ischemia.[2] Increased transpulmonary flow may precipitate pulmonary edema. Additionally, nonselective actions of vasodilators may result in worsening $\dot{V}/\dot{Q}$ mismatch. This risk is reduced with the use of inhaled vasodilators, which selectively affects vessels in ventilated lung units.

Inhaled Nitric Oxide

Inhaled NO (iNO) is a potent vasodilator able to lower PAP, PVR and RV oxygen demand.[62] It improves cardiac performance without altering RV contractility and CO.[63–65] Due to its ability to selectively dilate pulmonary vasculature in ventilated lung areas, it improves $\dot{V}/\dot{Q}$ mismatch and oxygenation.[66] It has a very short half-life, rapid onset, and almost no systemic vasodilatory effects, which is very important in the treatment of hemodynamically unstable patients.[9,66] Use of iNO patients with ARDS showed improvement in oxygenation for 24 to 48 hours and variable improvement in mPAP.[67] A combination of iNO and other interventions, such as PEEP and prone positioning, also had beneficial and additive effects on arterial oxygenation.[68] However, iNO had no favorable impact on the duration of ventilatory support or mortality rate in this patient population.[68,69] Nevertheless, some studies have shown that iNO may have some mortality benefit in patients with RV failure after heart transplantation.[70] When used in post–cardiac surgery patients with a history of PH, iNO use was associated with lower heart rates, higher RV ejection fraction, and a lower requirement for vasopressor agents while decreasing PVR by 36%.[71] iNO has been associated with improved outcomes in critically ill postoperative patients in whom severe PH or RV failure developed.[72,73] In addition to its high applicability in many acute conditions, iNO can be delivered in spontaneously breathing individuals by face mask or even nasal cannula as has been shown in pediatric practice.[74] Studies have shown the efficacy of iNO in varied doses from 5 to 40 ppm.[63,66,69,71] However, trials investigating the use of iNO for reversibility studies in group 1 PH patients demonstrated that maximum effects could be obtained at a level of 10 ppm.[71,75,76] iNO has been shown to provide sy nergistic pulmonary vasodilation when used in conjunction with inhaled and IV prostacyclin as well as PDE-5 inhibitors.[2] iNO treatment is associated with some side effects, including methemoglobinemia, nitrogen dioxide formation, damage to surfactant, and possible genotoxicity to cell DNA.[75,77] Abrupt withdrawal of iNO has been associated with rebound PH, a significant drop in the partial pressure of arterial oxygen (PaO_2), and life-threatening hemodynamic deterioration.[77,78] Rebound PH may be attenuated by the use of PDE-5 inhibitors during weaning.[79] Close monitoring and gradual discontinuation are important to prevent and detect rebound PH. iNO is the prototypical ideal agent to be used in a variety of causes of PH with RV dysfunction.

Prostanoids

Prostanoids are able to produce significant pulmonary vasodilatation and lower mPAP and PVR. They also possess antithrombotic, antiproliferative, and antiinflammatory properties. IV prostacyclin is highly effective in cases of severe PH and is also associated with a significant survival benefit.[80,81] In ARDS, IV prostacyclin reduced PVR and improved RV function but increased $\dot{V}/\dot{Q}$ mismatch.[2] Prostacyclin (PGI_2) and its analogs (iloprost, epoprostenol, and treprostinil) are available in inhaled forms for patients with

chronic PAH.[82,83] Inhaled forms of prostacyclin are delivered to ventilated lung units, decreasing the degree of V̇/Q̇ mismatch and hypoxia. However, prostanoids can significantly affect systemic hemodynamics, especially in the IV form, which limits their use in critically ill or hemodynamically unstable patients. Case reports have shown that inhaled prostacyclins have no significant effect on SVR.[84] However, in another case report, the use of inhaled prostacyclin after cardiac bypass was associated with systemic hypotension. Inhaled iloprost effectively decreased mPAP, the PVR/SVR ratio, and improved RV performance immediately after separation from cardiopulmonary bypass.[85] Inhaled iloprost was also successfully used in the treatment of acute RV dysfunction in the setting of acute PE and ARDS by improving PVR and oxygenation without affecting SVR.[2] It has been estimated that only 10% to 20% of inhaled prostaglandin (PG) I2 reaches the alveoli. In patients with ARDS, iloprost improved oxygenation, decreased PVR, and did not produce V̇/Q̇ mismatch or rebound PH when compared to iNO.[86] Concerns exist owing to the side effects of thrombocytopenia and platelet aggregation associated with prostanoids. After cardiac surgery and bypass, platelet function was affected by inhaled prostacyclin but no increase in clinical bleeding was noted.[87] Prostacyclins have a role in the treatment of patients with PH who have RV dysfunction but should be used with care given the potential for V̇/Q̇ mismatch and hypotension.

Phosphodiesterase-5 Inhibitors

Sildenafil and tadalafil are specific PDE-5 inhibitors. They inhibit the metabolism of cGMP, the second messenger that mediates the vasodilatory effects of NO and the natriuretic peptides. They have the ability to lower PVR and mPAP and to increase CO in patients with different forms of chronic PH.[88–90] In patients with systolic or diastolic HF with secondary PH, sildenafil reduced PVR/mPAP and increased CO without an increase in PCWP or decrease in SVR.[91,92] In the chronic setting, it is highly effective alone or in combination with other pulmonary vasodilators: prostacyclins,[93] endothelin receptor antagonists,[60] milrinone,[23] and iNO.[94] Sildenafil was able to improve central hemodynamics and RV function in ventilated patients with PH who required dobutamine administration.[95] PDE-5 inhibitors have been successfully used to minimize rebound PH after iNO discontinuation,[96] in weaning from IV vasodilators in patients after cardiac surgery,[79] as well as in chronic PH therapy[97] and in severe RV dysfunction related to chronic PH.[96] In post-LVAD placement, sildenafil facilitated weaning from iNO and inotropes without deleterious effects on systemic hemodynamics.[98] In patients with PAH, both sildenafil and iNO increased CO; however, sildenafil did so without a rise in PCWP, which is beneficial in patients with concomitant diastolic dysfunction.[88] However, in patients with bowel edema, oral sildenafil may not be well absorbed. In this case, 10 mg of IV sildenafil can be administered as the equivalent of 20 mg PO.[99] Additionally, PDE-5 inhibitors have long half-lives and can potentially cause hypotension and worsen hypoxemia, leading to pulmonary hypoxic vasoconstriction and V̇/Q̇ mismatch.[9]

Calcium Channel Blockers

Calcium channel blockers have been used in hemodynamically stable patients with PAH who demonstrated a pulmonary vascular response to acute vasodilator challenge.[100,101] There are limited data on use of calcium channel blockers in critically ill patients with acute PH. Acute administration of nifedipine in PAH patients did not cause pulmonary vasodilatation, increased RVEDP, and decreased RV contractility.[81] Prolonged half-life and negative inotropic effects, which may precipitate fatal worsening of RV failure, limit the use of calcium channel blockers in the treatment of acute PH.[102]

Endothelin Receptor Antagonists

Endothelin receptor antagonists (bosentan, macitentan, ambrisentan) appear to be highly effective in the treatment of group 1 PH in the outpatient setting with evidence for decreasing time to clinical worsening.[100,103,104] They have not been adequately studied in acute care settings. In an animal model, pretreatment with bosentan completely abolished endotoxin-induced acute PH and changes in pulmonary compliance and resistance.[18] Currently, the only possible implication in critically ill patients would be weaning or conversion from inhaled or IV pulmonary vasodilators to oral medication. Concerns also exist regarding the potential for liver toxicity and anemia.

Natriuretic Peptides

Natriuretic peptides have diuretic and vasodilatory properties and are able to counteract the renin-angiotensin system. In patients with RV failure, they produce dose-related pulmonary vasodilatation without worsening oxygen saturation or systemic hemodynamic and exert favorable neurohormonal effects by suppressing aldosterone.[105] Brain natriuretic peptide significantly attenuated the mPAP and acute hypoxic pulmonary vasoconstriction in otherwise healthy individuals, but they had no effect on mPAP or PVR in patients with PH.[106] In a study of precapillary and postcapillary PH, nesiritide decreased mPAP and PVR in patients with postcapillary PH but not those with precapillary.[107] Use of nesiritide in hemodynamically unstable and hypotensive patients is limited, mainly because of reduction of SVR and resulting profound systemic hypotension.[108]

Nitrates

Nitroprusside and nitroglycerin both can cause significant pulmonary vasodilation. However, nitroprusside has a longer half-life and can cause acute reduction of SVR leading to systemic hypotension, limiting its use in hemodynamically unstable and hypotensive patients.[63] The significant venodilator effect of nitroglycerin can decrease RV preload, leading to adverse consequences in patients with RV failure. Inhaled nitroglycerin may be a safer therapeutic option shown to decrease PVR without significant adverse effects on SVR.[109]

Novel Agents

Riociguat is a novel vasodilator approved for use in group 1 PH and the only vasodilator approved for the treatment of chronic thromboembolic PH.[58,110,111] Riociguat has a dual mechanism of action: it sensitizes soluble guanylate cyclase to endogenous NO, and it directly stimulates soluble guanylate cyclase receptors independent of NO availability, resulting in vasorelaxation and antiproliferative effects. This is in contrast to PDE-5 inhibitors, which target a component of the NO signaling pathway further downstream and have restricted efficacy in the presence of reduced NO levels. This quality may be useful in sepsis as endotoxin has been shown to increase PVR via suppression of NO synthesis.[12,112] In patients with systolic HF with group 2 PH, riociguat decreased PVR and SVR with an increase in CI.[113] There are few data on the use of riociguat in the acute care setting; however, potential exists for similar use in weaning as for endothelin receptor blockers and PDE-5 inhibitors.

Selexipag is a prostacyclin receptor agonist that decreases time to clinical worsening for patients with group 1 PH.[114] Its use in the critical care setting has not been evaluated. Theoretic concerns for hypotension exist as for the prostanoids; however, in a trial involving patients with chronic PH, no clear hypotension was noted.[114]

Augmenting RV Cardiac Output

Inotropes

Dobutamine

Dobutamine is a commonly used inotropic agent in patients with PH. It augments myocardial contractility via β_1-receptor stimulation.[115] In animal models of PH at doses of 5 to 10 μg/kg per minute, dobutamine caused increased blood pressure and CO without a change in PVR.[31] In another animal study, dobutamine at doses of 2.5 to 20 μg/kg per minute increased CO and decreased mPAP and PVR.[116] In patients with secondary PH awaiting lung transplant, dobutamine did not affect MAP and increased CO, but it increased heart rate and mPAP.[117] In patients with RV infarction, dobutamine at doses of 5 to 10 μg/kg per minute increased CO without affecting SVR or PVR.[118] In HF patients, dobutamine doses of 2.5 to10 μg/kg per minute increased CO and reduced PVR and SVR.[119] In studies in which dobutamine was combined with iNO, the effect on the rise in mPAP was neutralized.[116,117] Dobutamine can cause peripheral vasodilation owing to β_2 effects. At doses of 2.5 to 5 μg/kg per minute there is less chance of vasodilation.[9] Animal studies of PH have shown that dobutamine at doses above 10 μg/kg per minute increased PVR and HR with more hypotension.[2,116] In cases of systemic hypotension, patients may require concomitant use of vasopressors to maintain appropriate systemic perfusion pressures. Dobutamine also increases the risk of tachyarrhythmias, which can affect diastolic filling time in the setting of already elevated RV diastolic pressures.[37]

Levosimendan

Levosimendan sensitizes troponin C to calcium and selectively inhibits PDE-3, thereby improving myocardial contractility and vasodilation without increasing oxygen consumption. In animal studies of PE with RV failure, levosimendan increased CO and decreased PVR. This makes it particularly effective in the treatment of RV dysfunction related to PH.[120,121] In this setting, it restored RV function even better than dobutamine, mainly because of more efficient pulmonary vasodilation on top of similar inotropic effects. A study of patients with ARDS in association with septic shock showed that levosimendan improved RV performance mainly through pulmonary vasodilator effects.[122] It was also effective in restoring RV function in patients with cardiogenic shock after myocardial infarction.[123] In patients with HF who have group 2 PH, levosimendan decreased mPAP and PVR while increasing CO without a change in right atrial pressure or PCWP.[124,125] However, in trials of patients with HF, it has been associated with increased risk of cardiac arrhythmias and hypotension, which may negatively affect mortality.[126,127]

Milrinone

Milrinone is a selective PDE-3 inhibitor with significant inotropic and vasodilatory effects in both pulmonary and systemic circulation. It is widely used in patients with decompensated systolic HF [128,129] and those after cardiac surgery.[17,130] In animal models of both acute and chronic PH, milrinone significantly reduced PVR and improved RV function.[131] In combination with iNO, milrinone produced additive pulmonary vasodilatation in acute PH.[64,132] In another animal model of PH, addition of sildenafil to milrinone produced more effective pulmonary vasodilation than either agent alone without significant systemic hypotension. CO and RV performance were significantly improved after milrinone alone or in combination with sildenafil, but not with sildenafil alone.[133] The systemic vasodilatory effects of milrinone along with its relatively long half-life are the major limiting factors against its use in conditions associated with systemic hypotension or hemodynamic instability. Systemic vasopressors (norepinephrine and low-dose vasopressin) were effective in the treatment of the milrinone-induced systemic hypotension after cardiac surgery. However, a milrinone-vasopressin combination was associated with better hemodynamics than a milrinone-norepinephrine combination during the management of RV failure via a decrease in the PVR/SVR ratio.[134] A case series of patients with LVAD who had PH showed increased CO and decreased PVR with IV milrinone.[135] In animal models, inhaled versus IV milrinone after cardiac bypass caused less hypotension and tachycardia, but it decreased PVR to a lesser degree. Inhaled milrinone predominantly dilated pulmonary blood vessels, resulting in a reduced PVR/SVR ratio, improvement in hemodynamic and oxygenation profiles, and prevention of pulmonary endothelial dysfunction.[136] When compared with intravenous milrinone in patients with PH after cardiac surgery, inhaled milrinone demonstrated less systemic hypotension, less $\dot{V}/\dot{Q}$ mismatch, decreased mPAP, and increased CO and improvement in the Pa_{O_2}/F_{IO_2} (fraction of inspired oxygen) ratio.[130,137,138] In heart transplant candidates with PH, inhaled milrinone selectively dilated pulmonary vasculature. It decreased mPAP, PVR, and PCWP and increased RV ejection fraction without any change in SVR or CO.[139] The combination of inhaled milrinone and inhaled prostacyclin was found to be synergistic in post–cardiac surgery patients.[140] Although arrhythmias are a potential side effect, milrinone tends to be less arrhythmogenic than dobutamine.[12]

Rate and Rhythm Control

Maintaining sinus rhythm is essential to preserve appropriate CO. Irregular rhythms such as atrial fibrillation or conduction abnormalities are not well tolerated, as atrial contractility is an important contributor to RV filling in patients with noncompliant RVs.[9,25,141] In the setting of RV dysfunction, tachycardia causes further increases in RVEDP and CVP, with resulting venous congestion leading to decreased organ perfusion.[9]

Patients with RA dilatation or remodeling after surgery, chronic PH, or long-standing lung disease are more susceptible to developing foci for atrial fibrillation or flutter, whereas patients with infiltrative disease or RV myocardial infarction are at higher risk for conduction abnormalities.[22] Increases in RV afterload and elevated PAPs have been postulated to contribute to the increased risk of atrial fibrillation, with atrial fibrillation present in 14% to 18% of cases of acute PE.[142,143] Persistent atrial fibrillation in PAH has a 2-year mortality above 80%.[144]

Supraventricular arrhythmias are more common than ventricular arrhythmias in PAH. One single-center 6-year retrospective study reported 31 supraventricular arrhythmias among 27 of 231 patients for a cumulative 11.7% incidence and 2.8% annual risk per patient, with atrial flutter and atrial fibrillation accounting for 90% of

the arrhythmias.[145] A separate multicenter 4-year retrospective analysis reported ventricular fibrillation in 10 of 132 cardiac arrests (8%).[146]

In the setting of RV dysfunction, tachyarrhythmias and bradyarrhythmias can precipitate acute hemodynamic instability and require prompt cardioversion or pacing, respectively. Acute RV failure is associated with tricuspid regurgitation resulting from RV distention and stretch on the tricuspid annulus. Atrial pacing may be required at higher rates above 80 beats/min to reduce tricuspid regurgitation and RV distention and thus improve RV CO.[9] After sinus rhythm is restored, the use of pressors and inotropes to improve CO and systemic perfusion can sometimes exacerbate these rhythms and consequently cause clinical worsening.[25]

In tachycardia, the choice of rate-control agents can be challenging because calcium channel blockers and β-blockers can contribute to further RV dysfunction by their negative inotropic effects, which lead to reduced RV CO. The role of β-blockers in right HF is not as well defined as their role in left HF. One small study of patients with moderate to severe portopulmonary hypertension using β-blocker therapy for prophylaxis against variceal bleeding revealed that discontinuation of β-blockers led to decreases in PVR, increased CO, and improved exercise capacity.[147] Digoxin may be a useful alternative for rate control, and antiarrhythmic agents such as amiodarone may be beneficial for maintenance of sinus rhythm after cardioversion.[25]

Ventilatory Support

The goal of the heart and lungs is to maintain adequate oxygen delivery to all tissues while removing metabolic waste. It is important to remember that the heart and the lungs cannot in isolation fulfill this obligation but must function as a heart-lung unit. They are both confined to the same body cavity, which has critical implications in ventilated patients. Because the right ventricle, the lungs, and the left ventricle are arranged in a continuous series, an acute insult to one component can affect the function of all elements. Adopting proper ventilation strategies helps to maintain the function of this system and avoids cardiopulmonary conflicts. Noncardiopulmonary elements of oxygen consumption and delivery should be optimized concomitantly while delivering ventilatory or cardiac support therapies.

Supplemental oxygen remains important in hypoxemia. Lung hypoxemia is a powerful vasoconstrictor that can increase RV afterload. Correcting hypoxemia can mitigate cor pulmonale. The response of lung ventilation and perfusion to high F_{IO_2} depends on disease states and must be carefully monitored in ICU patients. For instance, patients with ARDS and chronic obstructive pulmonary disease can react unfavorably to 100% oxygen.

Hypercapnia and acidemia also increase RV afterload and should be corrected to near-normal levels if the overall ventilation strategy allows. Except when low-volume ventilation is necessary (e.g., ARDS), functional residual capacity should be the target of lung volumes.[20] Certain strategies can minimize RV functional compromise, especially in the setting of ARDS, such as using an intermediate tidal volume (8 mL/kg) with a PEEP below 10 mm H_2O, prone positioning, and low respiratory rate.[148] Additionally, maintaining plateau pressure below 27 mm H_2O, adapting PEEP to RV function, and maintaining the partial pressure of arterial carbon dioxide ($PaCO_2$) below 60 mm Hg are other strategies recommended to prevent or mitigate acute RV failure in ARDS.[26] Air trapping and ventilator dyssynchrony can also contribute to increasing RV afterload and should be treated expeditiously.[9]

Certain subgroups of patients with PAH (those with severe PAH) do not tolerate intubation and associated sedation well; such measures should be avoided as much as possible. If intubation is needed, consideration should be given to presedation catecholamine use to mitigate loss of RV contractility and autonomic tone.[25]

Mechanical Circulatory Support

Mechanical ventricular support should be instituted with clear goals in mind using a multidisciplinary team approach. Common goals include anticipated recovery or transplantation. In an otherwise unsalvageable condition, mechanical support will not avert mortality. Frequently, "failure" of mechanical support is due to late intervention, so timely therapy can be lifesaving.

Mechanical support may be needed in case of primary RV failure or in an overwhelmed, chronically compromised ventricle. In any event, all aspects of ventricular performance—namely, preload, afterload and contractility—must be balanced, and mechanical support augments or replaces pump function.

Three cardiopulmonary elements that should be considered in selecting mechanical support are the right ventricle, the lungs, and the left ventricle. If RV failure and lung failure co-exist then an extracorporeal support, such as venoarterial extracorporeal membrane oxygenation (VA-ECMO) or a right-sided tandem with oxygenator spliced in the circuit should be considered. If only RV support is needed, then an Impella device (Abiomed, Danvers, MA) would be suitable. If support is anticipated for a longer duration, then a surgically implanted RV assist device would be indicated so that extubation and mobility can be maintained. There are other iterations of surgically implanted devices that can either replace lung function or heart function. In cases of biventricular failure, bilateral Impella devices, bilateral Tandems, or VA-ECMO are options for short-term support and a surgically implanted biventricular assist device for longer-term support. An oxygenator can be spliced in several extracorporeal circuits if needed.

Placing percutaneous devices is a vascular-anatomic commitment because removal of the arterial limb often requires surgical repair. Some of these devices are better delivered from right-sided veins (e.g., venovenous ECMO dual-lumen cannula (Impella or Tandem) devices); thus access planning in an ICU patient is key. Frequently, a mechanical device is a bridge to another device and access can become a limiting factor.

Atrial Septostomy

Atrial septostomy can be used in centers with experience as a palliative or bridging procedure. Graded balloon septostomy has been reported to have lower risk than a blade septostomy. Because it is infrequently performed, guidelines have not included them in their recommendations.[25] Short-term hemodynamic improvement has been documented as improvement in the 6-minute walk test but long-term outcomes are not known. Atrial septostomy is generally used in patients with functional class IV disease with advanced right HF when medical therapy is not sufficient or is not available, and bridging to transplant or palliation are goals. One set of guidelines recommends against using atrial septostomy in patients with end-stage disease with a right atrial pressure above 20 mmHg and an oxygen saturation of less than 85%.[25] Atrial septostomy techniques, other indications, and contraindications have been reviewed elsewhere.[149]

Prognosis

PH in the ICU has an overall high morbidity and mortality and is challenging to manage. RV dysfunction and cardiogenic shock are believed to be the pathways for multiorgan failure and carry a significant burden.

Patients with PAH who have acute RV failure admitted to an ICU have been shown to have mortality rates as high as 41%. Low levels of natriuretic peptides, inflammatory markers, as well as relatively normal serum sodium and creatinine were demonstrated in one study to be associated with improved survival. Infection was not well tolerated.[37]

In patients with ARDS with protective ventilation, cor pulmonale is frequent (22%) and is associated with worse outcomes, higher needs for vasoactive medications for shock, and has a higher 28-day mortality.[150] Plateau pressure in this study was below 30 mm H_2O and mean PEEP was 8.8 mm H_2O.

Other subsets of patients such as those with acute PE and left HF who develop RV dysfunction from PH also have higher morbidity and mortality. Prognosis in the acutely decompensated patient can be modified by early recognition of worsening clinical status and prompt correction of acute insults while providing support to the failing ventricle.

Acknowledgment

The authors would like to thank Luke Chong and Anthony Lucev for their assistance with this chapter.

Key Points

- Pulmonary hypertension (PH) factors. PH is defined as a resting mean pulmonary artery pressure (mPAP) above 25 mm Hg and a pulmonary vascular resistance (PVR) greater than 240 dynes/sec per centimeter[5] (or >3 Woods units) as determined by right heart catheterization.
- Identifying the site of the underlying pulmonary vasculopathy allows determination of precapillary, postcapillary, or a combination of both precapillary and postcapillary factors responsible for PH.
- Determining the transpulmonary gradient (TPG) allows identification of precapillary or post capillary causes of PH. An elevated TPG indicates a precapillary contribution to the PH. If the TPG is normal, then high pulmonary artery pressure (PAP) is due to either high pulmonary vein pressure or high pulmonary blood flow, and a postcapillary contribution to the PH occurs. With increases in pulmonary vein pressure and TPG, both postcapillary and precapillary changes are present. In the latter case, combined PH is present. This may be either fixed or reversible depending on pulmonary vasodilator testing results.
- Treatment of PH and right ventricular (RV) failure should be dictated by four major goals:
  - Maintaining systemic vascular resistance and the pressure gradient between the aorta and right carotid artery (RCA) to ensure RCA perfusion
  - Optimizing preload. RV underfilling can lead to low cardiac output, whereas overfilling can cause elevated central venous pressure and venous congestion, which leads to decreased end-organ perfusion.
  - Reducing RV afterload and PVR
  - Augmenting RV cardiac output (CO)via improving contractility, rate and rhythm control, and atrioventricular synchronization
- The choice of vasopressor agents in patients with PH and RV failure requires careful consideration of associated factors (e.g., septic shock, postsurgical PH). Norepinephrine and vasopressin, or a combination of both agents, are preferred based on existing literature. Monitoring of hemodynamic parameters can help the intensivist gauge the response to therapy or become aware of untoward effects.
- Pulmonary vasodilators should be carefully applied after optimizing RV perfusion and CO. Intravenous (IV) prostanoids, nitroglycerin, and nitroprusside can affect systemic hemodynamics, thus limiting their use in critically ill and unstable patients. It is important to be mindful of side effects of vasodilators such as rebound PH or ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch with use of these agents. Inhaled nitric oxide can lower PAP, PVR, and RV oxygen demand in almost all etiologies of pulmonary hypertension owing to its properties of $\dot{V}/\dot{Q}$ matching. Inhaled prostacyclins may also have similar benefit.
- Inotropes can improve RV CO by either improving contractility or by pulmonary vasodilator effects. Although dobutamine has an established role in cardiogenic shock, the risk of tachyarrhythmias as well as mixed evidence regarding its effect on increasing mPAP and PVR may limit its use. Levosimendan is a promising agent that can improve CO without increasing mPAP, PVR, or pulmonary capillary wedge pressure, but certain trials show that is has an increased risk of arrhythmias and hypotension. Milrinone can augment RV output via inotropic as well as pulmonary vasodilatory effects. In combination with other agents such as sildenafil or vasopressin, IV milrinone can lead to favorable hemodynamic improvements. Furthermore, the use of inhaled milrinone offers the beneficial effect of pulmonary vasodilation with less systemic hypotension.
- Careful ventilator management is essential to address hypoxemia and hypercapnia, which can perpetuate pulmonary vasoconstriction and increase afterload, respectively. Application of low-tidal volume ventilation in acute respiratory distress syndrome can help to prevent further worsening of RV function.
- Anticipation of further decompensation and early initiation of advanced modalities of treatment such as mechanical circulatory support can be lifesaving.

Review Questions

1. A 40-year-old moderately obese man is admitted for same-day cardiac catheterization after presenting with 6 months of worsening chest tightness, dyspnea on exertion, and cough. His electrocardiogram examination did not show ischemic changes. Echography was technically difficult, precluding assessment of the left ventricle, but the right ventricle appeared mildly dilated with significant elevation of the pulmonary artery systolic pressure. Left heart catheterization showed non-obstructive coronary artery disease. Right heart catheterization revealed a mean pulmonary artery pressure (mPAP) of 45 mm Hg (pulmonary artery 60/30 mm Hg) with a pulmonary capillary wedge pressure (PCWP) of 10 mm Hg and a cardiac output of 5 L/min. Which condition is described best by this hemodynamic profile?

a. Severe mitral stenosis
b. Left heart failure owing to grade 3 diastolic dysfunction
c. Chronic thromboembolic pulmonary hypertension (CTEPH; group 4 denoted in the clinical classification of PH; see Box 43.1)
d. Combined precapillary and postcapillary pulmonary hypertension (PH) owing to left ventricular combined systolic and diastolic dysfunction

Answer: c. The patient has an elevated TPG of 35 (normal is less than 12) and this is associated with a PCWP of <15 mm Hg. The pulmonary vascular resistance, which is calculated from the mPAP-PCWP gradient (the TPG), divided by the CO is 7 Wood units > 3 Woods units and therefore meets all hemodynamic criteria to be classified as precapillary PH (see Table 43.2). CTEPH is a precapillary form of PH. A patient with severe mitral stenosis (choice a) would have a severely elevated mPAP as would a patient with left heart failure and advanced diastolic dysfunction (choice b) However in the setting of heart failure, the PCWP will be extremely elevated (≥15 mm Hg and the TPG will be 12 mm Hg or lower. These latter two patients have all the hemodynamic criteria to be classified as postcapillary PH. Similarly, a patient with left heart disease with combined precapillary and postcapillary PH (choice d) would have a severely elevated mPAP and a large TPG and a PVR or 3 Woods units or higher, but the PCWP would be at least 15 mm Hg or higher.

2. A 27-year-old female with a past medical history of scleroderma with associated pulmonary hypertension diagnosed 5 years ago presents with syncope. Her current medical regimen includes inhaled prostacyclin, an endothelin receptor blocker, and a phosphodiesterase inhibitor. Her vital signs show a blood pressure of 70/50 mm Hg and a heart rate of 88 beats/min. She is using chronic oxygen therapy and her oxygen saturation is 96% on 3 L (via nasal cannula). Owing to hypotension, she is transferred to the intensive care unit and a Swan-Ganz catheter is placed to assist in management. Hemodynamics reveal the following: central venous pressure (CVP) 20 mm Hg, pulmonary artery pressure (PAP) 90/40 mm Hg, and PCWP 12 mm Hg with cardiac output (CO) 3.9 L/min, and peripheral vascular resistance (PVR) 12 Woods units.

What is the next best step in management?

a. Inotropes to increase cardiac output
b. Decrease afterload with nitric oxide
d. Vasopressors to increase systemic vascular resistance (SVR)
d. Bolus intravenous (IV) fluid

Answer: c. The patient has group 1 PH associated with scleroderma. She presents with syncope and borderline cardiac output with hypotension. The best first step is to maintain the pressure gradient between aortic and right ventricular (RV) pressure to ensure right coronary artery (RCA) perfusion and reversal of RV ischemia by increasing the SVR with vasopressors. Bolus of IV fluid (choice d) is incorrect as her CVP is elevated and would result in overfilling of the RV, an increased transseptal gradient, and increased venous congestion. Choice a is incorrect as increasing contractility before correcting SVR can lead to an increase in right ventricular end-diastolic pressure and a decrease in RV coronary perfusion pressure. Choice c is a reasonable intervention to decrease PVR and improved CO but only after right carotid artery perfusion is restored.

3. You are asked to consult on a 35-year-old patient with idiopathic pulmonary artery hypertension (PAH) who was admitted to the ICU a few days ago with worsening respiratory status. Her condition was diagnosed 5 years ago and no associated conditions were found for her PAH. Her outpatient treatment needed escalation over time such that now she is receiving treprostinil subcutaneous infusion of 100 μg/kg per minute, ambrisentan 10 mg daily, sildenafil 40 mg 3 times a day, spironolactone 50 mg 2 times a day, digoxin 250 μg once a day, and torsemide 40 mg 2 times a day. Doses could not be uptitrated any further because of side effects. Her functional class at best was NYHA class II as an outpatient.

Since presenting to the hospital, her breathing worsened and she needed mechanical ventilation. IV catecholamines were started because of persistently decreased blood pressure. Her current vital signs are as follows: heart rate 110 beats/min, arterial blood pressure 93/67 mm Hg, oxygen saturation measured by pulse oximetry (SpO_2) 94%, CVP 23 mm Hg, and central venous saturation 45%. Urine output has been less than 20 mL/h for the past 6 hours. Echocardiogram shows severe right ventricular dilatation and hypokinesis. Chest radiography shows dilated pulmonary arteries.

The next step in her management is which of the following?

a. Continue the current course and allow her some more time to respond to therapy.
b. Stop treprostinil because one of the side effects is hypotension.
c. Insert a pulmonary artery catheter to obtain accurate hemodynamics and support her with an inotrope; if that approach fails, begin mechanical support.
d. Pulmonary artery catheter and mechanic support therapies are not indicated for right ventricular decompensation.

Answer: c. The current course is not sustainable and available data suggest decline. Stopping treprostinil (choice b) in such a setting could be detrimental, so it should be continued as it is playing a role in afterload reduction. Placement of a Swan-Ganz catheter is the next appropriate step. Inotrope and mechanical support should be considered, as should be candidacy for lung transplantation in this young patient without overt contraindications.

- Diffuse Alveolar Hemorrhage
- Vascular Abnormalities
- Trauma
- Vascular Monitoring Catheters

Invasive Pulmonary Interventions

Management
- Airway and Lung Protection
- Localization of Bleeding
- Hemorrhage Control
- Surgery
- Other Therapies

Hemoptysis varies in amount from intermittent blood-streaked sputum to massive arterial bleeding with asphyxiation or exsanguination. Massive hemoptysis is defined as the expectoration of blood from the respiratory tract in life-threatening quantities. Clinical definitions of massive hemoptysis focus on selected quantities of coughed blood between 200 and 1000 mL over 24 hours or less, with greater than 600 mL as the most common criterion.[1] Quantification of the amount of coughed blood is unreliable, often subjective, and fails to account for blood remaining in the lungs. The adverse clinical effects of hemoptysis, such as impaired gas exchange, airway obstruction, or hypotension, may be more relevant for defining a life-threatening condition.[2]

Fortunately, massive hemoptysis is rare and accounts for 4% to 18.5% of all cases of hemoptysis in recent studies.[3–5] Incidence studies are problematic because of the use of variable definitions. Although mortality rates as high as 71%[6] were reported in the past, mortality rates in recent studies of massive hemoptysis range from 0% to 38%.[2,3,7]

This chapter focuses on the most common causes of massive hemoptysis, clinical manifestations, and options for management.

Anatomic Considerations

The lung is unique among the visceral organs in that it receives a dual blood supply from different circulations. Because hemoptysis can occur from either the pulmonary or bronchial circulation, an anatomic understanding of these systems is important.

Pulmonary Circulation

The pulmonary artery bifurcates into left and right main pulmonary arteries after it leaves the right side of the heart. The pulmonary circulation is a low-pressure system, but pulmonary artery pressures may rise to approach systemic pressures in pulmonary parenchymal and pulmonary vascular diseases. Nevertheless, pulmonary hypertension alone rarely causes hemoptysis.

Prospective angiographic studies for hemoptysis in which both pulmonary and bronchial circulations have been imaged do not exist. Bleeding from the pulmonary arterial circulation accounts for less than 10% of massive hemoptysis cases and has been noted in a variety of destructive pulmonary lesions, including tuberculosis, lung abscess, and aspergillosis.[2,8] Aneurysms of the pulmonary artery, arteriovenous malformations (AVMs), and pulmonary artery rupture have also been reported.

Bronchial Circulation

Bleeding from the higher-pressure bronchial circulation has been estimated to cause 88% of the cases of massive and submassive hemoptysis.[9] The bronchial arteries arise from the descending aorta

with considerable anatomic variation. The one or two bronchial arteries that supply each lung in the majority of individuals[10] arise from the area near the first and second intercostal arteries. Particularly on the right side, the bronchial arteries may arise directly from the proximal first intercostal artery. The arteries course along the trachea, major bronchi, and bronchioles and have terminal communications with the pulmonary capillaries or pulmonary venules. The small-vessel bronchial supply to the trachea and major bronchi drains into the azygos vein with direct communication to the superior vena cava. Aneurysmal dilation of bronchial arteries (Dieulafoy vascular malformation) has been noted in some patients with hemoptysis, and it can occasionally be visualized endobronchially and noted on bronchial arteriography.[11]

A direct anastomotic communication between the bronchial and pulmonary arterioles has been sought to explain the preservation of lung parenchyma after injuries to the pulmonary vascular supply. Anatomic studies have found that intermeshing of pulmonary and bronchial capillary networks is the most common anastomotic arrangement that prevents pressurization of the pulmonary arterioles with systemic pressures.[12] However, in chronic inflammatory diseases of the airways, anatomic anastomoses have been found that allow direct pressurization of the pulmonary artery with systemic pressures.[13] The extent to which these vascular communications are related to hemoptysis remains unknown.

Bronchial arteries vasodilate in the presence of cholinergic, β_2-adrenergic, and some nonadrenergic, noncholinergic agonists. Although the effect of β_2-agonists on the course of hemoptysis remains unstudied, the balance between improved mucociliary clearance of blood affected by β_2-agonists and detrimental bronchial artery dilation should be considered.[14] Other physiochemical maneuvers can influence bronchial blood flow—cold air causes blanching of the human airway,[15] humidified air decreases bronchial blood flow compared with dry gas,[16] and increased alveolar pressure decreases bronchial blood flow by applied pressure at the capillaries.[12]

Nonbronchial Systemic Collateral Circulation

In diseases of the lung associated with inflammation, neovascularization of the lung parenchyma can occur. Although proliferation of the bronchial circulation is the most common mechanism to extend the vascular supply, an extensive network of systemic arteries may neovascularize the lung after crossing the pleural space. This most commonly occurs in diseases that produce pleural scarring, such as in aspergillomas and cystic fibrosis (CF). Anatomically these collateral vessels commonly arise from the intercostal, subclavian, axillary, and phrenic arteries. However, nonbronchial collaterals have also been described from the internal mammary, thyrocervical, carotid, and even the coronary arteries. Suspicion that these vessels may be involved is heightened by recurrence of hemoptysis after bronchial artery embolization (BAE), the presence of pleural disease, and the absence of bronchial arteries supplying an area of lung parenchyma on initial bronchial arteriography.

Pulmonary Venous Abnormalities

Bleeding from the pulmonary veins is most likely in cardiac disease such as mitral stenosis or mitral regurgitation. Focal varices of the pulmonary veins that are occasionally visualized on chest radiography, but are best identified on the venous phase of pulmonary arteriography, have been described.[17,18] More recently, massive hemoptysis owing to pulmonary vein stenosis has been reported as the result of atrial fibrillation ablation procedures.[19,20]

Causes of Hemoptysis

Bronchiectasis, tuberculosis or its sequelae, lung cancer, and aspergilloma (mycetoma) account for the largest proportion of massive hemoptysis cases. However, almost any of the many causes of hemoptysis (Box 44.1) can become massive on rare occasions. Clues to specific diagnoses are obtained by history, physical examination, chest radiography, and chest computed tomography (CT). Additionally, it is important to consider the demographics of the patient population when considering the cause of hemoptysis. For example, there is a predominance of causes related to infectious diseases (i.e., mycobacterial or parasitic) and their long-term complications in individuals from developing and impoverished countries. In contrast, malignancies and bronchiectasis are more common causes of massive hemoptysis in developed countries.

Bronchiectasis

Bronchiectasis is characterized by abnormal dilation of the bronchi with altered mucociliary clearance, persistent bacterial colonization, chronic inflammation of the bronchial mucosa, and submucosal neovascularization that predisposes to hemoptysis. Hemoptysis in bronchiectasis can present as a single life-threatening episode but is more commonly heralded by intermittent blood streaks intermixed with purulent sputum. In patients without a previous diagnosis, the evaluation can be difficult because chest radiographs can be normal or alveolar filling with blood can obscure abnormalities. Diagnosis can usually be confirmed with high-resolution chest CT. Suspicion of the diagnosis warrants broad-spectrum antibiotics to cover the multiple organisms causing infection in addition to management of the hemoptysis.

Bronchiectasis is the usual cause of massive hemoptysis in patients with CF and occurs in approximately 4.1% of patients during their lifetime.[21] It is the second leading cause of death in CF patients who have not undergone transplantation.[22] Massive hemoptysis is more common in patients older than 18 years of age and has been associated with pancreatic insufficiency, *Staphylococcus aureus* colonization, *Pseudomonas aeruginosa* colonization, reduced lung function, and diabetes.[21,23] The origin of the bleeding is most often upper lobe bronchial or systemic arteries. These patients are difficult to treat because of minimal pulmonary reserve in the majority of patients at the time of hemoptysis. Guidelines for treatment of massive hemoptysis in CF patients recommend empiric antibiotic coverage to include *S. aureus*, discontinuation of nonsteroidal antiinflammatory drugs, discontinuation of airway clearance therapies, discontinuation of aerosolized hypertonic saline solution, and use of BAE to control bleeding.[24] Although inhaled tobramycin and dornase alfa use were associated with a lower hemoptysis incidence,[21] consensus was not reached on whether to discontinue these therapies in massive hemoptysis.[24]

Tuberculosis

The resurgence of tuberculosis in many parts of the world and the prevalence of global travel mandate consideration of the disease whenever hemoptysis occurs. Hemoptysis can occur with active cavitary disease or as late sequelae of lung destruction causing bronchiectasis. Hemoptysis has also been reported in miliary

Mycetoma
Necrotizing pneumonia (*Staphylococcus aureus,* gram-negative aerobes, *Legionella, Actinomyces* species, *Stenotrophomonas, Kytococcus sedentarius, Leptospira* species, *Yersinia pestis, Francisella tularensis*)
Parasitic infection (paragonimiasis, amebiasis, ascariasis, clonorchiasis, echinococciasis, hookworm infestation, strongyloidiasis, trichinosis, schistosomiasis)
Parenchymal fungal infection (aspergillosis, mucormycosis, coccidioidomycosis, histoplasmosis, maduromycosis, botryomycosis)
Tuberculosis (active or inactive)
Viral tracheitis
Herpetic tracheobronchitis

Interstitial Lung Diseases
Lymphangioleiomyomatosis
Sarcoidosis
Tuberous sclerosis
Pneumoconiosis
Langerhans cell granulomatosis

Miscellaneous Disorders
Amyloidosis
Bronchogenic cyst
Broncholithiasis
Bronchopleural fistula
Thoracic endometriosis
Foreign body
Tracheopathia osteoplastica
Lipoid pneumonia
Organophosphate aspiration
Chronic pancreatitis

Neoplastic Disorders
Bronchial adenoma
Lung cancer
Tracheal tumors (mucoepidermoid, squamous cell, adenoid cystic, glomus)
Pulmonary blastoma
Pleuropulmonary angiosarcoma
Sarcoma (synovial, myofibroblastic)
Clear cell tumor
Metastatic disease (prostate, renal, breast, ovarian)
Tracheobronchial schwannoma

Pulmonary Airway Diseases
Bronchiectasis
Bronchitis
Granulomatous tracheobronchitis (ulcerative colitis, Crohn disease, Wegener granulomatosis)
Cystic fibrosis
Bullous emphysema

Traumatic Injury
Blunt chest trauma
Penetrating injury
Ruptured bronchus
Lightning injury
Thoracic splenosis

Vascular Disorders
Pulmonary embolism, infarction
Systemic cholesterol emboli
Intralobar sequestration
Pulmonary artery aneurysms
Behçet disease, Hughes-Stovin syndrome, traumatic pseudoaneurysms
Acquired arteriovenous malformations
Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia)
Takayasu arteritis
Aortic aneurysms
Trachea–innominate artery fistulas
Scimitar syndrome
Vena caval–bronchial
Dieulafoy disease of bronchus
Ventriculopulmonary fistulas
Hemangioma (sclerosing, cavernous, tracheal)

tuberculosis, although the mechanism is unknown. The pathologic lesion that causes hemoptysis in tuberculosis is often a Rasmussen aneurysm, a small aneurysm of the pulmonary circulation positioned within a cavity wall. Bleeding from the bronchial circulation can also complicate bronchial erosions in active tuberculosis, and study of both circulations is occasionally necessary when resection for local disease is not possible. Although all patients suspected of having hemoptysis secondary to tuberculosis should be placed in respiratory isolation, active pulmonary tuberculosis is found in only one third of such cases. Posttuberculous bronchiectasis requires antibacterial therapy.

Lung Malignancy

Lung cancer is associated with hemoptysis in 20% to 30% of cases and may be the presenting manifestation. Although the clinical course of hemoptysis is often that of chronic blood-streaked sputum, massive hemoptysis may occur with disease progression. Massive hemoptysis is most commonly associated with squamous cell type[25]; cavitation within the carcinoma[26]; and central endobronchial position, occasionally with invasion into the pulmonary arteries. The blood supply to most lung carcinomas is derived from diffuse neovascularization from the bronchial circulation, making BAE effective in some cases.

Other less common cancers can bleed when found in the lung. Kaposi sarcoma has a high incidence of bloody pleural effusions and hemoptysis. Angiosarcomas are vascular tumors that may bleed continuously from small tumor sites.[27] Choriocarcinomas may bleed profusely, particularly after initiation of chemotherapy. Metastatic disease, including renal, ovarian, and breast cancer, has rarely been associated with hemoptysis.

Massive hemoptysis may also result from interventions that treat lung malignancies. Endobronchial brachytherapy has resulted in massive, fatal hemoptysis and was found to be associated with direct contact of the brachytherapy applicator and tracheobronchial walls near great vessels.[28] Radiofrequency ablation of lung neoplasms

has been associated with massive bleeding owing to intraparenchymal hemorrhage and pulmonary artery pseudoaneurysm.[29,30] Bevacizumab, an angiogenesis inhibitor used in treatment regimens of non–small-cell lung cancer, is associated with an increased incidence and severity of hemoptysis.[31] Risk factors may include exposure to prior thoracic radiotherapy, the presence of tumor exposure in the central airway, and concomitant radiotherapy.[31] A consensus group suggested that patients with squamous histology and/or a history of hemoptysis of greater than or equal to 2.5 mL per event should not receive bevacizumab.[32]

Lung Abscess

Lung abscesses are commonly found in parenchymal areas prone to aspiration. The indolent course of these infections allows time for hypertrophy of the bronchial circulation within the walls of the abscess cavity. Additionally, these cavities may enlarge and erode into major pulmonary arteries and other thoracic vessels, including the aorta.[33] With either of these abnormalities, bleeding can be massive and recurrent. Although the abscesses are focal and amenable to surgery, the patient who chronically aspirates because of alcoholism or dementia may have other contraindications for surgery.

Chronic Bronchitis

Chronic bronchitis rarely causes massive hemoptysis, but it is a frequent cause of mild hemoptysis. The pathologic lesions responsible for bleeding are likely dilated bronchial arteries that are eroded during active inflammation of the airways. A comprehensive management approach is required to treat hemoptysis and ensure that other lesions such as lung cancer are not present.

Other Pulmonary Infections

Although hemoptysis can complicate any bacterial or fungal pneumonia, massive hemoptysis is rare unless tissue necrosis is present. Tissue necrosis is a hallmark of anaerobic, staphylococcal, and actinomycotic[34] pneumonias, but it can occur with many different bacterial causes. Septic pulmonary emboli, particularly from staphylococcal species, have a high incidence of concomitant lung cavitation. Mycotic pulmonary artery aneurysms may also be hidden within pneumonias and can be diagnosed by pulmonary arteriography or multidetector CT angiography.[35]

Hemoptysis is particularly common in fungal pneumonias that invade the vasculature. Invasive *Aspergillus* can be found in nonimmunosuppressed patients with chronic obstructive pulmonary disease[36] but is more commonly found in the persistently neutropenic patient. A characteristic radiographic pattern of cavitation and hemoptysis follows the recovery of neutrophils and should be anticipated in at-risk patients.[37,38] The use of prophylactic surgery to resect areas of infarcted lung tissue has been advocated[39] because of the high mortality rate associated with medical management of the hemoptysis. However, such surgery remains high risk. Although it is more rare, invasive pulmonary mucormycosis[40] may produce similar findings. Hemoptysis complicates primary coccidioidal infections in 15% of cases and may approach a 50% incidence in patients with chronic coccidioidal cavities. Histoplasmosis, cryptococcosis, and blastomycosis can also cause hemoptysis. Frequent and sometimes massive hemoptysis can occur with the parasitic diseases paragonimiasis,[41] echinococcosis,[42] strongyloidiasis, and ancylostomiasis.

Pulmonary Embolism

Hemoptysis occurs in approximately 30% of patients with thrombotic pulmonary emboli. Characteristically, hemoptysis is mild and requires no specific therapy. Hemoptysis usually implies some degree of pulmonary infarction with potential disruption of either vascular supply. The suspicion for pulmonary emboli is increased in the presence of risk factors for thrombosis, multicentric bleeding, and pleuritic chest pain. Paradoxically, this cause of hemoptysis must be treated with anticoagulants to prevent propagation of venous thromboemboli. The incidence of worsening hemoptysis after heparin or thrombolytics has not been documented. Nonthrombotic emboli have also been associated with hemoptysis. Septic emboli usually respond to antibiotics alone.

Aspergillus Fungus Balls

Hemoptysis occurs in more than half of patients with pulmonary *Aspergillus* fungus balls.[43] The cavity walls are richly vascularized by branches of the bronchial circulation, and enlargement of these cavities may also extend into large branches of the pulmonary artery. The mechanism of hemoptysis is likely multifactorial from secondary bacterial invasion of the fungal cavity, microinvasion of the cavity wall by *Aspergillus* (semi-invasive aspergillosis), or less commonly by truly invasive disease. Therapy of hemoptysis depends on the underlying cause for the cavitary lung disease.

Systemic antifungal therapy remains controversial because there is not a well-defined means to diagnose semi-invasive disease.[44] Intracavitary amphotericin B, however, instilled via a transthoracic catheter has proved successful at dissolution and sclerosis of the cavity with control of hemoptysis and is a viable option in patients who are poor surgical candidates.[45,46] Alternatively, antifungal therapy with ketoconazole,[47] miconazole,[48] or amphotericin B[49] has been given endobronchially for fungus ball dissolution and hemoptysis control, but these techniques are effective in less than half of patients.[50] A more recent study found better outcomes with bronchoscopic voriconazole installation resulting in significant improvement of hemoptysis in 68% of patients.[51] External radiotherapy has also been used as an adjunctive measure in nonoperable patients.[52]

Surgery remains the therapy of choice in patients with adequate pulmonary reserve owing to the recurrent nature of hemoptysis. Simple aspergilloma (no abnormality in surrounding lung) has an excellent response to surgical resection, most commonly a lobectomy. Complex aspergilloma with surrounding pleural and parenchymal involvement usually requires pneumonectomy and is associated with variable success.[53] Fungus balls complicating sarcoidosis usually occur in patients with bilateral upper lobe cavitary disease (stage IV), in which underlying lung function prohibits resection.

Cardiovascular Causes

Mitral stenosis is one of the most common cardiac abnormalities that can present with hemoptysis. The risk of hemoptysis is likely related to the elevation of pulmonary venous pressure and the rapidity with which the stenosis developed. An echocardiogram should be obtained for definitive diagnosis.

Other causes of increased pulmonary venous pressure, such as mitral regurgitation or severe congestive cardiomyopathy, may also produce hemoptysis that usually presents with radiographic pulmonary edema and a prodrome of pink frothy sputum. Fibrosing mediastinitis,[54] pulmonary veno-occlusive disease,[55] and congenital

pulmonary venous stenosis[56] are less common causes of pulmonary venous congestion.

Rarely, hemoptysis will occur from systemic venous hypertension in severe biventricular heart failure by azygous vein hypertension and dilation. Because the azygous vein drains the trachea and major bronchi, the submucosal dilated venous plexus of the trachea can be friable and produce major hemoptysis.

Interstitial Lung Disease

Only a few interstitial lung diseases are prone to hemoptysis. Lymphangioleiomyomatosis is a disease of smooth muscle proliferation around pulmonary lymphatics, airways, and vasculature. Any of the triad of hemoptysis, pneumothorax, and chylothorax should suggest the diagnosis in a woman of childbearing age.[57] The airway granulomas of sarcoidosis have also been associated with hemoptysis, although the presence of traction bronchiectasis may be a more common cause. Additionally, the erosion of calcified hilar lymph nodes into the vasculature can produce hemoptysis. Other interstitial lung diseases that cause hemoptysis usually have diffuse alveolar hemorrhage.

Broncholithiasis

Broncholithiasis is an infrequent cause of hemoptysis. The typical patient usually has an established diagnosis of mediastinal calcification from granulomatous disease. Previous infections of histoplasmosis, sarcoidosis, or tuberculosis are most common. Broncholithiasis is diagnosed by bronchoscopy when any degree of lymph node calcification is visualized in the bronchial lumen. Symptoms of cough, chest pain, airway obstruction, and hemoptysis can be seen. Lithoptysis, coughing out a broncholith, can also confirm the diagnosis.

Therapy of hemoptysis involves broncholith removal. Broncholith removal by rigid or flexible bronchoscopy is usually successful when the broncholith is free. When broncholiths are partially embedded in the airway wall, removal is best facilitated by rigid bronchoscopy[58] or by thoracic surgery. Surgical options include lymph node resection with or without bronchoplasty or lobectomy.[59]

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) most commonly presents abruptly and may or may not be associated with frank hemoptysis. The early manifestations are often confused with other alveolar filling processes such as pulmonary edema, bacterial pneumonia, or acute respiratory distress syndrome. Consideration of DAH is prompted by the presence of diffuse infiltrates on chest radiograph, the presence of systemic manifestations of vasculitis, the association of hemoptysis, hypoxemic respiratory failure, and the common finding of anemia. Unfortunately, the many causes of DAH are often differentiated on the basis of laboratory tests that may not be routine in many hospitals. Furthermore, specific therapy is often not initiated until a definitive diagnosis has been established by biopsy.

The differential diagnosis of DAH is listed in Box 44.2. Although some of these diseases have no specific therapy, establishing a diagnosis and instituting supportive care help to avoid unnecessary diagnostic and therapeutic maneuvers. Many of the vasculitides are stabilized only with aggressive immunosuppressive therapy, which would not be appropriate for infectious diseases that can present with the same features in a chest radiograph. DAH caused by infection is less common and specific etiologies vary with immunocompetency.[60]

Bronchoscopy with transbronchial biopsy and bronchoalveolar lavage (BAL) are usually performed in a patient with unknown pulmonary infiltrates if respiratory compromise is not severe. Although often not sufficient to establish a specific diagnosis, finding a bloody lavage, hemosiderin-laden macrophages, and the lack of specific pathogens can presumptively yield a diagnosis of DAH. The diagnosis of DAH is best made by quantitation of hemosiderin in alveolar macrophages obtained by BAL. A Prussian blue stain is graded by the methods of Kahn and colleagues[61]; hemosiderin scores above 100 are virtually diagnostic of alveolar hemorrhage. Hemosiderin-laden macrophages may not appear in BAL fluid until 48 to 72 hours after acute hemorrhage, resulting in a low sensitivity for hemosiderin scores in this setting.[62]

Immunologic Lung Disease

The differential diagnosis of DAH is narrowed significantly if renal abnormalities are present. Although pulmonary-renal syndromes can often be stabilized with high-dose corticosteroids alone pending further evaluation, directed therapy depends on the measurement of specific autoantibodies and evaluation of a renal biopsy. Alveolar hemorrhage is a hallmark of anti–glomerular basement membrane antibody disease (Goodpasture disease). This disease is 75% male-predominant and follows a flulike prodrome in 30% of patients. Pulmonary hemorrhage is the initial manifestation in 90%, and an abnormal urinalysis is found in 80%. An iron deficiency anemia from sequestration of iron within pulmonary alveolar macrophages is commonly associated with the disease. The immunoglobulin (Ig) G antibodies reacting to a component of type IV collagen are found in linear deposits on the basement membrane of both alveoli and glomeruli and are circulating in 90% of cases.[63] In the appropriate clinical setting, the presence of circulating anti–glomerular basement membrane antibodies is sufficient to make a diagnosis without biopsy and institute plasmapheresis with or without plasma exchange for severe pulmonary or renal disease. After initial stabilization, corticosteroids and immunosuppressive medications usually prevent further antibody production.

Steroids alone are usually sufficient to treat alveolar hemorrhage associated with the immune complex vasculitides. These disorders are usually associated with hypocomplementemia and an elevated titer of antinuclear antibody. Systemic lupus erythematosus (SLE) is the most frequent of the immune complex disorders causing alveolar hemorrhage. SLE rarely presents with alveolar hemorrhage without other manifestations of active disease. Although the alveolar hemorrhage of SLE usually occurs from acute lupus pneumonitis, the high incidence of pneumonia, congestive heart failure, and aspiration in these patients makes a presumptive diagnosis problematic. Lupus pneumonitis usually stabilizes with a regimen of 1 to 1.5 mg/kg per day of methylprednisolone.

DAH also complicates other connective tissue diseases and systemic vasculitides with or without immune complex deposition. Mixed connective tissue disease, cryoglobulinemia, polyarteritis nodosa, progressive systemic sclerosis, rheumatoid arthritis, Behçet disease, endocarditis and tumor-related vasculitis, Schönlein-Henoch purpura, and systemic necrotizing vasculitis have all been described in association with DAH. Specific diagnosis depends on the nonpulmonary features of disease presentation.

Alveolar hemorrhage is an unusual manifestation of Wegener granulomatosis.[64] The classic triad of renal dysfunction, upper airway disease, and pulmonary infiltrates is present in less than

• BOX 44.2 Causes of Diffuse Alveolar Hemorrhage

Immunologic Diseases

Anti–glomerular basement membrane antibody disease (Goodpasture syndrome)
Vasculitides associated with circulating or in situ immune complexes
- Systemic lupus erythematosus
- Mixed connective tissue disease
- Schönlein-Henoch purpura
- Essential mixed cryoglobulinemia
- Tumor-related vasculitis
- Endocarditis-related vasculitis
- Polyarteritis nodosa
- Systemic necrotizing vasculitis

Vasculitides associated with antineutrophil cytoplasmic antibodies
- Wegener granulomatosis
- Microscopic polyangiitis
- Idiopathic necrotizing crescentic glomerulonephritis

Rapidly progressive glomerulonephritis
Associated with other connective tissue diseases, pathophysiology unknown
- Rheumatoid arthritis
- Progressive systemic sclerosis
- Behçet disease

Associated with other renal diseases
Immunoglobulin A nephropathy
Diabetic nephropathy
Associated with precipitating antibodies to milk (Heiner syndrome)
Idiopathic pulmonary hemosiderosis
Primary antiphospholipid antibody syndrome

Chemical or Drug-Related Causes

Amiodarone
D-Penicillamine
Isocyanates
Nitrofurantoin
Retinoic acid
Trimellitic anhydride
"Crack" cocaine
Sirolimus
Everolimus
Propylthiouracil-induced vasculitis
Erlotinib
Bevacizumab
Gemcitabine
Infliximab

Transplant-Related Causes

Bone marrow transplant
Renal transplant
Lung transplant

Bleeding Diathesis

Thrombocytopenia
Leukemia with diffuse alveolar damage
Viral pneumonia
Bacterial or fungal sepsis
Radiation
Chemotherapy toxic to lung
Blast counts >80,000/μL
Extrinsic anticoagulants/thrombolytics
Warfarin overdose
Tissue plasminogen activator
Platelet glycoprotein IIb/IIIa inhibitors
Coagulopathies
Cirrhosis
Disseminated intravascular coagulation

Infections

Adenovirus
Aspergillosis (invasive)
Cytomegalovirus
Dengue
Hantavirus
Influenza
Legionella
Leptospirosis
Malaria
Mycoplasma
Staphylococcus aureus

Pulmonary Venous Hypertension

Mitral stenosis
Mitral regurgitation
Pulmonary capillary hemangiomatosis
Pulmonary veno-occlusive disease
Fibrosing mediastinitis
Congenital heart disease

Diffuse Lung Injury

Negative-pressure pulmonary hemorrhage
Breath-hold diving
Postictal neurogenic pulmonary edema

20% of patients at presentation; however, pulmonary infiltrates are present in 45%.[65] The pulmonary findings are characterized by nodules that may cavitate, lobar infiltrates that are often transient, upper airway obstruction from the granulomatous inflammation that follows airway ulceration, prominent interstitial markings with or without hilar and mediastinal adenopathy, or alveolar hemorrhage. Antineutrophil antibodies against proteinase 3 in cytoplasmic granules (c-ANCA) are found in the serum of 85% to 90% of patients with active Wegener granulomatosis and are 97% specific for the diagnosis.[66]

Among the many causes of rapidly progressive crescentic glomerulonephritis are small-vessel vasculitides such as microscopic polyangiitis that are associated with pulmonary hemorrhage in a third of patients.[67] Therapy of these vasculitides and Wegener granulomatosis usually includes corticosteroids and immunosuppressive therapy. In patients with life-threatening respiratory failure, extracorporeal membrane oxygenation has proved lifesaving in patients with ANCA-positive vasculitides and SLE awaiting onset of systemic therapy.[68,69] Use of recombinant factor VIIa has also been reported in this setting.[70,71]

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis is characterized by repetitive episodes of hemorrhage that occur without obvious precipitating factors. Open lung biopsy fails to demonstrate immune complexes, and no other organ system is affected. Therapy with corticosteroids

and occasionally cyclophosphamide has been attempted, although no controlled trials have been performed.

Immunocompromised Host

DAH is a serious complication of autologous and allogeneic bone marrow transplantation.[72] Risk factors include age younger than 40 years, the presence of underlying solid tumors, renal insufficiency, and severe mucositis. The typical presentation is characterized by onset near the time of leukocyte recovery and is heralded by high fever and diffuse pulmonary infiltrates. Typically lavage fluid appears progressively bloody over serial aliquots, and no pathogenic organisms are recovered on bacterial, fungal, or viral culture. The mortality rate has been reported to range from 80% to 100% despite aggressive supportive care[73] but may be improved with corticosteroid therapy.[74] The optimal dosage and duration of corticosteroid treatment remain controversial, but standard regimens include 1 g/day methylprednisolone administered for 3 days and thereafter tapered over 2 months.[74] The use of recombinant factor VIIa in patients with life-threatening DAH refractory to steroids has been reported.[71] More recent reports reveal a favorable prognosis in patients with early (first 30 days) versus late DAH and autologous versus allogeneic transplants with an overall mortality rate of 48%.[72]

A similar syndrome characterized by fever and pulmonary infiltrates has been noted in 5% of transplant patients, but hemoptysis is rare. Pulmonary capillaritis after lung transplant also can result in DAH. Hemoptysis is seen in up to 25% of cases, with fulminant respiratory failure seen in 18%.[75] This form of acute allograft rejection appears less responsive to corticosteroid therapy than acute lung rejection but has a more favorable response to plasmapheresis. No long-term adverse effects on allograft function are apparent.

Bleeding Diathesis

Although hemoptysis may occur with intrinsic coagulopathies, extrinsic anticoagulants and antiplatelet agents, thrombocytopenia, and fibrinolytics, patients at risk should undergo bronchoscopy to exclude other lesions such as neoplasm. Usually, the disorders of hemostasis are not in themselves solely responsible for hemoptysis, and bleeding can usually be ascribed to the combined presence of another cause, often as insignificant as an upper respiratory infection.

Leukemia patients may be particularly susceptible to DAH when chemotherapy-induced thrombocytopenia is combined with diffuse alveolar damage from other causes. Viral infections, sepsis, radiation, chemotherapy agents with pulmonary toxicity, and leukostasis from blast counts exceeding 80,000 cells/mm^3 may all produce diffuse alveolar damage in leukemia.[76] Therapy is directed toward correction of thrombocytopenia and supportive care of lung injury.

Drug-Induced Alveolar Hemorrhage

Hemoptysis owing to drug-induced alveolar hemorrhage is rare and may result from therapeutic medications, illicit drugs, and other agents. Implicated agents include crack cocaine,[77] amiodarone,[78] nitrofurantoin,[79] D-penicillamine,[80] retinoic acid,[81] propylthiouracil,[82] infliximab,[83] inhaled resins containing trimellitic anhydride,[84] and various chemotherapeutic agents.[31,85–89]

Vascular Abnormalities

Almost all blood vessels that course through the thoracic cavity have been associated with fistula formation to an airway with resultant hemoptysis. Often this occurs in the setting of endovascular infection, inflammation, congenital or acquired stenoses, aneurysms of these vessels, or chest surgery. Some of the rare vascular-to-airway fistulas that have been described include (1) carotid artery to trachea in a patient with occult laryngeal cancer[90]; (2) various abdominal arterial supplies to pulmonary sequestrations[91]; (3) syphilitic aneurysms of the ascending aorta and other thoracic arteries to pulmonary parenchyma[92]; (4) coronary artery bypass grafts to pulmonary parenchyma or bronchial artery[93,94]; (5) splenopulmonary shunt in portal hypertension following splenectomy[95]; (6) left ventricular pseudoaneurysms[96] to pulmonary parenchyma; and (7) vena caval–bronchial fistulas.[97] Several of the more common bronchovascular communications deserve comment.

Aortobronchial Fistulas

Dissecting aortic aneurysms are often of subacute or chronic duration with variable degrees of inflammation around the dissection. As an aneurysm enlarges it may cause lung compression, pleural adhesions, and dissection of blood into the pulmonary parenchyma. Particularly in situations in which an aortic graft has been previously placed, aortic graft infection may also be present. The net result is an often stuttering course of hemoptysis marked by sudden large bleeds. Therapy is surgical, although these operations are difficult in the presence of graft infections and prior operations.

Pulmonary Artery Aneurysms

Aneurysms of the pulmonary artery remain rare causes of hemoptysis.[98] Mycotic aneurysms are commonly caused by *Mycobacterium tuberculosis*, syphilis, *S. aureus*, and streptococcal species. Poststenotic dilation may occur in congenital pulmonary artery strictures. Structural vascular abnormalities such as those found in Marfan syndrome can also affect the pulmonary arteries.

Beçhet disease, characterized by oral ulcers, uveitis, arthritis, and cutaneous vasculitis, is the only common large-vessel vasculitis that affects the pulmonary arteries.[99] These multiple aneurysms may resolve with high-dose corticosteroid therapy or cyclophosphamide.[100,101]

An idiopathic syndrome characterized by fatal hemoptysis from pulmonary artery aneurysms, associated with fever and recurrent superficial and deep venous thromboembolism, was originally reported in 1959 by Hughes and Stovin.[102] Although infection and angiodysplasia have been proposed as possible causes of the aneurysms, the current consensus is that vasculitis is the primary process.[103]

Arteriovenous Malformations

Pulmonary arteriovenous malformations (PAVMs) present with progressive hypoxemia, paradoxical emboli, or bleeding complications including hemoptysis or hemothorax.[104] Although the majority of these lesions are likely congenital telangiectasias that enlarged over years,[105] acquired AVMs have been noted after chest surgery and trauma and have been associated with actinomycosis, schistosomiasis, cirrhosis, and metastatic carcinoma.[106] The hereditary Osler-Weber-Rendu disease (OWR) is associated with hemorrhagic telangiectasias in many organ systems. Approximately 15% of OWR patients have pulmonary arteriovenous aneurysms,[107] and up to 36% of patients with a single PAVM and 57% of patients with multiple PAVMs have OWR.[108] Bronchial artery telangiectasias with bleeding[109] have also been described, although the pathogenic relationship to pulmonary artery telangiectasias remains speculative. Treatment of PAVMs, particularly if hemoptysis has developed, is to obliterate the lesion with BAE.[110]

Trauma

Hemoptysis following major trauma requires emergent thoracic surgical consultation and management. Although some cases will be simple lung contusions that manifest as a focal radiographic abnormality on chest radiograph with blood-streaked sputum present, some thoracic trauma victims with hemoptysis need early exploration. The majority of cases with hemoptysis need bronchoscopy to localize bleeding and exclude a tracheobronchial rupture, which can be clinically silent for weeks. The most common reason for emergent thoracotomy remains pulmonary hemorrhage. Pneumonorrhaphy (suture repair of the lung) is preferred for minor injuries with lobectomy and pneumonectomy performed for more severe injuries.

Lung laceration is common after penetrating pulmonary injury. However, it can also occur after blunt thoracic trauma in which sheer forces of acceleration or deceleration leave intraparenchymal lacerations involving airways or vasculature. Continued bleeding into the lung can present with rupture into the pleural space (hemothorax), intraparenchymal hematoma formation, or hemoptysis. Thoracic splenosis is a rare and remote event from the time of trauma. In this condition, splenic tissue is transported across the diaphragm after penetrating injury, where it becomes functional and vascularized within the lung. Hemoptysis may thereafter occur spontaneously.

Vascular Monitoring Catheters

Use of pulmonary artery catheters has decreased significantly and complications causing hemoptysis occur rarely. More distal and prolonged inflation of the catheter balloon can cause fatal pulmonary artery dissection, pseudoaneurysm formation, or pulmonary artery rupture.[111,112] Endovascular damage may predispose to thrombus formation and pulmonary infarction. Preventive measures include placement of the catheter at an insertion distance when full inflation is required to obtain an occlusion pressure, slowly inflating the balloon (never inflating against resistance), full inflation of the balloon to prevent the catheter tip from projecting beyond the balloon, and daily monitoring of catheter position with chest radiography.

If hemoptysis occurs with a pulmonary artery catheter in place, rapid diagnosis and treatment are required. Risk factors for pulmonary artery rupture include concomitant anticoagulation, cardiopulmonary bypass, balloon migration, hypothermia, advanced age, and pulmonary hypertension.[112] Surgical resection of the involved lobe or angiographic ablation of the involved pulmonary artery has been successful in decreasing the incidence of recurrent and often fatal hemoptysis. Other successful interventions for acute conditions have included proximal reinflation of the pulmonary artery catheter to stop blood flow to the pulmonary artery segment that is bleeding; high levels (18 mm Hg) of positive end-expiratory pressure to decrease the pulmonary artery to bronchial pressure gradient; resumption of cardiopulmonary bypass for patients in cardiac surgery; and operative banding of the pulmonary artery, which can be unclamped 48 hours later.[112,113]

Invasive Pulmonary Interventions

Increasing use of new invasive diagnostic and therapeutic pulmonary interventions can be associated with iatrogenic complications including hemoptysis. Although the incidence is low, hemoptysis has been reported with percutaneous CT-guided transthoracic lung biopsy, endoscopic lung volume reduction coil treatment, and radiofrequency ablation.[114–117]

Management

The primary principles of managing massive hemoptysis are airway and lung protection, localization of the bleeding source, and control of hemorrhage. Assessments and interventions are frequently performed empirically because the cause of hemoptysis may not be known at the time of presentation. Therapy to control minor and moderate hemoptysis can usually proceed along diagnostic paths. The inability to determine when and whether an individual patient's hemoptysis will worsen suggests that all patients with an estimated blood loss of more than 200 mL should be hospitalized in a unit in which airway support can be rapidly provided if necessary.

Massive hemoptysis should be managed within a framework of expeditious therapy to stabilize and resuscitate the patient. Fig. 44.1 is a suggested algorithm for management. A multidisciplinary collaborative approach involving intensivists, pulmonologists, interventional radiologists, and thoracic surgeons is optimal to improve outcomes.[7] The urgency and aggressiveness of management are influenced by the rate of bleeding. The study by Crocco and colleagues[6] (Table 44.1) demonstrated that the incidence of death was 71% in patients with 600 mL of hemoptysis in less than 4 hours, compared with 22% and 5% mortality rate if 600 mL of hemoptysis occurred in 4 to 16 hours and 16 to 48 hours, respectively. Sputum containers should be placed at the bedside of patients who are not intubated to allow measurement of blood loss and an estimate of the bleeding rate. High bleeding rates, hemodynamic instability, and severe oxygenation failure signal the need for rapid evaluation and treatment. A critical care setting is optimal for patients with massive hemoptysis.

In addition to the management steps outlined later, laboratory studies should be obtained, including complete blood cell count,

TABLE 44.1 Mortality Associated With Rate of Bleeding

	OPERABLE					
	Surgical Management		No Surgery		Nonoperable	
Blood Loss	No. of Patients	Deaths	No. of Patients	Deaths	No. of Patients	Deaths
600 mL in <4 h	11	4 (36%)	6	6 (100%)	11	10 (91%)
600 mL/4–16 h	10	1 (10%)	3	1 (33%)	5	2 (40%)
600 mL/16–48 h	11	1 (9%)	0	0	10	0

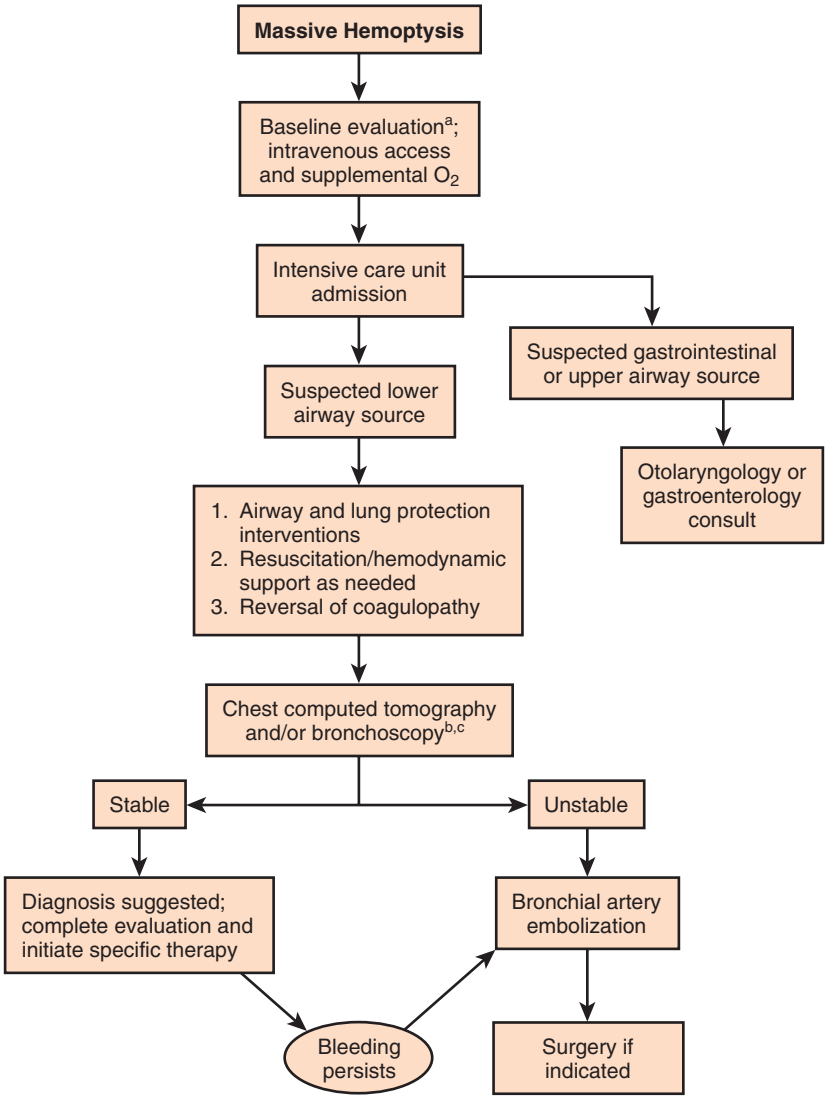

Fig. 44.1 Massive hemoptysis. [a]History and physical examination, complete blood cell count, coagulation studies, type and cross-match, chest radiograph, arterial blood gas levels. [b]Local availability and patient stability should guide choice; computed tomography is preferred in initial evaluation in stable patients. [c]Local measures, including topical vasoconstrictors, bronchial blockers, laser photocoagulation, electrocautery, and hemostatic agents, can be used endobronchially. *O_2,* Oxygen.

coagulation studies, and type and cross-match for possible blood transfusion. An arterial blood gas measurement may be needed to assess ventilation and acid-base status, although pulse oximetry is usually adequate to assess oxygenation. Additional studies may be needed to investigate possible causes of hemoptysis such as infection or vasculitis. The hemodynamic status of the patient should be evaluated and fluids or blood administered for hypotension or evidence of impaired oxygen delivery. Antibiotics may be indicated if there is suspicion of active infection.

Airway and Lung Protection

Patency of the airway and the ability to protect the airway should be assessed as soon as hemoptysis is noted. All patients should be provided with supplemental oxygen as needed to maintain adequate oxyhemoglobin saturation. Patients with mild to moderate amounts of hemoptysis usually do not require intubation, but intubation in massive hemoptysis is usually needed to facilitate diagnostic and therapeutic interventions as well as to provide support for oxygenation and ventilation. Additional steps may be needed to prevent contamination of the unaffected lung from blood and to preserve respiratory function.

Patient Positioning

If the source of bleeding is localized to one lung, the patient with massive bleeding should be positioned with the bleeding side down to keep bleeding contained to one lung. Once the airway is secured, the optimal patient position is more controversial. Clotting of blood in a dependent lung has the potential to tamponade the bleeding, yet clotted blood in the proximal airway can result

in lung collapse and atelectasis. Furthermore, if the pulmonary circulation is bleeding, it can be influenced by gravity by placing the bleeding segment higher than other areas of the chest. By converting that segment to a zone 1 condition in which alveolar pressure is higher than pulmonary artery pressure, bleeding may be decreased.

Endotracheal Intubation

Endotracheal intubation is often difficult in patients with active bleeding. Orotracheal intubation is preferred to allow use of a larger endotracheal tube (preferably 8 mm inner diameter or larger) to facilitate suctioning, ventilation, and bronchoscopy. The orotracheal route also allows for selective mainstem bronchial intubation if needed.

If the patient's physical examination, chest radiograph, and other imaging studies readily identify the bleeding lung, specific interventions to protect the airway to the normal lung can be attempted. Mechanisms to localize ventilation to one lung using a single-lumen endotracheal tube include selective intubation of one of the mainstem bronchi and selective endobronchial tamponade with a bronchial blocker (see later discussion).

Selective bronchial intubation is easiest in a patient with a bleeding left lung. Because of the leftward displacement of the carina in most individuals, an endotracheal tube advanced blindly will almost always intubate the right main bronchus. Unfortunately, the right upper lobe bronchus is so close to the carina that a right mainstem intubation may also cause right upper lobe atelectasis. The ability to ventilate and oxygenate a patient with the right lower and right middle lobes alone depends on the underlying cardiopulmonary reserve. Intubation of the left main bronchus is facilitated by placing the patient in a right lateral decubitus position to shift the mediastinum rightward. Angulation of the endotracheal tube curvature toward the left and progression of the tube over a coudé catheter may be helpful. Selective mainstem intubations can be facilitated by a bronchoscope.

Double-Lumen Endotracheal Tubes

Devices used for single-lung ventilation have also been applied to the management of hemoptysis.[118] A double-lumen endotracheal tube is an alternative to a single-lumen endotracheal tube for airway management in massive hemoptysis. Successful placement of this type of endotracheal tube requires training and experience.[119] The independent isolation of each mainstem bronchus allows for single-lung ventilation and isolation of the unaffected lung from blood contamination when bleeding is localized to one lung. The smaller suction ports of each independent lumen can cause difficulty in suctioning blood. Endobronchial evaluation requires a pediatric bronchoscope or double-lumen tube removal once bleeding has been controlled. Proximal airway masses may preclude placement of a double-lumen endotracheal tube.

Localization of Bleeding

Localization of bleeding facilitates diagnostic and therapeutic efforts regardless of the amount of hemoptysis. Because blood in the mouth can originate from the gastrointestinal tract or from diverse sites in the sinuses, nasal airway, or upper airway proximal to the larynx, an initial evaluation is needed to confirm that bleeding is from the lung. The characteristics of the expectorated blood and clinical presentation of the patient often help in differentiating hemoptysis from upper airway or gastrointestinal sources (Table 44.2). A pH assessment of the blood (low pH expected in gastric hemorrhage) and observation of expectorated sputum can be performed at the bedside.

TABLE 44.2 Features of Hemoptysis and Patient Presentation

Hemoptysis Feature	Clinical Presentation
Blood usually bright red	Often dyspneic
Portion of blood usually frothy Alkaline pH	Hypoxemia
Blood usually mixed with sputum	Preceding cough common
Alveolar macrophages may be present in sputum smear	Anemia and melena uncommon

Chest Radiograph

All patients with hemoptysis need a baseline evaluation that consists of a physical examination and chest radiograph. The chest radiograph may suggest specific diagnoses and help in localization of bleeding. However, blood filling the alveoli can obscure an underlying pathologic condition and present with bilateral infiltrates, making localization of the bleeding site problematic.

Chest Computed Tomography

The importance of chest CT in the diagnosis of acute hemoptysis and localization of bleeding has increased with advances in technology. In a series of 80 patients with massive hemoptysis, emergency high-resolution CT was not only equivalent to bronchoscopy in localizing bleeding (70% vs. 73%), but it was more efficient than bronchoscopy for identifying the cause of bleeding (77% vs. 8%).[120] High-resolution CT also allows the adequate prediction of nonbronchial systemic arterial supply, which can be the cause of bleeding in massive hemoptysis and a significant cause of recurrent bleeding after successful BAE.[121] Contrast enhancement increases the yield by identifying vascular abnormalities (i.e., thoracic aneurysm or AVMs) that would allow for more timely surgical referral.

The use of multidetector CT angiography to visualize the bronchial and nonbronchial systemic vasculature has been found to increase the number of pulmonary artery vaso-occlusions and reduce the number of urgent surgical resections compared with single-detector helical CT.[122] Multidetector CT angiography before BAE is helpful in identifying bronchial and nonbronchial systemic arteries causing hemoptysis and in determining the feasibility of BAE.[123–125]

CT modalities including multiplanar reconstruction and endobronchial simulation (i.e., virtual bronchoscopy) will likely increase the diagnostic yield of chest CT even further as these techniques become more available. Chest CT (preferably multidetector CT angiography), except in unstable patients, should therefore be performed in patients before bronchoscopy and BAE to efficiently guide management.

Bronchoscopy

Although the diagnostic yield of bronchoscopy remains low in hemoptysis owing to causes other than endobronchial carcinoma, it remains a vital tool in the management of acute massive hemoptysis in unstable patients. Localization of bleeding

can facilitate immediate interventions for hemorrhage control, including appropriate patient positioning, selective intubation, endobronchial tamponade, endobronchial infusions, laser photocoagulation, and guidance for BAE or surgical resection. However, patients with lateralizing radiography and known causation who are candidates for BAE usually do not need prior bronchoscopy unless bronchoscopic airway management is necessary.[20,126,127] This strategy can avoid delays in definitive therapy, reduce cost, and avoid the risk of airway compromise from sedation associated with bronchoscopy.

During massive hemoptysis the rigid bronchoscope has some advantages over flexible fiberoptic instruments. Ventilation is secured through the bronchoscope lumen, suctioning is not impeded, and visualization is less likely to be significantly impaired. The flexible instrument has advantages of subsegmental localization of bleeding and visualization of the upper lobes. Because the two bronchoscopes have complementary properties, they are often used together. The rigid bronchoscope is used to secure ventilation and localize the bleeding lung; the flexible scope passed through the rigid scope allows for further definition of the bleeding site and diagnosis.

Hemorrhage Control

Expectant Therapy

Cough suppression has been recommended for the majority of patients with massive hemoptysis; moderate doses of codeine are most commonly used. Although no prospective study has evaluated the efficacy of cough suppression on patient outcome, the large swings in intrathoracic pressure that occur with coughing are likely to be detrimental.

The additional factor that must be considered in cough suppression is the necessary removal of blood clots that can cause endobronchial obstruction. Particularly when a central airway lesion is responsible for bleeding, the suctioning necessary to remove blood clots may be associated with rebleeding and perpetuation of a vicious cycle. Blood clots left unsuctioned, however, may cause atelectasis, which is detrimental to patient weaning from the ventilator. Airway stabilization can usually be attained with serial bronchoscopies and suctioning. Additional techniques may be provided by interventional pulmonologists.

Endobronchial Tamponade

Acute lung bleeding may be amenable to control by endobronchial tamponade with balloon-tipped devices known as bronchial blockers.[129–132] Several types of devices are available: Fogarty vascular embolectomy catheter, a single-lumen endotracheal tube with an enclosed movable bronchial blocker, and a wire-guided bronchial blocker.[133] Regardless of the selected device, experience is required for successful placement and safe utilization.[119] The blocker is directed to the bleeding bronchus under guidance of fiberoptic bronchoscopy. By advancing the blocker to the smallest subsegment to which bleeding can be visualized, bleeding can be contained and diagnostic and a therapeutic workup can continue. Other balloon catheters can also be used for this purpose,[134] although they must be carried to the bleeding site on the outside of the bronchoscope by the bronchoscopic shuttle technique.[133] Multiple catheters can be placed if hemoptysis is multifocal and catheters can be left in place for 24 to 48 hours until bleeding is controlled.[132]

Bronchial occlusion in massive hemoptysis has also been achieved with endoscopic placement of silicone spigots.[136,137] The spigots are left in place for several days while more definitive interventions are instituted to control bleeding.

Endobronchial Agents

Although a variety of agents have been infused into the airway through the bronchoscope to control bleeding, no studies directly compare the agents with each other or with other modalities of therapy. Nevertheless, the potential advantage of these agents is their administration during bronchoscopy for the localization of bleeding. Thrombin and fibrinogen-thrombin mixtures have been used in some sites to provide a hemostatic clot in the area of bleeding, with good success.[138] Oxidized regenerated cellulose mesh, a biodegradable cellulose fabric, is an alternative procoagulant used in patients with massive hemoptysis and showed a 98% success rate in a series of 57 patients.[139] Once deployed in the area of hemorrhage, the mesh absorbs blood, swelling into a gelatinous mass that promotes tamponade and coagulation. Endobronchial sealing with *n*-butyl cyanoacrylate, a biocompatible glue with prothrombotic properties, has also been used with success in small case series.[140]

Topical vasoconstrictors, including iced saline solution, epinephrine,[141] and vasopressin or vasopressin derivatives,[142,143] have also been used effectively for airway bleeding in anecdotal reports. The likely mechanism is vasoconstriction of bronchial arteries. These may be safe, effective alternatives in patients without access to BAE or surgery, or in unstable patients in need of a temporizing intervention until definitive therapy is available.

Endobronchial use of agents affecting coagulation and fibrinolysis has also been reported. Bronchoscopically instilled factor VII has been used successfully in hemoptysis owing to DAH.[144] Tranexemic acid has been used by bronchoscopic instillation and nebulization to control bleeing.[145,146] A dry powder formulation of tranexamic acid has recently been developed.[147]

Laser Photocoagulation

The neodymium:yttrium aluminum garnet or argon plasma laser has been used successfully for airway carcinoma with persistent hemoptysis. Recognizing that carcinomatous bleeding is usually progressive and can be life threatening, aggressive photocoagulation of the endobronchial site may provide the only possibility for palliation after chemotherapy and radiation have been exhausted. Appropriate training, however, is imperative to ensure appropriate patient selection and to avoid catastrophic complications such as tracheal fire or vessel perforation.[148]

Bronchial Artery Embolization

BAE was first described in 1974 to control massive hemoptysis in the nonsurgical patient.[149] Subsequent studies on safety and efficacy have confirmed immediate, safe control of hemoptysis in 79% to 100% of a variety of patients, resulting in early use of BAE in the management strategy.[150–157] The technique for BAE localizes the bronchial arteries supplying the lobe that is bleeding. A bronchial arteriogram is performed to ensure that there is no communication to the anterior spinal artery, to determine whether a vascular pathologic condition is present, and to ensure that the bleeding area of lung parenchyma is served by the vessel. Only rarely will vascular extravasation indicative of bleeding be observed, usually in patients with massive bleeding. Angiographic signs that suggest a source of bleeding include hypertrophied/enlarged/tortuous bronchial arteries with parenchymal hypervascularity, bronchial artery aneurysms, and bronchial artery to pulmonary vein or pulmonary artery shunting.[158] The angiographic technique usually

begins with the injection of a contrast agent in the descending aorta just below the left subclavian artery to identify bronchial arteries supplying the majority of the lung and phrenic arteries supplying the lung bases. Identification of anomalous origins of the bronchial arteries may require a full arch aortogram in some patients.[159] For pathologic conditions of the lower lung, a selective phrenic artery injection is used if the entire lung is not visualized by bronchial injections. Rarely, these lower injections may demonstrate a pulmonary sequestration. For pathologic conditions of the upper lung zone, a unilateral subclavian artery injection is done to exclude nonbronchial systemic collateral arteries.

No studies have evaluated the optimal embolization material for control of hemoptysis. Gelatin sponge particles, polyvinyl alcohol particles, or liquid polymers (e.g., *n*-butyl cyanoacrylate) with a predetermined polymerization time have all been used with success.[160] Velour, polyurethane particles of varying size, metal coils, protein macroaggregates, and fibrinogen-thrombin mixtures[161] have also been instilled. Combinations of materials are used in a significant number of patients.[156,162] Liquid sclerosants, such as absolute alcohol or Gelfoam Powder (Pharmacia and Upjohn Company/Pfizer, Kalamazoo, MI), should be used with caution because they may pass into the smallest vessels at the bronchial surface, producing bronchial necrosis.[163]

Significant complications of BAE are rare when the appropriate technique is used. Chest pain, dysphagia, and fever are the most common complications. Myocardial infarction, bronchial wall necrosis, and esophageal necrosis may also rarely occur. The most devastating complication is spinal cord infarction resulting from embolization of the anterior spinal artery, which arises from the bronchial artery circulation in approximately 5% of normal patients. However, with proliferation of the bronchial artery circulation, as occurs in CF, communication to the anterior spinal artery may be found in up to 55% of cases.[164] By performing high-quality bronchial arteriograms to define vascular anatomy and avoiding the anterior spinal artery by wedging the angiography catheter distal to its takeoff (or by avoiding the vessel altogether), a safe procedure can almost always be ensured. The recent introduction of microcatheter technology (i.e., "superselective" catheterization) allows achievement of a more distal, safe catheter position and has greatly reduced the number of aborted procedures and complications arising from anterior spinal artery embolization.

Recurrent hemoptysis is common after BAE and can occur immediately, in the first several weeks to months (early), or after several years (late). Immediate recurrence of hemoptysis in the first few days after BAE may occur in approximately 10% of patients[151] and may be due to several causes. For the patient who continues to bleed during the procedure, the appropriate blood vessel usually has not been embolized. Other common causes include bleeding from nonbronchial systemic or pulmonary vessels, particularly if not evaluated initially, and lysis of the hemostatic plug in the embolized bronchial artery. Recurrence of hemoptysis in the first several months after BAE may be related to incomplete embolization, although later recurrence at 1 to 2 years may be related to neovascularization or recanalization related to inflammation or disease progression.[165] Reporting of outcomes varies considerably in BAE studies but early recurrence of bleeding may occur in 3.5% to 26% of patients.[152,154,156,166] Late recurrence of bleeding may occur in 10% to 40% of patients.[150,152,153,156,166] The incidence of recurrence is not uniform in all lung diseases, and higher recurrence rates are noted in *Aspergillus* fungus balls, bronchiectasis, tuberculosis, cavitary lung disease, and lung cancers.[9,150,155,156,165,167,168] The use of superselective embolization, which provides less of a stimulus for neovascularization, may improve recurrence rates.[169] BAE can be considered a palliative intervention for the acute cessation of massive hemoptysis that allows for a more controlled evaluation of the patient for potentially curative interventions.

Surgery

A significant question in control of massive hemoptysis is whether conservative management techniques including endobronchial tamponade and BAE are better than emergent surgery in improving outcomes. Given the high success rates of BAE and low associated morbidity and mortality rates, more conservative techniques are now considered first-line therapy over emergent surgery. The proportion of patients with massive hemoptysis who undergo emergent or urgent surgery often is not reported, but some studies found 12% to 14% of patients required surgical intervention.[157,170] Although perioperative and hospital mortality rates were high in past experience, more recent studies report a mortality rate of less than 15%.[170–174] The outcome of surgery is significantly influenced by the cause and severity of hemoptysis, patient comorbidities, extent of lung resection, and experience of the surgical team. Absolute indications for surgery do not exist, but patients with vascular disruptions (e.g., leaking aortic aneurysm, AVMs, pulmonary artery rupture, chest trauma); focal fungal disease, tuberculosis, or bronchiectasis; or failed BAE or early recurrence of bleeding after BAE should be considered for urgent surgery in the setting of massive hemoptysis.[155,168] Mycetomas, active tuberculosis, and bronchiectasis represent a large majority of the causes of hemoptysis in surgical reports.

Important issues in the assessment of a patient for thoracic surgery include the underlying cardiopulmonary reserve, precise localization of bleeding, and the focality of the patient's disease. Formal testing of lung function is not practical in the setting of massive hemoptysis, so a clinical assessment is often obtained on the basis of premorbid exercise tolerance.

Patients with fibrosis and adhesions between the lung and chest wall, commonly seen in tuberculosis, fungal disease, and bronchiectasis, have significant surgical risks because they often require pneumonectomy. Video-assisted thoracoscopic procedures may be successful in some patients.[175]

The decision regarding surgery for massive hemoptysis is a difficult one that often must be made rapidly, without all desired clinical information available. The availability of BAE and endobronchial tamponade may provide time for a reasoned decision to be made regarding surgery in all but the most rapidly bleeding patients.

Other Therapies

As new devices and interventions are developed for the management of other pulmonary and nonpulmonary conditions, some may be adapted to treat massive hemoptysis. Covered self-expanding stents have been used to occlude a bleeding site in a patient not treatable by BAE or surgery.[176,177] Recombinant activated factor VII has been used systemically to control hemoptysis in DAH[70,71,178] and focal bleeding associated with community-acquired pneumonia,[179] thoracic trauma,[180] and CF.[181] Recombinant activated factor VII is not approved for use in hemoptysis and can be associated with increased thrombosis. A pilot study of systemic tranexamic acid found a nonsignificant decrease in the severity of hemoptysis, but a recent review found insufficient evidence to determine if systemic tranexamic acid use is warranted.[182,183]

Key Points

- The adverse clinical effects of hemoptysis, such as impaired gas exchange, airway obstruction, and hypotension, are relevant for defining a life-threatening condition.
- Bleeding from the higher-pressure bronchial circulation (rather than the pulmonary circulation) causes almost 90% of the cases of massive hemoptysis.
- Massive hemoptysis is more common with bronchiectasis, tuberculosis or its sequelae, lung cancer, and aspergilloma than with chronic bronchitis, pneumonia, and pulmonary emboli.
- DAH should be considered a potential cause of hemoptysis in the presence of diffuse infiltrates on chest radiograph, systemic manifestations of vasculitis, hypoxemic respiratory failure, and anemia.
- The primary principles of managing massive hemoptysis are airway and lung protection, localization of the bleeding source, and control of hemorrhage.
- A multidisciplinary collaborative and organized approach to managing massive hemoptysis is needed to improve outcomes.
- Orotracheal intubation with a larger endotracheal tube (preferably 8-mm inner diameter or larger) is preferred for airway protection in massive hemoptysis to facilitate suctioning, ventilation, and bronchoscopy.
- Chest CT (preferably multidetector CT angiography), except in unstable patients, should be performed in many patients before bronchoscopy and BAE to efficiently guide management.
- BAE is a safe and effective technique to control bleeding in massive hemoptysis and should be used as the initial therapeutic modality in most patients.
- Patients with vascular disease; focal fungal disease, tuberculosis, or bronchiectasis; or failed BAE or early recurrence of bleeding after BAE should be considered for urgent surgery of massive hemoptysis if they have sufficient cardiopulmonary reserve.

Review Questions

1. Which of the following patients with recurrent massive hemoptysis after bronchial artery embolization would be the best candidate for surgical intervention?
   - **a.** A 68-year-old with chronic obstructive lung disease and hemoptysis owing to squamous cell lung cancer
   - **b.** A 21-year-old with severe cystic fibrosis and hemoptysis owing to bronchiectasis
   - **c.** A 65-year-old with chronic lymphocytic leukemia and hemoptysis owing to right upper lobe aspergilloma
   - **d.** 35-year-old bone marrow transplant patient with hemoptysis owing to diffuse alveolar hemorrhage

   Answer: c. Surgical intervention for massive hemoptysis is usually considered when bleeding recurs after bronchial artery embolization. Important issues in considering whether a patient is a candidate for surgery include the underlying cardiopulmonary reserve, precise localization of bleeding, and the focality of the patient's disease. Patient c is the best candidate for surgery owing to the focality of the disease causing hemoptysis. Patient a is unlikely to have sufficient pulmonary reserve to survive lung resection as is patient b with diffuse fibrotic and bronchiectatic lung disease. Patient d is not a good candidate owing to the diffuse nature of the hemorrhage.
2. A 54-year-old patient with prior treated tuberculosis presents with massive hemoptysis and is admitted to the intensive care unit (ICU) for management. Vital signs on admission are heart rate 110 beats/min, respiratory rate 28 breaths/min, blood pressure 108/54 mm Hg, and oxygen saturation by pulse oximetry is 90% on room air. The patient is intubated on arrival to the ICU. The chest radiograph shows a cavitary lesion in the right upper lobe and fibrotic changes of the right upper lobe. High-resolution computed tomography (CT) scan confirms the same findings. Which of the following is the next best intervention?
   - **a.** Bronchial artery embolization
   - **b.** Flexible fiberoptic bronchoscopy with iced saline solution lavage
   - **c.** Flexible fiberoptic bronchoscopy with placement of a bronchial blocker
   - **d.** Replace endotracheal tube with a double-lumen endotracheal tube

   Answer: a. This patient has only mild hemodynamic abnormalities and a focus for bleeding identified on CT scan which allows for immediate bronchial artery embolization (BAE). BAE is safe and effective and offers rapid control of bleeding. Bronchoscopy may delay definitive therapy if undertaken in this type of patient. Bronchoscopic interventions, such as iced saline solution lavage and placement of a bronchial blocker, are only temporizing measures and the patient would still require more definitive intervention to stop the hemorrhage. Similarly, placement of a double-lumen tube may allow for isolation of the bleeding lung but would not control bleeding.
3. Which of the following is the most common complication of bronchial artery embolization?
   - **a.** Myocardial ischemia
   - **b.** Spinal cord infarction
   - **c.** Bronchial wall necrosis
   - **d.** Fever

   Answer: d. Chest pain, dysphagia, and fever are the most common complications following bronchial artery embolization. Myocardial ischemia, bronchial wall necrosis, or esophageal necrosis is rare. The most devastating complication is spinal cord infarction owing to embolization of the anterior spinal artery, but high-quality bronchial arteriograms and superselective techniques make this complication rare today.

- Persistent Air Leak and Bronchopleural Fistula
- Recurrence Prevention
- Management Under Special Circumstances

Complications Related to Management

Definition and History

Pneumothorax is defined as air in the pleural space because of a break in the visceral or parietal pleura. The term *pneumothorax* was used for the first time in 1803.[1] Laennec[2] gave the first clinical description of pneumothorax in 1819; however, the first chest radiograph demonstrating this entity was not published until 1901.[3] Definitive therapy became available with the advent of tube thoracostomy in 1876.[4] It was thought to be always associated with tuberculosis until 1932 when "spontaneous pneumothorax in the apparently healthy" was first described.[5]

Spontaneous pneumothorax can be classified as primary or secondary. Primary spontaneous pneumothorax (PSP) occurs in patients with no apparent underlying lung disease. Secondary spontaneous pneumothorax (SSP) occurs in association with a known underlying lung disease such as chronic obstructive pulmonary disease (COPD).[6] Nonspontaneous causes of pneumothorax include traumatic and iatrogenic (Table 45.1).

Incidence

The incidence of PSP in men varies geographically from 7.4 per 100,000 population per year in the United States to 37 per 100,000 population per year in the United Kingdom. In women, the incidence is substantially less, ranging from 1.2 per 100,000 population per year in the United States to 15.4 per 100,000 population per year in the United Kingdom.[7] The reason for these differences is not known. In a study that evaluated 1199 patients with pneumothorax that included 865 male patients and 334 female patients, 60.3% of the pneumothoraces were spontaneous, 33.6% were traumatic, and 6.1% were iatrogenic.[8]

The estimates of the incidence of recurrent PSP range from 20% to more than 50% with most recurrences within the first year.[9]

Pathophysiology

Emphysema-Like Changes

PSP occurs in patients with no previously known lung disease. It is important to note, however, that this does not mean there is no underlying pathologic process. A finding of abnormal pleura is very common in PSP if looked for carefully.[10] Abnormalities seen in PSP are summarized in Table 45.2 and include blebs and bullae, which are otherwise known as emphysema-like changes (ELCs). These areas of weakness of the visceral pleura are prone to rupture, allowing air to leak into the pleural space. Abnormalities can be visualized radiographically with high-resolution computed tomography (CT) scans and macroscopically at thoracoscopy.[10,11] High-resolution CT imaging reveals these defects in approximately 80% of PSP with PSP. The literature is mixed as to whether the presence of or extent of ELCs is directly related to the risk of recurrence. Some case series suggest that there is no association,[12,13] although others suggest the presence of contralateral blebs/bullae is a risk factor for future pneumothorax.[14,15] The only clear conclusion that can be drawn is that there is a direct association between the presence of ELCs and the occurrence (but not necessarily recurrence) of a pneumothorax (Table 45.2 and Fig. 45.1).

TABLE 45.1 Classification of Pneumothorax

Type	Etiology
Primary spontaneous pneumothorax	No underlying lung disease (but blebs/bullae commonly present)
Secondary spontaneous pneumothorax	Associated with underlying lung disease (e.g., chronic obstructive pulmonary disease, cystic fibrosis, AIDS with emphysema)
Traumatic iatrogenic pneumothorax	Related to trauma to the thorax Secondary to transthoracic or transbronchial lung biopsy (10% risk), central venous catheterization, supraclavicular nerve block

From Grundy S, Bentley A, Tschopp JM. Primary spontaneous pneumothorax: a diffuse disease of the pleura. *Respiration.* 2012;83:185–189.

TABLE 45.2 Pathologic Changes Associated With Primary Spontaneous Pneumothorax

Pathologic Abnormality	Description
ELCs (i.e., blebs/bullae)	Macroscopically visible areas of weakness on visceral pleura Occasionally seen to be the site of air leak Present in approximately 80% of cases Often bilateral
Fluorescein enhancement	Represents areas of pleural/subpleural abnormality not visible with white light autofluorescence Often present at sites distinct from ELC in lungs of patients with PSP and not in those of control subjects Provides evidence of diffuse pleural porosity
Distal airway inflammation	Inflammatory infiltration with lymphocytes and macrophages within walls of bronchioles Associated fibrotic changes and compensatory emphysema

ELCs, Emphysema-like changes; *PSP,* primary spontaneous pneumothorax.

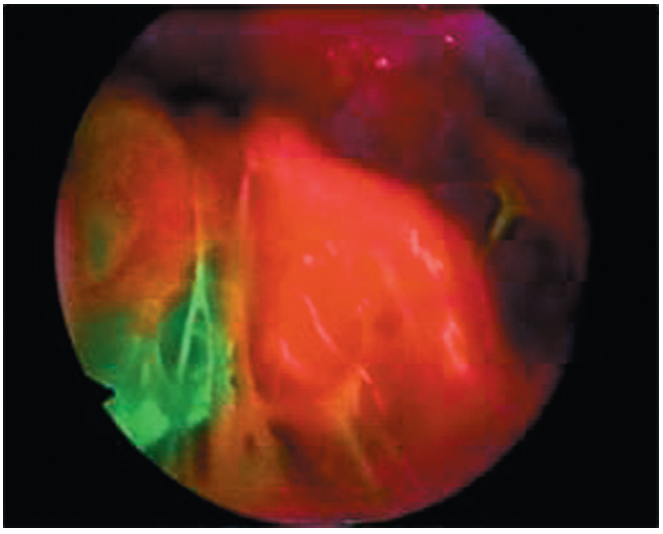
• **Fig. 45.1** Large bulla at the apex of the left lung in a 12-year-old boy with recurrent primary spontaneous pneumothorax. (From Noppen M, De Keukelieire T. Pneumothorax. *Respiration.* 2008;76:121–127.)



• **Fig. 45.2** Air leak identified by fluorescein-enhanced autofluorescence thoracoscopy in a 27-year-old man with recurrent primary spontaneous pneumothorax. The air leak was situated at the base of a highly vascularized, severe malformation of the apex of the lung. (From Noppen M, De Keukelieire T. Pneumothorax. *Respiration.* 2008;76:121–127.)

Pleural Porosity

ELCs are not the sole cause of PSP. Air leak has been described in areas where no ELCs are seen, leading to the concept known as "pleural porosity."[16,17] When evaluated with fluorescein-enhanced autofluorescence, areas of high-grade abnormality in the visceral pleura were frequently visualized separate from any area of abnormality seen with white light at thoracoscopy in patients with PSP. High-grade abnormalities were not seen in control patients.[18] Areas of fluorescein leak (i.e., areas of potential air leak) were visualized in only a small proportion of PSP, but these areas were noted to be distinct from areas of ELC. When studied with electron microscopy, the linings of some resected areas of ELC have been shown to be almost completely absent of mesothelial cells and have abnormal pores present[19] (Fig. 45.2).

Distal Airway Inflammation

Pathologic findings suggest an inflammatory cause to the formation of ELCs. Chronic distal airway inflammation with lymphocyte and macrophage infiltration alongside fibrotic changes and compensatory emphysema can be seen microscopically in areas of lung tissue from patients with PSP.[20] In a different study, the presence of respiratory bronchiolitis (RB) was seen in close to 90% of patients with PSP who underwent surgical resection in a different study.[21] However, all these patients in this study were smokers, and smoking is a recognized cause of RB. It has been proposed

that distal airway inflammation associated with PSP leads to obstructive gas trapping and consequent increases in distal airway pressure, which possibly causes air leak into the pleural space.[22]

Smoking

Cigarette smoking is a significant risk factor for PSP. It is thought to be due to the consequences of airway inflammation leading to airway obstruction with a check valve phenomenon, causing air trapping and development of pneumothorax.[22] The lifetime risk is 12% in smokers compared with 0.1% in nonsmokers. Risk is also directly related to the amount of cigarette smoking. Compared with nonsmokers, the relative risk of PSP in men was seven times higher in light smokers (1–12 cigarettes per day), 21 times higher in moderate smokers (13–22 cigarettes per day), and 102 times higher in heavy smokers (>22 cigarettes per day). For women, the relative risk was 4, 14, and 68 times higher in light, moderate, and heavy smokers, respectively.[23] Cessation of smoking appears to reduce the risk of recurrence,[9] and continued smoking increases the risk of recurrence.[24]

RB, a form of airway inflammation associated with cigarette smoking, may contribute to the development and recurrence of PSP. In a study with 115 patients with PSP who underwent video-assisted thoracoscopic surgery (VATS), pneumothorax recurrence rates were higher in patients with extensive rather than nonextensive RB for both nonoperative and postoperative pneumothorax.[25]

Genetics

Familial inheritance of pneumothorax describing the clustering of PSP in certain families has been published. Autosomal dominant, autosomal recessive, polygenic, and X-linked recessive inheritance mechanisms have been proposed.[26–28] Birt-Hogg-Dubé (BHD) syndrome is an autosomal dominant cancer disorder that predisposes patients to benign skin tumors and renal cancer. It is associated with pleuropulmonary blebs and cysts that lead to PSP.[29] In one study of 198 patients with this syndrome, 48 patients (24%) had a history of pneumothorax.[30] The gene responsible for this familial cancer syndrome *(FLCN)* has been mapped to chromosome 17p11.2.[31,32] Other mutations of *FLCN* have been associated with spontaneous pneumothorax and bullous lung disease in the absence of Birt-Hogg-Dubé syndrome.[33]

Patients with Marfan syndrome are tall, and pneumothorax is a common pulmonary complication. Marfan syndrome is caused by the mutation in *FBN1* gene on chromosome 15. This gene is responsible for the formation of 10- to 12-nm microfibrils in the extracellular matrix of connective tissue. It is hypothesized that familial spontaneous pneumothorax is caused by a connective tissue disorder that exhibits mendelian inheritance and *FBN1* has been postulated as the causative gene.[34]

Classification

Spontaneous Pneumothorax

Primary Spontaneous Pneumothorax

PSP is classically seen in previously healthy young men with an asthenic body habitus. The incidence of PSP rises with increasing height among adults of both sexes, more so in men. For those 76 inches or taller, the rate was 200 per 100,000 person-years.[35] It is hypothesized that individuals with tall stature and low body mass index combined with smoking are predisposed to develop ELCs owing to the pressure gradient between the lung base and the apex, resulting in increased alveolar distending pressures at the apex.[36] Smoking, as previously described, greatly increases the risk of PSP. Smoking increases the relative risk of developing spontaneous pneumothorax about 9-fold in women and 22-fold in men, and there is a statistically significant dose-response relationship between smoking and spontaneous pneumothorax.[37]

• BOX 45.1 Frequent and/or Typical Causes of Primary Spontaneous Pneumothorax

- Airway disease
  - Emphysema
  - Cystic fibrosis
  - Severe asthma
- Infectious lung disease
  - *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia
  - Tuberculosis
  - Necrotizing pneumonia
- Interstitial lung disease
  - Idiopathic pulmonary fibrosis
  - Sarcoidosis
  - Histiocytosis X (Langerhans cell histiocytosis)
  - Lymphangioleiomyomatosis
- Connective tissue disease
  - Rheumatoid arthritis, scleroderma, ankylosing spondylitis
  - Marfan syndrome
  - Ehlers-Danlos syndrome
- Malignant disease
  - Lung cancer
  - Sarcoma

From Noppen M, De Keukelieire T. Pneumothorax. Respiration. *2008;76:121–127.*

Secondary Spontaneous Pneumothorax

SSP has been described in a large variety of diseases, including COPD with emphysema, cystic fibrosis (CF), tuberculosis, lung cancer, human immunodeficiency virus (HIV)-associated *Pneumocystis jiroveci* pneumonia, followed by more rare but "typical" disorders such as lymphangioleiomyomatosis and histiocytosis X (Box 45.1). Because lung function in these patients is already compromised, SSP often presents as a potentially life-threatening disease requiring immediate action, as opposed to PSP, which is more of a nuisance than a dangerous condition. The general incidence is almost similar to that of PSP.[38]

Chronic Obstructive Pulmonary Disease

COPD is the most common cause of SSP, with nearly 70% of SSP attributed to COPD.[39] The peak incidence of SSP from COPD typically occurs later in life, averaging 60 to 65 years of age.[40] The clinical presentation of pneumothorax in COPD is often atypical—pain may be absent, anxiety and breathlessness may predominate and be out of proportion to the collapsed lung, and the classic sign of hyperresonance may not be helpful because of the underlying emphysema. The air leak in these patients is usually large, and the tissues are slow to heal, so it is weeks before the tubes can be removed.[41]

Pneumothorax in Drug Abusers

When the peripheral veins of chronic abusers of drugs become obliterated because of a sclerotic or infectious process, the individual

may attempt to use larger veins in the groin or neck. Attempted subclavian or supraclavicular ("pocket shot") injection of drugs in the street setting has led to unilateral or bilateral pneumothoraces.[42–44] Douglas and Levison[45] found that the incidence of pneumothoraces is equal in both sexes and that it is less of a problem in teenagers and in addicts older than 40 years of age. It was also noted that although most drug users describe using small (21- or 22-gauge) needles, a large, complete, or tension pneumothorax usually develops.

Pneumothorax in HIV-Infected Patients

Pneumothorax is an uncommon but potentially fatal complication of HIV infection. The first report of spontaneous pneumothorax in patients with AIDS was in 1984.[46] With the diagnosis of AIDS, a patient's risk of sustaining a nontraumatic pneumothorax increases to 450 times that of the general population.[47] It has since been described in a generalized HIV-infected population.[48,49] Pneumothorax complicated 1.2% of all hospital admissions in a cohort of 599 HIV-infected patients with follow-up over 3 years in a prospective observational study. There was also an associated increase in in-hospital mortality rate (31% vs. 6%) for patients without pneumothorax.[48]

A high incidence (2%–9%) of pneumothorax has been reported in patients with AIDS and *Pneumocystis carinii* pneumonia (PCP).[50–52] *P. carinii,* which was thought to be a protozoan, has been renamed as *Pneumocystis jiroveci* and is now classified as an archiascomycetous fungus.[53] Causes of pneumothorax in HIV-infected individuals include *P. jiroveci*[54–57] along with other infectious agents such as *Mycobacterium tuberculosis, Mycobacterium avium intracellulare,* pulmonary cytomegalovirus, *Pneumococcus* organisms,[54] or pulmonary toxoplasmosis.[54] Pneumothorax has also been described in HIV-infected individuals from Kaposi sarcoma.[58]

The cause of pneumothorax in patients with PCP is unclear. Several investigators believe that extensive tissue invasion within the alveolar interstitium in severe PCP is an important factor in causing necrosis and subsequent pneumothorax. Several observations highlight this point. The most common sites of tissue invasion with PCP are the alveolar septa, pleurae, and vasculature.[59] Tissue invasion could cause necrosis as a result of direct tissue injury by toxins from *Pneumocystis,*[59] infarction from vascular compromise,[60,61] or as a result of the host inflammatory response.[62]

The administration of aerosolized pentamidine has been implicated in the pathogenesis of cavitation, cyst formation, and pneumothorax,[50,63,64] but the biologic basis for this relationship is unknown. No direct toxic action of pentamidine on the lungs has been described, so an indirect effect may be present. Cavitation owing to PCP may occur primarily in the upper lobes and periphery because aerosolized pentamidine is preferentially delivered to the proximal parenchyma of the lower lobes. Inadequate deposition of pentamidine in the periphery of the lung could allow a chronic, low-grade infection with *Pneumocystis* to persist, leading to peripheral lung destruction and pneumatocele formation. Increased survival time of patients with AIDS owing to prophylaxis could allow for development of these lesions.[50]

Several other risk factors for AIDS-related pneumothorax have been identified. In addition to previous or active infection of *P. jiroveci* and aerosolized pentamidine, cigarette smoking and the presence of pneumatoceles on chest radiograph are risk factors.[65] The association between cigarette smoking and AIDS-related pneumothorax could be explained by subclinical obstructive disease preventing adequate deposition of aerosolized pentamidine in the lung periphery, resulting in subpleural *Pneumocystis* infection.[65] Pulmonary tuberculosis also appears to increase the risk of pneumothorax in AIDS.[66]

Catamenial Pneumothorax

In most cases, catamenial pneumothorax is related to pelvic or thoracic endometriosis.[67,68] Catamenial pneumothorax occurs typically within 24 to 72 hours after onset of menstruation. It is often recurrent and more common than previously thought. Two mechanisms have been described for pneumothorax related to endometriosis. The most common is the movement of endometrial implants to the diaphragm, preferentially to the right side because of the recognized peritoneal circulation up from the pelvis to the right side. These implants then create channels or "holes" through the diaphragm that allow the implants or air to move into the chest. The second and much less frequent cause of endometrial implants causing pneumothorax in the chest is through the venous implants that lodge into the lung itself.[69] Clinical manifestations of thoracic endometriosis include chest pain, dyspnea, and hemoptysis. Treatment for the prevention of recurrence is indicated after a first episode of catamenial pneumothorax because recurrences are frequent.[38]

Cystic Fibrosis

SSP occurs in approximately 6% of all patients with CF and this number increases to 16% to 20% among those who survive to 18 years of age.[70,71] SSP from CF is usually due to rupture of apical subpleural cysts. The risk of pneumothorax is inversely proportional to the forced expiratory volume in 1 second (FEV_1). Other factors associated with an increased risk of pneumothorax include infection with *Pseudomonas aeruginosa, Burkholderia cepacia* complex, or *Aspergillus* spp. A previous history of massive hemoptysis also increases risk.

Nonspontaneous Pneumothorax

Traumatic Pneumothorax

Pneumothorax ranks second to rib fractures as the most common sign of chest trauma. It occurs in up to 50% of chest trauma victims.[72] Most pneumothoraces are caused by a penetrating injury, but closed chest trauma causing alveolar rupture from thoracic compression, fracture of a bronchus, and esophageal rupture have also been reported.[73,74] Traumatic pneumothorax can be classified as open, closed, tension, or hemopneumothorax. A tension pneumothorax should be managed immediately by decompression with a large-bore needle, usually in the second anterior interspace in the midclavicular line. Open pneumothorax should have a moist sterile gauze pack placed over the open wound, followed by a chest tube. Hemopneumothorax (20% of trauma patients) requires insertion of a large-bore (28F–36F) chest tube.[38]

Occult pneumothorax may be present in half of patients with blunt abdominal trauma, and in many patients the pneumothorax is undetected by chest radiograph.[75–79] CT of the chest should therefore always be performed in these patients. Most surgeons and emergency physicians will place a chest tube in occult and nonoccult pneumothoraces. Studies suggest, however, that clinically stable patients and those who do not have an enlarging pneumothorax may be treated conservatively, ultimately requiring chest tube placement in about 10% of cases.[80]

Traumatic Iatrogenic Pneumothorax

Iatrogenic pneumothorax occurs most often after transthoracic needle biopsy (24%), subclavian vein catheterization (22%),

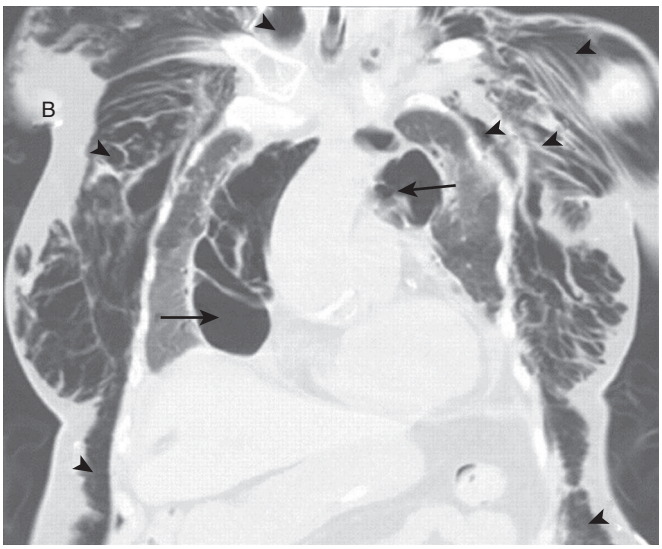
thoracentesis (20%), transbronchial lung biopsy (10%), pleural biopsy (8%), and positive-pressure ventilation (7%).[81] Diagnosis of iatrogenic pneumothorax is often delayed. Small and asymptomatic iatrogenic pneumothoraces, however, often do not need any treatment and resolve spontaneously. In larger or symptomatic pneumothoraces, simple manual aspiration or placement of a small catheter or chest tube attached to a Heimlich valve is usually sufficient.[82] Larger tubes may be necessary in patients with emphysema or when mechanical ventilation begins.

Pulmonary Barotrauma During Mechanical Ventilation

Pulmonary barotrauma (PBT) refers to alveolar rupture owing to elevated transalveolar pressure (the alveolar pressure minus the pressure in the adjacent interstitial space). PBT was previously estimated to range between 3.8% and 41.7% of patients undergoing mechanical ventilation.[83] The rate in actuality may be lower because low tidal volume ventilation is becoming more common. Consequences of barotrauma include pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous emphysema.

Positive-pressure ventilation increases transalveolar pressure, which can cause alveolar rupture.[84] Alveolar rupture allows air from the alveolus to enter the pulmonary interstitium where it can dissect along the perivascular sheaths toward the mediastinum. This can lead to pneumothorax, pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema[85,86] (Fig. 45.3). Bronchopleural fistula, tension pneumothorax, tension lung cyst, and subpleural air cyst have also been reported but are less common.[87]

In a multicenter prospective cohort study of 5183 mechanically ventilated patients, the incidence of PBT was 3%.[88] Asthma, chronic interstitial lung disease, and acute respiratory distress syndrome (ARDS) were identified as independent risk factors for barotrauma. Other studies have also demonstrated that acute lung injury and ARDS are independent risk factors for PBT.[89,90] Elevated peak and plateau pressures have been identified as risk factors.[91,92]



• **Fig. 45.3** Chest computed tomography revealing extensive subcutaneous emphysema *(arrowheads)* from the lower neck to the upper abdomen and pneumomediastinum *(arrows).* (From Lai JI, Po-Chou L, Wang WS, et al. Barotrauma related extensive pneumothorax, pneumomediastinum, and subcutaneous emphysema in a patient with acute respiratory distress syndrome with low tidal volume. *Postgrad Med J.* 2010;86:567–568.)

Neither open lung strategies using high levels of positive end-expiratory pressure (PEEP) nor recruitment maneuvers have been shown to increase the risk of barotrauma.[93,94]

Clinical Presentation

The clinical presentation of PBT can vary. With pneumothorax, patients may complain of dyspnea or chest pain. Physical findings can include tachycardia, tachypnea, hypertension, or oxyhemoglobin saturation accompanied by unilateral reduction of breath sounds. If a tension pneumothorax develops, there may be hypotension and tracheal deviation. As a general rule, in young male patients with a history of asthma, drug use, forceful cough, or intense physical activity who present with dyspnea, chest pain, and/or subcutaneous cervical emphysema, a high suspicion of spontaneous pneumomediastinum should be entertained until proved otherwise.[95] Patients with pneumomediastinum may complain of dyspnea and chest or neck pain. Other findings include tachycardia, tachypnea, and hypertension. A crunching sound may be heard during auscultation. Rarely, hypotension from decreased venous return and cardiac output may occur if tension pneumomediastinum develops.[96] Pneumoperitoneum may manifest itself as abdominal pain. Other physical findings include abdominal distention, tenderness, and tympany. Rarely, abdominal compartment syndrome may develop if the pneumoperitoneum progresses to a tension pneumoperitoneum.[97] Subcutaneous emphysema generally presents as painless soft tissue swelling. It typically appears in the upper chest, neck, and face. Compression of the affected areas can reveal crepitus. A rare consequence of severe subcutaneous emphysema is compartment syndrome.[98]

Diagnosis

The diagnosis of pneumothorax is suspected when a patient presents with the symptoms and signs described earlier and then confirmed with a portable chest radiograph. An upright chest radiograph has the highest diagnostic yield for pneumothorax, although diagnosis in the intensive care unit (ICU) may be difficult as most patients are semirecumbent or supine.[99] The difficulty in detection of a pneumothorax in a supine position in the ICU or after trauma is due to several factors. There are limitations in patient mobilization and positioning owing to overlying support apparatus and patient body habitus. Limitations in technique with portable chest x-rays often cause underexposed or overexposed images. The distribution of free air in the pleural space is highly variable and dependent on the patient's position, anatomy, and associated pathology in the lung parenchyma and pleural space. The imaging findings of pneumothorax in the supine position are frequently subtle, requiring expertise and a heightened degree of suspicion.[100]

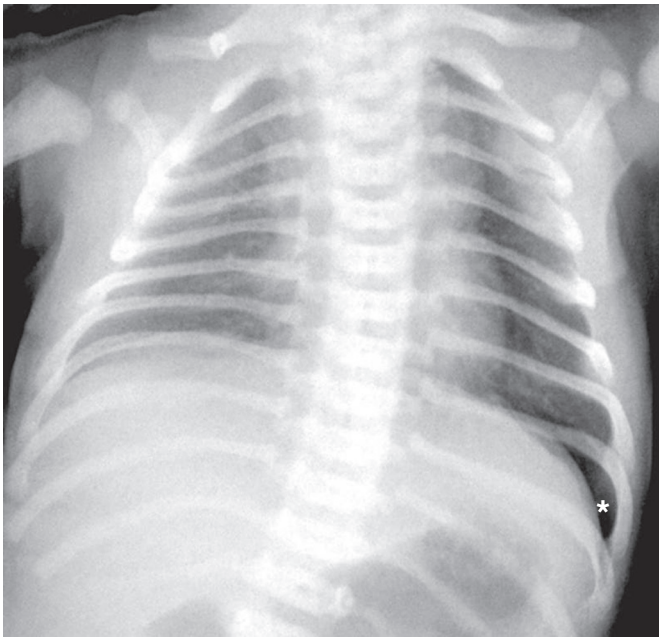
In a fully upright chest radiograph, a pneumothorax appears as a radiolucent collection between the visceral and parietal pleurae in the superior portion of the chest. In contrast, when a patient is supine, free air collects in the anterior chest, displacing the costophrenic angle inferiorly, often creating a "deep sulcus" sign. The deep sulcus sign refers to a unilateral increase in the apparent size of the costophrenic angle (Fig. 45.4).

Bedside ultrasound is being used more readily in the ICU to rapidly diagnose pneumothorax. Using the M-mode, the absence of "lung sliding" is indicative of the presence of a pneumothorax.[101]

Meta-analysis of studies using ultrasound to diagnose pneumothoraces has shown that the sensitivity and specificity of ultrasound in detecting pneumothorax are approximately 88% to 91% and 98% to 99%, respectively. These studies evaluated the use of ultrasound in diagnosing pneumothorax in critically ill and trauma patients.[102]

Tension pneumothorax is diagnosed clinically when a patient presents with unilateral absence of breath sounds, a shift of the trachea in the direction away from the absent breath sounds, and hemodynamic compromise in the appropriate setting. Immediate intervention is indicated as there is seldom time for a radiographic evaluation. Rapid clinical improvement after empiric aspiration of a suspected tension pneumothorax is diagnostically definitive. Subsequently, a tube thoracostomy is placed for ongoing management.

Pneumomediastinum frequently coexists with pneumothorax. It is usually diagnosed with a portable chest radiograph. It typically appears as radiolucent streaks in the mediastinum (Fig. 45.5).



• **Fig. 45.4** Supine chest radiograph of a neonate illustrates the deep sulcus sign with abnormal deepening and lucency of the left lateral costophrenic angle *(asterisk)*. (From Kong A. The deep sulcus sign. *Radiology.* 2003;228:415–416.)

Pneumoperitoneum is diagnosed with a chest radiograph less than one-third of the time. A suspected pneumoperitoneum is best evaluated by chest CT.[103] The patient should remain in position for 5 to 10 minutes before the radiograph is taken. This allows time for air to collect in a sufficient volume to be detected radiographically. Pneumoperitoneum may be identified on a supine abdominal radiograph (see Fig. 45.5). Free air accumulates anteriorly when the patient is supine and on a chest or abdominal radiograph may present in several ways. Gas appearing on both sides of the bowel wall is referred to as Rigler sign. Gas outlining the peritoneal cavity is known as the football sign. Gas outlining the medial umbilical folds is called an inverted V sign. Gas may also outline the falciform ligament or localize in the right upper quadrant.[104]

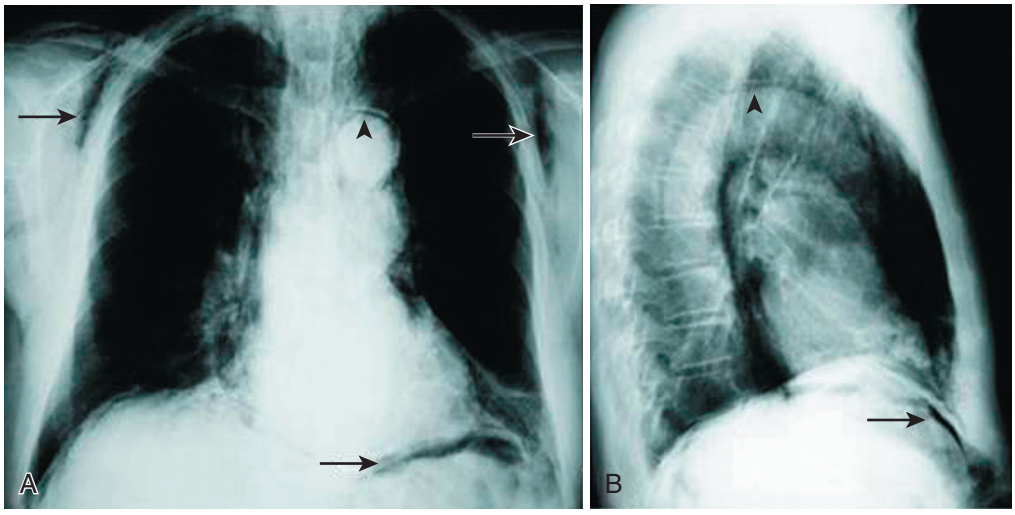
Subcutaneous emphysema is often found by identifying crepitus during physical examination. On chest radiograph of areas of tissue swelling, it can appear as radiolucent streaks throughout the subcutaneous tissue and muscle (see Fig. 45.5).

Prevention

To prevent barotrauma, it is generally recommended that plateau airway pressure be maintained at or below 35 cm H_2O. Plateau pressure is the most indicative of the alveolar pressure and therefore is the measure of greatest concern for the prevention of PBT. Lower plateau airway pressures have been associated with a lower incidence of PBT. A threshold pressure appears to exist at 35 cm H_2O, above which there is a higher incidence of barotrauma. A meta-analysis of 14 clinical trials demonstrated a strong relationship between PBT and a plateau airway pressure greater than 35 cm H_2O or a static compliance less than 30 mL per cm H_2O.[105] There have not been direct comparisons between management targeting a plateau airway pressure or peak airway pressure. Peak airway pressure is likely a less reliable predictor of PBT given the conflicting data.[106–112]

Management

The best treatment for PBT is early recognition, and immediate attempts should be made to reduce plateau airway pressure.[83] This may require lowering the tidal volume or PEEP, as well as increasing sedation, administering neuromuscular blockade, or advancing



• **Fig. 45.5** Chest radiographs revealing the presence of subcutaneous emphysema, pneumomediastinum, and pneumoperitoneum *(arrows)*. (From Alexiou K, Sakellaridis T, Sikalias N, et al. Subcutaneous emphysema, pneumomediastinum and pneumoperitoneum after unsuccessful ERCP: a case report. *Cases J.* 2009;2:120.)

treatment of the underlying condition. In cases of pneumothorax when patients are supported by a mechanical ventilator, there is no high-quality evidence that supports routine insertion of chest tubes for all patients. However, more than 30% of pneumothoraces in mechanically ventilated patients progress to tension pneumothoraces, indicating that these patients must be monitored closely. Treatment for mechanically ventilated patients in whom pneumomediastinum, pneumoperitoneum, or subcutaneous emphysema develops is generally supportive unless there is evidence of tension pneumomediastinum or compartment syndrome from pneumoperitoneum or subcutaneous emphysema.[96]

Prognosis

PBT appears to be associated with increased mortality rate, even though barotrauma is not a direct cause of death in most patients. In a multicenter prospective cohort study, patients with barotrauma had a significantly higher mortality rate (51% vs. 39%), a longer length of ICU stay (median 9 vs. 7 days), and a longer duration of mechanical ventilation (median 6 vs. 4 days) than patients without barotrauma.[88] Mortality rate may be related to the severity of the PBT. In one retrospective cohort study of 1700 mechanically ventilated patients, the mortality rate approached 100% when PBT caused a large (>500 mL per breath) bronchopleural fistula.[112] High-frequency jet ventilation is approved by the U.S. Food and Drug Administration (FDA) for the management of large bronchopleural fistulas, but this may be outweighed in some patients by increased plateau airway pressure (alveolar pressure), decreased oxygenation, or worse hypercapnia.[113]

Pneumothorax After Fiberoptic Bronchoscopy and Needle Biopsy of the Lung

Multiple literature reviews have documented the relative safety of fiberoptic bronchoscopy (FOB) with transbronchial biopsy. One review of more than 9000 such procedures found that the rate of pneumothorax was 1.9%.[114] An immediate postbronchoscopic chest radiograph rarely provides clinically useful information, and in FOB without transbronchial biopsy an immediate postbronchoscopy radiograph is not necessary.[115,116] Another study in 2006 concluded that in asymptomatic patients, routine radiograph after transbronchial biopsy is not necessary.[117] It was determined that certain patient populations should have routine radiographs performed after FOB with transbronchial biopsy: comatose or mentally retarded patients, patients receiving positive-pressure ventilation, patients with severe respiratory compromise as a result of disease or surgery, patients with bullous disease, patients who complain of chest pain, and outpatients. Pneumothorax after bronchoalveolar lavage without biopsy is extremely rare. The complication of pneumothorax after transbronchial needle aspiration is also low.[118]

Pneumothorax is the most common complication of needle aspiration or biopsy of the lung. It has been reported to occur in 17% to 26.6% of patients.[119–122] The chest tube insertion rate is much lower, ranging from 1% to 14.2%.[119–122] Risk factors for the development of biopsy-related pneumothorax include the presence of COPD, the absence of a history of ipsilateral surgery, small lesion size, a long needle path, and repeated pleural puncture.[119–124] Enlarging or symptomatic pneumothorax can be managed by manual aspiration or placement of a small-caliber chest tube.[123]

Delayed pneumothorax after percutaneous fine-needle aspiration has been reported. A study by Choi and colleagues[125] reported on their series of 458 patients who had undergone transthoracic needle biopsy. A follow-up chest radiograph was obtained immediately and at 3, 8, and 24 hours after the biopsy procedure. A pneumothorax that developed after 3 hours was defined as delayed pneumothorax. Pneumothorax developed in 100 of the 458 patients (21.8%), and delayed pneumothorax developed in 15 patients (3.3%). Female gender and absence of emphysematous changes correlated with an increased rate of delayed pneumothorax.

Pneumothorax After Thoracentesis

According to a 1998 National Center for Health Statistics study,[126] physicians perform an estimated 173,000 thoracenteses annually in the United States. Iatrogenic pneumothoraces resulting from thoracentesis increase the morbidity rate, mortality rate, and length of hospitalization. Previous reports indicated chest tube insertion may be required in up to 50% of cases with a mean duration of placement of approximately 4 days.[127,128] Gordon and colleagues[129] performed a systematic review and meta-analysis of 24 studies reporting pneumothorax rates after thoracentesis involving 6605 thoracenteses. The overall pneumothorax rate was 6%. In cases in which pneumothorax developed, 34.1% required chest tube placement. Statistically significant risk factors for developing thoracentesis included performing thoracentesis as a therapeutic procedure as opposed to as a diagnostic procedure; the presence of cough, dyspnea, or chest pain during the procedure; and witnessing the aspiration of air during the procedure.[129] Although not statistically significant, other possible predictors included the need for two or more needle insertions and concurrent mechanical ventilation.[129] Ultrasonography guidance,[130–132] more experienced operators,[133] and fewer needle passes conferred lower complication rates,[134] which paralleled findings from central venous catheter insertion studies. Various mechanisms may explain the pneumothoraces that occur after thoracentesis; the lung may be punctured at the time of needle entry or after the fluid has been withdrawn, or a small amount of air may be drawn into the chest during aspiration or along the needle track if high negative intrapleural pressure develops.[135]

Pneumothorax Resulting From Nasogastric Feeding Tubes

Small-bore Silastic (Dow Corning, Midland, MI) feeding tubes are being used with increasing frequency for short- and long-term enteral hyperalimentation. The first reported case of pneumothorax as a complication of passing a narrow-bore feeding tube was in 1978.[136] This once rare complication has now become more common.[137–139] Narrow-bore feeding tubes are particularly likely to give rise to pneumothorax because of the tube's small diameter (2.7 mm), self-lubricating properties, and wire stylet. These factors allow undetected entry of the tube into the tracheobronchial tree, perforation of pulmonary tissue, and lodging in the pleural cavity.[140] Other factors that increase the risk of a misplaced feeding tube include the presence of an endotracheal or tracheostomy tube (these may increase pulmonary passage of the tube by preventing glottis closure and perhaps by inhibiting swallowing), altered mental status, denervation of airways, esophageal stricture, enlargement of the heart, and neuromuscular weakness.[141] The clinical signs commonly used to determine correct placement of the feeding tube may be misleading. Normally, to confirm the correct placement of a feeding tube in the stomach, a small amount of air is injected. This produces a characteristic gurgle in the left upper quadrant of the abdomen, but a "pseudoconfirmatory gurgle" with a feeding tube in the chest has been reported.[142] Aspiration of large amounts of fluid through the tube is also taken to be a test of correct placement into the stomach, but delayed aspiration of a large

quantity of undigested feeding solution from the pleural space, mistaken for gastric contents, has been reported.[143]

Pneumothorax After Percutaneous Dilational Tracheostomy

Percutaneous dilational tracheostomy was first described in 1985 by Ciaglia and colleagues.[144] A case series described subcutaneous emphysema and pneumothorax as complications after percutaneous tracheostomy in a series of 326 cases.[145] Their review of the literature showed that the incidence of subcutaneous emphysema was 1.4% and that of pneumothorax was 0.8%. Findings associated with pneumothorax included difficult percutaneous dilational tracheostomy and the use of a fenestrated cannula.

Special Situations

Pneumothorax Ex Vacuo

Pneumothorax after partial resolution of total bronchial obstruction,[146] as a complication of lobar collapse,[147] and after therapeutic thoracentesis for malignant effusions[148] has been described. Acute lobar collapse results in a sudden increase in negative pleural pressure surrounding the collapsed lobe. Although the parietal and visceral pleural surfaces remain intact, the gas originating from the ambient tissues and blood is drawn into the pleural space, producing a pneumothorax called *pneumothorax ex vacuo*. Recognition of this type of pneumothorax is crucial because managing it requires relieving the bronchial obstruction rather than inserting a chest tube. The diagnosis of trapped lung requires documentation of chronicity and absence of pleural inflammation, pleural malignancy, or endobronchial lesion. The pathognomonic radiographic sign of a trapped lung is the pneumothorax ex vacuo, characterized as a small to moderate-sized air collection after evacuation of effusion.[149]

Sport-Related Pneumothorax

Pneumothorax as a result of blunt trauma from contact sports is a recognized but underreported event. Several cases of pneumothorax or pneumomediastinum sustained during a contact sport have been described in the literature.[150,151] In a large case series, Kizer and MacQuarrie[152] identified 20 patients who had sustained a spontaneous or traumatic air leak while engaged in an outdoor sport.

Barotrauma Unrelated to Mechanical Ventilation

Although the term *barotrauma* has traditionally been used to describe the development of extraalveolar air during mechanical ventilation, in other instances it may be due to increased intraalveolar pressure, causing air to leak out of the alveoli. PBT of ascent is a well-known complication of compressed air diving. Pulmonary edema and hemorrhage occur when lung volume decreases below residual volume. As a diver ascends and transalveolar pressure exceeds 20 to 80 mm Hg, overexpansion injury in the form of alveolar rupture can occur.[153–155] Divers who hold their breath as they ascend and those with obstructive airway diseases, such as asthma or COPD, are at increased risk.[156]

Pneumothorax is a relatively uncommon complication in divers, developing in only approximately 10% of those with evidence of barotrauma. Patients with a history of spontaneous pneumothorax, bullae, or cystic lung disease are at increased risk of pneumothorax and should be cautioned against diving.[157]

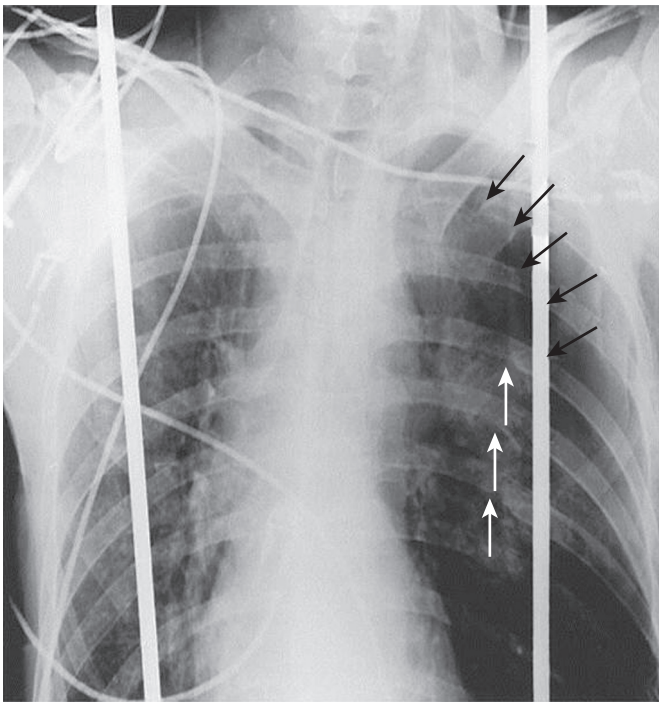
Pneumothorax develops when gas ruptures from the lung parenchyma into the pleural space. If this occurs at a significant depth, the pleural gas expands as the diver ascends (as described by Boyle's law) and can result in a tension pneumothorax. Manifestations include dyspnea, chest pain, tachycardia, hypotension, cyanosis, distended neck veins, tracheal deviation, hyperresonance to percussion, unilateral decrease in breath sounds, and accompanying subcutaneous emphysema in approximately 25% of cases.

If a pneumothorax results in severe hypoxemia or hemodynamic compromise, immediate pleural decompression is required. This is usually accomplished by inserting a large-bore needle into the second intercostal space in the midclavicular line of the affected hemithorax, followed by tube thoracostomy.

Tension Pneumothorax

With a tension pneumothorax, the pleural pressure in the affected hemithorax exceeds atmospheric pressure, specifically during expiration. This is usually the result of a check valve mechanism that facilitates the ingress of gas into the pleural space during inspiration but blocks the escape of gas from the pleural space during expiration. The results are the accumulation of gas leading to a buildup of pressure within the pleural space. There is eventual respiratory failure from compression of the contralateral normal lung followed by circulatory collapse with hypotension and subsequent traumatic arrest with pulseless electrical activity (PEA) due to obstruction of venous return to the heart.

The classic signs of a tension pneumothorax are deviation of the trachea away from the side with the tension, an increased percussion note, and a hyperexpanded chest that moves little with respiration. Radiographically, tension pneumothorax shows a distinct shift of the mediastinum to the contralateral side and flattening or inversion of the ipsilateral hemidiaphragm (Fig. 45.6). Clinically unstable patients should undergo immediate needle decompression



• **Fig. 45.6** Chest radiograph showing the collapsed visceral pleural line of left tension pneumothorax *(black arrows)* in a trauma patient. Note the mediastinal shift to the right, widened rib spacing, and posterior rib fractures on the left *(white arrows)*. A flattening of the left hemidiaphragm is also present (not shown). (From Barton E. Tension pneumothorax. *Curr Opin Pulm Med.* 1999;5:269–274.)

followed by chest tube insertion. Decompression is performed by advancing a standard 14- or 16-gauge intravenous catheter into the pleural space at the junction of the midclavicular line and the second or third intercostal space. The needle is advanced until air can be aspirated into a syringe connected to the needle. The needle is withdrawn and the cannula is left open to air. An immediate rush of air out of the chest indicates the presence of a tension pneumothorax. The maneuver essentially converts a tension pneumothorax into a simple pneumothorax. A chest tube can then be placed.

Clinical Features

PSP usually occurs when the patient is at rest.[158] Patients are typically in their early 20s when presenting with PSP, which is rare after age 40. Chest pain and dyspnea are the two main symptoms associated with the development of pneumothorax. One series evaluated 39 patients who presented with one of the two symptoms and 64% of them had both.[159] The pain is generally reported as ipsilateral, which usually resolves spontaneously within 24 hours.[40] The degree of dyspnea depends on the size of the pneumothorax and the condition of the underlying lung. Cough, malaise, orthopnea, and hemoptysis may also be presenting symptoms.

Physical examination can be normal in small pneumothoraces. Possible physical findings when a large pneumothorax is present include decreased chest excursion on the affected side, diminished breath sounds, and hyperresonant percussion. There may also be subcutaneous emphysema. Labored breathing accompanied by hemodynamic compromise (tachycardia or hypotension) suggests a possible tension pneumothorax, which necessitates emergency decompression. Tension pneumothorax occurs owing to the presence of a ball-valve mechanism; air enters the pleural cavity but cannot escape. As a result, positive pressure builds up. As the tension continues to increase, the diaphragm is flattened, the mediastinum is shifted to the opposite side, and ultimately cardiopulmonary collapse results.

Hypoxemia is common because collapsed and poorly ventilated portions of lung continue to receive significant perfusion. However, hypercapnia is unusual because underlying lung function is relatively normal and adequate alveolar ventilation can be maintained by the contralateral lung.[160] Acute respiratory alkalosis may be present if pain, anxiety, or hypoxia is substantial.

In certain situations, the symptoms of pneumothorax may have an atypical presentation and therefore require a high index of suspicion. During a transbronchial biopsy, a patient may complain of pleuritic chest pain followed by dyspnea. A pneumothorax after a subclavian vein catheterization may present with progressive dyspnea and an alteration of vital signs. In a mechanically ventilated patient, the initial presentation may include hypotension, new-onset respiratory distress, unilateral decrease in breath sounds, a decrease in static and dynamic compliance, and worsening oxygenation.[41,161,162]

Simultaneous bilateral pneumothoraces is a rare condition because, in humans, the left and right pleural spaces are completely separated. Patients can develop a persistent pleuro-pleuro channel after undergoing a median sternotomy, mediastinal surgery, or heart or heart-lung transplant surgery. This condition has been dubbed "iatrogenic buffalo chest" because the North American buffalo is one of few mammals that have communicating pleural spaces.[163] A unilateral thoracic procedure in this situation has been described to cause bilateral pneumothoraces[164,165] and "shifting pneumothorax."[166] Simultaneous bilateral spontaneous pneumothorax (SBSP) has been described in a case series with 12 patients.[167] Of the 12 patients, 5 had no underlying lung disease. In 7 patients, simultaneous bilateral spontaneous pneumothorax was secondary to pulmonary metastases, histiocytosis, undefined interstitial pulmonary disease, tuberculosis, pneumonia, and COPD.

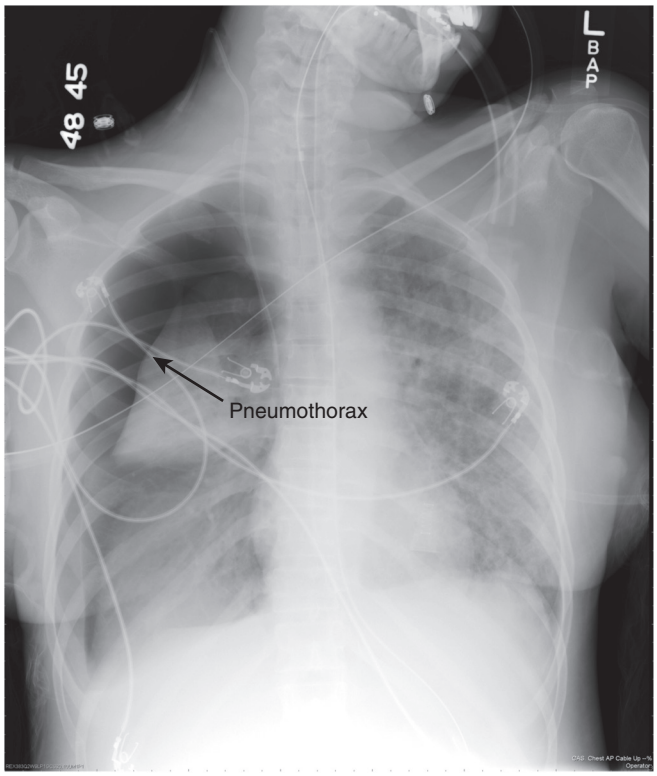
Electrocardiographic Features

The presence of a pneumothorax may lead to distinct electrocardiographic changes, which can be mistaken for myocardial ischemia or infarction. Most findings have been described for left-sided pneumothorax. Poor R-wave progression in the anterior precordial leads with a decrease in R wave from V_4 to V_5, rightward shift of frontal axis, diminution of precordial R voltage, decrease in QRS amplitude, and precordial T-wave inversion have all been described.[168–170] The absence of ST-segment elevation and a significant Q wave and reversal of electrocardiographic changes in the sitting position suggest pneumothorax. In right-sided pneumothorax, there is a loss of S wave in lead V_2 and prominent R-wave voltage, which may mimic posterior wall myocardial infarction.[171]

Diagnostic Imaging Modalities

Radiographic Signs

Chest radiography and CT are the first-line imaging modalities used to identify a pneumothorax. The main feature of a pneumothorax on a chest radiograph is a white visceral pleural line. This line separates the visceral pleura from the parietal pleura by a collection of gas (Fig. 45.7). A pneumothorax may be identified using an upright, supine, or lateral decubitus chest radiograph.



• **Fig. 45.7** Radiograph of right lung pneumothorax. The *arrow* points to the collapsed lung.

The lateral decubitus view is the most sensitive, and the supine view is the least sensitive.

Upright Chest Radiograph

In an upright patient with a pneumothorax, most pleural gas accumulates in an apicolateral location. The visceral pleural line appears either straight or convex toward the chest wall. As little as 50 mL of pleural gas may be seen on a chest radiograph.[172] Although there is generally a loss of lung volume with a pneumothorax, the collapsed lung preserves its translucency because hypoxic vasoconstriction diminishes the blood flow to the collapsed lung. The value of obtaining an expiratory chest radiograph has been overstated. Inspiratory and expiratory upright chest radiographs detected pneumothorax with equal sensitivity.[173]

Supine Chest Radiograph

In a supine patient with a pneumothorax, most pleural gas accumulates in a subpulmonary location. A deep sulcus sign occurs when gas outlines the anterior pleural reflection, the costophrenic sulcus, and the anterolateral border of the mediastinum (see Fig. 45.4). Rarely, pleural gas can accumulate in the phrenicovertebral sulcus. The visceral pleural line may be seen at the lung base and has a concave contour. Around 500 mL of pleural gas is needed to definitively diagnose pneumothorax on a supine chest radiograph.[172]

Lateral Decubitus Chest Radiograph

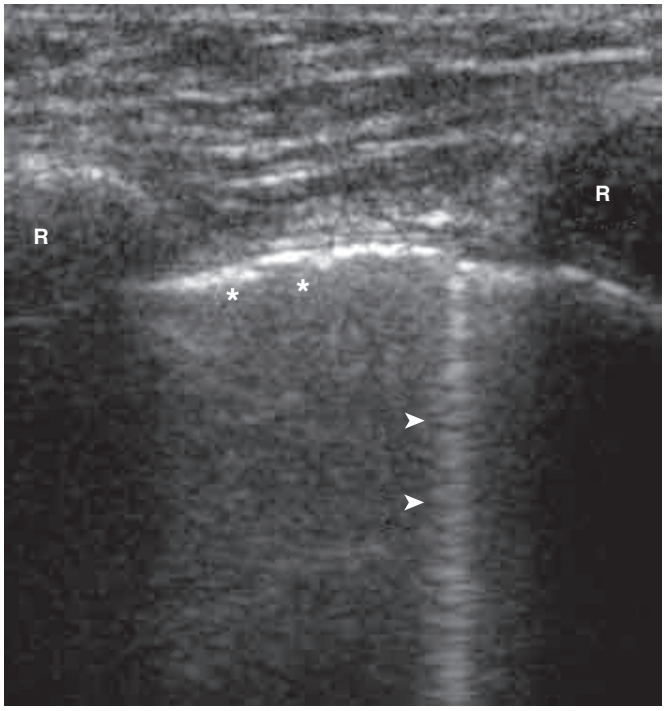
A pneumothorax is most easily detected with a lateral decubitus view. Most pleural gas in this position accumulates in the nondependent lateral location. The visceral pleural line appears as a straight or convex line toward the chest wall. As little as 5 mL of pleural gas may be visible on a lateral decubitus view.[172]

Computed Tomography

CT scanning is the most accurate imaging modality for the detection of pneumothorax although it is generally not the initial option. This method can identify small amounts of intrapleural gas, atypical collections of pleural gas, and loculated pneumothoraces. Complex pleural disease such as pleural effusion and cystic lung disease is optimally displayed by CT scanning.[174]

Pulmonary Ultrasonography

Ultrasound was first used to detect pneumothorax in a horse in 1986 and then in humans shortly thereafter.[175] In a normal lung, the visceral and parietal pleurae are adjacent, and ultrasound shows shimmering or sliding at the pleural interface during respiration.[176] The absence of lung sliding indicates a pneumothorax. Comet tails are an ultrasound artifact that arises when ultrasound encounters a small air-fluid interface (Fig. 45.8). The presence of sliding lung and comet tail artifacts appear to reliably rule out pneumothorax. The presence of a "lung point" sign is nearly 100% specific for the detection of pneumothorax. Here the visceral pleura is seen to be intermittently coming into contact with the chest wall during inspiration. The lung point sign may also be helpful in determining the actual size of the pneumothorax (Fig. 45.9). A review of four prospective studies found the sensitivity and specificity of ultrasound for pneumothorax to range from 86% to 98%, which was superior to supine chest radiography (sensitivity 28%–75%).[177] A small pneumothorax may be missed with ultrasound, and patients with blebs or scarring may have a false-positive finding.[178]



• **Fig. 45.8** Rib shadows *(R)* are visible as bright reflectors with distal shadow. The pleura *(double asterisks)* is a bright echogenic line beneath the ribs. Comet tail artifacts *(arrowheads)* arise from normal pleura reflecting sound waves. (From Mt. Sinai Emergency Ultrasound Division Tutorials. Pneumothorax. Available at http://sinaiem.us/tutorials/pneumothorax.)

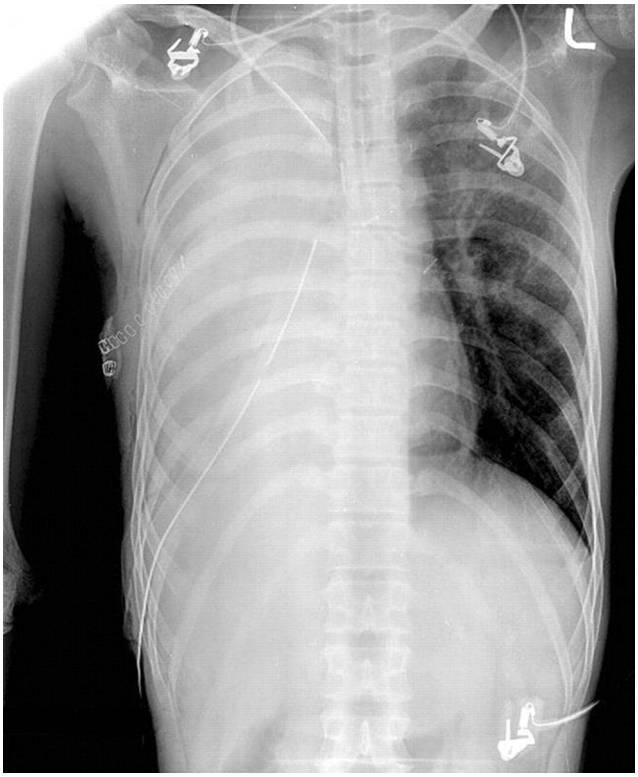
Differential Diagnosis: Conditions Mimicking Pneumothorax

Large subpleural bullae can mimic a loculated pneumothorax. Bullae can be distinguished from pneumothorax owing to the fact that only bullae typically have a medial border that is concave to



• **Fig. 45.10** Reexpansion pulmonary edema. (From Tung YW, Lin F, Yang MS, et al. Bilateral developing reexpansion pulmonary edema treated with extracorporeal membrane oxygenation. *Ann Thorac Surg.* 2010;89:1268–1271.)

the chest wall.[179] Exceptions to this distinction occur with subpulmonary collections of gas, loculated collections of gas, and pleural adhesions. In trauma cases, the stomach can herniate into the chest after rupture of the left hemidiaphragm, and a gas-filled stomach may be mistaken for a loculated pneumothorax. This can be disastrous if drainage with a thoracostomy tube is attempted. A skinfold can generally be distinguished from a pneumothorax by careful evaluation of the radiograph. Skinfolds generally extend beyond the rib cage, stop short of the ribs, and gradually increase in opacity with an abrupt dropoff at the edge of the image. Blood vessels often extend beyond the skinfold.[180]

Management

Fig. 45.10 represents an algorithmic approach to the management of pneumothorax.

Management of the First Episode of Pneumothorax

Initial management is directed at removing air from the pleural space followed by preventing recurrence. Approaches for the management of the initial episode include observation, supplemental oxygen, simple aspiration of the pneumothorax, and tube thoracostomy. The choice of therapy in a given patient depends on various factors such as the size of the pneumothorax, whether the pneumothorax is primary or secondary, the condition of the lungs, the clinical stability of the patient, the outcome of the patient, and whether the pneumothorax has occurred in a special setting. Various guidelines for managing pneumothorax have been published.[181,182]

Estimating the Size of a Pneumothorax

Determining the size of a pneumothorax is difficult. The average interpleural distance approximates the size of a pneumothorax from a frontal chest radiograph by taking the sum of the distances in millimeters between the ribs and the visceral pleura at the apical, midthoracic, and basal levels and then dividing the sum by 3. Another method is called the Light index. It uses the following calculation to estimate the size of a pneumothorax:

$$\%\ \text{Pneumothorax} = 100 - (D_L{}^3 / D_H{}^3 \times 100),$$

where D_L is diameter of the collapsed lung cubed, and D_H is diameter of hemithorax on the collapsed side cubed. Both methods express the size of the pneumothorax as a percentage, although the Light method better correlates with the amount of pneumothorax gas removed by suction.[183,184]

These methods are difficult to apply and tend to underestimate the size of a pneumothorax. As a result, some clinicians tend to describe a pneumothorax as large or small rather than use percentages. The American College of Chest Physicians guidelines defines a small pneumothorax as less than 3 cm in apex-to-cupola distance.[181] British Thoracic Society guidelines define a pneumothorax as small if the distance from the chest wall to the visceral pleural line is less than 2 cm. They define a large pneumothorax if the distance from the chest wall to the visceral pleural line is 2 cm or greater.[182] There is an ongoing trial comparing conservative versus invasive therapy in patients presenting with their first large (≥32%) PSP. Conservative management involves a period of observation before discharge, with intervention for worsening symptoms or physiologic instability.[185]

Treatment Options

Supplemental Oxygen

The choice of treatment depends on patient characteristics and clinical circumstances. Patients who are clinically stable who are having their first PSP can be observed with administration of supplemental oxygen if their pneumothorax is small (≤2–3 cm between the lung and chest wall on a chest radiograph).[186] Supplemental oxygen is used to facilitate reabsorption of pleural air, and its importance should not be underestimated. The absorption of gas depends in part on the gradient between the partial pressure in the capillaries and that in the pleural space. On room air, the net gradient is only 54 mm Hg, whereas it exceeds 550 mm Hg when the patient is receiving 100% oxygen.[183] A normal rate of reabsorption is 1.25% of the volume of the hemithorax per 24 hours.[7] The rate of reabsorption increases sixfold if humidified 100% oxygen is administered.[187] Therefore hospitalized patients with any type of pneumothorax who are not subjected to aspiration of air or tube thoracostomy should be treated with supplemental oxygen at high concentrations.[188]

Removal of Air From Pleural Space

In a patient whose pneumothorax is large (>20%–25%), progressive, tension type, or symptomatic or who has an underlying chronic lung disease, is supported by a ventilator, or has a recurrent pneumothorax, the pleural space air should be removed. Several therapies have been developed for this purpose.

Aspiration

Simple aspiration is most easily accomplished by using a commercially available thoracentesis kit. An 18-guage needle with an 8F to 9F catheter is inserted in the second intercostal space in the midclavicular line. Once the catheter is inserted into the pleural space, the catheter is threaded deeper into the pleural space, and then the needle is withdrawn. Air is manually withdrawn through the indwelling catheter until no more can be aspirated. If the lung has not expanded after 4 L has been aspirated, then it is assumed there is a persistent air leak. Thoracoscopy should then be performed. A chest tube should be inserted if thoracoscopy is not readily available.

Once no further air can be aspirated, one of two methods may be approached.[189] A closed stopcock can be attached and the indwelling catheter secured to the chest wall. After 4 hours, a chest radiograph should be obtained and if there is adequate lung expansion, the catheter can be removed. After another 2 hours of observation, another chest radiograph should be performed. If the lung remains expanded on this chest radiograph, the patient can be discharged.[190] Alternatively, the catheter can be left in place and attached to a Heimlich (i.e., one-way) valve. The patient can then be discharged with follow-up within 2 days.[181,191] One advantage of aspiration over tube thoracostomy is that the patient need not be hospitalized whether the catheter is removed after aspiration or left attached to the Heimlich valve. There is a lower morbidity rate compared with tube thoracostomy and the procedure is better tolerated. Outcomes have been found to be similar between thoracostomy and aspiration. In a meta-analysis of three randomized controlled trials (194 patients) that compared aspiration versus tube thoracostomy, aspiration resulted in shorter hospitalization stays and similar clinical outcomes.[192] In another randomized trial, 137 patients who had a first episode of PSP were assigned to receive manual aspiration versus tube thoracostomy. The groups had similar rates of immediate (62% vs. 68%) and 1-week success (89% vs. 88%). Aspiration was associated with a shorter hospital stay (1.8 vs. 4 days).[193]

Tube Thoracostomy

If necessary, most patients with PSP can be managed with a small chest tube (≤22F) or chest catheter (≤14F).[194,195] In the absence of trauma and with good aseptic technique, prophylactic antibiotics are not recommended.[196] The preferred location for insertion of the chest tube is via an incision at the fourth or fifth intercostal space in the anterior or midaxillary line.[197–199] In men, this corresponds to the nipple line and in women, to the inframammary crease. It is important to direct the tube anteriorly because the tube tends to track between the lobes in patients who have complete fissures. If this happens, the tube may get walled off by the lung and cease functioning. A more recent study found the position of a chest tube in the pleural cavity categorized as upper, middle, or lower third of the pleural cavity did not significantly influence chest tube duration.[200] The second intercostal space in the midclavicular line has been suggested as an alternative site for tubes, but this requires placement through the pectoralis muscle. This chest tube site is more painful for the patient and the tube is more difficult to dress and manage. Once an insertion site is identified, the tube is inserted using blunt dissection and secured in place.

The chest tube can then be connected to a water seal device, with or without suction, and left in position until the pneumothorax resolves. Once the air leak has resolved, the lung has fully expanded, and the pleural air removed, then the chest tube can be removed in a sequential fashion. The chest tube can generally be removed if there is no visible air leak present and air does not accumulate when suction is removed. If there is any question as to whether an air leak has resolved, a "clamp trial" can be performed. This involves clamping the chest tube and performing a chest radiograph repeated at intervals (e.g., 2, 6, and then 12 hours). If air does not reaccumulate, the tube can be removed.

Percutaneous Pneumothorax Catheters and Thoracic Vents

Alternatives to tube thoracotomy involve using small-lumen catheters or thoracic vents (one-way valve feature). Small catheter tubes have the advantages of ease of insertion, good response, and low incidence of complications. Liu and colleagues reported that in their study using pigtail catheters in 50 patients versus traditional chest tubes in 52 patients that the pigtail drainage was no less effective than the traditional chest tube.[201] Complications can include catheter failure from kinking, malposition, inadvertent removal by the patient, and occlusion of the tube or valve by pleural fluid. A thoracic vent can also be used to manage a simple pneumothorax.[202,203] It is inserted in the second intercostal space in the midclavicular line. This device has the advantages of a urethane tube that does not kink, a self-contained one-way valve, and a unique signal diaphragm that reflects pleural pressure. This device is not suitable for use in patients who are expected to have large-volume or protracted air leaks.

Thoracoscopy

VATS is an effective treatment of PSP.[204–206] Pleurodesis is created by pleural abrasion or a partial parietal pleurectomy. When necessary, an endoscopic stapler can be used to resect bullae.[207–210]

Persistent Air Leak and Bronchopleural Fistula

If a lung is at least 90% inflated but an air leak is present after 3 days, more aggressive treatment may be warranted. The simplest approach is to attach the chest tube to a unidirectional flutter valve such as a Heimlich valve. This allows rapid discharge of the patient with subsequent outpatient follow-up. An alternative approach is to perform an autologous blood patch.[211,212] This involves withdrawing blood from the patient's peripheral vein and aseptically infusing the blood into the pleural space through the chest tube. The ideal amount of blood to infuse is not known. The range in different series has been 24 to 200 mL. After infusion of the blood, the tubing from the chest tube is draped over a hook approximately 60 cm above the patient's head and then down to a water seal device on the floor. The chest tube is then removed 24 hours after cessation of the air leak. The most serious side effect is empyema, which occurred in 9% of patients in one series.[213]

An air leak persisting for more than 7 days is termed a *bronchopleural fistula* (BPF) and can occur in up to a third of pneumothorax cases.[214] The term refers to the presence of a connection between the tracheobronchial tree and the pleural space. It most commonly occurs as a complication of pulmonary resection, but may develop after spontaneous pneumothorax, mechanical ventilation, chest trauma, or lung infection, particularly where an abscess ruptures onto the pleural surface.[215]

After 7 days of a persistent air leak, tube thoracostomy is deemed to have failed and more definitive treatment can be planned. Currently, the first-line treatment of patients with BPF or persistent

air leak is considered to be thoracic surgical intervention (VATS) unless there is a contraindication for surgery. Bronchoscopic techniques can be considered a complementary rather than a competing intervention.

The first step in management of a persistent air leak is localization of the source. CT scanning is a noninvasive technique that offers the potential of identifying the bronchial segment or subsegment. Flexible bronchoscopy offers two different methods of identifying the site of a BPF or persistent air leak. A central BPF, located in a main, lobar, or segmental bronchus, may be directly visible, either as a defect within the mucosa or after the installation of saline solution via the bronchoscope when bubbling at the site of a bronchial resection margin may be visible.[215] When the origin of the air leak is located more distally in the bronchial tree or within the lung parenchyma, the technique of sequential balloon occlusion of bronchi can be used.[216]

Various techniques have been described to achieve bronchial occlusion. There have been no randomized controlled trials comparing the efficacy between these techniques. The techniques that have been used to occlude bronchi include insertion of a mechanical device,[217] use of stents,[218] instillation of a liquid material that subsequently solidifies,[219] submucosal injection of a filler or sclerosant,[220] use of thermal energy via laser or argon plasma coagulation to seal a visible defect,[221] or endobronchial valves.[222]

Recurrence Prevention

Once the initial episode of pneumothorax has resolved, the decision to prevent future pneumothoraces must be made. Different recurrence rates have been reported in the literature: from 20% to 52% after the first PSP.[223–225] In the following groups of patients, further management against recurrence is recommended: recurrent pneumothorax, patients with chronic air leak, patients with large bullae, patients who live in remote areas, and patients in which a recurrence could be a hazard (e.g., airline personnel or divers). The following are established risk factors for recurrence: more than one previous episode, COPD, air leak for more than 48 hours after first episode, and large cysts seen on radiograph. The following are possible risk factors for recurrence: nonoperative management of first episode (vs. tube drainage) and tube drainage for only 24 hours during first episode (vs. 3–4 days). Further management in these high-risk groups is aimed at preventing recurrence. Therapies to prevent recurrence include chemical pleurodesis, VATS, or surgical thoracotomy.

Chemical Pleurodesis

In patients who are unable or unwilling to undergo VATS, pleurodesis (adhesion of visceral and parietal pleura) can be done by introducing the sclerotic agent via the chest tube. Tetracycline had been used for pleurodesis,[226] but sterile tetracycline is no longer available. As a result, intrapleural instillation of doxycycline has been used as an alternative for pleurodesis.[227] Intrapleural doxycycline can be painful, so it is recommended that patients be premedicated with analgesics or anxiolytics. Talc slurry, which is composed of finely powdered magnesium silicate, can also be used for pleurodesis.[228–230] Recurrence rates after treatment vary between 5% and 8%. Controversy exists whether talc should be used as a sclerosant in young, otherwise healthy individuals owing to safety concerns and fear of long-term complications. Intrapleural injection of talc for malignant pleural effusions has been associated with development of ARDS in 1% to 2% of patients.[231] Extensive pleural thickening and calcifications were reported in another patient years after treatment.[232] However, several studies support the safety of talc pleurodesis for prevention of recurrent pneumothorax.[228,233,234]

Video-Assisted Thoracoscopic Surgery Pleurodesis

VATS is effective not only in the treatment of spontaneous pneumothorax but also in the prevention of recurrent pneumothorax.[235,236] The rate of recurrence is less than 5% after VATS with bleb/bullae resection and pleurodesis. Mechanical pleurodesis with dry gauze, chemical pleurodesis with talc, and laser ablation of the parietal pleura are among the techniques used.

Surgical Thoracotomy

Surgical management for the first episode of spontaneous pneumothorax is indicated under the following circumstances: 3% to 4% of patients have a persistent leak resulting from a large fistula that needs to be closed surgically; about 5% of patients have frank hemothorax and surgical intervention is required to control the bleeding; and a trapped lung that fails to reexpand may require decortication.

The indications for open thoracotomy are the same as those for VATS. Thoracoscopy has virtually replaced open thoracotomy in the management of spontaneous pneumothorax owing to shorter hospitalizations and less postoperative pain.[237,238] Thoracotomy is recommended only if thoracoscopy is unavailable or has failed.

Management Under Special Circumstances

Secondary Spontaneous Pneumothorax

Patients with SSP should be hospitalized owing to their diminished pulmonary reserve from their underlying lung disease. Patients with a small pneumothorax (≤2 cm between the lung and chest wall on a chest radiograph) who are clinically stable may be observed. Patients with a large pneumothorax or who are clinically unstable should have a chest tube placed. Tube thoracotomy is generally preferred over needle aspiration because it is more likely to be successful. In one trial, tube thoracostomy was more likely to have the pleural air completely evacuated than with needle aspiration (93% vs. 67%).[239] About 80% of patients with SSP will have lung expansion and cessation of their air leak within 7 days after tube thoracostomy.[240,241] Patients who are supported by mechanical ventilation or who are at risk for a large air leak should be managed with a 24F to 28F chest tube. A smaller chest tube (16F–22F) is preferred for most other patients. The chest tube should be connected to a water seal device with or without suction. In general, the chest tube should remain in place until a procedure is performed to prevent a recurrent pneumothorax. Patients who decline preventive interventions can have their chest tube clamped 12 hours after the last evidence of an air leak. A chest radiograph should be done 24 hours after the last evidence of an air leak, and if the pneumothorax has not recurred, the chest tube can be removed.

Pneumothorax in Patients With HIV Infection

Because the majority of pneumothoraces in HIV-infected patients occur in association with *P. jiroveci,* all patients with HIF infection who present with a pneumothorax should undergo a diagnostic evaluation for *P. jiroveci* infection. *P. jiroveci* pneumonia–related pneumothorax is complicated by a virulent form of necrotizing subpleural lesions with resultant diffuse air leaks refractory to standard treatment.[242] Asymptomatic patients with a small pneumothorax (<15%–20%) may be observed. Symptomatic patients and those with a larger pneumothorax will need chest tube

thoracostomy, and those with a persistent air leak will likely need additional therapy with VATS for stapling and pleurodesis. Patients who are poor operative candidates may benefit from bedside pleurodesis.

Pneumothorax in Cystic Fibrosis

Pleurodesis as an initial step in the management of pneumothorax in CF is considered contraindicated because it results in extensive pleural adhesions that jeopardize subsequent lung transplantation.[243] If initial tube thoracostomy does not bring resolution of air leak within 5 days, blebectomy should be performed. If blebectomy is unsuccessful, a definitive pleural ablative procedure should be considered.

Catamenial Pneumothorax and Pneumothorax Complicating Pregnancy

The initial episode is managed in the usual manner. Recurrences, which occur 72 hours before or after menstrual flow, are managed by pleurodesis or hormonal treatment.[244] Therapeutic options include oral contraceptive pills, danazol, progestational agents, and gonadotropin-releasing hormone analogs.[69] Thoracotomy should be considered if the patient is unable to take ovulation-suppressing drugs, has a recurrent pneumothorax while taking drugs, or wants to become pregnant. Pneumothorax complicating pregnancy is managed in the usual way, but because of the high rate of recurrence during parturition, thoracotomy with resection of blebs if present should be considered.[245]

Pneumothorax in Air Travelers

The volume of gas is inversely proportional to the pressure at which it is exposed. As barometric pressure falls in the aircraft cabin during ascent, trapped air in any noncommunicating body cavity, such as in a lung bleb or bulla, will expand. Regulatory government agencies, such as the Federal Aviation Administration, have requirements specifying that commercial aircraft cabins be pressurized to simulate an altitude (so-called cabin altitude) of approximately 8000 ft (2438 m). It is estimated that the volume of air in a noncommunicating body cavity will increase by approximately 38% upon ascent from sea level to the maximum "cabin altitude" of 8000 feet (2438 m).[246] For patients who develop signs and symptoms of a pneumothorax in-flight, administration of supplemental oxygen is the most important intervention. For patients in respiratory distress, emergency landing at the nearest airport will allow prompt evaluation and insertion of a chest tube, if needed. The optimal length of time to wait after resolution of a pneumothorax is unknown.[247] For patients with a prior pneumothorax, the decision regarding air travel must be made on an individual basis. One must take into consideration the likelihood of recurrence and how well the patient would tolerate a subsequent pneumothorax. A patient with relatively normal lung parenchyma could be permitted to fly 2 weeks after resolution of an iatrogenic pneumothorax. In a patient with severe bullous emphysema, limited cardiopulmonary reserve, and a prior spontaneous pneumothorax, air travel may be contraindicated.

Pneumothorax in Lymphangioleiomyomatosis

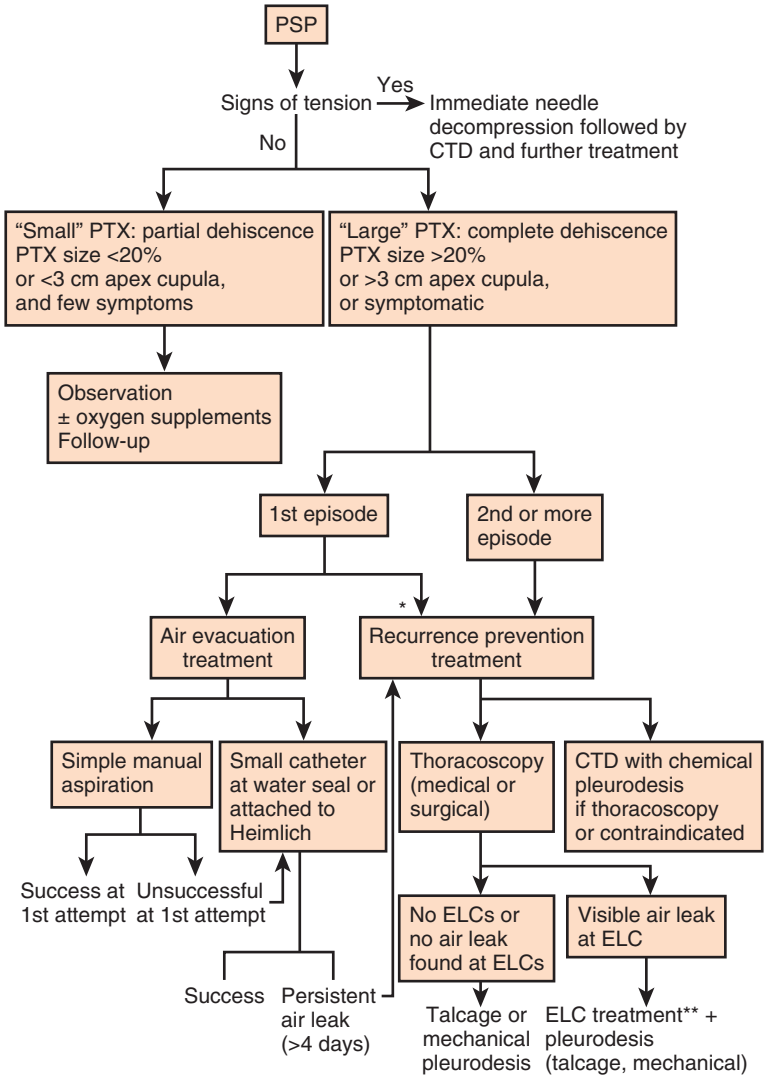
Lymphangioleiomyomatosis is a rare and often fatal disease that affects predominantly women of childbearing age. The normal architecture of the lung is distorted by multiple small cysts, ranging from 0.1 cm to several centimeters in diameter, with progressive decline in lung function. Spontaneous pneumothorax occurs in 50% of cases. It is often recurrent, can be bilateral, and may necessitate pleurodesis.[248,249] Because of the morbidity and cost associated with multiple recurrences, recommendations include definitive intervention at the time of the initial pneumothorax. Pleurodesis in these cases does not preclude successful transplantation.[250]

Complications Related to Management

Reexpansion pulmonary edema may occur after rapid reexpansion of a collapsed lung in patients with a pneumothorax. It is typically unilateral[251] (Fig. 45.11). The pathophysiologic mechanism is unknown. The incidence of reexpansion pulmonary edema initially appeared to be related to the rapidity of lung reexpansion and to the severity and duration of lung collapse. However, a study examining development of reexpansion pulmonary edema after thoracentesis found that it was independent of the volume of fluid removed and pleural pressures, and recommended that even large pleural effusions be drained completely as long as chest pain or end-expiratory pleural pressure less than −20 cm H_2O does not develop.[252] Patients typically present soon after the inciting event, although presentation can be delayed for up to 24 hours in some cases. The clinical course varies from isolated radiographic changes to complete cardiopulmonary collapse. Mortality rates as high as 20% have been described.[253] Treatment is generally supportive. Supplemental oxygen is administered and, if necessary, mechanical ventilation is used. The disease is usually self-limited.

Key Points

- PSP occurs primarily in tall, thin, previously healthy young men, most of whom are smokers. The chest radiograph often shows apical subpleural blebs or bullae. Rupture of these bullae is *not* related to physical activity but may be related to changes in atmospheric pressure. COPD is the most common cause of secondary pneumothorax. Presentation of pneumothorax in COPD is often atypical and causes excessive morbidity and mortality rates.
- A high incidence of pneumothorax occurs in HIV-infected patients, related to PCP and the mechanical ventilation and bronchoscopy that are commonly required in these patients. In this group of patients, pneumothorax is frequently bilateral, recurrent, and unresponsive to conservative therapy.
- Traumatic pneumothorax, which occurs as a result of a penetrating injury, may occur with closed chest trauma.
- Pneumothorax is a common complication of mechanical ventilation. Interstitial emphysema is a harbinger of this complication. High peak and mean airway pressures, PEEP, use of volume-cycled ventilators, intubation of right mainstem bronchus, chronic airway obstruction, and aspiration pneumonia increase the incidence.
- Simultaneous bilateral pneumothoraces and "shifting pneumothoraces" are rare but interesting conditions that may develop



• **Fig. 45.11** An algorithmic approach to the treatment of primary spontaneous pneumothorax *(PSP)*.*After informed consent or in certain patient groups (aircraft personnel, divers).** Staple bleb/bullectomy, electrocoagulation, ligation. *CTD,* Chest tube drainage; *ELCs,* emphysema-like changes; *PTX,* pneumothorax. (From Noppen M, De Keukelieire T. Pneumothorax. *Respiration.* 2008;76:121–127.)

because of persistent pleuropleural communication called *iatrogenic buffalo chest.*

- An immediate postbronchoscopy chest radiograph is rarely useful but should be done in certain groups of patients (e.g., comatose, mentally retarded, ventilated, or with respiratory compromise).
- Pneumothorax induced by a misplaced small-bore feeding tube is not uncommon. Clinical signs may be misleading.
- A visceral pleural line with absence of lung markings peripherally is the classic radiographic sign of pneumothorax. When the chest radiograph is obtained in the supine position, the signs are very different.
- Pulmonary ultrasonography is a promising technique for detection and exclusion of pneumothorax, especially in critically ill patients.
- PBT refers to alveolar rupture owing to elevated transalveolar pressure. The clinical presentation can vary, ranging from absent symptoms with subtle radiographic findings to respiratory distress or cardiac arrest owing to a large tension pneumothorax. Prevention is critical and limiting plateau pressures to less than 30 cm H_2O may be an effective approach.
- The approach to management of a pneumothorax is dictated by the clinical condition rather than merely the size of the pneumothorax, which is best estimated by CT scan of the chest. Expectant therapy is recommended for a small PSP in a stable patient. Reabsorption of air is hastened by 100% oxygen.
- Air can be removed by simple aspiration, a small-lumen catheter, or tube thoracostomy. Unstable patients with a large secondary pneumothorax must be managed with tube thoracostomy.
- Tension pneumothorax is a medical emergency and requires a high clinical suspicion followed by prompt thoracostomy if the patient is clinically stable. However, in an unstable patient, needle decompression followed by chest tube placement may be required.
- Definitive management of recurrent pneumothorax or persistent leak can be done by open thoracotomy or video-assisted

thoracoscopy associated with pleurodesis, pleural abrasion, parietal pleurectomy, or bullectomy. In patients unsuitable for or unwilling to undergo surgery, chemical pleurodesis via a chest tube may be done.

- Pneumothorax tends to recur in patients with CF. Blebectomy, without stripping the pleura, is recommended in these patients so that they may remain transplant candidates. Pleurodesis should not be done in these cases because adhesion development jeopardizes subsequent lung transplantation.
- Pneumothorax in pregnancy is managed in the usual manner initially. In view of the high recurrence rates during parturition, thoracotomy with resection of blebs should be considered.

Review Questions

1. A 58-year-old man with a history of COPD presents to the emergency department with dyspnea. A chest x-ray confirms the presence of a pneumothorax. Which of the following increased his risk for developing a spontaneous secondary pneumothorax?
   a. COPD
   b. Body mass index (BMI) of 28
   c. Previous history of tobacco use
   d. Previous history of intravenous drug use
   Answer: a. COPD is a known risk factor for developing a pneumothorax. Current, not previous, intravenous drug abuse is a risk factor related to attempted subclavian or supraclavicular injection attempts. A previous history of tobacco use or a BMI of 28 are not risk factors.
2. Pulmonary barotrauma (PBT) refers to alveolar rupture as the result of elevated transalveolar pressure (the alveolar pressure minus the pressure in the adjacent interstitial space). Which of the following has been identified as an independent risk factor for PBT?
   a. BMI greater than 30
   b. Plateau pressure less than 30 cm H_2O
   c. Acute respiratory distress syndrome (ARDS)
   d. Pneumonia
   Answer: c. ARDS has been identified as an independent risk factor for developing PBT. BMI greater than 30 and pneumonia have not been identified as risk factors. Plateau pressure less than 30 cm H_2O will help prevent PBT.
3. A 45-year-old woman with a history of asthma is intubated urgently in the intensive care unit (ICU) because of a severe asthma exacerbation. Three hours after intubation, despite heavy sedation, her peak and plateau pressures on the ventilator continue to increase. Her systolic blood pressure has decreased from 150 mm Hg to 84 mm Hg. Physical examination reveals decreased/absent breath sounds over the right lung. Her trachea is deviated to the left. Which of the following is the most correct next step?
   a. Obtain a chest x-ray
   b. Initiate paralytics
   c. Insert an 18-gauge needle in the second intercostal space for midclavicular line followed by aspiration of air
   d. Disconnect from ventilator and perform bag-mask ventilation
   Answer: c. The patient has signs of a tension pneumothorax involving the right lung with hemodynamic compromise. The correct answer is to aspirate the air as described.
4. A 60-year-old man presents to his pulmonologist after being discharged from the hospital after experiencing a pneumothorax. The patient is asking if he is at risk for a recurrent pneumothorax. Which of the following are established risk factors for recurrence of a pneumothorax?
   a. Age greater than 50
   b. COPD
   c. More than one episode of pneumothorax
   d. b and c
   Answer: d. Explanation: Both COPD and a prior episode of a pneumothorax are established risk factors for developing a subsequent pneumothorax.
5. A 21-year-old man presents to the local emergency department (ED) with sudden onset of chest pain. A chest x-ray confirms the presence of a 2-cm left pneumothorax. While in the ED the patient's chest pain resolves. His vital signs are stable on room air. Which of the following is the correct next step?
   a. Simple aspiration with an 18-gauge needle followed by a chest x-ray
   b. Chest x-ray in the ED to confirm stability of the pneumothorax. Once confirmed, discharge from the ED with follow-up with his primary care physician in 24 to 48 hours and a repeat chest x-ray.
   c. High-flow oxygen with inpatient admission
   d. Tube thoracostomy followed by admission to the hospital
   Answer: b. Based on a study evaluating outcomes of patients presenting to an ED with a primary spontaneous pneumothorax, patients who are clinically stable with a small (<2–3 cm) pneumothorax may be observed. A large pneumothorax (>25% of the pleural space) or a symptomatic patient may require more invasive treatment.

Epidemiology

The global burden of disease represented by inhalation injuries continues to grow. Industrialization of developing nations results in increased morbidity and mortality. Inhalation injury can be defined as "an injury due to the inhalation of thermal and/or chemical irritants" and consists of both acute and chronic exposures.

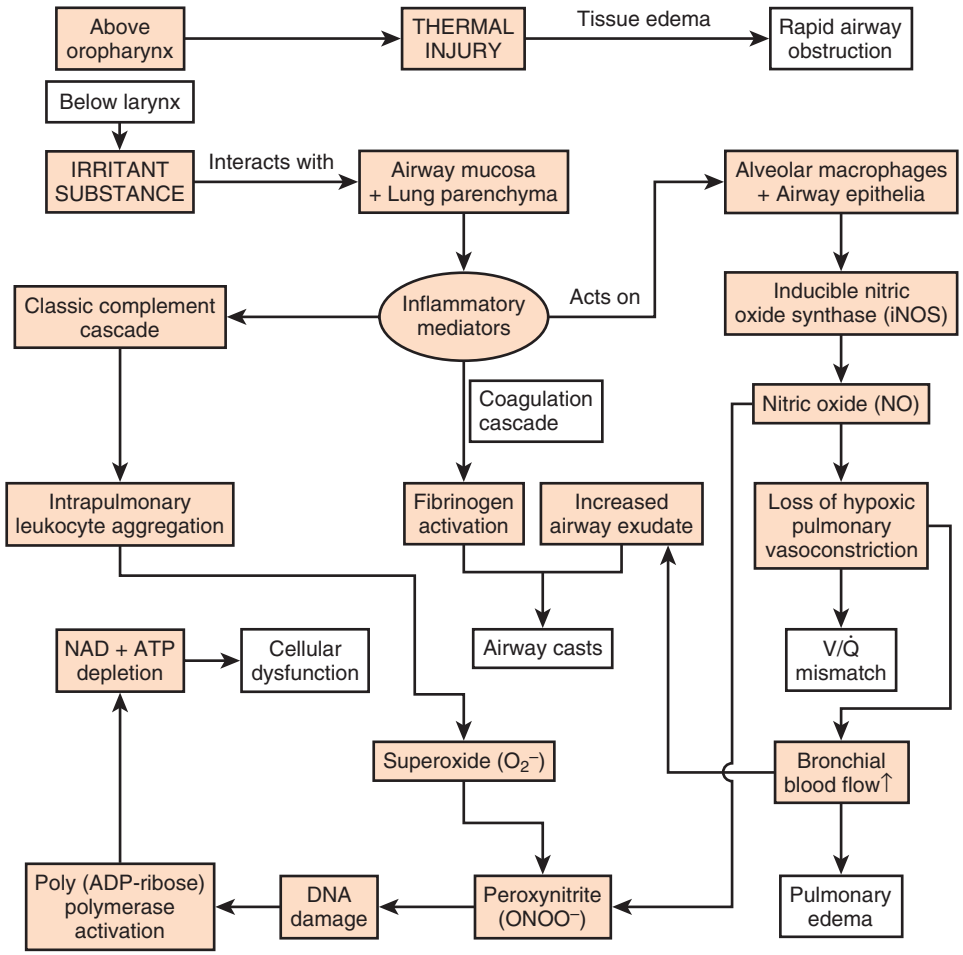
Chronic exposure to inhalation of atmospheric pollution may damage the lung over decades, predisposing to infection, pulmonary fibrosis, or cancer.[1] The World Health Organization estimates that more than a billion people, mainly in developing countries, develop airway and pulmonary inflammation resulting from inhaled smoke from indoor cooking fires, forest fires, and burning of crops.[2] In the industrial world, chronic inhalation injury may be due to cigarette smoking or occupational exposure (e.g., asbestos). This aspect of inhalation injury is not further discussed in this textbook, and readers are referred to other resources.[3]

Acute smoke inhalation results in approximately 23,000 injuries and 5000 to 10,000 deaths per year in the United States alone. Among industrial countries, the United States has one of the highest incidences of smoke inhalation injuries.[4] The ensuing pulmonary derangements, which follow burn and smoke inhalation injuries, are major contributors to morbidity and mortality in fire victims. The pathophysiology of the injury is multifaceted and induces distant organ dysfunction (Fig. 46.1). The consequences of the profound airway inflammation are heightened by pulmonary shunting and augmented microvascular pressure gradient, resulting in hypoxemic respiratory failure.[5] Although survival from burn injury continues to improve, this is not mirrored in inhalation management. The acute lung injury (ALI) caused by smoke inhalation and pneumonia has a major negative impact on mortality figures in patients with burn injuries. Inhalation injury alone increases mortality in burn victims by approximately 20% and pneumonia increases the rate by approximately 40%, with a maximal increase of approximately 60% when both are present.[6] However, age and burn surface area are risk factors of mortality, whereas the impact of patient- and center-level variables and treatments on survival is unknown. In a recent study of burn and nonburn centers at 68 U.S. academic medical centers, it was shown that in addition to older age and major surface burns, mortality in smoke inhalation–related ALI is predicted by initial vasopressor use, higher diagnostic-related group–based risk-of-mortality assignment, and care at centers with fewer than 500 beds, but not by initial antibiotic therapy.[7] Inhalation injuries are considered an independent risk factor for acute respiratory distress syndrome (ARDS).[8] The mainstay of treatment of the person with smoke inhalation remains optimal respiratory support with airway toilet, adequate fluid resuscitation, early and aggressive surgical interventions, and precise antimicrobial interventions. Continued research into this systemic process is needed to stop smoke inhalation injury from being the major cause of death in fire victims.[9]

History

Inhalation injuries resulting from both toxins and smoke have been recorded in the history books for several thousand years and have been used with enmity from the outset. Thucydides records the Spartans burning pitch, naphtha, and sulfur to produce sulfur dioxide while attacking Athenian cities in 423 BC.[10] The fifteenth century brought incendiary devices filled with sulfa and belladonna.[11]

The history of toxic gases other than smoke tends to run hand in hand with military conflict, and it was not until the First World War, during which at least 14 different toxic respiratory agents were used, that the increased usage sparked off once more. The years 1914 and 1915 marked the modern nascence of inhalation warfare when France released chloroacetone and Germany released thousands of liters of chlorine gas in Belgium, at Ypres. More than



• **Fig. 46.1** Pathophysiology of acute smoke inhalation injury. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *NAD,* nicotinamide adenine dinucleotide; *V̇/Q̇,* ventilation-perfusion.

1 million casualties were attributed to the use of chemical agents during that war, with sulfur gas being anointed as the "king of battle gases."[12]

The 1925 Geneva Protocol signed by many countries pledged never to use gas warfare again.[11] Sadly, this has not been adhered to, with Italy being accused of using mustard gas against Abyssinia in Ethiopia. The Chinese suffered gas inhalation at the hands of the Japanese during the Second World War, and the Kurds were victim to similar agents during the attacks by Iraq through the 1980s.[13] Sarin gas poisoning was used in Japan in the mid-1990s. In 1994 and 1995, inhaled biochemical weapons were used for terrorism acts like the sarin gas attacks in Japan.[14] More recently, it is believed that gas inhalation has been used extensively by the Assad regime in Syria.[15] Cyanide (CN) may be considered one of the most likely agents of chemical terrorism, as it is capable of causing mass incapacitation and casualties and can cause mass confusion, panic, and social disruption. In addition, CN possesses all attributes of an ideal terrorist weapon: it is plentiful, readily available, and easily obtainable because of its widespread use in industry and laboratories.[16] Although military interest in biochemical warfare diminished after World War II, there was an understanding of the devastation possible with nuclear weapons; terrorist organizations understand the fear, panic, and collapse of infrastructure that could be realized through the release of such a substance in a busy city. It seems likely that there are many areas of the world where such agents are, or can be, manufactured in great quantities.[11]

Equally, smoke inhalation has a long record in history, with the first recording by Pliny in the first century AD. He described the execution of prisoners over greenwood smoke, and it seems he may have died through toxic smoke inhalation himself during the eruption of Mount Vesuvius in 79 AD. More recently, two much more industrial occurrences highlighted the problems of smoke inhalation. The Cocoanut Grove fire of 1942 resulted in the deaths of 491 people who were trapped in a burning building. The number of patients who sustained burns was minimal, and it was then that the realization hit that smoke alone could kill as easily, if not more so, than cutaneous burns.[17] More than 2000 burn/smoke casualties resulted after the chain of fires and explosions that rippled through refineries and factories in Texas City, Texas, in the 1940s.[18] The understanding of smoke and carbon monoxide (CO) inhalation in enclosed spaces was further highlighted in the fire at the MGM Grand Hotel in Las Vegas in 1980 and the Stardust Nightclub fire in Dublin in 1981. Again, the small number of burn injuries was dwarfed by the deaths resulting from smoke and CO.[19] CN's independent role became clear in the 1980s, particularly after the aircraft fire at Manchester International Airport, Manchester, UK, in 1985 in which the majority (87%) of the 54 individuals who died had potentially lethal levels of CN in their blood, as opposed to only 21% of the victims with carboxyhemoglobin (COHb) levels

exceeding 50%. This event highlighted that different combustants produce different inhalants, and depending on the environment, these may be more lethal than CO, which had been regarded as the primary toxic threat.[4] Hence, the determinants of inhalants are both environment and material being combusted. It is therefore a mixed toxicology after smoke inhalation.

The terrorism attacks on September 11, 2001, on the World Trade Center in New York were associated with a high incidence of inhalation injuries. Among the 790 injured survivors, 49% incurred inhalation injury caused by toxic compounds in the smoke and dust.[20,21] Industrial catastrophes, biochemical warfare, and terrorism will continue to occur. This chapter's aim is to help physicians diagnose and then manage patients with inhalation injuries.

Pathogenesis of Inhalation Injury

Toxic Smoke Compounds

Smoke is a heterogeneous compound. Each fire produces different toxic features relating to the material combusted and the environment in which the fire occurs, specifically oxygen content. Hence, each patient with smoke inhalation may represent a new condition with a possibility of many different inhalants.[22] The components of smoke that cause damage are as follows:

- Heat.
- Particulates, deposited in the airways according to their size, with substances smaller than 1 μm in diameter able to reach the alveolar zone suspended in air. At that site, these chemically laden particles increase airway resistance and cause cell lysis and irritation while diminishing pulmonary surfactant production and efficacy.[22]
- Systemic toxins, such as CO and CN, that adversely affect oxygen transport by erythrocytes and utilization by mitochondria.[23]
- Respiratory irritants are implicated in the high mortality rates. Water-soluble gases such as ammonia and hydrogen chloride react with water contained in mucous membranes and produce strong alkalis and acids, which elicit profound inflammatory reactions, which rapidly induce systemic changes via the dense alveolar-capillary interphase. Lipid-soluble irritants (e.g., oxides of nitrogen, phosgene, and aldehydes) exert their effects more slowly as they dissolve into the cellular membrane.[24]

Heat

Burns to the nasal and oropharyngeal mucosa are common in fire-exposed victims, but it is rare to encounter thermal injury below the vocal cords. This is because the oropharynx acts as an effective "heat sink," with the thermal energy of the heated air dissipating into the cells they pass by, causing rapid cell injury, necrosis, and swelling of the upper airway (Fig. 46.2). This can result in upper airway obstruction, which can be fatal before the sequelae of pulmonary burn become apparent. Superheated steam is an exception, where the oropharynx cannot absorb all the thermal energy, and hence airway burn occurs in this situation.[25]

Systemic Toxins

Systemic toxins are products of incomplete combustion and include CO and hydrogen cyanide. CO intoxication, together with heat incapacitation and a hypoxic environment, is the most common immediate cause of death from fire.[23] CO is an odorless, colorless gas that binds to erythrocyte hemoglobin with about 250 times the affinity of oxygen. The resulting COHb molecule is unable to transport oxygen, thus impairing oxygen delivery to the tissue and shifting the oxygen-dissociation curve to the left.[26] Furthermore, at the tissue level, CO competes with, and inhibits, oxygen binding to the cytochrome oxidase system of enzymes, inhibiting the aerobic metabolism chain and thus incapacitating cellular respiration.[24] Hence, CO paralyzes oxygen carriage in the blood and subsequent utilization in the tissue (see Table 46.1). Thermal decomposition of nitrogen-containing polymers in oxygen-poor environments produces smoke containing hydrogen cyanide, inhibiting electron transport and cellular respiration.[22] Therefore inhalation of oxygen-deficient gas can cause hypoxic brain injury, which is treated like any anoxic brain injury; the neurologic outcome of treatment is variable.[27]

• **Fig. 46.2** Swollen hyperemic epiglottis and narrowed laryngeal opening.

Airway Injury

Although the inhaled gases as described earlier can cause significant and fatal alterations in physiology, the chief mediator of the pathophysiology of smoke inhalation is particulate matter. Carbonaceous particles (soot) impregnated with a multitude of toxins reach the alveolar level suspended in air.[28] The chemicals associated with these particles vary depending on the products combusted but commonly include aldehydes from cellulose-based materials such as wood and paper; nitrogen oxides from fabric combustion; halogen acids and sulfur dioxide from rubber; ammonia from wool, silk, and polyurethane; and phosgene from polyvinyl chloride.[25] Water-soluble compounds are readily soluble in airway mucus and interact freely with tissue at more proximal levels of the respiratory system. Less water-soluble compounds (such as phosgene) penetrate the airway mucosa deeply and may cause severe delayed damage through late interaction with distal airway tissues, up to 48 hours after exposure. This is an important consideration when treating patients who initially present with apparently mild clinical effects after smoke inhalation.[25]

Pulmonary Parenchymal Injury

Although thermal injury is mostly adsorbed in the upper airway, the other components of smoke—particulate materials, systemic

toxins, and respiratory irritants—descend to the lung and trigger a cascade of events, resulting in pulmonary edema, bronchiolar obstruction, cell death, and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch.[22]

Of paramount importance is the cascade of inflammatory mediators activated by the interaction of irritant substances with the airway mucosa and lung parenchyma. The main inflammatory mediators involved are tumor necrosis factor α, interleukin [IL]-8, IL-6, IL-1β, and nuclear factor κβ.[29] Intrapulmonary leukocyte aggregation after activation of the classic complement cascade releases even more chemokines and cytokines, leading to the production of free radicals of oxygen and nitrogen[30] from nitric oxide synthase (NOS)-triggered nitric oxide (NO) and peroxynitrite ($ONOO^-$) production. The vasodilation induced by NO rapidly increases bronchial blood flow and decreases the degree of the protective hypoxic pulmonary vasoconstriction in poorly ventilated areas of the lung, resulting in $\dot{V}/\dot{Q}$ mismatch.[31] This also intensifies the spread of irritants from the pulmonary to systemic circulation. NO also combines with superoxide (O_2^-) produced in large quantities by activated neutrophils to form $ONOO^-$. This reactive nitrogen species leads to DNA damage and subsequent activation of poly (adenosine diphosphate ribose [ADP-ribose]) polymerase, an enzyme important in DNA repair. This activation and subsequent action requires a large amount of chemical energy in the form of adenosine triphosphate and nicotinamide adenine dinucleotide (NAD), the depletion of which causes necrotic cell death of deprived energy-dependent tissues.[30] The combination of these effects contributes to tissue injury and increased pulmonary vascular permeability, leading to decreased diffusion, edema, and $\dot{V}/\dot{Q}$ mismatch. Furthermore, neutrophils are sequestered from the systemic circulation to the intrapulmonary compartment and are activated, and fibrinogen release by inflammatory mediators causes airway cast formation and widespread plugging. These casts obstruct a number of the smaller airways, and subsequent efforts to mechanically ventilate this inhomogeneous lung can induce ventilator-induced barotrauma as normal lung is overdistended, whereas other regions collapse and atelectasis occurs. The further tissue injury is heightened with biotrauma of ventilation, and the production of chemokines leads to a potent accumulation of damage.[24]

Much of the study of smoke inhalation injuries in animal models has focused on aspects of this pathophysiologic sequence. Attempts to manipulate and alter the chain of effects experimentally have reinforced these theories and suggested exciting treatment targets. Nevertheless, experimental treatments have yet to deliver specific therapeutic modalities that improve the course of smoke inhalation injury.[5]

Diagnostics and Treatment

Initial Prehospital Rescue

The first priority at the injury scene is rescue of the victim from the source of fire to minimize the exposure time. This is usually the responsibility of firefighters.[4] The patient must be assessed as a trauma patient and not merely as the victim of an isolated burn or smoke inhalation injury. Standard early management of severe trauma protocols must be observed, including stabilization of the neck. After the immediate administration of a high flow of O_2 to reduce COHb levels (Table 46.1), a primary survey must then follow to assess accompanying injuries, such as burns or trauma with simultaneous estimation of the extent of smoke inhalation. In addition, it is important to determine whether the victim has been exposed to an explosion and to assess the possibility of blast injury to the lung. If possible, information about comorbidities should be obtained. Standard cardiopulmonary monitoring (electrocardiogram, pulse oximetry, and noninvasive blood pressure) and intravenous access should be established.[32] CO poisoning can result in an erroneously high arterial oxygen saturation (SaO_2) reading owing to the light absorption of the classic "cherry red" hemoglobin in smoke inhalation. After these basic measures, the safety of the airway must be assessed. The risk of rapidly developing airway edema has to be taken into account even if no dyspnea is present, but it must be balanced by the real risks faced by endotracheal intubation itself in an unstable, potentially hypoxic patient with possible neck injuries. In the authors' opinion, endotracheal intubation that is entirely prophylactic is ill advised. Nevertheless, the airway with early edema is likely to worsen, particularly if significant fluid resuscitation is required for burn injury, and hence repeated and thorough assessment of the airway is mandatory.

Patients with evidence of stridor or heat and smoke inhalation injury combined with extensive face or neck burns may mandate early intubation. In the case of oral burn without inhalation injury, an airway secured early represents the safest approach. However, victims with smoke inhalation injury but no facial or neck burns can be carefully observed and can be intubated later, if necessary.[33] The patient's head should be elevated to 45 degrees to minimize facial and airway edema. In the field, fluid resuscitation can be minimized to reduce the risk of airway compromise if the necessary skills or equipment are not readily available for intubation. Nebulized adrenaline or corticosteroids may be used in the hope of minimizing upper airway edema, although there is no conclusive evidence for the efficacy of these treatment strategies.[34] Bronchospasm is frequently observed, and the nebulized administration of bronchodilators, such as β_2-agonists, will reduce this effect while improving respiratory mechanics by decreasing airflow resistance and peak airway pressures in ventilated patients. This results in improved dynamic compliance. In addition, β_2-agonists provide antiinflammatory properties, represented by a decrease in inflammatory mediators, such as histamine, leukotrienes, and tumor

TABLE 46.1 Carboxyhemoglobin Concentration and Related Symptoms

COHb (%)	Symptoms
<20	Slight headache and dilation of peripheral blood vessels
21–40	Severe headache and pulsating in temporal blood vessels, vertigo, dizziness, nausea and vomiting, circulatory collapse
41–60	Symptoms as above, syncope, tachycardia, hyperventilation, intermittent seizures, cyanosis, coma, shock, Cheyne-Stokes respiration
61–80	Coma, intermittent seizures, impaired heart and lung function, weak pulses, slow breathing, death within hours
>81	Death occurs within minutes

COHb, Carboxyhemoglobin.

necrosis factor α. Finally, β_2-agonists are associated with improved airspace fluid clearance and stimulation of mucosal repair.[35–37]

After initial stabilization of the patient, information about the type of fire and combustible materials involved, whether the fire occurred in an enclosed space, and the estimated duration of exposure should be sought. In cases of presumed specific intoxication, appropriate therapies should begin.[24] Diagnosis of such intoxications is impossible in the field, but a high degree of suspicion must be maintained if the combustion materials and enclosed space lead the treating practitioner to assume risk of CO or CN. All patients should be immediately administered 100% O_2 from a high-flow face mask to reduce the CO binding to hemoglobin. Specific therapies exist to treat the toxicity of CO and CN, which aim to reduce the serum levels of these substances (discussion to follow,[38] Table 46.2). Depending on the Glasgow Coma Scale score, the severity of injury, and the symptoms, the patient's condition may mandate intubation and mechanical ventilation with a fraction of inspired oxygen (FIO_2) of 1.

TABLE 46.2 Treatment Strategies for Acute Smoke Inhalation

Current	Under Investigation
Rescue victim from source	Activated protein C
High-flow 100% oxygen	Antiinflammatory drugs Methylprednisolone Phenytoin
Body check	Nitric oxide synthase inhibitors
Intravenous access	Antioxidants γ-Tocopherol 21-Aminosteroid
± Intubation	Endothelin-1–receptor antagonist tezosentan
If upper airway edema: Nebulized adrenaline Nebulized corticosteroids	P-selectin blockade
If bronchospasm: Nebulized α_2-agonists	Nebulized deferoxamine-pentastarch complex
If elevated COHb: High-flow 100% oxygen Hyperbaric oxygen	Mechanical ventilation: High-frequency percussive ventilation Airway pressure release ventilation Volumetric diffuse ventilator
If cyanide intoxication: Amyl nitrate Sodium thiosulfate Hydroxocobalamin Cyanokit	Extracorporeal membrane oxygenation
Mechanical ventilation Low tidal volume	Arteriovenous carbon dioxide removal
Nebulized heparin	Pulmonary decontamination with nebulized amphoteric chelating agents
Nebulized N-acetylcysteine	

COHb, Carboxyhemoglobin

Airway Management

Clinical suspicion of inhalation injury of the upper airway is aroused by the presence of certain risk factors such as history of exposure to fire and smoke in an enclosed space or a period of unconsciousness at the accident scene, burns including the face and neck, singed facial or nasal hair, altered voice, dysphagia, oral or nasal soot deposits, or carbonaceous sputum. The most immediate threat from inhalation injury is upper airway obstruction resulting from edema (see Fig. 46.2). Early intubation is recommended when this complication threatens and the patient was not intubated on scene.[39] However, exposure to smoke does not always lead to severe injury, and in the absence of overt evidence of respiratory distress or failure it may be difficult to identify patients who will experience progressive inflammation and ultimately require intubation of the trachea. When intubation occurs in the field, the optimal technique to secure a difficult airway is a contentious issue. Experienced operators may attempt to preserve spontaneous breathing, which allows patients to maintain their own reflexes even when intubation is not possible. Others may elect to perform a rapid-sequence induction, which provides better intubating conditions but oblates all of the patient's own airway reflexes. Attention should be given to gastric residuals during enteric feeding after admission to the burn intensive care unit (ICU). In addition, the development of sepsis can slow gastric emptying, which can result in retained fluids in the stomach and risk of aspiration.[32]

The condition of a patient with a compromised airway has evolved to maintenance of the airway at all costs. This primitive survival instinct is neutralized if paralyzing agents or heavy sedation is administered and the safe airway can rapidly become unsalvageable. Intubation of a spontaneously breathing patient, though more technically challenging, is safer as the patient will continue breathing at all costs. In terms of anesthetic airway management, the most profound and clinically significant effect of burn injuries on drug response relates to muscle relaxants. Burn injuries influence responses to both succinylcholine and the nondepolarizing muscle relaxants. In burned patients, sensitization to the muscle relaxant effects of succinylcholine can produce exaggerated hyperkalemic responses severe enough to induce cardiac arrest, although this tends to occur 24 to 48 hours after injury rather than immediately.[40] However, recommendations regarding the safe use of succinylcholine after burn injury cannot be given. Various authors recommend avoidance of succinylcholine at intervals ranging from 24 hours to 21 days after burn injury,[41] but it seems clear that the hyperkalemic response associated with burn does not occur in the first day and hence the drug can be used with standard precautions at this stage.

An increase in the numbers of acetylcholine receptors and the proliferation of these receptors away from the neuromuscular junction have been suggested as common mechanisms explaining both reduced sensitivity to nondepolarizing relaxants and the exaggerated hyperkalemia that may follow succinylcholine administration in burned patients. Resistance is apparent by 7 days after injury and peaks by approximately 40 days. Sensitivity returns to normal after approximately 70 days. In contrast to other nondepolarizing neuromuscular blockers, mivacurium dosage requirements in pediatric patients appear to be unchanged by burn injury.[42]

Preoxygenation may be more difficult in victims of smoke inhalation, and relative loss of mandibular mobility may impair airway manipulation, making bag-mask ventilation difficult. The swelling and distortion of the mouth and mandibular aspect of the airway may make preoxygenation and direct laryngoscopy difficult or impossible. Preoxygenation with small aliquots of

anxiolysis and analgesics (such as 0.5- to 1-mg increments of midazolam and 25- to 50-μg boluses of intravenous fentanyl) with sequential direct spraying of lignocaine to the oropharynx and then subsequently under direct vision of the larynx/epiglottic area is technically difficult but safe in experienced hands. Fiberoptic intubation with nebulized or directly sprayed lignocaine spray while maintaining spontaneous ventilation is equally safe but requires a substantial level of skill with the bronchoscope. However, pediatric patients are unable to cooperate and must be adequately sedated. Because deep sedation and full anesthesia cause collapse of pharyngeal tissues and airway obstruction, they are unsuitable for fiberoptic intubation in patients whose airway would be difficult to manage with a mask.[43]

Agents that may prove useful to facilitate fiberoptic intubation include the ultrashort-acting remifentanil. The novel α_2-adrenergic agonist dexmedetomidine, which provides sedation, anxiolysis, and analgesia with much less respiratory depression than other sedatives,[44] may be considered, although further data are required until its widespread use is adopted. Ketamine remains a very useful drug, as it provides some analgesia and facilitates a degree of spontaneous breathing while allowing dissociative anesthesia; however, airway secretions may be copious and the clinician must always be aware of this.

Securing an endotracheal tube in a patient with facial burns presents a variety of problems. Tape or ties across damaged or grafted skin can worsen tissue loss or induce graft failure. A useful technique to avoid these problems involves the use of a nasal septal tie.

The use of a laryngeal mask airway has also been successful for airway management during burn surgery for children.[45] In the acute phase or in the ICU, the laryngeal mask airway serves as a rescue device when endotracheal intubation fails, but it must be replaced with a definitive airway as soon as is practically possible, as gastroparesis is common in the burn patient.

Monitoring and Investigations

Damages to the airway and lung from inhalation injury often develop with a latency of several hours and are affected by other injuries and degree of fluid resuscitation required. Nevertheless, airway management and the oxygenation status of the patient, regardless of intubation status, need to be frequently reevaluated; such is the dynamic nature of smoke inhalation injury.[25] After stabilization of cardiopulmonary hemodynamics and pulmonary gas exchange, the assumed diagnosis of smoke inhalation injury needs to be verified. However, as no uniform criteria are available, the diagnosis of smoke inhalation injury has a subjective component based on history, physical examination with supporting imaging, and blood gas assays. Bronchoscopic examination of the airway represents the gold standard to detect a pathognomonic mucosal hyperemia with soot staining below the larynx being diagnosed (Fig. 46.3). Although chest radiographs are mandatory and may reveal injuries consistent with trauma—that is, fractured ribs, pneumothorax, and pulmonary contusion—they provide little information acutely as to the degree of smoke inhalation. Specific changes that may be seen related to the smoke inhalation include signs of diffuse atelectasis, pulmonary edema, or bronchopneumonia.[46] It has been shown that airflow narrowing owing to airway wall thickening is related to the development of pneumonia and the number of mechanical ventilation days and represents an important factor of respiratory deterioration in smoke inhalation injury. The utility of computed tomography scanning on admission can reveal airway wall thickening and can be predictive for pulmonary deterioration.[47]

• **Fig. 46.3** Soot staining in the hyperemic trachea.

A uniform algorithm for assessing inhalation injury or a reliable indicator of progressive respiratory failure in patients with smoke inhalation injury has not yet been established. This failure is largely explained by the extreme heterogeneity of the clinical presentation. In addition, the delay in the manifestation and development of ALI as a consequence of systemic inflammatory response syndrome, initiated by accompanying burns or trauma, complicates the evaluation of the isolated effects of smoke inhalation. Frequent blood gas and sputum analyses are useful to monitor patients with smoke inhalation injury.[33] In addition, inexplicably high lactate levels, despite adequate fluid resuscitation, are helpful for the diagnosis of CN poisoning. In a study by Pham and colleagues,[48] CN poisoning in the canine model showed two phases of injury. The first (compensated) phase had a mechanism consistent with a traditional global oxygen consumption defect. The second (decompensated) phase had a mechanism consistent with heart failure. This heart failure was due to bradycardia. The systolic blood pressure remained relatively constant, whereas diastolic blood pressure decreased by 19%. Cardiac output, heart rate, and oxygen delvery (DO_2) increased to a maximum of 6%, 10%, and 10%, respectively, at 40 minutes, after which they declined to a low of 32%, 28%, and 30% below baseline, respectively. Stroke volume remained constant. Oxygen consumption initially increased by 5% and then decreased to 24% below baseline. The oxygen extraction ratio initially declined to 35% below baseline and then increased throughout the rest of the study. In clinical practice, serial venous blood gases may unmask cytopathic hypoxia, by insufficient O_2 extraction, that may be seen as increased central venous ($ScvO_2$) or mixed venous (SvO_2) oxygen saturations.

Fluid Resuscitation

Optimal fluid management is critical to the survival of the victim of a major thermal injury, with additional or isolated inhalation injury, and when septic complications occur. Modern fluid resuscitation formulas originate from experimental studies in the pathophysiology of burn shock. Fluid resuscitation in the patient with thermal injury has been recognized as an essential aspect of the care since the first studies were published in 1905.[49] The

improvement in outcome with cutaneous burns can be related to the development of a protocol based on providing adequate fluid resuscitation to allow optimal organ function while minimizing the physiologic cost associated with overresuscitation.

Burn shock is both hypovolemic shock and cellular shock and is characterized by specific hemodynamic changes, including decreased cardiac output, extracellular fluid, plasma volume, and oliguria. As in the treatment of other shock forms, the primary goal is to restore and preserve tissue perfusion to avoid ischemia. However, in burn shock, resuscitation is complicated by obligatory burn edema, and the voluminous transvascular fluid shifts that results from a major burn are unique to thermal trauma.[50] Blalock may have been the first to postulate the mechanism, where he induced burn to one side of mongrel dogs and assessed the weight changes in both burned and unburned tissue, demonstrating that burn tissue edema correlated to the drop in blood pressure and was similar in composition to plasma.[51] Although the exact pathophysiology of the postburn vascular changes and fluid shifts is still unclear, major components of burn shock are the increase in total body vascular permeability and the changes in microcirculation. Fluid resuscitation is aimed to support the patient throughout the initial 24-hour to 48-hour period of hypovolemia and has existed since the early 1950s.

Cope, in his seminal paper after the Cocoanut Grove disaster, was the first to report the increased fluid requirement seen in patients with smoke inhalation injury.[52] This observation has been confirmed by multiple other papers, despite the lack of thermal injury below the larynx; hence fluid loss seems unlikely. One theory, which concurs with much of the known pathophysiology, relates to inflammatory excess seen after smoke inhalation. Approximately 28% of all neutrophils reside in the human lungs, and this percentage increases after inhalation insult. As described earlier, it is well recognized that the particulate and chemical nature of inhalation injury induces neutrophil activation and the release of numerous cytokines, proteases, and free radicals. This further recruits neutrophils from the systemic circulation, and the local inflammatory state rapidly becomes systemic owing to the vast alveolocapillary interphase transporting these mediators and modulators of vasodilatation to distant organs. The upregulation is not only in number but also in responsiveness to endotoxin.[24,53] Regardless of mechanism, numerous authors have reported that smoke inhalation per se increased the fluid requirement substantially.[54–56]

Although underresuscitation in thermal and smoke inhalation injury is known to induce organ failure and death, there are growing concerns with overresuscitation, where the "fluid creep" can induce increased extravascular water content, resulting in compartment syndrome in extremities or in the abdomen.[57] Even after thousands of patients have been saved by fluid resuscitation, resuscitation formulas are still controversially discussed, depending on advantages and disadvantages for the individual patient. Crystalloid solutions, such as lactated Ringer solution (sodium concentration 130 mEq/L), are the most popular resuscitation fluids currently used. Crystalloid formulas are the Parkland formula (which recommends 4 mL/kg per percent total body surface area [TBSA] burn in the first 24 hours, with half of the amount administered in the first 8 hours) and the modified Brooke formula (which recommends 2 mL/kg per percent TBSA burn). Colloid formulas, the dextran formula, and hypertonic saline solution formulas are also in use.[50,58–60]

Concerns with colloid administration in the resuscitation of early burns began with the work of Goodwin and colleagues in the 1980s,[61] who suggested that there was a lack of benefit over crystalloid and potential pulmonary harm, and research grew substantially in the late 1990s, but more recent work suggests that concerns of increased capillary leak, particularly in the lungs, are overplayed, and the pendulum seems to be swinging back toward the judicious use of colloid to minimize the risk of abdominal compartment syndrome (ACS). A randomized controlled trial (RCT) by O'Mara and colleagues compared plasma with crystalloid in burn resuscitation and showed that colloid resulted in less abdominal compartment syndrome but no demonstrable improvement in outcome.[62]

Early studies in fluid resuscitation post smoke inhalation suggest a mean fluid requirement of 5.8 mL/kg per percent TBSA burn for optimal outcomes, but more recent studies suggest the figure may be lower than originally expected.[55]

Hypertonic salt (HTS) solutions have been known for many years for effectiveness in the treatment of burn shock by fluid-sparing effects and a reduction of volume load in the early phase of injury.[63] Rapid infusion leads to serum hyperosmolarity and hypernatremia, reducing the shift of fluids from intravascular to interstitial areas, which may prevent edema formation and the need for escharotomy.[64,65] The use of HTS, however, is controversial because although there may be beneficial effects, other studies have demonstrated an increase in mortality with HTS treatment of major burns.[66]

Part of the dubiety regarding the exact volume required relates to the lack of consensus of scoring severity of inhalation injury. The extent of cutaneous burn can be readily assessed. Such a scoring system for inhalation injury is lacking, and inhalation can be mild to moderate or severe. In a 3-year retrospective review by Endorf and Gamelli, numerous demographic and injury-related factors, including bronchoscopic scoring, failed to determine which patients with inhalation injury required increased fluid resuscitation. From its 80-patient cohort, the authors postulated that a PaO_2/FIO_2 ratio of less than 350 may be the best early determinant of which patients would require excess fluid resuscitation.[67]

In addition to hypovolemia, the risk of infection in smoke inhalation patients is extraordinarily high. Shirani and coworkers[6] have shown that inhalation injury alone increased the mortality of burn patients by a maximum of 20%, and pneumonia by a maximum of 40%, with a maximum increase of approximately 60% when both are present. These data indicate that inhalation injury with additional septic complications such as pneumonia has significant, independent, additive effects on burn mortality and that these effects vary with age and burn size. The presence of inhalation injury and sepsis increases the fluid requirements for resuscitation from burn shock after thermal injury.[54] Chen and coworkers[68] have demonstrated that HTS confers beneficial effects on burn shock, reduces bacterial translocation, and enhances host defenses by several mechanisms in the treatment of burn shock and sepsis. It is of high interest to further investigate HTS in animal models and later in humans. Future studies with HTS alone and in combination with already established resuscitation formulas are needed to find a risk/benefit ratio for such a treatment. HTS may have the potential to improve resuscitation strategies and outcome in burn care, but it cannot be recommended at the present time because of a lack of evidence.[69]

Despite the treatment of septic complications after inhalation injury, the gradual shift toward less fluid in both burn and smoke inhalation may relate to the changes in the ICU modalities of care—including point-of-care devices to assess oxygenation, less injurious ventilation, and more rapid debridement of burn tissue.[70]

Debates and ongoing research on fluid resuscitation may last for decades, but they are needed to improve outcomes in this patient population. However, in the authors' experience

it is worthwhile to start fluid resuscitation using the modified Brooke formula (which recommends 2 mL/kg per percent TBSA burn) to closely monitor urine output (0.5–1 mL/kg per hour recommended) and to increase fluid administration up to a rate that will maintain the recommended urine output. This strategy may prevent initial overresuscitation in many patients, decreasing edema formation, and will suit the increased needs of patients with inhalation injury who may need up to 6 to 8 mL/kg per hour to maintain adequate organ perfusion. Excessive fluid administration beyond a urine output of 1 mL/kg per hour is ill advised.

Although protocols should not be abandoned, a routine and recurrent assessment of the patient with inhalation injury would be essential to minimize physiologic injury as a result of fluid resuscitation, whether too little or too much.

Treatment of Carbon Monoxide Intoxication

Current treatment recommendations of CO poisoning begin with cessation of exposure, immediate administration of 100% oxygen, and supportive care.[71] The rationale of hyperbaric oxygenation therapy (HBOT) is based on its ability to rapidly displace CO from hemoglobin, thus reducing the duration of the hypoxemic state. Administration of 100% oxygen at 3 atmospheres reduces the CO half-life from 250 minutes in room air to 30 minutes.[33] Besides this efficiency, its use remains controversial owing to the questioned correlation between COHb levels and outcomes. This may also be explained by limited access to the patient during HBOT, which has a major impact on the treatment quality of combined burn injuries.[33] A Cochrane database review of six RCTs did not reveal a beneficial effect of HBOT compared to standard treatment in respect to neurologic sequelae.[72] However, the results should be interpreted with care, as concerns have been raised regarding the design and analyses in all the included trials. In summary, all patients with CO intoxication should be immediately treated with 100% oxygen. Although data do not support its routine use, HBOT may be considered in stable patients with severe neurologic symptoms and high COHb concentrations (>50%), but no major burns or severe pulmonary injury.[53]

Treatment of Cyanide Intoxication

Hydrogen cyanide in fire smoke is an underappreciated threat and one of the most common poisonings in patients who incur smoke inhalation.[73] Its lipophilicity and lack of dissociation allow it to penetrate through mucous membranes with ease, resulting in a myriad of symptoms within minutes, and possible death if the dose is large enough.[74] Patients may describe a burning, dry throat with inexplicable feelings of anxiety. Clinical signs range from a patient presenting with tachypnea, confusion (and the classic almond breath fetor) to unconsciousness, cardiovascular collapse, and death, generally from respiratory arrest (Table 46.3).[23] The key for the receiving clinician is to have a high index of suspicion in such a patient, as there is no immediately available laboratory test. Blood gas analysis may reveal an inexplicably high lactate level in the absence of CO poisoning or other trauma. However, CN poisoning frequently coexists with significant CO poisoning, and hence may be overlooked.[4,75] For adequate treatment of CN poisoning after smoke inhalation injury, several antidotes are available: The "CN antidote kit" includes amyl nitrite, thiosulfate, and sodium nitrite.[76] Because these substances are methemoglobin generators, which may additionally impair oxygen transport, they should be used only in the case of proven diagnosis (increased plasma levels of CN) and under continuous monitoring in the ICU, particularly in episodes of poisoning with CO simultaneously.[33] Methemoglobin chelates CN to form cyanmethemoglobin. As cyanmethemoglobin dissociates, free CN is converted to thiocyanate by liver mitochondrial enzymes (rhodanese) using thiosulfate as a substrate. Thiocyanate is then excreted into the urine.[77] In contrast to these antidotes, hydroxocobalamin, a vitamin B_{12} derivative, actively binds CN by forming cyanocobalamin, which will be directly excreted by the kidneys.[38] Data are growing regarding the safety and efficacy of hydroxocobalamin. Prospective observational studies reveal that empiric administration of hydroxocobalamin was associated with survival among 67% of patients who were confirmed after administration to have had CN poisoning. An RCT in pigs assessed the efficacy of hydroxocobalamin versus sodium thiosulfate in the treatment of acute CN toxicity. The study indicated that in severe poisoning (CN administered to hypotension to 50% of baseline blood pressure), hydroxocobalamin was safe, efficacious, and resulted in much improved survival. Worryingly, sodium thiosulfate failed to reverse CN-induced shock. The authors concluded that only hydroxocobalamin was effective.[78] In case of intoxication with cyanide the recommended initial dose is 70 mg/kg IV infusion over 15 minutes.[79] Because of the avoidance of methemoglobin production, hydroxocobalamin can be used safely in the preclinical setting. Accordingly, hydroxocobalamin represents the active compound of the Cyanokit (Meridian Medical Technologies, Inc., Columbia, MD), which is used in the prehospital management of smoke inhalation injury in Europe with a reported improvement in mortality.[38]

Aggressive restoration of cardiopulmonary function augments the hepatic clearance of CN via the enzyme rhodanese and has been reported to be successful in severe CN poisoning (blood levels 5.6–9 mg/L) as well as after ingestion or smoke inhalation, even without the use of antidotes.[80–82] Hydroxocobalamin has been used safely and successfully by emergency personnel in out-of-hospital settings and may represent a new option in cases of suspected or confirmed CN poisoning in the field.[83] Therefore the standard care of CN poisoning should combine the aggressive supportive therapy with current data supporting the use of hydroxocobalamin as the optimal specific therapy.[53]

TABLE 46.3 Hydrogen Cyanide Concentration in Air and Related Symptoms

Hydrogen Cyanide (ppm)	Symptoms
0.2–5	Odor threshold
10	Occupational exposure limit
18–36	Slight symptoms, headache
45–54	Will be tolerated for 30–60 min
100	Death within 1 h
110–135	Death within 30–60 min
181	Death within 10 min
280	Immediate death

Bronchoscopy

Within each burn center, diagnostic as well as treatment options are determined by the availability of resources (such as xenon 133 scans, fiberoptic bronchoscopy, or 24-hour/day anesthesia staff coverage) and local tradition. A clear diagnosis proving smoke inhalation has occurred allows for the planning and delivery of therapeutic interventions.[46] Inhalation injury can be diagnosed with confidence based on clinical presentation and bronchoscopic findings. Changes observed with bronchoscopy include erythema, lesion, erosion, ischemia, or necrosis of the mucous membrane, as well as small to significant edema, blisters, and unidentified damage of the lung parenchyma when the changes in the lower respiratory tract are below the reach of the fiberoptic scope, which can be used for inspection of the upper (oropharynx) and main (trachea and bronchi) respiratory tract[84] (see Figs. 46.2 and 46.3).

Early prediction of which patients are vulnerable to resuscitation stresses, increased pulmonary complications, respiratory failure, and mortality is complex and frequently not possible. Many attempts to identify prognostic indicators for patients with smoke inhalation injuries have been made.[85,86] It has been difficult to identify reliable indicators of progressive respiratory failure in patients with smoke inhalation injury. Most of these studies have involved small numbers of patients and assessed a small number of clinical features. Prognostic estimations will ultimately rely on a system that allows quantification of the severity of inhalation injury.[46] Many observational studies have compared outcomes with various grading systems.[73,84,87,88] These grading systems often combine bronchoscopic findings with a small number of other clinical findings. However, it has been recognized that proximal injury observed by bronchoscopy is frequently greater than the peripheral, parenchymal injury. Masanes and colleagues[89] found that inhalation injury could be diagnosed by fiberoptic bronchoscopy in some burn patients who were otherwise asymptomatic. Liffner and colleagues[88] found that their scoring system for grading the severity of bronchoscopic evidence of inhalation injury did not correlate with the development of ARDS. Similarly, although it is generally recognized that inhalation injury increases fluid resuscitation needs in burn patients, Endorf and Gamelli found no correlation of severity of bronchoscopic findings with fluid resuscitation requirements.[67] In a review article, Woodson concluded that a consensus may be facilitated when a clinical variable or constellation of variables is identified that is reliably related to the development of respiratory failure or other complications in patients who have inhaled smoke.[46] A large multicenter study combining the experience of several institutions is more likely to identify such a correlation. However, consensus in diagnosis and quantification of inhalation injuries may await a theoretic advance with identification of a mediator or marker of cell injury or cell death that reliably and in some concentration-dependent way correlates with pulmonary or systemic complications of inhalation injury.

A widely accepted grading system for inhalation injury severity is presently not available. However, a randomized controlled multicenter trial to validate a standardized scoring system for inhalation injury that can be used to both quantify injury severity and predict mortality after inhalation injury is warranted.[46]

Mechanical Ventilation

Since the advent of positive-pressure ventilation, there has been an understanding that this therapeutic maneuver can paradoxically cause harm as well as save lives. Numerous studies have tried to identify optimal ventilatory strategies, positive end-expiratory pressure (PEEP) levels, and modes. An open lung strategy with low–tidal volume ventilation has been shown to be associated with improved outcome and reduced duration of ventilation.[90] In keeping with the ARDS Network data, low tidal volumes are mandated to minimize ventilator-induced lung injury).[91] An open lung strategy is advised owing to the decrement of surfactant in this population, but no study has shown an improved outcome with higher levels of PEEP. The frequent casts that occur after smoke inhalation result in areas of collapsed alongside open lung, and application of PEEP may result in tidal hyperinflation in areas of the lung, whereas there is an inability to aerate the collapsed area of lung. Hence, frequent airway toilet with mucolytics is essential to minimize ventilator-induced lung injury. Newer modalities such as electrical impedance tomography to assess breath-to-breath changes have demonstrated the rapid changes in ventilatory inhomogeneities seen after smoke inhalation.[92] A number of modalities have been suggested specific to the ventilatory idiosyncrasies associated with smoke inhalation.[93]

High-frequency oscillation (HOV) has been advocated by some as an alternative to the classic ARDS Network low–tidal volume ventilation in patients with smoke inhalation–induced ARDS.[93] However, a randomized trial of the use of HFO as the initial mode of mechanical ventilation in ARDS published in 2013 was stopped early owing to increased mortality in the HOV arm (47%) versus control (35%).[94] It is now recommended that HOV not be used in the initial mechanical ventilation of ARDS.

The volumetric diffusive respirator (VDR) is a pneumatically powered, pressure-limited ventilator that stacks oscillatory breaths to a selected peak airway pressure by means of a sliding venture called a Phasitron (Percussionaire Corporation, Sandpoint, ID), resulting in low tidal volumes. Exhalation is passive and a level of continuous positive airway pressure can be selected. In addition, VDR reestablishes the physiologic diffusive gas exchange, whereas standard ventilation modes induce a convective gas exchange.[95] A prospective clinical analysis revealed an improved gas exchange and a decrease in peak pressures.[96] A retrospective study in 330 patients with inhalation injury even reported a lower mortality rate.[97] Although these studies compared the VDR to high-volume ventilatory strategies, data regarding a comparison with modern low–tidal volume ventilation are still lacking. This may represent one reason why VDR is not universally accepted. Another factor might be that the VDR differs from other ventilators and therefore requires special training. In addition, tidal and minute volumes cannot be monitored, and humidified air and nebulized saline solution are necessary to prevent airway desiccation.[53]

As in conventional long-term ventilation of patients, common complications must be considered. Mosier and associates[98] documented that patients with combined thermal and inhalation injury requiring urgent intubation or prolonged ventilation have a high incidence of bacterial bronchial contamination. Inhalation injury creates a damaged tracheobronchial mucosa, and early intubation provides a portal for bacterial contamination. In patients with smoke inhalation that necessitated urgent intubation, a 50% incidence of ventilator-associated pneumonia has been described.[99]

The use and timing of tracheostomy in burn patients elicit a great deal of passionate discussion but very little solid data. Burn survivors with TBSA greater than 60% are more likely to undergo repeated surgery and have burns to the head and neck region, therefore increasing the requirement for tracheostomy. However, an association has been demonstrated between tracheostomy and the high prevalence of chest infection in patients with inhalation

injury, greater burn size, and prolonged mechanical ventilation.[100] The authors would advise caution in overinterpreting this study, as association does not infer causation, and sicker patients tend to be ventilated for longer periods, resulting in a higher incidence of both tracheostomy and ventilator-associated pneumonia. The tracheostomy allows for less sedation, earlier mobilization, and a more comfortable method of ventilation for a long-term patient.

Nebulization Treatments

As described previously, smoke-inhalation injury causes airway damage by the destruction of the ciliated epithelium that lines the tracheobronchial tree. Casts produced from these cells, polymorphonuclear leukocytes, and mucus can cause upper airway obstruction, contributing to pulmonary failure.[24] In the early 2000s, it was proposed that a combination of aerosolized heparin and a mucolytic agent, N-acetylcysteine, can ameliorate cast formation and reduce pulmonary failure secondary to smoke inhalation. In a study of 90 consecutive pediatric burn patients at the Shriners Hospitals for Children in Galveston, Texas, who had bronchoscopically diagnosed inhalation injury requiring ventilatory support, 5000 units of heparin and 3 mL of a 20% solution of N-acetylcysteine aerosolized every 4 hours the first 7 days after the injury resulted in a significant decrease in reintubation rates, in incidence of atelectasis, and in mortality for patients treated with the regimen when compared with controls, and this practice has ever since been part of the ventilation protocol at this institution.[101] Clinical studies of frequent nebulization therapy have presented conflicting results, suggesting that increasing frequency of nebulization may increase the risk of pneumonia. Although nebulization is used in many centers, this therapy has not been universally adopted.[102]

A recent systematic review on inhaled anticoagulation regimens, in both preclinical and clinical studies, has shown improved survival and decreased morbidity without altering systemic markers of clotting and anticoagulation. In some preclinical and clinical studies, inhaled anticoagulants were associated with a favorable effect on survival. This approach appears sufficiently promising to merit a well-designed prospective study to validate its use in patients with severe smoke inhalation–associated ALI requiring mechanical ventilation.[103]

Nonventilatory Pulmonary Treatments

Extracorporeal membrane oxygenation (ECMO) is used in specialized centers for neonatal, pediatric, and adult respiratory and cardiac failure. It requires a highly skilled team of intensivists and perfusionists, and echocardiographic support is essential for optimal usage of this modality.[104,105] The goal of ECMO is to support gas exchange, allowing the intensity of mechanical ventilation to be reduced and thus decreasing the potentially injurious effects of ventilator-induced lung injury until recovery. Furthermore, ECMO may be considered the definitive rescue therapy for refractory life-threatening hypoxemia, as pulmonary gas exchange is not required. Our group performed a systematic review and meta-analysis of the literature to collect all available clinical data to elucidate the role and present evidence of ECMO on severe hypoxemic respiratory failure resulting from burn and smoke inhalation injury.[106] Only a small number of clinical trials with a limited number of patients were available. The data suggested a higher ECMO therapy survival than nonsurvival rate of burn patients with acute hypoxemic respiratory failure. ECMO run times of less than 200 hours correlate with higher survival compared with 200 hours or more, and scald burns show a tendency of higher survival than flame burns. A case series, which was published after our meta-analysis, suggested a 90-day survival rate of 28% out of 11 burn patients in ARDS requiring ECMO.[107] In contrast, data from the University Hospital of South Manchester show weaning from ECMO in 100% and a 80% survival rate in five patients (personal communication, data submitted January 2017). Most recently, a group from Taiwan reported in a small case series that venoarterial ECMO did not provide benefits for circulatory support in patients with more than 90% TBSA burn resulting from a stun grenade explosion. However, the one patient who sustained "only" 50% TBSA second-degree burns and inhalation injury that resulted in hypoxemia survived using venovenous ECMO.[108] Based on the low number of studies and patients, as well as the low grade of evidence of these studies, there are currently inadequate data to support the use of ECMO in burn or smoke inhalation injury. Even though reports are promising, especially in the pediatric burn population, this review highlighted the lack of evidence for the use of ECMO in this setting. ECMO in adult respiratory failure is controversial, as early randomized trials showed poor outcomes[109–111] and use has been limited to highly specialized centers. Nevertheless, ECMO technology and expertise have improved. Recently the Conventional Ventilation versus ECMO for Severe Adult Respiratory Failure trial[112] and selected case series have shown improved outcomes, with survival of 75% to 85% in refractory respiratory failure.[113,114] Therefore RCTs of patients with burn and smoke inhalation injury are warranted to provide definitive recommendations and to further advance this therapeutic option in patients when other ventilatory modalities have failed. Currently there are large animal studies assessing the efficacy of ECMO in severe smoke inhalation that have shown promising results.[115]

Experimental Treatments

Against the background of the current literature, there has been a remarkable increase in our knowledge about the pathogenesis of smoke inhalation injury. There are several promising therapeutic approaches, including the nebulization of adrenaline, β_2-agonists, antioxidants, anticoagulants, intratracheal instillation of perfluorohexane, as well as the use of different ventilation modes.[116–126] However, as has been highlighted, smoke inhalation may begin as a single-organ injury but rapidly becomes systemic. Hence, although treatment paradigms may focus on smoke inhalation, it is more frequently a mixed insult of smoke and burn, smoke and pneumonia, smoke and toxicology, and smoke and trauma. Even isolated smoke inhalation generally induces distant organ dysfunction rapidly after injury. Hence, it is unlikely that a single "magic bullet" will be found for this condition, and the clinician is best equipped with a comprehensive understanding of the complex pathophysiology and multitudinous clinical presentations of smoke inhalation injury. The treatment can then be patient and inhalation specific, with a systemic rather than organ-specific approach to these patients (see Table 46.2).

Key Points

- Smoke inhalation represents a huge burden of disease in patients with and without burn injury.
- Early signs may be mild, so a high index of suspicion must be maintained, particularly in burn victims from an enclosed environment.
- Prophylactic control of the airway should be considered in patients with worsening symptoms.
- Concomitant poisoning with carbon monoxide or cyanide should be considered when an enclosed smoke inhalation occurs, and definitive treatment should be considered early.
- Bronchoscopy is a more useful tool than chest radiograph to determine severity of inhalation injury.
- Injurious ventilatory parameters can exacerbate the acute and late-phase lung injury.
- Despite a great deal of research, exemplary critical care management is the only process that improves outcome in smoke inhalation management.

Review Questions

1. What is the most common cause of death in patients with acute smoke inhalation?
- **a.** Carbon monoxide toxicity
- **b.** Cyanide toxicity
- **c.** Thermal injury to the lung parenchymal tissue
- **d.** Inflammatory excess induced by adsorption of toxins and interaction of irritants with mucosa

Answer: d. Carbon monoxide poisoning occurs—mostly in an enclosed space—as the result of an oxygen-deficient environment. Cyanide toxicity is similar but requires a fire substrate high in nitrogenous compounds (e.g., artificial foam, wool). Thermal injury below the cords is unusual unless the patient is deeply comatose or superheated steam is involved. The vast alveolar-capillary interphase in the lung means that there is rapid transfer of inflammatory proteins and irritants rapidly transferred systemically, which result in the majority of late-phase deaths.

2. Initial management of smoke inhalation at the scene of the injury should focus on which of the following?
- **a.** Intubation and ventilation in all smoke inhalation victims
- **b.** Provision with high concentration oxygen, with assessment of airway and cervical spine control
- **c.** Provision of intravenous hydrocortisone to minimize airway swelling
- **d.** Assessment of the size of burn and fluid requirements before determining the degree of airway injury

Answer: b. Smoke inhalations normally occur in association with trauma and must be treated as a potential neck injury until proven otherwise. Intubation can be hazardous in inhalation injury and should be undertaken only when the risk/benefit ratio has been assessed and the cervical spine status is clear. Airway injury will cause death rapidly, whereas any pathologic developments owing to fluid losses take substantially longer to occur. The key is to maximize oxygen administration as this reduces the half-life of the carboxyhemoglobin complex, minimizing the cytopathic hypoxia that results.

3. A 76-year-old female prisoner presents via ambulance after setting fire to her mattress in the local prison. She is normotensive, but despite fluid bolus her blood pressure is 114/66 mm Hg, with a pulse of 88 beats/min, and she has a serum lactate level of 6.8 mmol/L despite only a 10% body surface area (BSA) burn. The patient appears more anxious and agitated than seems normal with such a burn size. The carboxyhemoglobin level is 3.0 g/dL. What is the cause of the elevated lactate level?
- **a.** Burn shock owing to hypoperfusion
- **b.** Low cardiac output state
- **c.** Cytopathic hypoxia
- **d.** Liver failure

Answer: c. Lactate elevation is most likely due to cytopathic hypoxia (blockage of intracellular processing of oxygen) owing to cyanide. An oxygen-deficient environment with burning of a nitrogenous compound (such as furniture) can cause raised levels cyanide. There is no rapid test to define levels, and the carbon monoxide level is too low to have caused carbon monoxide toxicity. The burn size is too small to cause such a high lactate level. Cyanide toxicity must be considered in situations when the patient is "sicker" than the smoke inhalation and burn suggest they should be. The key is the environment (small space) and material combusted. Cyanide levels can be measured. The numerous methods of cyanide antidote are described in the chapter.

Nosocomial Infection in the Intensive Care Unit

CONSTANTINE TSIGRELIS, ROBERT A. WEINSTEIN, AND DENNIS G. MAKI

CHAPTER OUTLINE

Incidence and Profile
- Definitions
- Incidence
- Profile and Secular Trends

Morbidity and Economic Impact

Pathogenesis and Epidemiology
- Pathogenesis
- Reservoirs and Transmission
- Risk Factors

General Infection Control Measures
- Hospital Infection Control Programs
- Role of the Microbiology Laboratory
- Infrastructure—Architectural, Environmental, and Staffing—Issues
- Reliable Sterilization Procedures, Chemical Disinfectants, and Antiseptics
- Hand Hygiene
- Isolation Precautions for Communicable Infections
- Antibiotic Stewardship

Nosocomial Infections and Specific Infection Control Measures
- Intravascular Device–Related Bloodstream Infection
- Ventilator-Associated Pneumonia
- Catheter-Associated Urinary Tract Infection
- Control of Antibiotic Resistance

Avant Garde Infection Control Measures
- Selective Digestive Decontamination
- Preemptive Barrier Isolation

Approach to a Nosocomial Epidemic

Protection of Health Care Workers in the Intensive Care Unit
- General Precautions Against Biohazardous Exposure
- Vaccine-Preventable Diseases
- Non–Vaccine-Preventable Diseases of Major Interest

Goals for the Future

Intensive care units (ICUs) have contributed greatly to the survival of patients with trauma, shock states, and other life-threatening conditions[1–3] but are associated with a greatly increased risk of nosocomial (hospital-acquired) infection. Rates of nosocomial infection in patients requiring more than 1 week of advanced life support within an ICU are three to five times higher than in hospitalized patients who do not require ICU care.[4–8] Infection, usually nosocomial, is the most common cause of death, directly or indirectly, of patients who survive the early period after major trauma or full-thickness burns and is the most commonly identified cause of multiple-organ dysfunction syndrome.[9–11]

Although most of this book focuses on the diagnosis and management of critically ill patients in the ICU, we highlight prevention activities. Nosocomial infections are clearly one of the most common and serious complications of ICU care and are usually a consequence of invasive monitoring or life support therapies. Thus they are greatly preventable, and it is appropriate that measures to prevent nosocomial infections be addressed.

Published guidelines for prevention are now available, based increasingly on randomized trials that have established the efficacy of specific control measures. Knowledge and technology of asepsis with regard to surgery and high-risk medical devices are now sufficiently advanced that, if evidence-based preventive measures described in this chapter are applied consistently, the risk of nosocomial infection can be greatly reduced.[12–15]

Incidence and Profile

Definitions

Meaningful data on rates of nosocomial infection form the basis for tracking problems and measuring success of control measures within a hospital and, with a number of caveats, among hospitals. To monitor secular trends and to assess the efficacy of control measures, infection control programs must begin with clear, unambiguous definitions of nosocomial infections. Although there are no standardized definitions for infection at specific sites that are universally accepted by clinicians or investigators, the Centers for Disease Control and Prevention (CDC) has published definitions for the purpose of surveillance of nosocomial infection within hospitals, which most U.S. centers and an increasing number of hospitals around the world have adopted (Box 47.1).[16,17] For research purposes, more stringent definitions for specific infections will usually be necessary,[18] especially for pneumonia.[19]

• BOX 47.1 Definitions for Health Care–Associated Infections of the Centers for Disease Control and Prevention

Central Line–Associated Bloodstream Infection

1. Patient has a recognized pathogen cultured from one or more blood cultures (does not include organisms considered common commensals—see below) AND the organism cultured from blood is not related to an infection at another site
   OR
2. Patient has common commensal organisms (e.g., coagulase-negative staphylococci [including *Staphylococcus. epidermidis*], diphtheroids [*Corynebacterium* spp. not *C. diphtheriae*], *Bacillus* spp. [not *B. anthracis*], *Propionibacterium* spp., viridans group streptococci, *Aerococcus* spp., and *Micrococcus* spp.) cultured from two or more blood culture samples drawn on separate occasions AND at least one of the following signs or symptoms: fever (>38°C), chills, or hypotension AND signs and symptoms and positive laboratory results are not related to an infection at another site
   AND
3. Central line was in place for >2 days on the date of the bloodstream infection

Possible Ventilator-Associated Pneumonia

1. After a baseline period of ≥2 days of stable or decreasing daily minimum F_{IO_2} or PEEP values on the ventilator (i.e., daily minimum is defined by the lowest value of F_{IO_2} or PEEP during a day maintained for at least 1 h), patient has at least one of the following indicators of worsening oxygenation: increase in daily minimum F_{IO_2} of ≥0.20 over the baseline period for ≥2 days, or increase in daily minimum PEEP values of ≥3 cm H_2O over the baseline period for ≥2 days
   AND
2. After ≥3 days of mechanical ventilation and within 2 days before or after the onset of worsening oxygenation, the patient meets *both* of the following criteria:
   - Temperature (>38° C or < 36°C), OR white blood cell count ≥12,000 cells/mm^3 OR ≤4000 cells/mm^3.
   - New antimicrobial agent(s) is started and continued for ≥4 days
   AND
3. After ≥3 days of mechanical ventilation and within 2 days before or after the onset of worsening oxygenation, the patient meets *ONE* of the following criteria:
   - Positive quantitative culture at following threshold values (or corresponding semiquantitative result)[a] of one of the following specimens:
     Endotracheal aspirate ≥10^5 CFU/mL
     Bronchoalveolar lavage ≥10^4 CFU/mL
     Lung tissue ≥10^4 CFU/g
     Protected specimen brush ≥10^3 CFU/mL
     [a]If the laboratory does not perform quantitative cultures, use corresponding semiquantitative result that matches the quantitative thresholds (e.g., "moderate" or "heavy" growth, or 2+, 3+, or 4+ growth)
   - Purulent respiratory secretions (i.e., >25 neutrophils and <10 squamous epithelial cells per low-power field) plus organism identified from qualitative culture or quantitative/semiquantitative culture without sufficient growth to meet above threshold values from one of the following specimens: sputum, endotracheal aspirate, bronchoalveolar lavage, lung tissue, or protected specimen brush.
   - One of the following: (a) Organism identified from pleural fluid (from thoracentesis or initial placement of chest tube and NOT from an indwelling chest tube). (b) Lung histopathology, defined as either: abscess formation or foci of consolidation with intense neutrophil accumulation in bronchioles and alveoli; evidence of lung parenchyma invasion by fungi (hyphae, pseudohyphae or yeast forms); or evidence of infection with the viral pathogens listed later based on results of immunohistochemical assays, cytology, or microscopy performed on lung tissue. (c) Diagnostic test for *Legionella* species. (d) Diagnostic test on respiratory secretions for influenza virus, respiratory syncytial virus, adenovirus, parainfluenza virus, rhinovirus, human metapneumovirus, or coronavirus.

Catheter-Associated Urinary Tract Infection

Must meet at least *ALL* of the following three criteria:

1. Patient had an *indwelling urinary catheter* at the time of specimen collection or onset of signs or symptoms, or had an indwelling urinary catheter *removed the day before* specimen collection or onset of signs or symptoms.
   AND
2. Patient has at least *one* of the following signs or symptoms:
   - Fever (>38°C)
   - Suprapubic tenderness or costovertebral angle pain or tenderness (with no other recognized cause)
   - Urinary urgency, urinary frequency, or dysuria (for patients without a urinary catheter)
   AND
3. Patient has a urine culture with no more than two species of organisms identified, at least one of which is a bacterium of ≥10^5 CFU/mL

CFU, *Colony-forming units;* F_{IO_2}, *fraction of inspired oxygen;* PEEP, *positive end-expiratory pressure.*

Incidence

The incidence of hospital-acquired infection is most commonly expressed as the number of infections per 100 patients hospitalized and is highest in burn units[7,20] and surgical ICUs,[5–7,20–23] with intermediate risk in medical ICUs,* and lowest risk in coronary care units.[4,7,8,20]

Recognizing that the risk of nosocomial infection within ICUs is heavily influenced by the length of stay and that the length of stay ranges widely among ICUs in the same hospital and among different hospitals, the CDC has advocated the use of rates expressed per 1000 patient-days to permit more meaningful intrainstitutional and, especially, interhospital comparisons.[25–27] Furthermore, recognizing the powerful influence of exposure to invasive devices on susceptibility to infection[28,29] and the great variation in use of devices among different ICUs in the same hospital and among different hospitals, the CDC has further recommended surveillance of device-associated nosocomial infections expressed as infections per 1000 device-days.[25] Representative rates of device-associated nosocomial infection in U.S. hospitals, which can be used for intrahospital and interhospital comparisons, are shown in Table 47.1.[25–27,30] In the future, device-associated infection rates will be sought in accreditation reviews by The Joint Commission[31] as this influential organization continues to move toward measurement of patient outcomes as the most effective way to improve patient care in the United States.

Profile and Secular Trends

Approximately 40% of endemic nosocomial infections within ICUs are catheter-related urinary tract infections, and 25% are pneumonias—most associated with endotracheal intubation and mechanical ventilatory support. Up to 10% of patients hospitalized in a medical-surgical ICU for more than 72 hours acquire a nosocomial bloodstream infection (BSI), most commonly from an intravascular device (IVD).[25,32,33] Postoperative surgical site infections, Clostridium difficile infection, nosocomial sinusitis, and nosocomial meningitis account for the remainder of ICU-related infections.[4–8,25,34–38]

Nearly 50% of nosocomial infections in the ICU are caused by aerobic gram-negative bacilli, especially Pseudomonas aeruginosa, Escherichia coli, and Klebsiella pneumoniae, and 35% are caused by gram-positive cocci, most commonly coagulase-negative staphylococci, Staphylococcus aureus, and enterococci (Fig. 47.1).39[40] Almost 15% are caused by Candida species.[39,40] Filamentous fungi such as Aspergillus and mucormycosis are being increasingly encountered in patients with hematologic malignancy or those who received solid organ transplants.[41–43] Legionella species account for up to 10% of nosocomial pneumonias in centers that make efforts to diagnose Legionella infections.[44]

The microbial profile of infections at individual sites in ICU patients is shown in Table 47.2.[40] There has been an unrelenting increase in nosocomial infections caused by intrinsically antibiotic-resistant organisms, especially P. aeruginosa, Acinetobacter species, and other resistant gram-negative bacilli; coagulase-negative staphylococci, S. aureus, enterococci; and Candida.[32,39,40,45,46] Moreover, the incidence of infection caused by organisms with acquired resistance mechanisms, especially methicillin-resistant S. aureus (MRSA); enterococci resistant to vancomycin (VRE); gram-negative bacilli resistance to extended-spectrum β-lactams and fluoroquinolones has increased even more sharply over the past several decades.[40,47] The emergence of carbapenem-resistant Enterobacteriaceae has become a significant problem as there are limited therapeutic options to treat these pathogens.[40,48] Finally, Candida auris is an emerging Candida species that has often been found to be multidrug-resistant, including in some cases to all three major antifungal classes, and has caused health care–associated outbreaks with high mortality.[49,50] There is evidence that C. auris may spread within health care settings and the CDC recommends certain preventive measures for patients colonized or infected with

TABLE 47.2 Profile of Nosocomial Infections in the Intensive Care Unit

Infection	Major Pathogen(s)	Risk Factors
Urinary tract infection	*Escherichia coli*	Urinary catheter
	Pseudomonas aeruginosa	Monitoring of urine output
	Klebsiella pneumoniae Other gram-negative bacilli	Other urologic manipulation or bladder irrigations
	Enterococcus spp.	Renal transplantation
		Diabetes
		Female > male
Pneumonia	*Staphylococcus aureus*	Tracheostomy
	P. aeruginosa	Endotracheal tube, reintubation
	Acinetobacter spp.	Nasogastric tube
	Enterobacter spp.	Intracranial pressure monitoring
	K. pneumoniae Other gram-negative bacilli	Stress ulcer prophylaxis with histamine H_2-blocker or antacids Immunosuppression Granulocytopenia
Surgical site infection	*S. aureus* Coagulase-negative staphylococci Enterococci	Trauma, especially penetrating abdominal injury Gastrointestinal or radical gynecologic surgery
	E. coli and other gram-negative bacilli	Prolonged operation Immunosuppressive therapy
	Bacteroides fragilis and other bowel anaerobes	Granulocytopenia Hepatic transplantation
	Candida spp.	Central venous catheter in place >5 days
Intravascular device–related bacteremia	Coagulase-negative staphylococci *S. aureus*	Heavy colonization of insertion site skin Femoral vein insertions
	Enterococcus spp.	Catheter guidewire exchanges
	Gram-negative bacilli	
Contaminated infusate	*Enterobacter* spp. *Serratia marcescens* *Citrobacter* spp. *Pseudomonas cepacia* or *Xanthomonas maltophilia*	
Antibiotic-associated diarrhea or colitis	*Clostridium difficile*	Prolonged antibiotic therapy, especially with clindamycin or broad-spectrum β-lactams Enteral tube feeding
Candidemia	*Candida* spp.	Broad-spectrum, prolonged antimicrobial therapy Mucosal or urinary colonization Central venous catheter Hyperalimentation Renal failure

Modified from Maki DG. Nosocomial infection. In: Parrillo JE, ed. *Current Therapy in Critical Care Medicine.* 2nd ed. Philadelphia: BC Decker; 1991.

C. auris in acute-care hospitals, including Standard and Contact Precautions and thorough daily cleaning and disinfection of patient rooms.[49,50] Chlorhexidine has been shown to be active against antifungal-resistant biofilms formed by C. auris and may be an option for cutaneous disinfection.[51]

Nosocomial infections acquired in the ICU clearly differ from infections acquired in non-ICU patient care units within the same institutions. Overall rates are two to three times higher, and rates of ventilator-associated pneumonia (VAP) and primary bacteremia—most of which originate from IVDs—are 10 times higher. A far greater proportion of ICU-acquired infections are caused by antibiotic-resistant bacteria because the intensive antimicrobial therapy characteristic of modern-day ICUs grossly distorts patients' microbiomes. Moreover, more than half of all nosocomial epidemics

now occur among the 10% of hospitalized patients confined to an ICU.[20,32] Finally, the risk of occupationally acquired infection among health care workers (HCWs), particularly by bloodborne viruses and herpes simplex virus (HSV), is highest among ICU personnel, as contrasted with those who work in non-ICU patient care units (see "Protection of Health Care Workers in the Intensive Care Unit" later).

Morbidity and Economic Impact

Nosocomial infections have a considerable impact on morbidity and mortality rates and are estimated to affect more than 2 million patients in U.S. hospitals annually.[52] Table 47.3 summarizes major studies that have examined mortality, length of stay, and costs associated with the major nosocomial infections in U.S. hospitals.[2–19] Nosocomial infections have been ascribed by the National Academy of Medicine to be responsible for more than 80,000 hospital deaths each year and in 1995 resulted in more than $5 billion in excess health care costs.[52] Considering that nosocomial infections acquired by ICU patients account for nearly half of all infections in most hospitals, progress in reducing the incidence of infection acquired within ICUs could produce substantial economic benefits.

Pathogenesis and Epidemiology

Pathogenesis and Epidemiology are presented in the online supplement.

General Infection Control Measures

Hospital Infection Control Programs

Beginning in the late 1960s, scattered U.S. hospitals began to establish infection control programs to conduct surveillance, to develop infection control policies, and especially to attempt to implement control measures more consistently.[120] In 1976, The Joint Commission added to its requirements for hospital accreditation the establishment of a formal infection control program.

TABLE 47.3 Estimated Extra Days, Extra Charges, and Deaths Associated With Nosocomial Infections in U.S. Hospitals as Reported in Major Studies

Pathogenesis and Epidemiology

Pathogenesis

The occurrence of nosocomial infection reflects the conjunction in space and time of a pathogenic microbe and a vulnerable patient, catalyzed by events associated with hospitalization and the patient's care. Many patients admitted to an ICU are intrinsically more susceptible to infection because of underlying diseases or conditions associated with impaired immunity, such as cancer, trauma,[53] or advanced age,[54] or because of immunosuppression associated with malnutrition,[55] therapy with corticosteroids,[56] cancer chemotherapeutic agents,[57] or other immunosuppressive drugs.[58] Moreover, many drugs, such as narcotics or sedatives, have indirect effects that increase susceptibility to infection that impair the capacity to protect the airway, or antacids or H_2-histamine receptor antagonists that neutralize gastric acidity, producing gastric overgrowth by gram-negative bacilli,[59] thereby increasing the risk of nosocomial pneumonia.[60] Even transfusion therapy produces immunosuppression and increases the risk of nosocomial infection.[61]

Moreover, most nosocomial pathogens exhibit resistance to antibiotics (see Fig. 47.1),[45,46,48,62–65] and many are also more virulent because of (1) their capacity to subsist or even multiply in aqueous reservoirs for prolonged periods (e.g., pseudomonads[66] or Legionella pneumophila[67]); (2) the elaboration of endotoxins (e.g., all of the gram-negative bacilli) or exotoxins (P. aeruginosa,[68] C. difficile,[69] or S. aureus[70]); or (3) the production of adhesions[71] or exoglycocalyx[72] (e.g., coagulase-negative staphylococci), conferring the capacity to adhere avidly and form biofilms on biologic and prosthetic surfaces resistant to host defenses[73] and even antibiotics.[74] Because most patients in ICUs receive broad-spectrum antibiotics, resistant nosocomial organisms have an enormous ecologic advantage and, in Darwinian fashion, predictably supplant the normal cutaneous, respiratory, and gastrointestinal microbiomes.

In most cases, colonization is the first step in the progression to nosocomial infection caused by bacteria and Candida spp,[75] especially if the patient is already vulnerable because of underlying disease, if the organism is more virulent or resistant to antibiotics, or if the patient has invasive medical devices that assist invasion by colonizing organisms, bypassing or further impairing host defenses.

Reservoirs and Transmission

The epidemiology of an infection consists of the reservoirs and mode or modes of transmission of the pathogen or pathogens and those factors associated with an increased (or decreased) risk of infection. Understanding the epidemiology of an infection is essential to developing effective strategies for its prevention.

In the ICU the major reservoir of nosocomial organisms is the infected or colonized patient (Fig. 47.e1).[28] Most aerobic bacteria—particularly S. aureus,[76] enterococci,[29] and the enteric gram-negative bacilli[77]; many viruses such as hepatitis A, respiratory syncytial virus,[78] and rotaviruses[79]; C. difficile[80]; and even Candida[81]—are spread in the ICU on the inadequately cleaned hands of medical personnel, who themselves are not infected or even permanently colonized. Most respiratory viruses, rubella,[82] influenza,[83] and some bacterial respiratory infections (e.g., Streptococcus pneumoniae)[84] are spread by large droplet nuclei that travel 3 to 6 feet from the source. True airborne spread of pathogens from infected individuals occurs for Mycobacterium tuberculosis,[85–87] measles,[88] and varicella; "opportunistic airborne transmission" (when humidity and other conditions are favorable) may occur for severe acute respiratory syndrome (SARS), pandemic influenza, and some agents of bioterrorism.[89] Airborne transmission from contaminated environments can result in infections with Legionella,[44] Aspergillus, or mucormycosis.[41–43] Surgery and exposure to invasive devices of all types greatly amplify transmission, colonization, and susceptibility to infection.[28,90]

Outbreaks of group A streptococcal infection[91] usually indicate a health care provider who is a carrier of the epidemic strain. Airborne spread of gram-negative bacilli is probably rare unless unusual environmental circumstances generate massively contaminated aerosols.[92]

Increasing evidence suggests that many nosocomial infections that develop in the ICU derive from the altered microbiome that sick patients bring into the ICU, including resistant organisms of enteric origin[93–96] or that are present on skin[93,94] or in the lower respiratory tract[95] on admission to the ICU. This explains the failure of conventional infection control practices, based on the use of barriers, to control such endogenous resistant bacteria.[97] Whereas food[98] and even enteral feeding preparations[99] and water may be heavily contaminated by microorganisms, studies have not conclusively linked such contamination to disease.

Nosocomial organisms originating from colonized or infected patients are readily perpetuated and may be spread via contaminated medical apparatus or devices[28] such as urine-collection receptacles,[100] respiratory therapy equipment,[101,102] transducers used for hemodynamic monitoring,[103] dialysis machines,[104,105] and fiberoptic bronchoscopes and endoscopes.[102,106–108] Given the implicit close proximity of vulnerable ICU patients and the HCWs who have repeated contact with them each day, it is almost predictable that the ICU is a milieu within the hospital uniquely conducive to the epidemic infection, especially infections caused by antibiotic-resistant pathogens.

Although successful immune enhancement could in theory create a protective final barrier against infection by nosocomial organisms, the unique features of nosocomial infection—enormous microbial heterogeneity, pervasive effects of invasive devices and procedures, and often large infecting inocula—can overwhelm the healthiest patient's immune defenses. Measures to eradicate reservoirs of nosocomial pathogens and to block transmission, based on a thorough understanding of epidemiology, seem much more likely to be protective at present.

Risk Factors

Risk factor analysis using statistical techniques such as multivariate analysis can identify variables that put a patient at increased risk for nosocomial infection and further guide the development of preventive strategies. Risk factors based on prospectively collected data and, in most cases, the use of multivariate analysis, are listed in Table 47.2 for urinary tract infection,[109,110] pneumonia,[111,112] surgical site infection,[113] IVD-related BSI,[114] ventriculostomy-associated meningitis,[115] C. difficile infection,[34,116] and candidemia.[117–119]

Critical care medicine is synonymous with cutting-edge, high-tech medicine; mechanical ventilatory support; hemodynamic monitoring; total parenteral nutrition; hemodialysis; intracranial pressure monitoring; innovative forms of surgery; and a huge arsenal of drugs, especially anti-infectives of every genre. This technology, more than anything else, has forced critical care medicine to embrace the necessity for nosocomial infection control. In general,

invasive devices of all types are far more important in determining susceptibility to nosocomial infection than are underlying diseases (see Tables 47.2 and 47.e1). However, this should be viewed as welcome news: There is far more hope for reducing nosocomial infections in the coming years by innovative improvements in aseptic technique and advances in the technology of invasive devices than by breakthroughs that will reverse the ravages of chronic organ failure or degenerative diseases such as type 1 diabetes mellitus.

TABLE 47.E1 Significant Risk Factors for Nosocomial Infection in Medical and Surgical Intensive Care Units as Determined by Multivariate Analysis of Prospectively Collected Databases

Risk Factor	Approximate Magnitude of Increased Risk[a]
Urinary catheter >10 days	3.2
ICU confinement >3 days	2.5
Intracranial pressure monitor	2.5
Arterial line	1.5
Shock	2.5

[a]Relative risk or odds ratio: values >1 denote significantly increased risk of infection, and ratios less than 1 denote decreased risk, vis-à-vis a protective effect.
ICU, Intensive care unit.

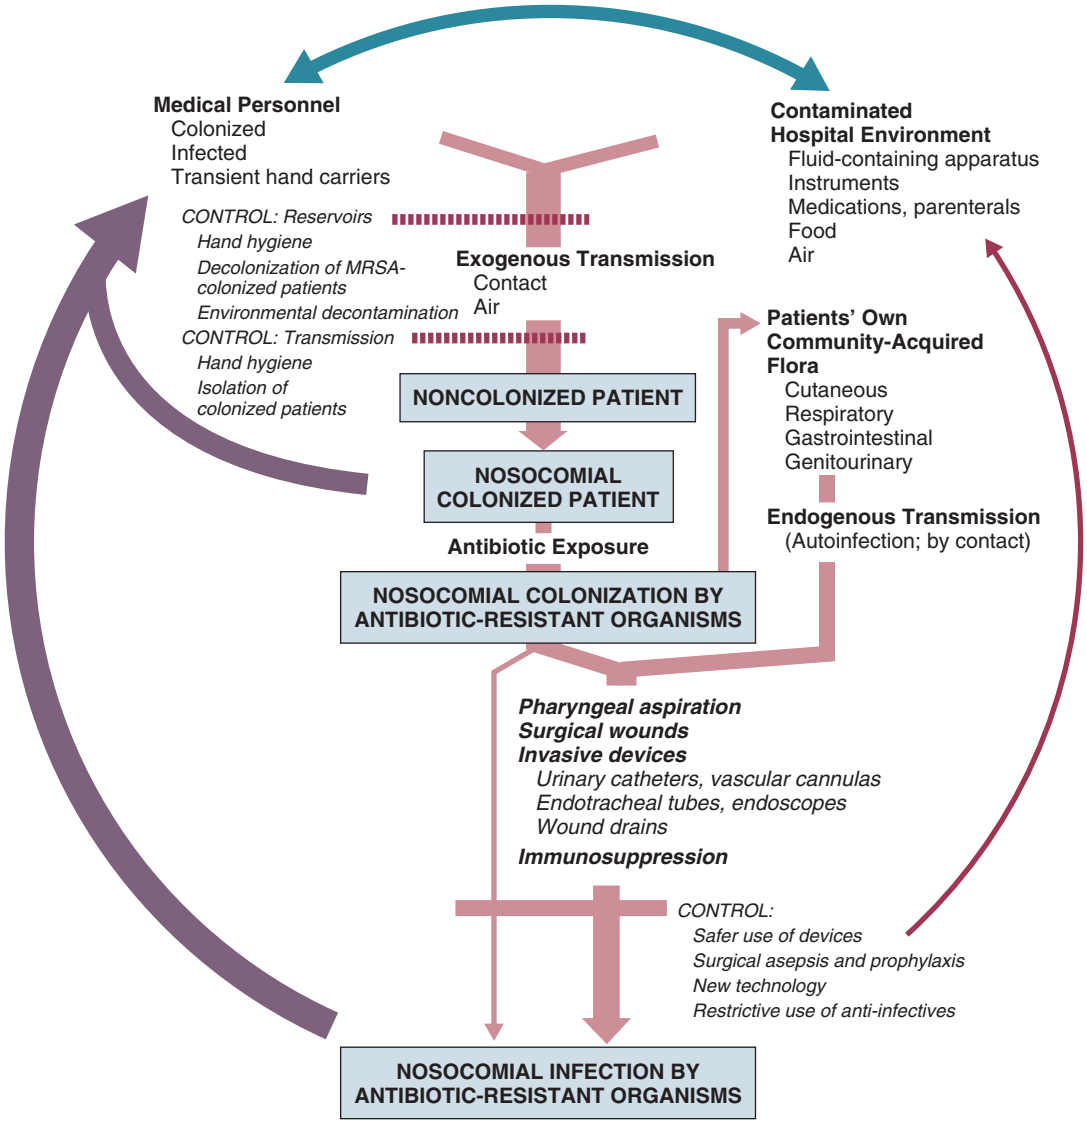

Fig. 47.e1 The epidemiology of nosocomial infection. Transmission occurs mainly by contact spread and, to a much lesser extent, the airborne route. Aspiration, surgical wounds, and exposure to invasive medical devices enormously amplify transmission, colonization, and susceptibility to infection. (From Maki DG. Control of colonization and transmission of pathogenic bacteria in the hospital. *Ann Intern Med.* 1978;89[5 Pt 2 suppl]:777–780.)

In the early 1970s the CDC studied the effectiveness of nosocomial infection surveillance and control programs in the United States through the Study on the Efficacy of Nosocomial Infection Control (SENIC). The goals of SENIC were to determine the extent to which infection control programs had been adopted by U.S. hospitals and to ascertain via a before-after comparison how much these programs had reduced rates of nosocomial infection. SENIC was launched by a survey of all U.S. hospitals to determine the characteristics of infection control programs and was completed in 1975–1976 by a review of more than 339,000 patient medical records in 338 randomly selected hospitals.[121]

The SENIC found that hospitals reduced their nosocomial infection rates by approximately 32% if their surveillance and infection control program included four components: (1) emphasis on both surveillance and an infection control program, (2) at least one full-time infection control practitioner for every 250 beds, (3) a trained hospital epidemiologist, and (4) surveillance of surgical wound infections with feedback of wound infection rates to practicing surgeons.[122] However, the relative importance of each component varied for the four major types of nosocomial infections (surgical wound infections, urinary tract infections, BSIs, and pneumonia).[122,123] SENIC suggested that nearly one-third of all nosocomial infections were in theory preventable, whereas a 1983 survey of surveillance and control programs in a random sample of U.S. hospitals found that failure to implement all essentials of the program, particularly to have an adequate number of infection control practitioners or a trained hospital epidemiologist or to disseminate wound infection rates to surgeons, greatly limited the potential for prevention: U.S. hospitals were estimated to be preventing only 9% of all infections.[124]

It is hoped that surveillance and control programs will continue to evolve. Prevention of nosocomial infections is a major priority of the U.S. Public Health Service,[125] The Joint Commission,[31] and the National Academy of Medicine.[126] With the shift to prospective-payment reimbursement and public reporting of infection rates, hospitals now have a powerful financial and public relations incentive to reduce their rates of nosocomial infection,[127] and it can be anticipated that efforts to prevent hospital-acquired infections will assume ever greater importance.

The Joint Commission mandates that all hospitals have an active program for the surveillance, prevention, and control of hospital-acquired infections, which begins in most hospitals with an institutional infection control committee with representation from the major clinical services and hospital departments, including the institution's ICUs. The most essential members of the infection control program are the infection control practitioner(s) and the hospital epidemiologist, usually a physician with training in infectious diseases or microbiology, who implement the policies developed by the committee, educate hospital personnel about nosocomial infection control, and investigate suspected outbreaks (Box 47.2).

Surveillance of nosocomial infections is the cornerstone of an effective infection control program and offers numerous potential benefits.[123,128] (1) It permits determination of baseline (expected) infection rates, assisting recognition of outbreaks and evaluation of new policies and control measures. (2) It identifies institutional problems that require attention, permitting focused infection control efforts and education. (3) It provides reliable data that can be disseminated to individual departments, increasing awareness and involvement of individual staff members. (4) It increases the visibility of the infection control staff on patient care units, providing an opportunity for consultation and ad hoc education. (5) It facilitates the earliest discovery of patients with communicable infections, permitting timely institution of isolation precautions to limit spread. Because total manual surveillance (of all infections) is labor intensive, many hospitals have focused their surveillance efforts on infections that are associated with high morbidity (e.g., nosocomial pneumonia), that greatly increase health care costs (e.g., post–cardiac surgery sternotomy infections), that are caused by antibiotic-resistant organisms with potential for spread (e.g., MRSA, C. difficile), or that are highly preventable (e.g., IVD-related BSIs).[123,129] However, electronic medical record systems and commercial computerized surveillance programs may allow for broader surveillance of nosocomial infections.[130]

The 1990s were characterized by major efforts by hospitals to apply the numerous facets of health care principles of quality improvement developed by industry. Hospital infection control programs had been working on quality improvement[131] but, influenced by The Joint Commission, were probably too heavily focused on process—namely, policies and procedures—rather than documenting outcome vis-à-vis reduced infection rates. Infection control programs in most U.S. hospitals are now closely allied with their institutional quality improvement departments.[131,132]

• BOX 47.2 Facets of a Hospital Infection Control Program

- Active infection control committee, with representation from major departments and services including the intensive care units (ICUs)
- Surveillance of nosocomial infections, especially in each intensive care unit
- Comprehensive and regularly updated institutional policies and procedures for prevention of nosocomial infection:
  - Surveillance of nosocomial infections
  - Isolation and universal precautions
  - Sterilization and disinfection
  - Indications for and management of invasive procedures and devices:
    All types of intravascular catheters
    Hemodynamic monitoring
    Tracheostomy and endotracheal intubation
    Mechanical ventilation and other respiratory therapy
    Bronchoscopy and gastrointestinal endoscopy
    Anesthesia and the operating room
    Hemodialysis
    Intra-aortic balloon pumps
    Cardiopulmonary bypass
    Intracranial pressure monitoring
- Antimicrobial stewardship program
- Guideline for investigation of an epidemic
- Strong liaison with clinical microbiology laboratory
  - Representation on the infection control committee
  - Laboratory-based surveillance
  - Monitoring and reporting of trends in antimicrobial susceptibility
  - Retaining important isolates
  - Microbiologic support of all infection control activities
  - Subtyping of isolates for investigations or studies
- Educational programs for new employees, periodic updates dealing with nosocomial infection control
- Active employee health department:
  - Free immunizations (hepatitis B, measles, mumps, rubella, varicella, pertussis, influenza A)
  - Tuberculin screening
  - Postexposure protocols
- Quality assurance review of implementation of infection control policies and practices

Modified from Maki DG. Nosocomial infection. In: Parrillo JE, ed. Current Therapy in Critical Care Medicine. *2nd ed. Philadelphia: BC Decker; 1991.*

Hospital infection control programs also must abide by the regulations of the Occupational Safety and Health Administration in terms of institutional standards and programs to protect HCWs from bloodborne pathogens[133] and tuberculosis.[134] The Environmental Protection Agency[135] has also published regulations in terms of disposal and tracking of medical waste—only a small fraction of which is truly biohazardous.[136]

Finally, it is essential that all health care personnel working in an ICU receive training in the epidemiology and control of nosocomial infections. This may be most important for house officers in teaching hospitals, who rotate through the ICU often with only the most rudimentary knowledge of asepsis but have hands-on contact with numerous patients and devices each day. ICU physicians and nurses must be especially familiar with their hospitals' guidelines for the management of invasive devices, particularly intravascular catheters of all types,[137] urinary catheters,[138,139] endotracheal tubes,[140] and tracheostomies.[140] Moreover, all physicians need to be made aware that broad-spectrum antimicrobial therapy greatly increases the risk of superinfection by antibiotic-resistant bacteria and Candida, as well as C. difficile.

Role of the Microbiology Laboratory

Accurate and timely diagnostic microbiology is as essential for nosocomial infection control as it is for the clinical management of patients' infections. Although many infections can be diagnosed on the basis of clinical criteria alone, cultures and other laboratory tests allow infections to be diagnosed with much greater certainty, and certain infections such as bacteriuria, bacteremia, and fungal and viral infections cannot be diagnosed without cultures or other laboratory tests (see Box 47.1).[16,17] Moreover, accurate antimicrobial susceptibility testing of clinical isolates is the only means of monitoring trends in antibiotic resistance of hospital organisms.[141] Most importantly, identifying the microbial cause of nosocomial infections allows epidemiologic tracking of individual pathogens within the hospital, especially those that are commonly spread from patient to patient such as S. aureus, enterococci, and the numerous gram-negative bacilli.

From an organizational standpoint, the institutional infection control program and clinical microbiology laboratory must have a close working relationship (see Box 47.2) to assist surveillance, which must be strongly laboratory based,[123,142] and to permit the detection and resolution of potential problems. The laboratory director or a senior member of the laboratory staff should be a permanent member of the infection control committee.

The primary role of the clinical microbiology laboratory in any infection control program is to provide up-to-date clinical microbiologic data for use in the surveillance of nosocomial infections and identification of potential outbreaks.[142] Protocols should be developed to ensure that laboratory staff immediately contact infection control personnel after the isolation of certain important pathogens such as MRSA or VRE or the appearance of new resistance patterns in endemic organisms, such as resistance of Klebsiella species to third-generation cephalosporins and carbapenems, or P. aeruginosa to aminoglycosides, fluoroquinolones, and carbapenems. Sifting through these data can be time-consuming, and developing electronic information systems that streamline this process is essential to improving the efficiency of the infection control program. Commercial software programs that can automate this process are now available. Many of these programs automatically collate microbiologic data, provide rudimentary geographic information, and perform basic statistical analyses that can assist in the surveillance of nosocomial infections and identification of potential outbreaks.[143,144]

Reporting cumulative summaries of antimicrobial susceptibility data (antibiograms) is another essential responsibility of the clinical microbiology laboratory.[145,146] When implemented appropriately, the timely dissemination of antibiograms helps guide the choice of empiric antimicrobials, pending the results of clinical cultures, and provides valuable data to help the infection control department monitor institutional antimicrobial resistance trends and identify potential outbreaks.[147] The Clinical and Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards) recommends that institutional antibiograms be updated at least annually and has recently published standards for their content and format.[148] Automated electronic systems for collating and disseminating nearly real-time antibiograms with antibiotic-use decision support exist and, when implemented properly and aggressively, have been effective in improving antimicrobial utilization within the hospital setting.[149,150]

Monitoring of sterilizers with spore tests, environmental sampling, and advanced microbiologic support for epidemiologic investigations are additional responsibilities expected of most clinical microbiology laboratories, although some university hospital programs have dedicated personnel within their infection control programs who perform these activities.[142]

The clinical microbiology laboratory is a key resource in the investigation of a suspected outbreak. One of the first and foremost actions when a nosocomial outbreak is suspected is to immediately retrieve all available isolates of the putative epidemic pathogen for possible subtyping.[151] The need to move rapidly becomes apparent when it is realized that most hospital laboratories discard cultures as soon as the isolates have been fully characterized. All blood isolates should be routinely saved for at least 1 year.[151] Laboratory personnel must be requested to save clinical isolates of any unusual organisms that are encountered for the first time or clusters of any organism and to inform infection control personnel of the findings and availability of the isolates.

The rapid evolution of molecular microbiology has revolutionized epidemiologic investigation of nosocomial outbreaks. Molecular-based tests for the rapid diagnosis of bacterial,[152] viral,[83,153] and fungal[154] infections are now routinely available in most hospital-based and reference laboratories. Modern molecular tests can reliably detect minute numbers of organisms, allowing direct testing of clinical samples without the need for culture. In modern-day clinical virology, molecular tests based on polymerase chain reaction (PCR) for amplification of the pathogen's DNA or ribonucleic acid (RNA) have supplanted tissue cultures and now allow rapid diagnosis of infections that would otherwise often not be identifiable by classic methods.

The availability of molecular subtyping systems has greatly strengthened investigations of outbreaks, as well as research on the epidemiology of nosocomial infections.[155,156] The antimicrobial susceptibility pattern (antibiogram) or the detailed biochemical profile (biotype) is often useful for the initial epidemiologic subtyping of many bacteria and may be adequate for identifying an epidemic caused by an unusual pathogen. However, if an epidemic organism is a common species such as S. aureus, it can be difficult or even impossible to know with certainty that an outbreak derives from a common source using these techniques because they lack sufficient discriminatory power.[155]

The new molecular techniques of subtyping such as plasmid profile typing by agarose gel electrophoresis or the use of restriction endonuclease digests with pulsed-field electrophoresis (DNA

fingerprinting)[155] are now available in most infection control research laboratories but should be adaptable by many hospital laboratories. Genetic probes and whole genome sequencing promise even more powerful tools for investigating outbreaks, particularly those caused by antibiotic-resistant organisms.[152]

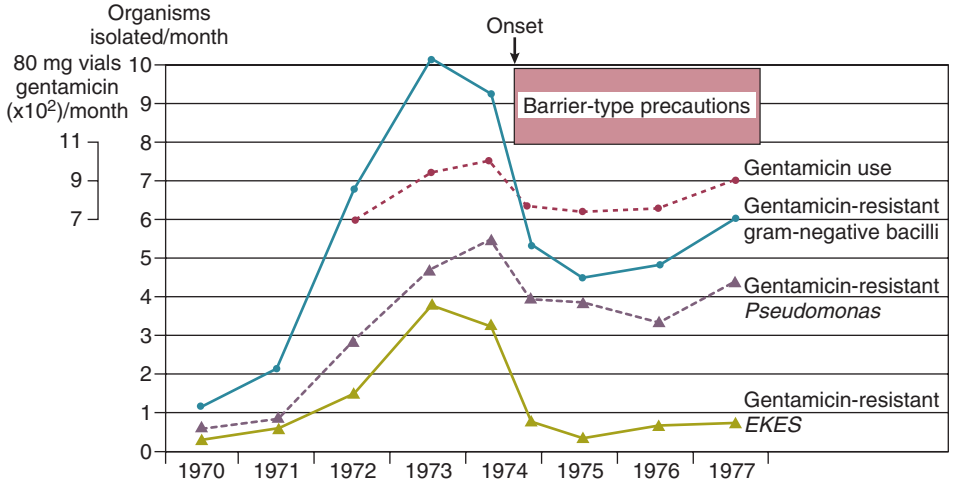
Additionally, technologies that offer rapid identification of organisms in blood cultures are available, including PCR-based detection systems, multiplex detection of pathogens, matrix-assisted laser desorption-ionization time-of-flight (MALDI-TOF) mass spectroscopy, among others.[157] In one clinical trial evaluating a multiplex PCR that tested for 24 gram-positive, gram-negative and yeast pathogens and 3 antibiotic-resistance genes, directly from positive blood culture bottles, the time from blood culture bottle Gram stain to microorganism identification was significantly shorter in the multiplex PCR group (1.3 hours) compared with conventional blood culture technique (22.3 hours).[158] Also, time to escalation of antimicrobial therapy was significantly shorter in the multiplex PCR group (4 hours) compared with conventional blood culture technique (18 hours). And time to de-escalation of antimicrobial therapy was significantly shorter in the multiplex PCR group but only with involvement of the antimicrobial stewardship team (20 hours), compared with conventional blood culture technique (39 hours) or the multiplex PCR group without involvement of the antimicrobial stewardship team (36 hours).

Although molecular-based tests offer several advantages over traditional microbiologic techniques, they are not a panacea. For example, non-culture technologies may limit access to isolates for epidemiologic typing. And a number of molecular diagnostic assays (e.g., analyte-specific reagents) marketed for clinical practice do not require approval by the U.S. Food and Drug Administration.[152] In the absence of published data on their accuracy and precision, the results of these tests must be interpreted with caution and should always undergo extensive in-house validation before adoption. Moreover, the exquisite sensitivity of many of these tests renders them more susceptible to false-positive results as a consequence of environmental contamination[159,160] and mandates stringent quality control practices and procedures.

Infrastructure—Architectural, Environmental, and Staffing—Issues

The role of the inanimate environment on the transmission of nosocomial infections has been a subject of intense debate for decades. It has been shown that hospital surfaces are almost universally contaminated by potentially pathogenic bacteria such as S. aureus,[161] Enterococcus,[162] spores of C. difficile, and gram-negative bacilli such as Acinetobacter baumannii.[163] Before the 1970s, infection control personnel routinely sampled hospital surfaces. Despite this level of surface colonization, early studies found that the inanimate environment—surfaces, walls, and even air—does not contribute materially to the occurrence of most nosocomial infections,[164] other than invasive infections caused by airborne Aspergillus and other filamentous fungi in seriously immunocompromised patients.[41,42]

Although inanimate surfaces may rarely be involved in the direct transmission of infection to patients, more recent evidence suggests that surfaces may well play an important role in the nosocomial acquisition of pathogenic bacteria, indirectly, through contact with HCWs' hands and equipment (Fig. 47.2). This indirect route of infection is of particular importance in the ICU, where all patients are heavily exposed to invasive devices and have a high risk of infection. In the ICU the inanimate environment may become a reservoir for the transmission of resistant nosocomial organisms such as MRSA,[165,166] C. difficile,[80,167] VRE,[162,168] and gram-negative bacilli, particularly Pseudomonas spp. in wet environments and Acinetobacter spp.[169,170] Studies have shown that enhanced surface decontamination with hypochlorite-containing cleaning solutions has been necessary to terminate outbreaks caused by C. difficile[171] and Acinetobacter baumannii.[163]



• **Fig. 47.2** Impact of implementing barrier-type precautions (gown and gloves) with patients known to be colonized or infected by gram-negative bacilli resistant to gentamicin. Frequency of infections by gentamicin-resistant gram-negative bacilli and gentamicin use at Michael Reese Medical Center, 1970–1977. Data are plotted as the monthly average, and the averages for the first 7 and last 5 months of 1974 are plotted separately to demonstrate the effect of barrier-type precautions implemented in August 1974. *EKES, Escherichia coli, Klebsiella pneumoniae, Enterobacter* species, and *Serratia* species. (From Weinstein RA, Nathan C, Gruensfelder R, et al. Endemic aminoglycoside resistance in gram-negative bacilli: epidemiology and mechanisms. *J Infect Dis.* 1980;141:338–345.)

It has been shown that patients admitted to a room previously occupied by a patient colonized or infected with a pathogen have a higher chance of developing colonization or infection with that pathogen.[172,173] Improved terminal cleaning of rooms (i.e., disinfection of a room between occupying patients) has been demonstrated to decrease the rate of individual patient colonization and infection and also facility-wide patient colonization and infection.[172,173] However, some studies have shown that surfaces in hospital rooms are poorly cleaned and remain contaminated.[172] Therefore "no-touch" methods of terminal room cleaning such as ultraviolet (UV) light devices or hydrogen peroxide systems have been explored.[172] A multicenter cluster-randomized crossover trial involving more than 21,000 patients tested the effect of disinfecting ultraviolet (UV-C) light for terminal room disinfection on the acquisition and infection due to MRSA, VRE, C. difficile, and multidrug-resistant Acinetobacter.[173] The addition of UV-C light to quaternary ammonium disinfectant (or to bleach for C. difficile) decreased the incidence of MRSA, VRE, and multidrug-resistant Acinetobacter by 30% among exposed patients admitted to the targeted room, but it did not decrease the risk of C. difficile compared with bleach alone.[173]

Although the ICU environment cannot be made microbe free, certain organizational, architectural, and environmental issues may be addressed with the design or remodeling of an ICU. The capacity to systematically improve the care of critically ill patients and prevent nosocomial infection requires a structural foundation on which the processes of care can be optimized (i.e., make it easy for HCWs to do it right and difficult to do it wrong). Accountability for compliance with critical policies and procedures and ongoing assessment of outcomes needs to be built into the administrative structure of the ICU.

An ICU must be adequately staffed to allow the processes of care to be carried out but also ensure a high level of compliance with essential infection control measures such as hand hygiene and barrier isolation. Adequate staffing cannot be overemphasized; numerous studies have found greatly increased rates of nosocomial infection when ICUs are staffed suboptimally or when staffing requirements are met with temporary personnel who are unfamiliar with ICU infection control policies and procedures.[174,175] In a large nosocomial outbreak of Enterobacter cloacae infection in a neonatal ICU, Harbarth and colleagues[176] found that infection rates during periods of understaffing were strikingly higher than during periods with adequate levels of staffing (relative risk [RR] 6, 95% confidence interval [CI] 2.2–16.4). The effects of understaffing are likely multiple; however, erosion of basic hygienic practices with excessive patient-to-staff ratios likely explains much of this phenomenon.[177]

Many of the published recommendations for ICU architectural design[178] are empiric, and evidence that they reduce rates of nosocomial infection is, by and large, lacking. Although more research is necessary before specific features of ICU design achieve a level of evidence sufficient for an evidence-based guideline, certain facets of the ICU layout deserve attention:

- ICUs should be located in areas that limit traffic flow to essential ICU personnel.
- ICU facilities should be designed with ICU professionals in mind, ensuring appropriate space, resources, and environment for day-to-day operations.[178] Recognizing the growing variety and complexity of life support equipment required for the care of many patients, each cubicle or room should provide a minimum of 11 m^2 per bed.[179] The area should be large enough to accommodate the bed and all equipment yet allow immediate access to the patient at all times from both sides of the bed. Adequate space must also be provided for storage of nursing supplies. Facilities for disposal of biohazardous waste (e.g., bedpan flushers); for cleaning, reprocessing, and storage of ICU equipment; and for storage of housekeeping supplies should be separate from patient care areas. Single-patient rooms may increase the likelihood of attention to handwashing and improve adherence with isolation practices, reducing the risk of cross-infection. For example, Mulin and colleagues[180] found that converting from an open unit to single rooms in their ICU greatly reduced rates of patient colonization with A. baumannii, and Shirani and colleagues[181] found that renovation of their burn unit to include separate bed enclosures reduced rates of nosocomial infection by 48%.[181]
- Materials used for fixtures, furniture, and other surfaces should be smooth and easy to clean; surfaces made of porous materials foster bacterial colonization.[182]
- An adequate number of sinks must be available for convenient handwashing by ICU personnel. Ideally, a sink should be located at the entrance of each cubicle or patient room to encourage handwashing by all entering personnel who will have contact with the patient or the immediate environment.[183,184] Separate sinks should be used for cleaning and reprocessing contaminated equipment. Sinks and sink drains are normally contaminated by pseudomonads,[185] and there have been outbreaks of infections with contaminated handwashing sinks as a potential source, including from extended-spectrum β-lactamase (ESBL)-producing Klebsiella oxytoca and carbapenemase-producing Enterobacteriaceae.[186,187] Sinks should be designed to minimize aerosol formation and splash back.
- All ICUs should be equipped with one or more negative-pressure isolation rooms, which include an anteroom for gowning and handwashing and the necessary modifications (negative pressure, roofline exhaust) to permit it to be used for patients with tuberculosis or other airborne infections, such as chickenpox, measles, disseminated HSV infection, or a highly contagious emerging pathogen such as the SARS human coronavirus. If an ICU treats bone marrow transplant patients or other patients with prolonged severe granulocytopenia, positive-pressure isolation rooms using high-efficiency particulate air (HEPA) filters should be available to lessen risk of infection by airborne fungal spores such as those of Aspergillus. Doors of isolation rooms for patients with infections transmitted by the respiratory route or to protect profoundly granulocytopenic patients must be kept closed to ensure that the direction of airflow is maintained as designed.
- A centralized, filtered air-handling system that provides at least six room exchanges per hour is essential.[179,188]

A variety of microorganisms, including bacteria, mycobacteria, fungi, and parasites, can be isolated from hospital water and have been implicated in endemic and epidemic nosocomial infections.[189] Many of these outbreaks were caused by bacteria typically thought of as "water" organisms such as P. aeruginosa,[185] Stenotrophomonas maltophilia,[190] and A. baumannii[16,191,192]; however, the most important and epidemiologically linked hospital water pathogen is the Legionella group.[193]

Nosocomial legionellosis was first described in 1979,[194] and it is estimated that up to 50% of cases of legionellosis are acquired in the health care setting,[195] with a mortality rate that approaches 30%.[196] Contamination of hospital potable water remains underappreciated despite studies showing that Legionella species can be recovered from 12% to 70% of hospital water systems,[197] and a number of studies in which nosocomial cases were identified only

when specific diagnostic and surveillance methods were used.[198,199] Characteristics of hospital water systems that are associated with Legionella contamination include piping systems with dead ends that facilitate stagnation, large-volume water heaters that result in inefficient heating of hospital water, sediment buildup, water heater temperatures less than 60°C, and tap water temperatures less than 50°C, maintaining water pH greater than 8, and receiving municipal water untreated with monochloramine.[200–202]

Despite the ubiquity of water systems colonized with Legionella species and studies demonstrating a correlation between the level of colonization and risk of infection, the CDC does not recommend routine surveillance of hospital water systems,[195] although this stance is controversial.[197] Researchers from Pittsburgh, Pennsylvania, and the Allegheny County Health Department have recommended a more proactive stepwise approach that involves initial surveillance of hospital water for Legionella contamination, regardless of the presence or absence of institutional nosocomial legionellosis, followed by continued surveillance based on the level of water contamination found or the presence of institutional legionellosis.[197]

Legionella species are resistant to chlorine and heat, making it challenging to eradicate them from contaminated hospital water systems.[202] Attempts to hyperchlorinate hospital water have been partially successful if chlorine levels are continuously maintained between 2 and 6 parts per million at all times but produce rapidly accelerated corrosion of water pipes and are expensive.[203] Thermal eradication is feasible, using a "heat-and-flush" method to raise water tank temperatures to greater than 70°C and distal water sites to greater than 60°C for short periods of time.[204] Although effective, superheating is labor intensive and there is the constant fear that patients or health care personnel may sustain scald injuries if they wash or shower with tap water during a flushing period. The use of technologies such as instantaneous steam heat for incoming water[204] and UV light[205] are technically feasible with newer hospital water systems but may be incompatible with older hospital water systems.

Perhaps the most attractive, effective, safe, and cost-efficient method for Legionella eradication may be the use of continuous copper-silver ionization systems to sterilize hospital water systems. These systems have been well studied over the past decade and have proved to be highly effective for reliably eradicating Legionella contamination of hospital water and, most importantly, for eliminating nosocomial legionellosis in institutions when other interventions have failed.[206] In an institution of one of the authors (D.G.M.), two clusters of nosocomial legionellosis prompted a retrospective review that identified 10 cases over an 11-year period. Surveillance of the hospital water system found that 75% of all samples contained low levels of L. pneumophila, which were shown to be clonally related to the 10 cases of nosocomial legionellosis. Installation of a continuous copper-silver ionization system led to complete eradication of Legionella from water samples.

Reliable Sterilization Procedures, Chemical Disinfectants, and Antiseptics

Reliable sterilization, disinfection, and antisepsis are essential for prevention of nosocomial infection.[207,208] In the 1960s, Spaulding described an approach to sterilization and disinfection based on intended use of the medical device or surgical instrument.[207] Critical items, which are introduced directly into the bloodstream or into other normally sterile areas of the body, such as surgical instruments, cardiac and urinary catheters, implanted devices, and ultrasound probes used in sterile body cavities, must be reliably sterile and should be either purchased as sterile or sterilized by steam sterilization if possible.[207] Heat-sensitive objects may be sterilized with ethylene oxide, hydrogen peroxide gas plasma, vaporized hydrogen peroxide, or hydrogen peroxide vapor and ozone.[207] Liquid chemical sterilization is only recommended to be used for critical items that are heat-sensitive and not compatible with other sterilization methods.[207] Semicritical items, which come into contact with mucous membranes or nonintact skin, such as fiberoptic endoscopes, endotracheal tubes, or ventilator circuit tubing, can be decontaminated between patients by pasteurization (i.e., 65°C–77°C for 30 minutes) or the use of high-level chemical disinfection (e.g., glutaraldehyde, hydrogen peroxide, ortho-phthalaldehyde, peracetic acid, peracetic acid–hydrogen peroxide, or hypochlorite), which kill all microorganisms except high numbers of bacterial spores.[207] Noncritical items, which normally come into contact only with intact skin, such as blood pressure cuffs or electrocardiograph electrodes, require low-level disinfection (e.g., alcohol, hypochlorite, improved hydrogen peroxide, quaternary ammonium compounds, phenolics, or peracetic acid–hydrogen peroxide), which kills bacteria, some fungi and viruses, but not mycobacteria or spores.[207]

An important exception to the Spaulding classification scheme is devices that pose a risk of transmitting prion-related diseases, including Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD).[207,209,210] Prions are not readily inactivated by conventional sterilization procedures.[207,210] As a result, devices that pose a risk for transmission of prion-related diseases should undergo special sterilization procedures after cleaning that involve sodium hydroxide followed by low-temperature autoclaving (121°C) or high-temperature autoclaving (132°C for 1 hour or 134°C for ≥18 minutes).[210] Despite concerns that procedures involving semicritical items such as endoscopes and bronchoscopes may pose a risk for transmission of prion-related infections, there has not been a single report of CJD or vCJD associated with these devices. As a result, current guidelines recommend that only critical items and semicritical items that have come in contact with neurologic tissue (e.g., brain [including dura mater], spinal cord, eye, and pituitary tissue) should undergo special prion inactivation sterilization procedures.[208,210,211]

Numerous epidemics of gram-negative infection have been described in association with respiratory therapy equipment,[101,102] diagnostic equipment such as bronchoscopes and endoscopes,[102,106–108] and solutions used for cutaneous antisepsis.[212,213] Most of these outbreaks were traced to improper procedures or malfunction of automated systems used for the disinfection and sterilization of medical devices, although a number of epidemics in years past arose as a result of extrinsic contamination of solutions used for cutaneous antisepsis.[212,213] For these reasons, the importance of strict adherence to recommended policies and procedures for cleaning and reprocessing medical equipment used in the ICU cannot be overemphasized.

Endoscopes and bronchoscopes are essential diagnostic and therapeutic instruments in the ICU. Although most post-endoscopy nosocomial infections are caused by inoculation of components of mucosal microbiomes into normally sterile, vulnerable anatomic sites during the procedure, numerous epidemics have been traced to contaminated endoscopes.[102,106–108] After use for bronchoscopy, endoscopes are typically contaminated with 6×10^4 colony-forming units per milliliter (CFUs/mL).[214] Endoscopes are considered semicritical medical devices by the Spaulding classification and therefore require high-level disinfection after use.[207,211] To ensure their safe use, flexible endoscopes should be reprocessed with the

following procedures: (1) physical cleaning to reduce microbial bioburden and remove organic debris; (2) high-level disinfection with adequate contact time between the disinfectant and device surface; (3) after disinfection, rinsing with sterile or filtered tap water to remove disinfectant residue; (4) flushing of all channels with 70% to 90% ethyl or isopropyl alcohol; and (5) drying with forced air.[211] Devices used with endoscopes that violate mucosal barriers, such as biopsy forceps, need to be reprocessed as critical medical items with full sterilization.[211] Other devices used in the delivery of respiratory care are also considered semicritical under the Spaulding classification and therefore should be reprocessed in a manner similar to endoscopes before reuse.[140,207]

In 2013, an epidemic of 39 cases of carbapenem-resistant E. coli associated with duodenoscopes was reported.[215] However, there were no processing breaches or duodenoscope defects identified as had been reported with prior outbreaks, and it was hypothesized that the complicated design of duodenoscopes made cleaning and disinfection difficult.[215,216] After changing from high-level disinfection with ortho-phthalaldehyde to sterilization with ethylene oxide, no additional cases were identified.[215] This prompted the Food and Drug Administration to convene a panel in 2015 that recommended reclassifying duodenoscopes based on the Spaulding classification from semicritical to critical to support a shift from high-level disinfection to sterilization.[217]

In contrast to disinfectants that are applied only to inanimate objects, antiseptics are agents that kill microorganisms that are applied to living tissue and skin.[208] The most commonly used antiseptics are chlorhexidine (with or without alcohol), alcohol (with or without chlorhexidine or iodophors), and iodophors (with or without alcohol).[207] Other antiseptics include phenol derivatives, triclosan, and quaternary ammonium compounds.[207] Iodophors (e.g., 10% povidone-iodine) were previously the most common agents used for cutaneous disinfection in North America. However, a large, prospective, randomized trial of cutaneous antiseptics used for drawing blood for cultures showed that chlorhexidine was superior to 10% povidone-iodine and was associated with a more than twofold reduced rate of contaminated blood cultures (odds ratio [OR] 0.40, 95% CI 0.21–0.75, P = 0.004).[218] Moreover, a meta-analysis examining the impact of different cutaneous antiseptic agents found that chlorhexidine was superior to povidone-iodine for both the prevention of intravascular catheter colonization and catheter-related BSI.[219] On the basis of these and other studies,[220,221] chlorhexidine-containing solutions are the preferred cutaneous antiseptics for insertion of IVDs in the ICU.[137] Whatever agent is used, it is essential that it be applied with vigorous scrubbing for a minimum of 1 minute to allow adequate time for germicidal activity.

Hand Hygiene

The major reservoir of nosocomial infection in the ICU is infected or colonized patients, and the major mode of spread of most nosocomial bacterial pathogens, many viruses, and even Candida from patient to patient is by transient carriage on the hands of medical personnel (see Fig. 47.2). Studies of hand carriage of nosocomial pathogens by ICU personnel, using a simple rinse technique to quantify the transient microbiome,[222] have shown that, on average, approximately 60,000 CFUs (or 4.6 logs) are recovered from the hands of ICU personnel randomly sampled (Table 47.4). Nearly half of HCWs in whom cultures are obtained at any point in time will be found to be carrying gram-negative bacilli, and 10% will be carrying S. aureus.[223] Serial culturing has shown that all ICU personnel, at various times, carry gram-negative bacilli and that nearly two-thirds carry S. aureus. Carriage of both gram-negative bacilli and S. aureus is typically transient: sampling persons every other day over a prolonged period has shown S. aureus or the same gram-negative species in consecutive cultures only 16% of the time; prolonged carriage of a single gram-negative species seems to be rare—but has been reported.[224]

Hygienic handwashing before undertaking invasive procedures, handling open wounds, or having manual contact with high-risk patients (e.g., newborns or patients in ICUs) or after touching a source or object likely to be contaminated has been recognized since the time of Semmelweis and Lister as one of the most basic and important infection control measures. Despite universal acknowledgment of handwashing as a cornerstone of nosocomial infection control programs, compliance rates much above 50% have been difficult to achieve, and handwashing rates among HCWs have ranged from 9% to 50% in numerous observational studies.[177,225,226]

Recent investigations have undertaken to better understand the reasons for poor compliance in the face of the compelling evidence that hand hygiene is essential for prevention of nosocomial infection,[177] identifying cutaneous irritation, inconvenient sink location, time constraints, high workload, and understaffing. Of concern,

TABLE 47.4 Studies of Microorganisms Carried on the Hands of Hospital Personnel Working in a Neurosurgery Unit[a]

Study Parameter	All Microorganisms	Gram-Negative Bacilli	*Staphylococcus aureus*

risk factors for noncompliance with hand hygiene include being a physician (rather than a nurse); working in an ICU; and paradoxically, engaging in patient care activities with a high risk of cross-transmission.[177] Interventions to redress these deficiencies have included the current emphasis on waterless alcohol-based hand rubs; targeted education; feedback; convenient location of sinks and hand hygiene agents; use of alternative, less irritating hand hygiene agents; hand care lotions or creams[227]; and patient education.[228] Additionally, although direct observation by trained auditors is considered the gold standard for measuring hand hygiene compliance, addition of electronic hand hygiene monitoring technologies as part of a multimodal strategy deserves further investigation.[229,230] Electronic compliance monitoring (ECM) systems estimate hand hygiene compliance by monitoring both HCW entry and exit into patient rooms and the number of times alcohol-based handrub or soap dispensers are used, by using either sensors, a specialized badge, or a camera system.[229] The advantages of ECM systems include fewer personnel resources, no observer bias, and some systems can provide feedback to HCWs regarding their hand hygiene performance.[229] Disadvantages include cost, potential issues with accuracy, inability to monitor hand hygiene before clean/aseptic procedures or after body fluid exposures, inability to monitor hand hygiene technique and glove use, and privacy concerns with respect to compliance data.[229,230]

Studies done with working hospital staff have shown that hygienic handwashing with an antiseptic-containing agent reduces the count of microorganisms on the hands of the user far more effectively than handwashing with a nonmedicated soap.[222] Repeated use of some antiseptics such as chlorhexidine has a cumulative suppressive effect on the transient hand microbiome. Routine use of an antiseptic-containing handwashing agent could, in theory, enhance the effectiveness of the handwashing that is done. Moreover, if an agent that exhibits prolonged antimicrobial activity, such as chlorhexidine, is used, it might also confer protection against contaminants acquired between handwashings.[222] However, antiseptic-containing handwashing agents are more expensive and often more irritating to the skin. Irritation can result in dermatitis and, paradoxically, increased colonization by gram-negative bacilli.[231]

Clearly, antiseptic-containing soaps are more effective in removing microorganisms from the hands of users, but will routine use of these agents for hygienic handwashing reduce the incidence of nosocomial infection in patients? Discontinuation of hexachlorophene for handwashing by personnel and bathing of infants in the United States in 1973 was followed by a marked upsurge in S. aureus infections in nurseries,[232] and use of chlorhexidine-containing handwashing agents was considered an essential measure for control of hospital outbreaks caused by multiply resistant Klebsiella[233] and MRSA.[234,235] However, since Semmelweis's study, few studies have prospectively evaluated the efficacy of antiseptic-containing handwashing agents for reducing endemic nosocomial infections, particularly infections caused by gram-negative bacilli.[231,236]

In 1982 a comparative sequential trial of three handwashing agents—a nonmedicated tissue soap, 10% povidone-iodine (Betadine Surgical Scrub), and 4% chlorhexidine (Hibiclens)—was undertaken in the trauma-surgical ICU of the University of Wisconsin Hospital.[231] Each agent was used exclusively for approximately 6 weeks, during which time hand cultures of ICU personnel were done at random and surveillance of infection in patients was carried out. Risk factors for infection in patients hospitalized during the use of each agent were comparable; nearly two-thirds of the patients in each period required ventilatory support and hemodynamic monitoring, and almost all had urinary catheters. The incidence of nosocomial infection in all groups was expectedly high, but it was 30% lower during the use of the two antiseptic-containing handwashing agents than during the use of the nonmedicated soap ($P < 0.001$). Povidone-iodine was irritating to the hands of most staff, and chlorhexidine had a slightly drying effect but was well tolerated, comparable with the nonmedicated soap.

In a similar study at the University of Iowa Hospital, Massanari[236] did not find significant differences in the rates of nosocomial infection when nonmedicated soap was used exclusively compared with alternating cycles during which 4% chlorhexidine (Hibiclens) was used in surgical ICUs; however, the incidence of infection in the medical ICU was 50% lower during use of chlorhexidine ($P < 0.05$).

In the largest multiple-crossover prospective study—1894 adult patients in three ICUs—of the relative efficacy of antiseptic-containing handwashing agents used by personnel in ICUs, Doebbeling and colleagues[237] found that the use of 4% chlorhexidine (Hibiclens) was associated with a 30% reduction in nosocomial infections (OR = 0.73), as contrasted with rates when a 60% alcohol hand-rinsing agent (Cal Stat) was used. Both regimens were well tolerated.

Recently alcohol-based waterless hand rubs have become the agents of choice for hand hygiene and are now universally used in U.S. hospitals because of their convenience and broad-spectrum activity.[228] Alcohols have the most rapid and pronounced bactericidal action and greatly reduce the time needed for hand disinfection. A vigorous 1-minute rubbing with a sufficient volume of alcohol to wet the hands completely has been shown to be highly effective at reducing the density of skin bacteria.[238] Ethanol and iso- and n-propanol are the constituents of most commercially available alcohol-based hand rubs; at equal concentrations, n-propanol is most effective and ethanol the least. However, all have limited efficacy with gross soilage so that visibly soiled hands should always be washed with antiseptic soap and water.[183] Moreover, at least 3 mL of an alcohol-based rub is necessary to completely coat the hands and achieve optimal degerming. Additionally, C. difficile spores are highly resistant to killing by alcohol, and hand washing with soap and running water is recommended to physically remove C. difficile spores.[239] The use of alcohol hand rubs or gels will be augmented by making conveniently located calibrated dispensers widely available. However, many HCWs prefer individual containers that can be carried in a pocket, which makes it difficult to ensure that an adequate volume is used with each application.

Few trials have been conducted to evaluate the efficacy of alcohol-containing hand rubs for reducing nosocomial infection. Most are quasi-experimental before-after studies, and most have shown a short-term reduction in nosocomial infection rates with use of alcohol-containing hand rubs.[184,240,241]

The major factor limiting acceptance of alcohol products for hand antisepsis in the past was desiccation and irritation of skin. This is now obviated by incorporating emollients into alcohol-based hand rubs, which has enhanced acceptance by HCWs and may augment antibacterial activity by slowing the evaporation of alcohol.[242] A recent randomized clinical trial in 50 ICU HCWs compared a conventional 2% chlorhexidine gluconate wash with water to a waterless alcohol-based hand rub (61% ethanol with emollients) and showed that use of the waterless alcohol-based product produced significantly less skin scaling and irritation[243]; unfortunately, degerming was not assessed.

A recent review describes in detail the various hand hygiene agents available and their spectrum of activity.[228] Recommendations for hand hygiene by the CDC have been published (Table 47.5),183 emphasizing hand antisepsis with an antiseptic-containing soap

TABLE 47.5 Recommendations for Routine Hand Hygiene From the Centers for Disease Control and Prevention Guideline

Recommendation	Level of Evidence[a]
• When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with either a nonantimicrobial soap and water or an antimicrobial soap and water.	IA
If hands are not visibly soiled, use an alcohol-based hand rub or, alternatively, wash hands with an antimicrobial soap and water, for the following situations: Before direct contact with patients Before putting on sterile gloves when inserting a central vascular catheter Before inserting a urinary catheter, peripheral vascular catheter, or other invasive procedure not requiring surgery After contact with patient's intact skin (e.g., while taking a pulse or blood pressure or lifting the patient) After contact with body fluids, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled Moving from a contaminated body site to a clean body site during patient care After contact with inanimate objects (e.g., medical equipment) in the immediate vicinity of the patient After removing gloves	IB
Before eating and after using a restroom, wash hands with a nonantimicrobial soap and water or with an antimicrobial soap and water.	IB
Antimicrobial-impregnated wipes are not a substitute for using an alcohol-based hand rub or antimicrobial soap.	IB
If exposure to *Bacillus anthracis* is suspected or proved, wash hands with nonantimicrobial soap and water or antimicrobial soap and water.	II

[a]Categorization of recommendations: *IA*, strongly supported for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies. *IB*, Strongly recommended for implementation and supported by certain clinical or epidemiologic studies and by strong theoretical rationale. *IC*, Required for implementation, as mandated by federal or state regulation or standard. *II*, Suggested for implementation and supported by suggestive clinical or epidemiologic studies or by strong theoretical rationale. *NR* (no recommendation/unresolved issue): practices for which insufficient evidence or no consensus exists about efficacy.

Data from Boyce JM et al. Guideline for Hand Hygiene in Health-Care Settings. Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. Society for Health Care Epidemiology of America/Association for Professionals in Infection Control/Infectious Diseases Society of America. *MMWR Recomm Rep.* 2002;51:1–45.

or detergent or an alcohol-based hand rub (1) before and after direct contact with patients or the environment and equipment in the immediate vicinity of the patient; and (2) before performing invasive procedures such as insertion of an IVD or urinary catheter. Use of skin care products—lotions or creams—to minimize irritant contact dermatitis associated with frequent handwashing and improve compliance with hand hygiene practices is highly recommended.

Institutional commitment is essential to improve compliance with recommended hand hygiene practices. The CDC guideline recommends that institutions (1) monitor and record adherence to hand hygiene by ward or service; (2) provide feedback to HCWs about their performance; and (3) monitor the volume of alcohol hand rubs used per 1000 patient-days.[183]

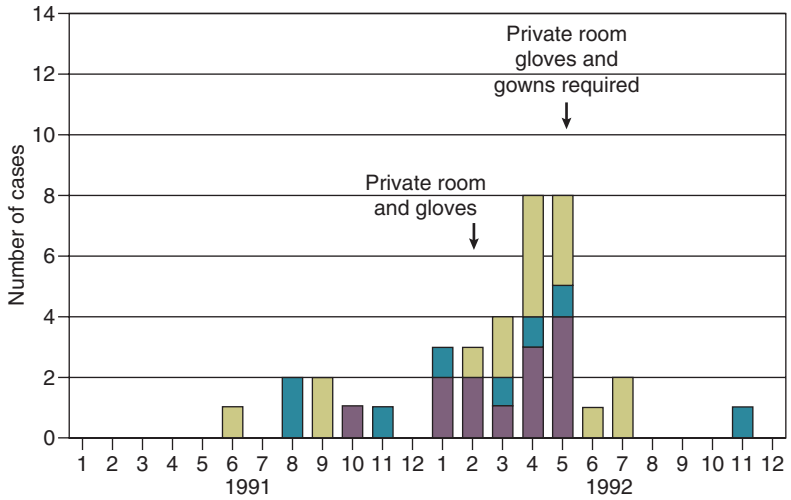
Clearly, further studies are necessary, particularly large comparative trials in which rates of nosocomial infection, rather than levels of cutaneous colonization, are used as the index of comparison. In the meantime the available data indicate that routine use of a chlorhexidine-containing product or alcohol-containing product, with the exception for C. difficile–infected patients, will be more effective than use of a nonmedicated soap for hand hygiene in the high-risk areas of the hospital, such as ICUs, where cross-infection is most likely to occur.

Isolation Precautions for Communicable Infections

Isolation, the use of special precautions in the care of infected patients, is the one means of curtailing the spread of contagious microorganisms and preventing epidemics, especially in ICUs, where the risk of cross-infection is highest. Although requiring all persons entering an infected patient's room to wear gloves and a gown, possibly even a mask, may seem ritualistic and almost archaic, each aspect of the isolation procedure is directed at interrupting a potential mode of spread and is based on the known epidemiology of the infecting organism.[244] To be maximally effective, however, isolation procedures require compliance by each person coming into contact with the patient, including physicians. Isolation is also indicated, usually for the entirety of hospitalization, for all patients infected or known to be colonized by antibiotic-resistant nosocomial pathogens such as MRSA, multidrug-resistant gram-negative bacilli, or VRE; in such cases, isolation has been shown to be effective in reducing endemic infections[245,246] (Figs. 47.2 and 47.3) and in controlling outbreaks.[246] Nevertheless, increasingly for some pathogens, particularly MRSA and VRE,[247–249] contact precautions have been viewed by many hospitals as unnecessary in the absence of an epidemic. One institution did not see an increase in MRSA or VRE isolates 1 year after elimination of routine contact precautions for MRSA and VRE, and demonstrated cost savings from decreased gown use and estimated HCW time.[249] There is less evidence, however, to support eliminating contact precautions for multidrug-resistant gram-negative bacilli and C. difficile.[245,250,251]

Isolation Systems

CDC guidelines separate basic precautions into (1) standard precautions designed for the care of all patients in hospitals, regardless of their diagnosis or presumed infection status, and (2) additional



• **Fig. 47.3** Impact of specific control measures on an institutional outbreak of vancomycin-resistant *Escherichia faecium.* Cases, by date of first positive culture for the epidemic strains (from January 1991 to December 1992). Number of cases = case patients in the intensive care unit (ICU) at time of first positive culture for the epidemic strain × other patients with previous exposure to the ICU × case patients never in the ICU. (From Boyce JM, Opal SM, Chow JW, et al. Outbreak of multidrug-resistant *Enterococcus faecium* with transferable vanB class vancomycin resistance. *J Clin Microbiol*. 1994;32:1148–1153.)

transmission-based precautions designed for the care of specified patients who are known or suspected to be infected with highly transmissible or epidemiologically important pathogens.[188] Standard precautions synthesize the major features of universal blood and body fluid precautions and are designed to reduce the risk of transmission of microorganisms from patient to patient and from patient to HCW, from both recognized and unrecognized sources of infection in the hospital. Transmission-based precautions are divided into three subgroups on the basis of the mode of transmission: contact precautions, droplet precautions, and airborne precautions. Contact precautions are recommended with multidrug-resistant bacteria that can be acquired by contact with the colonized patient or environmental surfaces or objects. Droplet precautions provide additional measures for transmission by large-particle droplets, such as during suctioning or bronchoscopy. Airborne precautions are added to standard precautions for the care of patients with tuberculosis and other microorganisms transmitted by the airborne route. In general, transmission-based precautions usually specify a private room—always for airborne precautions.

Special Issues in the ICU

An environmental issue pertaining to isolation may be most relevant in the ICU— namely, the greater potential for fomites or environmental surfaces to contribute to the spread of nosocomial infection, especially with antibiotic-resistant microorganisms. Although previous studies have not been able to demonstrate that the inanimate hospital environment, particularly surfaces, walls, or floors, contribute materially to the occurrence of nosocomial infection,[164,165] accumulating evidence suggests that this may not necessarily be true for ICUs, where uniform exposure to invasive devices makes patients unduly susceptible. A number of careful studies of the epidemiology of ICU-acquired infection with resistant organisms such as MRSA,[165,166] C. difficile,[80,167] and VRE[162,168,252] have shown heavy contamination of the inanimate environment immediately contiguous to the patient by strains implicated in nosocomial infections occurring in patients. Even if gloves are being worn as part of protective isolation or universal precautions, the possibility of transmission of microorganisms from the environment to patients on the gloved hands of HCWs is real. Prolonged wearing of gloves in the ICU, which is common, may increase the risk of nosocomial cross-infection, expanding the epidemiologic role of the inanimate environment with certain pathogens such as MRSA or VRE.[252]

Similarly, the use of common stethoscopes, sphygmomanometers, or electronic thermometers with multiple patients provides further opportunity for organisms to spread. Although stethoscopes are commonly contaminated by nosocomial organisms,[253] their role in cross-infection is less clear.[253] On the other hand, spread of VRE[254] and C. difficile[255] has been traced to contamination of electronic thermometers. All surfaces contiguous to the ICU patient should be wiped down with the general hospital disinfectant at least daily, and each ICU patient should have a dedicated stethoscope and sphygmomanometer. The use of electronic temperature measuring devices on multiple patients within an ICU bears reevaluation, unless stringent efforts are made to assure reliable decontamination of the device after each use.

As discussed, many nosocomial infections appear to derive from organisms carried on the hands of ICU personnel, who during the working day have contact with multiple patients. To improve nursing care and reduce the risk of cross-infection, ICUs must have an adequate number of staff. Although the optimal nurse-patient ratio for patients in an ICU is not known, increased rates of infection and outbreaks have occurred when nurses have been assigned to multiple critically ill patients who require complicated nursing care.[175] One-to-one nurse-patient ratios may significantly reduce the risk of cross-infection.

To contain the spread of certain resistant organisms in the ICU (e.g., MRSA, VRE), cohort nursing is strongly recommended. In cohort nursing, the care of patients known to be infected (or colonized) by the organism is provided by nurses (and respiratory therapists) who will not provide care during that shift for noninfected patients, and the nursing care of noninfected patients is restricted

to personnel who will not have contact with infected patients, except in an emergency. Cohorting of patients known to be colonized or infected with MRSA is widely practiced but has not been adequately studied. In one recent prospective study, the authors found that there was no evidence of increased transmission of MRSA when patients were not cohorted.[256]

Tuberculosis

The upsurge in tuberculosis since 1985, particularly the numerous nosocomial outbreaks caused by multidrug-resistant strains,[85–87,257,258] demonstrates the importance of isolation precautions to prevent the spread of tuberculosis within hospitals, especially within ICUs.[134] Guidelines[134] reemphasize the importance of air control by mandating the use of private negative-pressure rooms, combined with the use of UV lights or ventilatory modifications in which all air exiting the room is either filtered or exhausted directly to the roofline, away from hospital intake vents. Isolation room doors must be kept closed to maintain control over the direction of airflow, and all persons who enter a room in which tuberculosis isolation precautions are in effect must wear a disposable particulate respirator such as an N95 respirator or a powered air-purifying air respirator in which a battery-powered blower provides positive airflow through a filter, cartridge, or canister to a hood or face piece.[259] Gowns usually are not indicated. All ICUs should have one or more negative-pressure isolation rooms for the care of patients requiring respiratory isolation for tuberculosis and other airborne infections, such as chickenpox or disseminated herpes zoster, disseminated HSV infection, or emerging, highly contagious airborne infections such as SARS. To reduce the risk of contaminating a ventilator or discharging M. tuberculosis into the environment, when mechanically ventilating a patient with suspected or confirmed pulmonary tuberculosis, a bacterial filter capable of filtering particles as small as 0.3 μm, with a filter efficacy of greater than 95%, should be placed on the patient's endotracheal tube or at the expiratory side of the breathing circuit of a ventilator.[134] ICU patients with tuberculosis not requiring mechanical ventilation should wear a surgical mask if leaving the negative-pressure isolation rooms for radiographic or other procedures.[134]

Standard Precautions

In 1987 the CDC and the U.S. Department of Labor issued detailed guidelines for Universal Blood and Body Fluid Precautions[260,261] to prevent exposure of HCW workers and patients to potentially hazardous blood or body fluids. Universal precautions were based on the concept that all blood and body fluids that might be contaminated with blood should be treated as infectious because patients with bloodborne infections, such as human immunodeficiency virus (HIV), can be asymptomatic or unaware they are infected. The relevance of universal precautions to other aspects of disease transmission was recognized, and in 1996 the CDC expanded the concept and changed the term to standard precautions.[262] Standard precautions integrate and expand the elements of universal precautions into a standard of care designed to protect health care personnel and patients from pathogens that can be spread by blood or any other body fluid, excretion, or secretion. Standard precautions apply to contact with (1) blood; (2) all body fluids, secretions, and excretions (except sweat), regardless of whether they contain blood; (3) nonintact skin; and (4) mucous membranes.

Gloves are recommended for venipunctures, insertion of IVDs, and whenever it can be anticipated that the hands could become contaminated by blood or another high-risk body fluid. If there is potential for splatter or contamination of clothing, a gown is added. When there is potential for aerosolization of body fluids, such as during surgery, intubation, endoscopy, or insertion of an arterial catheter, a mask and eye shielding are included. Because the vast majority of occupationally related HIV infections have involved needle sticks or other sharps injuries, every effort must be made to avert such injuries that could result in percutaneous inoculation of HIV or other bloodborne viruses.[260,263]

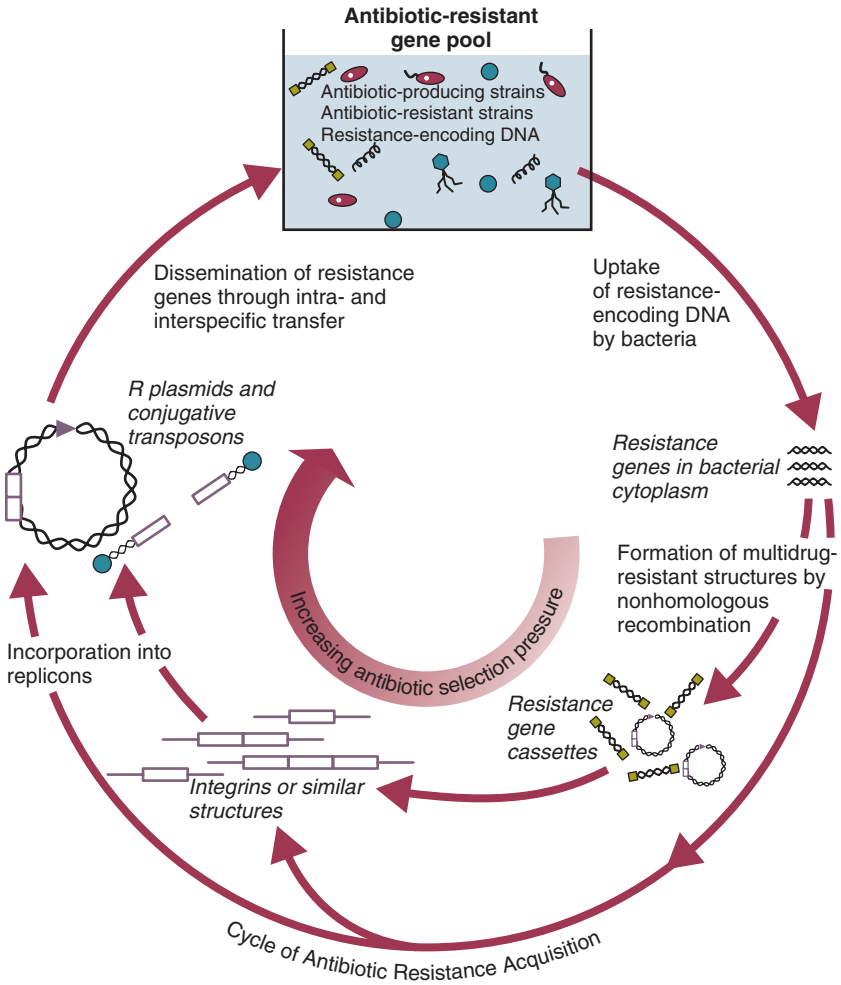
Because prophylactic use of barrier precautions appears to be of some benefit for the prevention of nosocomial infection[181,250,264] and all U.S. hospitals are currently mandated to follow standard precautions, it has been suggested that the use of gloves for all patient contacts, so-called universal gloving, as is now common in many U.S. hospitals, should implicitly reduce the risk of nosocomial infection. Several studies have demonstrated decrease infection rates with universal gloving, including in ICUs.[265–267] The greatly expanded use of gloves as part of standard precautions in hospitals must now be accompanied by educational programs on how to use gloves effectively and in a manner that will not jeopardize patients. Staff must be strongly encouraged to wash their hands after removing gloves. Moreover, if the gloved HCW has had hands-on contact with a patient colonized by MRSA or VRE, the process of removing the gloves will result in contamination of the hands of the HCW by these organisms up to one-third of the time.[266]

Antibiotic Stewardship

Antimicrobials have had a tremendous impact on the practice of critical care medicine, allowing for the treatment of once unmanageable life-threatening infections. However, it is estimated that up to 50% of antimicrobial use in U.S. acute care hospitals is either inappropriate or unnecessary, which is associated with a number of adverse outcomes, including antimicrobial resistance, C. difficile infection, treatment failures, and adverse drug reactions.[268] Antimicrobials are unique as compared with other medications in that misuse is associated with antimicrobial resistance and C. difficile, which may spread to other patients (even to the next patients to occupy that bed[172,173]), causing harm to patients not exposed to antimicrobials.[268]

There is a world crisis in antibiotic resistance, which reflects profligate antibiotic use in health care and in animal husbandry; environmental contamination with resistant bacteria, particularly in low-income countries; and intrinsic resistance elements, present long before the antimicrobial era. Antimicrobial resistance has been labeled by the World Health Organization as one of the three greatest threats to human health.[269] In the United States, it is estimated by the CDC that at least 2 million people are infected with antimicrobial-resistant microorganisms each year, resulting in at least 23,000 deaths annually.[270] Additionally, an estimated 250,000 patients are infected with C. difficile each year, resulting in at least 14,000 deaths annually in the United States.[270] More alarmingly, there are few novel antimicrobials in development for the treatment of antimicrobial-resistant microorganisms, making it imperative to optimally use currently available antimicrobials.

Antimicrobial therapy has its greatest ecologic impact in the close confines of the ICU. Most nosocomial outbreaks caused by antibiotic-resistant microorganisms[271,272] have occurred in patients hospitalized in an ICU. Antibiotic pressure, which promotes the exchange of genes encoding drug resistance by a variety of transfer mechanisms (Fig. 47.4),[273] has been shown to be the single most important factor predisposing patients to nosocomial infection



• **Fig. 47.4** Schematic depicting the route by which antibiotic-resistant genes are acquired by bacteria in response to selection pressure of antibiotic use. The resistance gene pool represents all potential sources of DNA encoding antibiotic-resistant determinants in the environment; this includes hospitals, farms, or other microenvironments where antibiotics are used to control bacterial development. After uptake of single- or double-stranded DNA by the bacterial host, the incorporation of the resistance genes into stable replicons (DNA elements capable of autonomous replication) may occur by several different pathways that have not yet been identified. The involvement of integrins, as shown here, has been demonstrated for a large class of transposable elements in the *Enterobacteriaceae.* The resulting resistance plasmids could exist in linear or circular form in bacterial hosts. The final step in the cycle, dissemination, is brought about by one or more gene transfer mechanisms. (From Davies J. Inactivation of antibiotics and the dissemination of resistance genes. *Science.* 1994;264:375–382.)

with resistant organisms. Modern-day ICUs are the breeding grounds for the multiply resistant bacteria that are now being encountered in hospitals throughout the world: MRSA; VRE; extended-spectrum β-lactamase–producing and carbapenem-resistant Enterobacteriaceae, Enterobacter, Serratia, Citrobacter; P. aeruginosa resistant to fluoroquinolones, aminoglycosides, or extended-spectrum β-lactams; and multidrug-resistant Acinetobacter.[48,62–65] Broad-spectrum antimicrobial therapy is the root cause of antibiotic-associated diarrhea and colitis caused by C. difficile.[80]

Clearly, antimicrobials are widely overused and misused; more than 75% of patients in U.S. ICUs, other than coronary care units, receive antimicrobial agents, whereas studies indicate that up to half of hospitalized patients receiving antimicrobial therapy have no evidence of infection or clear justification to be receiving antibiotics.[268] Moreover, within ICUs, a high proportion of the antibiotics used are broad-spectrum/extended-spectrum penicillins, third- and fourth-generation cephalosporins, carbapenems, aminoglycosides, fluoroquinolones, or vancomycin. Greater efforts must be directed to improving the use of systemic antibiotics, especially within ICUs.

Antibiotic stewardship is defined as coordinated interventions designed to improve and measure the appropriate use of antibiotic agents by promoting the selection of the optimal antibiotic drug regimen, including dose, duration of therapy, and route of administration.[274] Antibiotic stewardship programs have been shown to improve infection cure rates, reduce treatment failures, increase frequency of correct antibiotic prescribing, and decrease antibiotic resistance and C. difficile infection.[268] The CDC recommended in 2014 that all acute care hospitals implement an antimicrobial stewardship program.[268] Subsequently, The Joint Commission

required that all hospitals have an antibiotic stewardship program as of January 1, 2017.[275] Additionally, The Centers for Medicare & Medicaid Services proposed in June 2016 to require hospitals to have policies and procedures for, and to demonstrate evidence of, an active and hospital-wide antibiotic stewardship program.[276]

There are multiple guidelines available that outline implementation of an antibiotic stewardship program.[268,274,277] The core elements of antibiotic stewardship programs are discussed in detail later under "Control of Antibiotic Resistance."

Excellent resources,[278–280] including other chapters in this book (Chapters 20, 51 and 52), are available to guide the selection and use of anti-infective drugs in critically ill patients. However, several principles can reduce unnecessary antimicrobial therapy and improve the use of the drugs that are given:

1. Fever without other indications of infection should not mandate automatically beginning antimicrobial therapy in an ICU patient.
2. Unless antimicrobial therapy is being given for surgical prophylaxis, it is most likely being given for the treatment of suspected or proved infection. Gram-stained smears, cultures (especially of blood before any antibiotic is administered), and other appropriate diagnostic tests, as indicated, should be done without fail before beginning antimicrobial therapy for treatment of presumed infection in an ICU patient.
3. Whenever antimicrobial therapy is begun, the reason should be documented in the patient's record (e.g., "for the treatment of pneumonia," "for surgical prophylaxis").
4. When possible, the most narrow-spectrum drug or drugs should be used, especially if the infecting organism or organisms are known at the outset.
5. The need for continued antimicrobial therapy should be reassessed daily. If cultures identify the infecting microorganism or microorganisms, therapy should be modified, aiming for the most narrow-spectrum drug or drugs likely to be effective. If results of diagnostic studies are negative after 48 to 72 hours and the patient is not exhibiting signs of sepsis, antibiotic therapy should be discontinued unless the patient is profoundly granulocytopenic.
6. Beyond monitoring for efficacy and adverse drug effects such as hypersensitivity or organ toxicity, it is essential that monitoring include surveillance for superinfection by resistant bacteria or Candida and for C. difficile infection.
7. Surgical antimicrobial prophylaxis should not extend beyond 24 hours postoperatively[281,282] and in most operations can be limited to doses given intraoperatively.[281]

Nosocomial Infections and Specific Infection Control Measures

As noted earlier, most nosocomial infections, especially in immunologically competent patients and in ICUs, are causally related to exposure to invasive devices of various types or to invasive procedures such as surgery (see Tables 47.1 and 47.2). Comprehensive guidelines for the prevention of infection with procedures or devices that pose the greatest risk (urinary catheters,[138,139,283] endotracheal intubation and mechanical ventilatory support,[140] intravascular catheters and infusion therapy,[137] hemodialysis,[284] and surgery[281]) have been published and can form the basis for institutional policies and procedures. Health care professionals working in ICUs are obligated to be informed about prevention of infection associated with the procedures they perform and the devices with which they work daily.

Intravascular Device–Related Bloodstream Infection

Impact

Obtaining and maintaining reliable vascular access has become one of the most essential features of modern-day intensive care. Unfortunately, vascular access is associated with substantial and generally underappreciated potential for producing iatrogenic disease, particularly BSI originating from infection of the percutaneous IVD used for vascular access (i.e., IVD-related BSI), often referred to as "line sepsis." Nearly 60% of all nosocomial bacteremias derive from vascular access in some form,[18] and it is estimated that more than 500,000 IVD-related BSIs occur in the United States each year.[285,286] Early studies found that IVD-related BSIs are associated with excess attributable mortality rate ranging up to 35%[287]; however, subsequent case-control studies have not consistently found excess mortality rates, especially of this magnitude.[288–290] This controversy aside, all studies examining the impact of IVD-related BSI on patient outcomes have found that IVD-related BSIs are associated with increased length of hospitalization and excess health care costs, averaging $30,000 per case.[287–290]

IVD-related BSIs are largely preventable and are considered to be "never events" in many hospitals. The goal must not be simply to identify and treat these infections but rather to prevent them. By drawing on existent knowledge of the pathogenesis and epidemiology of IVD-related BSI, rational and effective guidelines for prevention can be formulated.

Definitions

IVDs are associated with both local and systemic infection. The CDC has published definitions for IVD-related infection (see Box 47.1).[16,17] These definitions are useful for the purposes of surveillance but rely heavily on the construct, central line–associated bloodstream infection, which implicitly assumes that each primary BSI (i.e., a BSI without an identifiable local infection) originates from a central venous catheter (CVC). This practice results in an overestimation of the true risk of CVC-related infection because not all primary BSIs originate from a central venous device; some are secondary BSIs deriving from unrecognized postoperative surgical site, intraabdominal infections, nosocomial pneumonias, gastrointestinal source (i.e., "translocation") in patients with severe neutropenia, or originate from other vascular devices such as peripheral venous catheters or arterial catheters used for hemodynamic monitoring.

By applying molecular subtyping techniques[114,291,292] to the results of semiquantitative or quantitative cultures of the removed IVD and blood cultures or the results of cultures of blood drawn through the IVD and a separate concomitant percutaneous peripheral blood culture, it is possible to reliably determine whether an IVD was the source of a nosocomial BSI. Using these diagnostic techniques allows the formulation of simple but more rigorous definitions for IVD-related infection (Table 47.6), which we believe bear consideration as the standard for randomized trials and epidemiologic studies of IVD-related infection.[18] Published guidelines from the Infectious Diseases Society of America have outlined clinical definitions of IVD-related BSI similar to those listed in Table 47.6, although molecular subtyping methods are not recommended for routine clinical diagnosis of IVD-related BSI.[293]

Recognition and Diagnosis

Clinical Features

Evidence-based guidelines from the American College of Critical Care Medicine and the Infectious Diseases Society of America

TABLE 47.6 Proposed Definitions for Intravascular Device–Related Colonization, Local Infection, and Bloodstream Infection Based on Microbiologic Confirmation of the Device as Source

IVD colonization	(i) A positive semiquantitative[a] (or quantitative[b]) culture of the implanted portion or portions of the IVD; (ii) absence of signs of local or systemic infection.
Local IVD infection	(i) A positive semiquantitative[a] (or quantitative[b]) culture of the removed IVD or a positive microscopic examination or culture of pus or thrombus from the cannulated vessel; (ii) clinical evidence of infection of the insertion site (i.e., erythema, induration, or purulence); but (iii) absence of systemic signs of infection and negative blood cultures, if done.
IVD-related BSI	*If the IVD is removed:* (i) A positive semiquantitative[a] (or quantitative[b]) culture of the IVD or a positive culture of the catheter hub or infusate (or positive microscopic examination or culture of pus or thrombus from the cannulated vessel) AND one or more positive blood cultures, ideally percutaneously drawn, concordant for the same species, ideally by molecular subtyping methods; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI. *If the IVD is retained:* (i) If quantitative blood cultures are available, cultures drawn both from the suspect IVD and a peripheral vein (or another IVD) are both positive and show a marked step-up in quantitative positivity (fivefold or greater) in the IVD-drawn culture; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI. OR (i) If automated monitoring of incubating blood cultures is available, blood cultures drawn concomitantly from the suspect IVD and a peripheral vein (or another IVD) show both are positive, but the IVD-drawn blood culture turns positive more than 2 hours before the peripherally drawn culture; (ii) clinical and microbiologic data disclose no other clear-cut source for the BSI.

TABLE 47.7 Clinical, Epidemiologic, and Microbiologic Features of Intravascular Device–Related Bloodstream Infection

Nonspecific	Suggestive of Device-Related Etiology
Fever	Patient unlikely candidate for sepsis (e.g., young, no underlying diseases)
Chills, shaking rigors[a]	Source of sepsis inapparent, no identifiable local infection
Hypotension, shock[a]	Intravascular device in place, especially central venous catheter
Hyperventilation, respiratory failure	Inflammation or purulence at insertion site
Gastrointestinal[a]	Abrupt onset, associated with shock
Abdominal pain Vomiting Diarrhea	Bloodstream infection caused by staphylococci (especially coagulase-negative staphylococci), *Corynebacterium, Candida, Trichophyton, Fusarium,* or *Malassezia* species[b]
Neurologic[a]	Very high-grade (>25 CFUs/mL) candidemia
Confusion Seizures	Cluster of cryptogenic infusion-associated bloodstream infections caused by *Enterobacter cloacae, Pantoea agglomerans,* or *Serratia marcescens*[a,b] Sepsis refractory to antimicrobial therapy or dramatic improvement with removal of cannula and infusion[a]

[a]Commonly seen in overwhelming gram-negative sepsis originating from contaminated infusate, peripheral suppurative phlebitis, or septic thrombosis of a central vein.
[b]Conversely, bacteremia caused by streptococci, aerobic gram-negative bacilli, or anaerobes is unlikely to derive from an intravascular device.
CFUs, Colony-forming units.

provide information on the evaluation of the ICU patient with fever or other signs of sepsis.[35] Before any decision regarding initiation of antimicrobial therapy or removal of an IVD, the patient must be thoroughly examined to identify all plausible sites of infection, including VAP, catheter-associated urinary tract infection, surgical site infection, IVD-related BSI, C. difficile infection, and other infections.[35]

Despite the challenge of identifying the source of a patient's signs of sepsis,[35] several clinical, epidemiologic, and microbiologic findings point strongly toward an IVD as the source of a septic episode (Table 47.7).[285] Patients with an abrupt onset of signs and symptoms of sepsis without any identifiable local infection such as pneumonia or surgical site infection should prompt suspicion of infection of an IVD. The presence of inflammation or purulence at the catheter insertion site is now uncommon in patients with IVD-related BSI.[294] However, if inflammation, especially any purulence, is seen in combination with signs and symptoms of sepsis, it is highly likely the patient has IVD-related BSI and should prompt removal of the device. Finally, recovery of certain microorganisms in multiple blood cultures, such as staphylococci, Corynebacterium or Bacillus species, or Candida or Malassezia, strongly suggests infection of an IVD.

Blood Cultures

Initiating the use of anti-infective drugs for suspected or presumed infection in the critically ill patient without first obtaining blood cultures from two separate sites, at least one of which is drawn from a peripheral vein by percutaneous venipuncture, is indefensible. The volume of blood cultured is essential to maximize the sensitivity of blood cultures for diagnosis of bacteremia or candidemia: in

adults, obtaining at least 20 mL, ideally 30 mL, per drawing (each specimen, containing 10 or 15 mL, inoculated into aerobic and anaerobic media) significantly improves the yield compared with obtaining only 5 mL at each drawing and culturing a smaller total volume.[295,296] In adults, if at least 30 mL of blood is cultured, 99% of detectable bacteremias should be identified.[295,297] Similar operating characteristics are achieved in the pediatric population using a weight-based graduated volume approach to blood cultures.[298] Standard blood samples for cultures drawn through CVCs provide excellent sensitivity for diagnosis of BSI but are less specific than cultures obtained from a peripheral vein.[299,300] If the patient has a long-term multilumen catheter, it may be reasonable to obtain a specimen from each lumen of the catheter because studies have found discordance (≈30%) among cultures obtained from different lumens of the same catheter.[301] Nevertheless, some hospitals have prohibited routinely drawing of blood for cultures from vascular access devices because of increased blood culture contamination rates and resultant overuse of vancomycin.

Every effort must be made to prevent introduced contamination when drawing samples for blood cultures because a single contaminated blood culture has been shown to prolong hospitalization by 4 days and increase the costs of hospitalization by $4100 to $4400.[302,303] Tincture of iodine, isopropyl alcohol, chlorhexidine, or povidone-iodine combined with alcohol rather than povidone-iodine alone should be used for skin antisepsis before venipuncture for blood cultures, recognizing that studies have shown significantly reduced rates of contamination with use of these agents.[218,303,304] Up to 30% of blood cultures positive for coagulase-negative Staphylococcus represent true infection[305,306]; however, the majority of single positive cultures represent contamination,[306] a finding that should reemphasize the need to obtain cultures from two separate sites whenever BSI is suspected.

Cultures of Removed Intravascular Devices

Removal and direct culture of the IVD has historically been the gold standard for confirming the presence of IVD-related BSI, particularly with short-term IVDs. Studies have shown that culturing catheter segments semiquantitatively on solid media[307] or quantitatively in liquid media (e.g., removing the adherent organisms by sonication[308]) provides superior sensitivity and specificity for diagnosis of IVD-related BSI, with a strong correlation between high colony counts and line sepsis. Growth of greater than or equal to 15 CFUs from a catheter segment by semiquantitative culture or growth of greater than or equal to 10^3 CFUs from a catheter cultured after sonication with accompanying local inflammation or signs of sepsis indicates local catheter infection. Significant growth in the absence of local or systemic inflammation suggests colonization of the device, which reinforces the recommendation that catheter tips should be cultured only for clinical indications and not routinely. If continued vascular access is necessary, a new device should be placed in a new location rather than replacing it with a new one in the same location by guidewire exchange because of greater risk of subsequent infection when the old site is used.

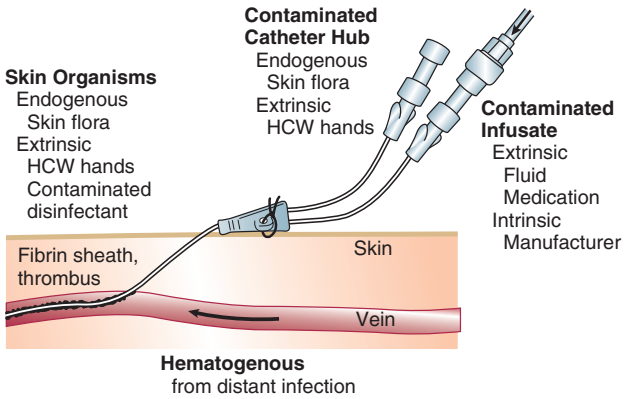
Although studies[309] have suggested that quantitative methods (e.g., sonication) are superior to the semiquantitative methods (e.g., roll plate), other studies have shown them to be equivalent.[310,311] Because hub contamination progressing to intraluminal colonization is the primary route of infection for long-term devices (e.g., devices in place >10 days), quantitative techniques may be superior to semiquantitative techniques in detecting infections from devices in place over the long term, because quantitative techniques remove organisms from both the internal and external surface of catheters.[311] In contrast, semiquantitative methods may be preferred over quantitative methods in cases of suspected infection related to a short-term device (e.g., devices in place <10 days) because the primary route of infection in this setting is caused by extraluminal ingress of skin organisms at the catheter insertion site and the semiquantitative method is simple, is the only method available in most non-research labs, is less expensive, and allows identification of the infecting organisms a day earlier.

Direct and impression Gram stains[312] or acridine orange stains[311] of intravascular segments of removed catheters have shown excellent correlation with quantitative techniques for culturing catheters and can permit rapid diagnosis of catheter-related infection.

To rigorously identify the mechanism of IVD-related BSI in prospective research studies, it is necessary to culture all potential sources of microorganisms at the time of catheter removal for cause (Fig. 47.5): skin of the insertion site, each catheter hub, infusate from each lumen, as well as implanted catheter segments. If the results of these cultures appear to link a BSI with microorganisms isolated from one or more portions of the device by phenotypic criteria, efforts then need to be made to conclusively establish concordance, beyond speciation and antimicrobial susceptibility pattern, using one or more molecular subtyping systems.[291,292,296,313]

Diagnosis of Infection With Implanted Long-Term Intravascular Devices

The methods described earlier require removal of the device for confirmation of IVD-related BSI. This can pose formidable challenges to management with long-term, surgically implanted IVDs such as Hickman and Broviac catheters, cuffed and tunneled hemodialysis catheters, and subcutaneous central venous ports. Only 15% to 45% of long-term IVDs that are removed for suspected infection are truly colonized or infected at the time of removal.[314–317] To avoid unnecessary removal of IVDs, methods have been developed to diagnose IVD-related BSI while allowing the device to remain in place: (1) paired quantitative blood culture samples drawn from the IVD and percutaneously from a peripheral vein[311] and (2) differential time to positivity (DTP) of paired standard blood cultures, one drawn from the IVD and the other from a peripheral vein.[318]



• **Fig. 47.5** Potential sources of infection of a percutaneous intravascular device (IVD): the contiguous skin flora, contamination of the catheter hub and lumen, contamination of infusate, and hematogenous colonization of the IVD from distant, unrelated sites of infection. *HCW,* Health care worker. (From Crnich CJ, Maki DG. The promise of novel technology for the prevention of intravascular device-related bloodstream infection. I. Pathogenesis and short-term devices. *Clin Infect Dis.* 2002;34:1232–1242.)

Although seldom available outside the research setting, automated quantitative systems for culturing blood (e.g., Isolator lysis centrifugation system, Wampole Laboratories, Cranbury, NJ), allow for samples for quantitative blood cultures to be drawn through the IVD and concomitantly by venipuncture from a peripheral vein (or another IVD), which can permit the diagnosis of IVD-related bacteremia or fungemia to be made with sensitivity and specificity in the range of 80% to 95%,[311] without removal of the catheter, if empiric antimicrobial therapy has not yet been initiated. IVD-drawn cultures demonstrating 5- to 10-fold higher concentrations of microorganisms per milliliter, as compared with counts of the same microorganism obtained in a culture drawn from a peripheral vein, confirm the presence of IVD-related BSI.

A more readily available method is the DTP of paired blood cultures, where one sample for blood culture is drawn through the IVD and the second, concomitantly from a peripheral vein. The time required for blood cultures to turn positive is accessible from the automated blood culture system, available from the microbiology department. DTP has also been shown to reliably identify IVD-related BSI of long-term IVDs if the blood for culture drawn from the IVD turns positive 2 or more hours before the culture drawn peripherally. In studies of patients with long-term IVDs, the sensitivity and specificity of DTP ranged from 82% to 94% and 88% to 91%, respectively.[311,318] The performance of DTP in short-term IVDs has been examined, with disappointing results,[319] a finding that is not entirely unexpected given the predominant extraluminal route of infection with these devices.

Detection of Contaminated Infusate

When a patient becomes acutely septic temporally related to an infusion of intravenous (IV) fluid or medication, the infusate should be considered as a source of infection. To diagnose infection caused by contaminated infusate, a sample of IV fluid, aspirated from the line, should be cultured quantitatively and qualitatively[307] and information about the infused material (manufacturer, lot number) and the infusate container should be retained; concordance with positive peripheral blood cultures, without another identifiable source for the patient's BSI, definitively implicates infected infusate as the cause of the BSI. Anaerobic culture techniques are not necessary unless blood or another biologic product is involved.

Incidence

Prospective studies, in which every attempt was made to conclusively identify the presence of an IVD-related BSI, show that every type of IVD carries some risk of causing BSI; however, the magnitude of risk varies greatly, depending on the type of device (Table 47.8).[320]

TABLE 47.8 Rates of Intravascular Device–Related Bloodstream Infection Caused by Various Types of Devices Used for Vascular Access in Adults

					RATES OF IVD-RELATED BSIS			
					Per 100 Devices		Per 1000 IVD Days	
Device	Studies *(n)*	Catheters *(n)*	IVD days *(n)*	BSIs *(n)*	Pooled Mean	95% CI	Pooled Mean	95% CI
Peripheral intravenous catheters	11	10,910	28,720	13	0.1	0.1-0.2	0.5	0.2-0.7
Arterial catheters	14	4,366	21,397	37	0.8	0.6–1.1	1.7	1.2–2.3
Short-term, nonmedicated central venous catheters	79	20,226	322,283	883	4.4	4.1–4.6	2.7	2.6–2.9
Pulmonary artery catheters	13	2,057	8143	30	1.5	0.9–2.0	3.7	2.4–5.0
Hemodialysis catheters:								
Temporary, noncuffed	16	3,066	51,840	246	8.0	7–9	4.8	4.2–5.3
Long-term, cuffed, and tunneled	16	2,806	373,563	596	21.2	19.7–22.8	1.6	1.5–1.7
Peripherally inserted central catheters (PICCs):	15	3,566	105,839	112	3.1	2.6–3.7	1.1	0.9–1.3
Long-term, tunneled, and cuffed central venous catheters	29	4,512	622,535	1013	22.5	21.2–23.7	1.6	1.5–1.7

BSIs, Bloodstream infections; *CI,* confidence interval; *IVD,* intravascular device.

Modified from Maki DG, Kluger DM, Crnich CJ. The risk of bloodstream infection in adults with different intravascular devices: a systematic review of 200 published prospective studies. *Mayo Clin Proc.* 2006;81:1159–1171.

The device that poses the greatest risk of IVD-related BSI today is the CVC in its many forms (see Table 47.8). Short-term, noncuffed, single-lumen, or multilumen catheters inserted percutaneously into the subclavian or internal jugular vein have shown rates of catheter-related BSI in the range of 3% to 5% (2 to 3 per 1000 IVD days).[320] Far lower rates of infection have been encountered with surgically implanted cuffed Hickman or Broviac catheters and subcutaneous central venous ports (1 and 0.2 per 1000 IVD days, respectively).[320] Contrary to popular belief, peripherally inserted central catheters (PICCs) used in inpatients and arterial catheters are associated with rates of catheter-related BSI approaching those seen with short-term, noncuffed, and nontunneled, multilumen CVCs—up to 2.1[321] and 3.4[322] BSIs per 1000 IVD-days, respectively.

Pathogenesis and Risk Factors

Two major sources of IVD-related BSI exist: (1) colonization of the IVD, catheter-related infection, and (2) contamination of the fluid administered through the device, infusate-related infection.[285] Contaminated infusate is the cause of most epidemic IVD-related BSIs; in contrast, catheter-related infections are responsible for most endemic IVD-related BSIs.[18]

For microorganisms to cause catheter-related infection, they must first gain access to the extraluminal or intraluminal surface of the device, where they can adhere and become incorporated into a biofilm that allows sustained infection and hematogenous dissemination.[323] Microorganisms gain access to the bloodstream by one of three mechanisms (see Fig. 47.5): (1) skin organisms invade the percutaneous tract, probably assisted by capillary action, at the time of insertion or in the days following; (2) microorganisms contaminate the catheter hub (and lumen) when the catheter is inserted over a percutaneous guidewire or later manipulated; or (3) organisms are carried hematogenously to the implanted IVD from remote sources of local infection such as pneumonia.

With short-term IVDs (e.g., in place <10 days) such as peripheral IV catheters; arterial catheters; and noncuffed, nontunneled CVCs, most device-related BSIs are of cutaneous origin, from the insertion site, and gain access extraluminally, occasionally intraluminally at insertion with the guidewire.[324,325] In contrast, contamination of the catheter hub and luminal fluid is the predominant mode of invasive infection with long-term IVDs (e.g., in place >10 days) such as cuffed Hickman- and Broviac-type catheters, subcutaneous central ports, and PICCs.[326,327]

Also important is recognizing that infusate (parenteral fluid, blood products, or IV medications) administered through an IVD can also occasionally become contaminated and produce device-related BSI. Contaminated fluid is fortunately an infrequent cause of endemic infusion-related infection with most short-term IVDs; it is, however, an important cause of BSIs with arterial catheters used for hemodynamic monitoring and long-term IVDs such as Hickman or Broviac catheters, cuffed hemodialysis CVCs, and subcutaneous central venous ports.[325,328,329]

Most nosocomial epidemics of infusion-related BSI have been traced to contamination of infusate by gram-negative bacilli, introduced during its manufacture (intrinsic contamination) or during its preparation and administration in the hospital (extrinsic contamination).[151,330] If an epidemic is suspected, the epidemiologic approach must be methodical and thorough yet expeditious, directed toward establishing the bona fide nature of the putative epidemic infections (i.e., ruling out "pseudoinfections")[331] and confirming the existence of an epidemic; defining the reservoirs and modes of transmission of the epidemic pathogens; and most importantly, controlling the epidemic quickly and completely. Control measures are predicated on accurate delineation of the epidemiology of the epidemic pathogen. The essential steps in dealing with a suspected nosocomial outbreak have recently been reviewed (and are discussed later).[285]

Risk factors associated with an increased risk of IVD-related BSI are outlined in Table 47.9. Prolonged hospitalization and severity of illness clearly influence the risk, and clinical states such as granulocytopenia, AIDS, and bone marrow transplantation have been associated with fourfold to sixfold increased rates of IVD-related BSI.[332,333] However, the features of the IVD, its insertion, and its maintenance appear to have far greater impact on the overall risk of infection. In 289 patients, Merrer and colleagues[334] found that insertion of an IVD in the femoral versus the subclavian vein was associated with a greatly increased risk of infection (20 vs. 3.7 BSIs per 1000 IVD days, $P < 0.001$) and thrombotic complications (21.5% vs. 1.9%, $P < 0.001$).[334] Moreover, Robert and colleagues[335] found that patients with primary BSI were more likely to have received care during times when there was a lower nurse-to-patient ratio and a higher proportion of temporary ("float") nurses rather than the full-time nursing staff.[335]

Microbiology

Fig. 47.6 summarizes the microbial profile of IVD-related BSI from 159 published prospective studies.[336] As might be expected from knowledge of the pathogenesis of these infections, skin microorganisms account for the largest proportion of these infections.

Treatment

Treatment of IVD-related BSI is discussed in Chapter 51 (see "Device-Related Endovascular Infections").

Strategies for Prevention

Recommendations for the prevention of IVD-related BSIs were published by the Healthcare Infection Control Practices Advisory Committee (HICPAC).[137] Table 47.10 summarizes the recommendations of the 2011 HICPAC guideline for the prevention of IVD-related BSI and scores each recommendation on the basis of the quality of the available scientific evidence. It must be reaffirmed that measures for prevention of any nosocomial infection must, wherever possible, be based on the best understanding of pathophysiology and epidemiology and, whenever possible, controlled clinical trials.

At-Device Insertion

1. Choice of catheter and site of device insertion. Obviously, the choice of IVD inserted into a patient will be guided primarily by that patient's particular needs (e.g., hemodialysis vs. fluid administration). However, the astute clinician can mitigate much of the risk associated with vascular access by choosing the best device for the task at hand and inserting the IVD in a location associated with the least risk of infection. Studies suggest that multilumen IVDs are associated with a higher risk of infection than single-lumen catheters.[337] That said, if a patient has need for multiple infusions, inserting several single-lumen catheters will pose greater risks than a single multilumen catheter.

   To date, there have been no randomized studies designed to evaluate the optimal location for placement of short-term CVCs. However, the data accumulated from numerous observational studies suggest that the lowest risk of IVD-related BSI is seen with subclavian vein insertion and the highest risk with

TABLE 47.9 Risk Factors for Intravascular Device–Related Bloodstream Infection With Short-Term Use

Risk Factor (No. of Studies)	Relative Risk or Odds Ratio
Underlying Disease	
AIDS (2)	4.8
Neutropenia (2)	1–15.1
Gastrointestinal disease (1)	2.4
Surgical service (1)	4.4
ICU/CCU placement (3)	0.4–6.7
Extended hospitalization (3)	1–6.7
Other intravascular devices (2)	1–3.8
Systemic antibiotics (3)	0.1-0.5
Active infection at another site (2)	8.7–9.2
High APACHE III score (1)	4.2
Mechanical ventilation (1)	2–2.5
Transplant recipient (1)	2.6
Features of Insertion	
Difficult insertion (1)	5.4
Maximal sterile barriers (1)	0.2
Tunneling (2)	0.3–1
Insertion over a guidewire (8)	1–3.3
Insertion Site	
Internal jugular vein (6)	1–3.3
Subclavian vein (5)	0.4–1
Femoral vein (2)	3.3–4.8
Defatting insertion site (1)	1.0
Use of a multilumen catheter (8)	6.5
Catheter Management	
Routine change of IV set (2)	1.0
Staffing in SICU (nurse-to-patient ratio) (1)	
1:2	61.5
1:1.5	15.6
1:1.28	4.0
1:1	1.0
Inappropriate catheter usage (1)	5.3
Duration of catheterization >7 days (5)	1–8.7
Colonization of catheter hub (3)	17.9–44.1
Parenteral nutrition (2)	–4.8

APACHE III, Acute Physiology and Chronic Health Evaluation III; *CCU*, critical care unit; *ICU*, intensive care unit; *IV*, intravenous; *SICU*, surgical intensive care unit.
Modified from Safdar NS, Kluger DM, Maki DG. A review of risk factors for catheter-related infection caused by percutaneously inserted, noncuffed central venous catheters: implications for preventive strategies. *Medicine.* 2002;81:466–479.

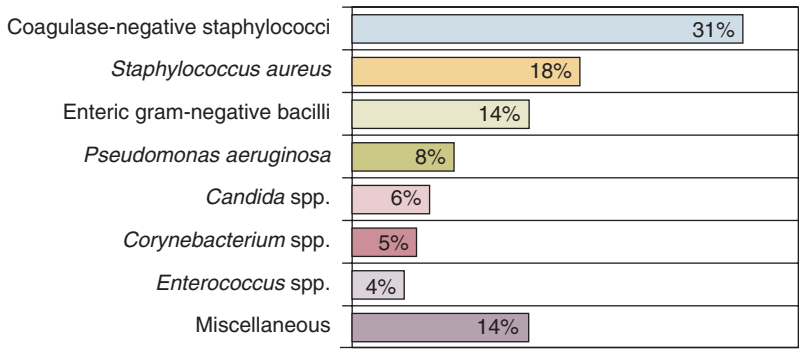
femoral vein insertion, with an intermediate level of risk associated with jugular vein insertions.[325,334]

The femoral vein is often used for central venous access, especially on nonsurgical services, because of the ease of cannulation and the lower risk of mechanical complications from insertion (i.e., bleeding or pneumothorax). Unfortunately, prospective studies evaluating the risk of femoral vein device placement have shown that CVCs placed in the femoral vein are more likely to be colonized at the time of removal than catheters placed in the internal jugular vein (RR 4.7, CI 2–8.8, P = 0.0001)[338] and are associated with an increased risk of IVD-related BSI when compared with CVCs placed in the subclavian vein (4.4% vs. 1.5%, P = 0.07).[334] Furthermore, prospective studies have found higher rates of catheter-related deep vein thrombosis with femoral catheters, in the range of 7% to 25%.[333,334] In general, we believe femoral access should be used only if emergent access is required, the inexperience of the operator limits placement in the upper body, or there is a contraindication to placement in the upper body (no available sites, an extensive burn, or severe coagulopathy). If a short-term CVC must be placed in the femoral vein or artery, we believe it is important that the catheter insertion site be located at least 2 inches (5 cm) below the inguinal crease or an intertriginous area, which is heavily colonized with bowel organisms and yeasts; this also allows a more secure protective dressing to be affixed.

In contrast to short-term CVCs, observational studies of hemodialysis catheters have not been able to confirm a lower rate of infection with catheters inserted in the subclavian vein compared with those inserted in the internal jugular vein,[339] although there is still excess risk associated with femoral vein placement.[340] More importantly, prospective studies of catheters used for hemodialysis have demonstrated a significant risk of great vein thrombosis and stenosis in catheters inserted into the subclavian vein that approaches 40% to 50% compared with rates of 0% to 10% with catheters inserted into the internal jugular vein.[341,342] On the basis of these data, internal jugular vein insertion is preferable to subclavian vein insertion for central access for hemodialysis.

2. Barrier precautions. Hand hygiene with an antiseptic-containing preparation, either conventional handwashing with chlorhexidine (2%–4%) or with a waterless alcohol rub or gel,[183] must always precede the insertion of an IVD and should also precede subsequent handling of the device or its administration set.[137] A new pair of disposable, nonsterile gloves, using a "no-touch" technique, is adequate for the placement of peripheral IV catheters in most patients; however, sterile gloves should be used during insertion in high-risk patients such as those with granulocytopenia. Sterile gloves are strongly recommended for placement of all other types of IVDs that are associated with a 1% or higher risk of associated bacteremia, specifically arterial catheters and all types of centrally placed devices including PICCs.[137]

Studies have shown that the use of maximal barriers, including a long-sleeved, sterile surgical gown, mask, cap and large sterile drape, and sterile gloves, significantly reduces the risk of CVC-related BSI (0.08 BSIs with maximal barriers vs. 0.5 BSIs per 1000 IVD days without maximal barriers, P = 0.02).[343] The use of maximal barriers has further been shown to be highly cost-effective.[343] Considering that of all IVDs, CVCs are most likely to produce nosocomial BSI, a strong case can be made for mandating maximal barrier precautions during the insertion



• **Fig. 47.6** Microbial profile of intravascular device–related bloodstream infection based on an analysis of 159 published prospective studies. (Modified from Maki DG, Kluger DM, Crnich CJ. The microbiology of intravascular device-related (IVDR) infection in adults: an analysis of 159 prospective studies and implications for prevention and treatment. In: *Abstracts and Proceedings from the 40th Annual Meeting of the Infectious Disease Society of America*. Chicago: Infectious Disease Society of America; 2002.)

TABLE 47.10 Summary of CDC/HICPAC Guideline Recommendations for Prevention of Intravascular Device–Related Bloodstream Infection in Adults

Recommendation	Strength[a]
General Measures	
• Educate health care personnel regarding indications for IVD use, proper procedures for IVD insertion/maintenance, and infection control measures. Periodically assess knowledge of and adherence to guidelines. Designate only trained personnel who demonstrate competence in IVD insertion/maintenance.	IA
• Ensure adequate nursing staffing levels in ICUs.	IB
• Use "bundles," whereby multifaceted strategies are bundled together to improve compliance with evidence-based recommended practices.	IB
Hand Hygiene, Aseptic Technique, and Maximal Sterile Barrier Precautions	
• Perform hand hygiene and maintain aseptic technique, before and after inserting, replacing, accessing, repairing, or dressing an IVD.	IB
• Use maximal sterile barrier precautions during insertion of CVCs, PICCs, or guidewire exchange: mask, cap, sterile gown, sterile gloves, sterile full-body drape.	IB
• Use minimum of cap, mask, sterile gloves, and small sterile fenestrated drape during insertion of peripheral arterial catheters.	IB
• Use maximal sterile barrier precautions during insertion of axillary or femoral artery catheters.	II
• Don new sterile gloves before handling new catheter during guidewire exchange.	II
• Use either clean or sterile gloves when changing the dressing on IVDs.	IC
IVD Insertion	
• Use subclavian site for nontunneled CVC placement, rather than jugular or femoral (IB) (except avoid subclavian site for patients undergoing dialysis or with advanced kidney disease—IA).	See text
• Avoid femoral vein for central venous access.	IA
• Weigh risks against benefits of placing CVC at recommended site to reduce infectious complications versus risk for mechanical complications (e.g., pneumothorax).	IA
• Use radial, brachial, or dorsalis pedis sites for peripheral arterial catheters, rather than femoral or axillary.	IB
• Prepare clean skin with >0.5% chlorhexidine preparation with alcohol before insertion of CVCs and peripheral arterial catheters and during dressing changes; can use tincture of iodine, an iodophor, or 70% alcohol in patients with a contraindication to use of chlorhexidine.	IA
• Use sutureless securement device to reduce risk of infection.	II
• Use sterile sleeve to protect pulmonary artery catheters during insertion.	IB
• Use either sterile gauze or sterile, transparent, semipermeable dressing to cover catheter site.	IA
IVD Maintenance	
• Promptly remove any IVD that is no longer essential.	IA
• Replace gauze dressings on short-term CVC sites every 2 days.	II
• Replace transparent dressings on short-term CVC sites at least every 7 days.	IB
• Replace dressing if it becomes damp, loosened, or visibly soiled.	IB
• Monitor IVD insertion site when changing dressing or by palpation through intact dressing on regular basis; dressing should be removed to examine site if local or systemic signs of infection are present.	IB
• Do not use systemic antibiotic prophylaxis; and do not use topical antibiotic ointments on IVD exit sites, except for dialysis catheters.	IB

Continued

TABLE 47.10 Summary of CDC/HICPAC Guideline Recommendations for Prevention of Intravascular Device–Related Bloodstream Infection in Adults—cont'd

Recommendation	Strength[a]
• Use a 2% chlorhexidine wash for daily skin cleansing.	II
• Replace administration sets in continuous use no more frequently than at 96-h intervals but at least every 7 days (IA). When blood, blood products, or fat emulsions are given, replace tubing within 24 h of initiating the infusion (IB). With propofol infusions, replace tubing every 6 or 12 h, when the vial is changed (IA).	See text
• Change needleless IV catheter system components at least as frequently as the administration set, but no more frequently than every 72 h (for needleless connectors, do not change more frequently than every 72 h or according to manufacturers' recommendations).	II
• Minimize contamination of needleless IV catheter systems by scrubbing the access port with an appropriate antiseptic (chlorhexidine, povidone-iodine, an iodophor, or 70% alcohol) and accessing the port only with sterile devices.	IA
• Replace peripheral IV lines every 72–96 h.	IB
• Do not routinely replace CVCs, PICCs, hemodialysis catheters, pulmonary artery catheters (IB), or arterial catheters (II) solely for prevention of infection.	See text
• Do not remove CVCs or PICCs solely because of fever unless IVD infection is suspected, but replace catheter if purulence is seen at the exit site, especially if the patient is hemodynamically unstable and IVD-related BSI is suspected.	II
• Do not use guidewire exchanges to replace a non-tunneled catheter suspected of infection; a new device should be placed in a new location.	IB
• When adherence to aseptic technique cannot be ensured (e.g., with insertion of catheter during a medical emergency), replace the catheter as soon as possible (i.e., within 48 h).	IB
Technology	
• Use chlorhexidine–silver sulfadiazine or minocycline-rifampin–impregnated CVC in patients whose catheter is expected to remain in place >5 days, if the rate of IVD-related BSI is not decreasing after successful implementation of a comprehensive strategy to reduce rates of such infections.	IA
• Use chlorhexidine-impregnated sponge dressing for temporary short-term catheters if the IVD-related BSI rate is not decreasing despite adherence to basic prevention measures.	IB
• Use prophylactic antibiotic lock solution *only* in patients with long-term IVDs who have continued to experience IVD-related BSIs despite consistent application of infection control practices.	II

[a]From the CDC/HICPAC system of weighting recommendations based on scientific evidence: *IA,* strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies. *IB,* Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale; or an accepted practice (e.g., aseptic technique) supported by limited evidence. *IC,* Required by state or federal regulations, rules, or standards. *II,* Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale.

Data from O'Grady NP, Alexander M, Burns LA, et al, Guidelines for the prevention of intravascular catheter-related infections. *Clin Infect Dis.* 2011;52:e162–e193.

of all central IVDs.[137] They are not necessary, however, for arterial catheters used for hemodynamic monitoring, during which sterile gloves and a sterile fenestrated drape will suffice, because using maximal sterile barrier precautions does not appear to reduce the risk of arterial catheter-related BSI.[344] However, guidelines for the prevention of IVD-related BSI[137] recommend that in addition to a using a minimum of a cap, mask, sterile gloves, and a small sterile fenestrated drape during the insertion of all peripheral arterial catheters, maximal sterile barrier precautions should be used for axillary and femoral artery catheter insertion (see Table 47.10), although the evidence to support this recommendation is not strong.[345]

3. IV teams. Good technique is also essential. Studies have shown that the use of special IV therapy teams, consisting of trained nurses or technicians who can ensure a consistent and high level of aseptic technique during catheter insertion and in follow-up care of the catheter, has been associated with substantially lower rates of catheter-related BSI and is cost-effective.[346,347] But even if an institution does not have an IV team, it can greatly reduce its rate of IVD-related BSI by formal education of nurses and physicians and stringent adherence to IVD care protocols.[348,349]
4. Cutaneous antisepsis. Given the evidence for the importance of cutaneous microorganisms in the pathogenesis of short-term IVD-related infections, measures to reduce colonization of the insertion site would seem of the highest priority, particularly the choice of chemical antiseptics for disinfection of the site. Nine randomized, prospective trials comparing a chlorhexidine-containing antiseptic to either povidone-iodine or alcohol for preparation of the skin before insertion of a short-term IVD have been reported.[219–221,350] In the largest study to date, a randomized trial in 1050 CVCs and arterial catheters placed in a university hospital ICU, cutaneous antisepsis with 1% tincture of chlorhexidine showed a highly significant reduction in IVD-related BSIs compared with an iodophor (RR 0.35, $P < 0.01$).[350] A meta-analysis that examined results from eight of the nine aforementioned studies found that use of chlorhexidine was associated with a nearly 50% reduction in the risk of

IVD-related infections compared with povidone-iodine (RR 0.49, 95% CI 0.28–0.88).[219]

Insertion Site Care and IVD Maintenance

1. IVD dressings. IVDs can be dressed with sterile gauze and tape or with a sterile transparent, semipermeable, polyurethane film dressing. The available data suggest that the two types of dressings are equivalent in terms of their impact on IVD-related BSI with peripheral IVs and short-term CVCs.[351–353] In contrast, results from studies of arterial catheters have found that polyurethane dressings greatly increase the risk of IVD-related BSI.[351,354] As a result, polyurethane dressings should probably not be used on arterial catheters until future studies confirm their safety.
2. Topical antimicrobial ointments. In theory, application of a topical antimicrobial agent to the catheter insertion site should confer some protection against microbial invasion. Clinical trials of a topical combination antibacterial ointment containing polymyxin, neomycin, and bacitracin with peripheral IVs have shown marginal benefit,[355] but the use of polyantibiotic ointments has been associated with a fivefold increased frequency of Candida infection, limiting their utility.[355,356] One double-blind, placebo-controlled, randomized clinical trial in hemodialysis patients with permanent tunneled cuffed dialysis catheters showed that the use of topical bacitracin, gramicidin, and polymyxin B at the catheter exit site, compared with topical placebo, was associated with a reduction in catheter-related bacteremia (0.63 vs. 2.48 per 1000 IVD days, $P = 0.0004$) and mortality rate (3 vs. 13 deaths, $P = 0.004$), without an increase in Candida infection.[357]

   The topical antibacterial mupirocin, which is active primarily against gram-positive organisms, was shown in one study to significantly reduce colonization of internal jugular catheters without increasing colonization by Candida spp.,[358] and a study by Sesso and colleagues[359] showed significant reductions in hemodialysis catheter colonization (3.17 vs. 14.27 per 1000 IVD days, $P \leq 0.001$) and S. aureus IVD-related BSIs (0.71 vs. 8.92 BSIs per 1000 IVD days, $P \leq 0.001$).[359] Unfortunately, resistance of S. aureus[360] and coagulase-negative staphylococci[361] rapidly emerges during wide-scale mupirocin use,[362] which contravenes its use as a topical agent for the prevention of IVD-related BSI at this time.[137]

   Three prospective studies of topical povidone-iodine ointment applied to CVC sites have failed to show a statistical benefit to its use,[355,363,364] but a single comparative trial in subclavian hemodialysis catheters showed that the use of topical povidone-iodine ointment was associated with a fourfold reduction in the incidence of IVD-related S. aureus BSI.[365]

   Based on these data, if a topical agent is to be used with hemodialysis catheters, either an iodophor or topical bacitracin, gramicidin, and polymyxin B (not currently available in the United States) may be most desirable.[137]
3. Replacement of the device. Studies have shown that peripheral IVs may be safely left in place for up to 96 hours if the patient and the insertion site are monitored closely.[366] Studies have suggested that the duration of peripheral catheterization may be prolonged even further,[367] but viewing reports of nosocomial S. aureus bacteremias linked to prolonged peripheral venous catheterization,[368] more studies are required before this can become considered acceptable routinely.

   Scheduled replacement of short-term, noncuffed, nontunneled CVCs has long been practiced in many centers; however, some studies have called this practice into question.[369] Moreover, a meta-analysis found no benefit to routine replacement of short-term CVCs.[370] On the basis of these data, there appears to be no indication for scheduled replacement of short-term CVCs that are functioning well and show no clinical signs of infection.
4. Guidewire exchanges of CVCs. The management of CVCs that must be replaced, either because of mechanical malfunction or suspected infection, deserves special attention. Replacement of CVCs by guidewire exchange is associated with a reduced risk of mechanical complications[369,370]; however, it is also associated with an increased risk of the newly placed CVC becoming infected and causing CVC-related BSI.[369] As a result, if circumstances necessitate guidewire exchange for placement of a new catheter (e.g., the patient has limited sites for access, is morbidly obese, or is at high risk of mechanical complications because of underlying coagulopathy), the same strict aseptic technique, which includes full barrier precautions, must be used. However, the tip or intracutaneous segment(s) of the removed CVC should routinely be sent for culture to determine whether the insertion tract is colonized. If it is, the newly inserted CVC should be promptly removed and a new CVC placed percutaneously in a new site. If the tract is not colonized, the newly exchanged CVC can remain in the old insertion site.

   Although small studies have found some utility of guidewire exchange in the management of CVCs suspected of being infected,[371,372] we believe that, in the absence of randomized studies demonstrating its safety, guidewire exchange generally should not be performed if there is suspicion of IVD-related BSI, especially if there are signs of local infection such as purulence or erythema at the insertion site or signs of systemic sepsis without a source. In these cases the old catheter should be removed and cultured, and a new catheter should be inserted in a new site.
5. Replacing the delivery system. Whereas most infusion-related BSIs are caused by infection of the device used for vascular access, infusate can occasionally become contaminated and cause endemic BSIs.[325,373] If an infusion runs continuously for an extended period, the cumulative risk of contamination increases, and there is further risk that contaminants can grow to concentrations that could produce BSI in the recipient of the fluid. For more than 25 years, most U.S. hospitals have routinely replaced the entire delivery system of patients' IV infusions at 24- or 48-hour intervals[374] to reduce the risk of BSI from extrinsically contaminated fluid. Prospective studies indicate that IV delivery systems need not be replaced more frequently than every 72 to 96 hours, including infusions used for total parenteral nutrition or any infusions in ICU patients[366,375]; extending the duration of use can permit cost savings to hospitals.[375]

   Four clinical settings might be regarded as exceptions to using 72 hours as an interval for routine set change[375]: (1) administration of blood products, (2) administration of lipid emulsion, (3) arterial pressure monitoring, and (4) suspicion of an epidemic of infusion-related BSI. In these circumstances, it may be most prudent for administration sets to be changed routinely at 24- or 48-hour intervals or in the case of suspected infusion-related BSI, immediately.

   Arterial infusions used for hemodynamic monitoring appear to be more vulnerable to becoming contaminated during use and producing endemic[373] or epidemic septicemia,[103] caused by gram-negative bacilli. If the infusion for hemodynamic monitoring is set up so that the fluid flows continuously through

the system, thus eliminating a blind stagnant column of fluid, extrinsic contamination appears to be greatly reduced and may even eliminate the need to replace the administration set, transducer assembly, and other components of the system at frequent intervals.[376,377] If disposable transducers are used, there appears to be no need to replace the transducer assembly and other components of the delivery system more frequently than every 4 days,[376] and it may be safe to replace them even less frequently.[377]

6. Anticoagulation. Thrombus formation on an IVD is associated with an increased risk of infection.[378,379] Two prospective studies have been performed to examine the efficacy of warfarin anticoagulation for reducing rates of IVD-associated thrombosis with long-term IVDs.[380,381] Both studies found that use of warfarin in a dose of 1 mg/day was associated with significantly reduced rates of thrombosis with long-term IVDs, although no data were provided on rates of IVD-related BSI.

   The use of prophylactic heparin for reducing rates of IVD-related thrombosis and infection has been evaluated in a meta-analysis.[382] Examining a variety of different administration techniques in 14 randomized controlled studies, Randolph and colleagues[382] concluded that systemic heparinization significantly reduced the risk of IVD-associated thrombosis (RR 0.43, CI 0.23–0.78) and device colonization (RR 0.18, CI 0.06–0.6) but failed to show a reduction in IVD-related BSIs. Heparin-bonded pulmonary artery catheters may be less prone to IVD-related BSI than nonheparinized catheters.[325,383,384]

   On the basis of these studies, low-level anticoagulation with warfarin is warranted for long-term IVDs as long as there is no contraindication (bleeding diathesis, brain tumor, or predilection to falls) and the international normalized ratio is maintained below 1.6.[380] For short-term IVDs, the use of low-dose subcutaneous heparin is more appropriate; it is commonly given to patients with CVCs or arterial lines as part of ICU thromboembolism prophylaxis.

Novel Technology

Despite compliance with recommended guidelines, many centers continue to have high rates of IVD-related BSI. Novel technology holds much promise (Box 47.3). Innovative technologies designed to reduce the risk of IVD-related BSI have proved not only to be effective but also to reduce health care costs, both with short-term and long-term IVDs.[323,385]

1. Novel securement devices. In a randomized trial of a novel sutureless device for securing noncuffed vascular catheters (StatLock, Venetec International, San Diego, CA), premature loss of pediatric PICCs caused by accidental extrusion and PICC-associated thrombosis were significantly reduced,[386] and in two additional trials the incidence of catheter-related BSI was significantly reduced with the use of the novel securement device, both in adults and children with PICCs.[386,387]

   The promise of this device for reducing infection may derive from elimination of a festering skin suture wound contiguous to the newly inserted catheter and minimizing to-and-fro movement of the catheter, which may promote invasion of the tract by cutaneous microorganisms through capillary action.[388]

2. Novel dressings. Studies of polyurethane dressings, which contain antiseptics such as povidone-iodine or ionized silver, have been disappointing. However, on the basis of demonstrated superiority of chlorhexidine for cutaneous disinfection of access sites, a novel chlorhexidine-impregnated sponge dressing has been developed (BioPatch, Johnson and Johnson Medical, Inc., Brunswick, NJ). It maintains a high concentration of the antiseptic on the insertion site under the dressing. The largest study to date found that use of the chlorhexidine-impregnated sponge dressing was associated with a 60% reduction in catheter-related BSI (RR 0.37, P = 0.01).[389] Although there were no adverse side effects associated with the use of this dressing in this trial in adults, a pediatric trial found that 15% of low-birth-weight neonates developed local dermatotoxicity.[390]

3. Anti-infective impregnated catheters. IVDs directly coated or impregnated with antimicrobials or antiseptics have been intensively studied over the past several decades. Eighteen randomized trials evaluating the efficacy of chlorhexidine-silver-sulfadiazine–impregnated or minocycline-rifampin–impregnated CVCs have been published in full article or abstract form since 1994.[291,292,313,391,392]

   Of the 16 published studies that examined the effect of antimicrobial-impregnated CVCs on rates of CVC-related BSI, 12 found either a statistically significant reduction or a strong trend toward a reduction in rates of CVC-related BSI.[391,392]

• BOX 47.3 Novel Technology for Prevention of Intravascular Device–Related Bloodstream Infection That Has Been Examined in Randomized Clinical Trials

- Sutureless securement devices
  - Topical antimicrobials/antiseptics
  - Topical anti-infective creams or ointments
  - Polymyxin-neomycin-bacitracin polyantibiotic ointment
  - Bacitracin, gramicidin, and polymyxin B ointment
  - Povidone-iodine ointment
  - Mupirocin ointment
- Dressings
  - Transparent, polyurethane film dressings
  - Hyperpermeable polyurethane dressings
  - Hydrocolloid dressings
  - Chlorhexidine-impregnated sponge dressings
- Innovative IVD design
  - Cuffed and tunneled central venous catheters
  - Subcutaneous central venous ports
  - Attachable silver-impregnated cuffs
- Anti-infective-coated catheters
  - Benzalkonium chloride–impregnated catheters
  - Chlorhexidine–silver sulfadiazine–coated catheters
  - Cefazolin-coated catheters
  - Minocycline-rifampin–coated catheters
  - Silver-impregnated catheters
- Anti-infective catheter hubs
  - Iodinated chamber
  - External povidone-iodine–saturated sponge cap
- Anti-infective lock solutions for long-term intravascular devices
  - Gentamicin
  - Vancomycin
  - Vancomycin-ciprofloxacin
  - Trisodium citrate–gentamicin
  - Minocycline–ethylenediaminetetraacetic acid
  - Ethanol
  - Taurolidine
  - Scheduled (prophylactic) thrombolysis with urokinase

Modified from Crnich CJ, Maki DG: The promise of novel technology for the prevention of intravascular device-related bloodstream infection. I. Pathogenesis and short-term devices. Clin Infect Dis. *2002;34:1232–1242.*

Aggregate analysis of the 15 studies that compared antimicrobial-impregnated CVCs with nonimpregnated CVCs,[391,392] encompassing a total of 4250 CVCs, shows that antimicrobial-impregnated CVCs are associated with a 40% reduction in CVC-related BSI (61 BSIs/2129 devices vs. 101 BSIs/2118 devices, OR 0.60, 95% CI 0.44–0.82, P = 0.001), a result remarkably similar to the findings of three published meta-analyses.[323,393,394]

Finally, two rigorous and sophisticated economic analyses have found that antimicrobial-impregnated CVCs are cost-effective.[395,396] Veenstra and colleagues showed that antimicrobial-impregnated CVCs remained cost-effective even if the cost of a CVC-related BSI was as low as $687 per case; cost savings were $196 per antimicrobial-impregnated CVC when a more realistic cost of a CVC-related BSI of $9738 was used in the analysis.[395] Shorr and colleagues[396] showed that use of antimicrobial-impregnated CVCs was associated with a cost savings of $9600 per CVC-related BSI prevented and that $165 to $280 would be saved for every patient who received an antimicrobial-impregnated CVC.

On the basis of this large body of data, two national advisory panels have recommended the use of antimicrobial-impregnated CVCs in clinical settings where, despite rigorous application of other preventive interventions, rates of IVD-related BSI remain unacceptably high (i.e., ≥3.3 BSIs per 1000 IVD days).[137,397]

4. Antimicrobial lock solutions. Given the importance of hub contamination and intraluminal colonization in the genesis of IVD-related BSI with long-term IVDs, intraluminal instillation of an antibiotic or antiseptic solution has the potential to reduce the risk of BSI associated with these devices. Six randomized, prospective trials have examined a vancomycin-containing antibiotic lock solution for the prevention of IVD-related BSI, the largest of which found that use of a vancomycin or vancomycin/ciprofloxacin lock solution reduced the risk of IVD-related BSI nearly 80% (P = 0.005), with no evidence that the use of the lock solution promoted colonization or infection by vancomycin-resistant bacteria or fungi.[398,399] Yet concern about the emergence of resistance with prophylactic antibiotic-containing lock solutions has limited their wider acceptance to date. However, the use of prophylactic antibiotic lock solution is considered acceptable in the 2011 HICPAC Guideline if a patient with an essential long-term IVD has continued to experience recurrent IVD-related BSIs despite consistent application of infection control practices.[137]

   Various other prophylactic lock solutions have been studied as a means of preventing IVD-related BSI including trisodium citrate/gentamicin,[400] minocycline/ethylenediaminetetraacetic acid,[401] ethanol,[402] and taurolidine-containing solutions.[403] Concerns about increased IVD complication rates[403] and drug-related toxicity[400] associated with the use of certain types of lock solutions, combined with the limited number of patients who have been studied while receiving these agents, preclude their routine use at this time.
5. Catheter hubs. A novel catheter hub that contains a chamber filled with iodinated alcohol has been shown to be effective in preventing colonization of IVDs in an animal model.[404] Use of this same hub model in some clinical studies has demonstrated significantly lower rates of IVD colonization compared with IVDs with control hubs.[405,406] One clinical trial has also demonstrated reduced rates of IVD-related BSIs with use of this hub (4% vs. 16%, P < 0.01). A subsequent study also showed a reduction in hub-related IVD-related BSIs (1.7% vs. 7%, P < 0.049), but overall rates of IVD-related BSIs in both groups were similar.[406] Another study was unable to find any benefit with regard to IVD colonization or IVD-related BSI with use of the novel hub.[407] This device is not yet available in the United States and until further studies more conclusively demonstrate its benefit, its use cannot be recommended at this time.

Ventilator-Associated Pneumonia

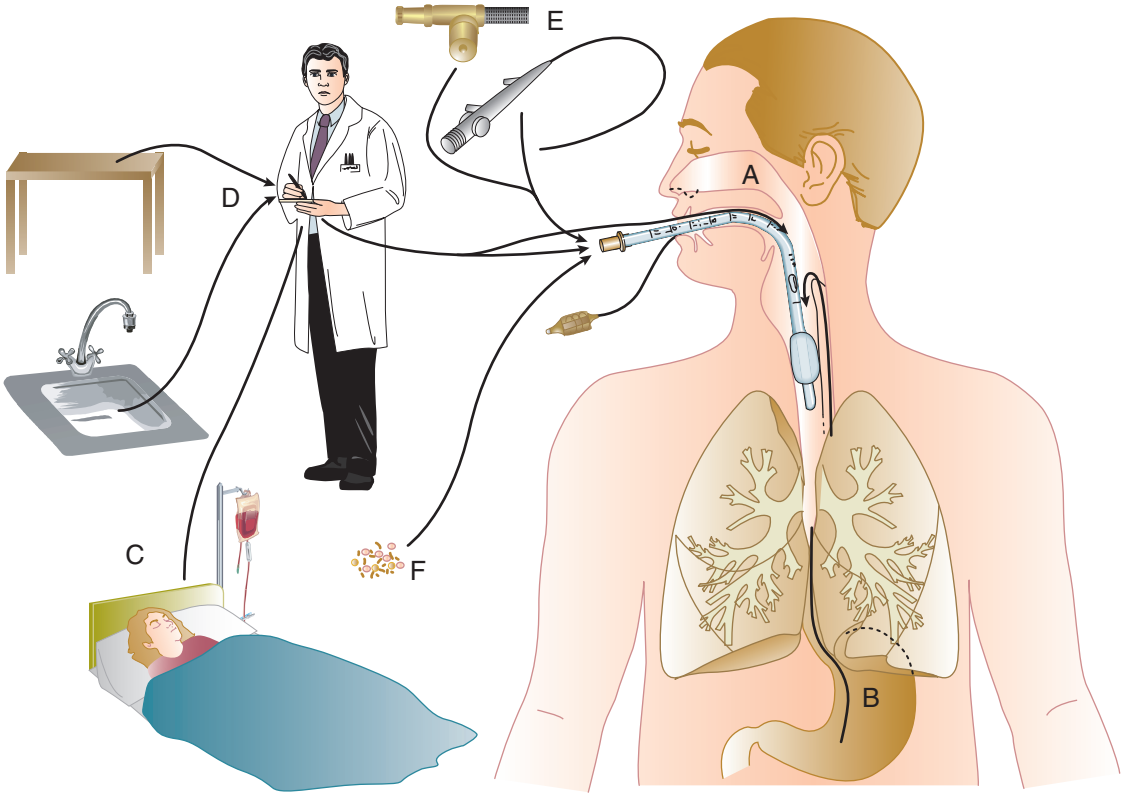
Incidence and Impact

Hospital-acquired pneumonia (HAP) is defined as pneumonia that develops more than 48 hours after hospitalization.[408,409] VAP is a subset of HAP and is defined as pneumonia that occurs more than 48 to 72 hours after initiating mechanical ventilation.[408,409] Nearly 300,000 episodes of HAP occur in U.S. hospitals each year.[410] More than 90% of HAPs occur in patients undergoing mechanical ventilation, and VAP develops in 10% to 20% of mechanically ventilated patients.[411] Incidence rates of VAP are highest in trauma, burn, neurosurgical, neurologic, and surgical ICUs (see Table 47.1).[25] VAP increases length of hospitalization by 6.1 days and health care costs by $10,019 when compared with matched control subjects in whom VAP did not develop.[411] More importantly, VAP is associated with more nosocomial deaths than is infection at any other site[412]—at least 50,000 deaths in U.S. centers annually—and increases hospital mortality rate at least twofold in affected individuals.[411]

Pathogenesis

In the normal nonsmoking host, multiple host defense mechanisms contribute to protection against pneumonia.[413] The respiratory tract above the vocal cords is normally heavily colonized by bacteria, but unless the person has chronic bronchitis or has had respiratory tract instrumentation, the lower respiratory tract is normally sterile; although healthy adults aspirate frequently during sleep, the lower airways and pulmonary parenchyma of healthy, nonsmoking persons without lung disease are remarkably free of microbial colonization.[414] The major defense mechanisms include anatomic airway barriers, the cough reflex, mucus,[415] and mucociliary clearance.[416] Below the terminal bronchioles, the cellular and humoral immune systems are essential components of host defense.[417] Alveolar macrophages and leukocytes remove particulate matter and potential pathogens, produce cytokines that activate the systemic cellular immune response, and act as antigen-presenting cells to the humoral arm of immunity.[418] Immunoglobulins and complement opsonize bacteria and bacterial products within the respiratory tract, assisting phagocytosis.

In the mechanically ventilated patient, numerous factors conspire to compromise host defenses; critical illness, comorbid conditions, and malnutrition impair the immune system.[419,420] Endotracheal intubation thwarts the cough reflex; compromises mucociliary clearance; injures the tracheal epithelial surface; and provides a direct conduit for bacteria from the mouth, hypopharynx, and stomach to gain direct access to the lower respiratory tract.[421] Moreover, the cuff of the endotracheal tube allows pooling of oropharyngeal secretions in the subglottic region, forming an ideal medium for microbial growth, which periodically leaks around the cuff into the trachea. It would probably be more accurate pathogenically to rename VAP as "endotracheal intubation–related pneumonia." This combination of impaired host defenses and continuous exposure of the lower respiratory tract to large numbers of potential pathogens through the endotracheal tube



• **Fig, 47.7** Routes of colonization/infection in mechanically ventilated patients. Colonization of the aerodigestive tract may occur endogenously (A and B) or exogenously (C through F). Exogenous colonization may result in primary colonization of the oropharynx or may be the result of direct inoculation into the lower respiratory tract during manipulations of respiratory equipment (D), during use of respiratory devices (E), or from contaminated aerosols (F). (From Crnich CJ, Safdar NS, Maki DG. The role of the intensive care environment in the pathogenesis and prevention of ventilator-associated pneumonia. *Respir Care.* 2005;50:813–836.)

puts the mechanically ventilated patient at great jeopardy of developing VAP.

For microorganisms to cause VAP, they must first gain access to the normally sterile lower respiratory tract, where they can adhere to the mucosa and produce sustained infection. Microorganisms gain access by one of four mechanisms (Fig. 47.7): (1) aspiration of microbe-laden secretions, either from the oropharynx directly or, secondarily, by reflux from the stomach into the oropharynx, then into the lower respiratory tract[422–424]; (2) inhalation of contaminated air or medical aerosols[425]; (3) direct extension of a contiguous infection such as a pleural space infection[426]; or (4) hematogenous carriage of microorganisms to the lung from remote sites of local infection such as an IVD-related BSI.[427]

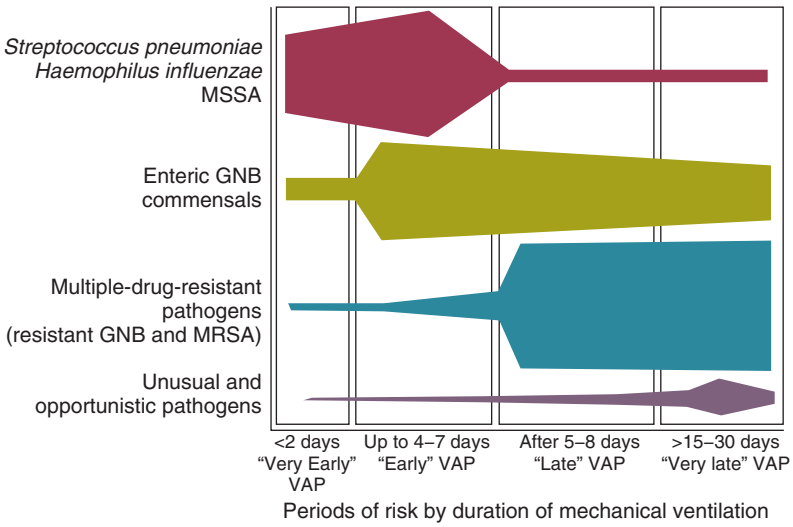
Although numerous epidemics of VAP have been caused by contaminated aerosols or medical respiratory devices,[101,102,107] the preponderance of evidence suggests that most endemic VAPs derive from aspiration of endogenous or hospital-acquired oropharyngeal organisms[42,428]:

- The oropharynx of critically ill patients is rapidly colonized with the pathogens that cause VAP, especially aerobic gram-negative organisms and S. aureus.[419]
- Studies in which multiple anatomic sites are cultured simultaneously over time have shown that the pathogenic microorganisms implicated in VAP are usually first recovered from the oropharynx and later from the tracheobronchial tree and stomach.[422–424,429] Moreover, heavy oropharyngeal colonization is a powerful independent predictor of subsequent tracheobronchial colonization and VAP.[424]
- Reducing oropharyngeal colonization with topical antimicrobials and antiseptics has been shown to significantly reduce the risk of VAP.[430–433]

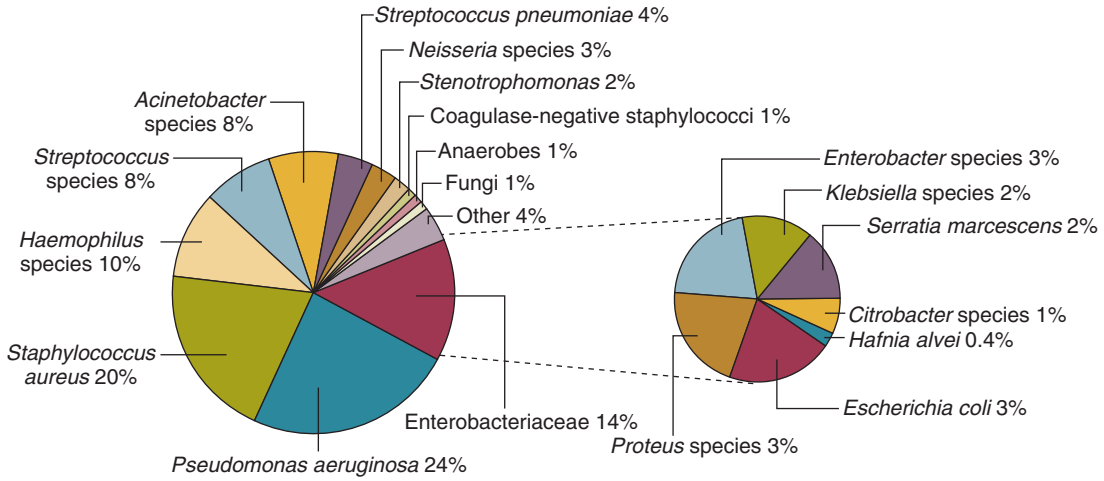
By this route, aspiration of oropharyngeal contents containing a large microbial inoculum overwhelms host defenses already compromised by critical illness and the presence of an endotracheal tube, readily leading to the development of VAP.

Microbiology

Pathogens causing VAP may be part of the host's endogenous microbiome at the time of hospitalization or may be acquired exogenously after admission to the health care institution from the hands, apparel, or equipment of HCWs; hospital environment; and use of invasive devices (Fig. 47.8). The normal flora of the oropharynx in the nonintubated patient without critical illness is composed predominantly of viridans streptococci, Haemophilus species, and anaerobes. Salivary flow and proteins (immunoglobulin, fibronectin) are the major host factors maintaining the normal microbiome of the mouth (and dental plaque). Aerobic gram-negative bacilli are rarely recovered from the oral secretions of healthy patients.[434] During critical illness, especially in ICU patients, the oral microbiome shifts dramatically to a predominance of aerobic gram-negative bacilli and S. aureus.[419] Bacterial adherence to the orotracheal mucosa of the mechanically ventilated patient



• **Fig. 47.8** Microbial causes of ventilator-associated pneumonia based on increasing length of mechanical ventilation. The relative importance of each microbial category is indicated by the thickness of the bars as they progress through each stage from left to right. *GNB,* Gram-negative bacilli; *MRSA,* methicillin-resistant *S. aureus*; *MSSA,* methicillin-susceptible *S. aureus*; *VAP,* ventilator-associated pneumonia. (Data from Chastre J, Fagon JY. Ventilator-associated pneumonia. *Am J Respir Crit Care Med.* 2002;165(7):867–903.)



• **Fig. 47.9** Microbial causes of ventilator-associated pneumonia. The relative proportions of microbial causes of ventilator-associated pneumonia from 1689 bronchoscopically confirmed cases involving 2490 individual isolates reported in 24 published studies. (From Park DR. The microbiology of ventilator-assisted pneumonia. *Respir Care.* 2005;50:742–765.)

is assisted by reduced mucosal IgA and increased protease production, exposed and denuded mucous membranes, elevated airway pH, increased numbers of airway receptors for bacteria because of acute illness, and antimicrobial use.

Early-onset VAP, which manifests within the first 4 days of hospitalization, is most often caused by community-acquired pathogens, such as S. pneumoniae and Haemophilus species (Fig. 47.8).[435] However, the microbial spectrum of VAP shifts to typical nosocomial pathogens with increasing lengths of mechanical ventilation and exposure to broad-spectrum antimicrobials (Fig. 47.9).[435] That the preponderance of episodes of VAP have a late onset is supported by the fact that the most common pathogens recovered from mechanically ventilated patients with pneumonia are P. aeruginosa, S. aureus, and the Enterobacteriaceae (see Fig. 47.9).[435,436] VAP is polymicrobial in up to 20% to 40% of cases. The role of anaerobic bacteria in VAP is not well defined.

Diagnosis

The CDC's National Healthcare Safety Network definition for VAP was revised in 2013 owing to the lack of objective and reliable criteria, and was replaced with the term ventilator-associated events,[17] which was intended to be used for surveillance purposes and not for the diagnosis and treatment of VAP.[409] Within ventilator associated events, a new more specific term, possible ventilator-associated pneumonia, was also introduced, based on the following criteria: increase in fraction of inspired oxygen or positive end-expiratory pressure; and fever or hypothermia or leukocytosis or leukopenia; and new antimicrobial agent started; and, positive respiratory culture or other criteria (see Box 47.1), but did not include radiographic criteria.[16,17] Clinical criteria for the diagnosis of HAP/VAP, which were initially developed empirically more than three decades ago,[437] and recommended by the 2005 and 2016 Infectious Disease Society

of America/American Thoracic Society HAP/VAP guidelines,[408,409] include (1) a new or worsening infiltrate on chest radiograph, and (2) signs of infection that suggest the infiltrate is of infectious origin—fever, leukocytosis or leukopenia, purulent sputum, and decline in oxygenation.[408,409] Positive qualitative cultures of endotracheal aspirates are used to support the clinical diagnosis of HAP/VAP. Unfortunately, even when used in combination, the specificity of clinical criteria is poor, with an overall diagnostic accuracy of approximately 60% in published studies.[438,439]

Many experts have advocated routine use of invasive procedures when VAP is suspected—bronchoalveolar lavage (BAL), cultures of protected specimen brush (PSB) samples obtained by bronchoscopy, or blind (mini)-BAL—on the grounds that these diagnostic techniques have comparable sensitivity, greater specificity, and superior accuracy compared with clinical criteria alone.[436,440–443] More rigorous clinical criteria such as the Clinical Pulmonary Infection Score have relatively poor sensitivity (65%) and specificity (64%) for the diagnosis of VAP.[409,444] Whether or not the use of quantitative cultures of endotracheal aspirates improves diagnostic accuracy without the need for invasive procedures is an unsettled issue.[445]

Although invasive procedures—BAL, PSB, and mini-BAL—are clearly more specific than clinical criteria, their impact on patient outcomes is much less clear.[409,446,447] Fagon and colleagues[446] found that patients with suspected VAP who were managed using an invasive diagnostic approach—bronchoscopic-guided PSB or BAL—had a significantly reduced 14-day mortality rate, reduced antibiotic days, and reduced 28-day mortality rate on multivariate analysis, compared with patients managed using a clinical diagnostic approach (hazard ratio [HR] 0.65, 95% CI 0.46–0.91, P = 0.01).[446] However, Heyland and colleagues[447] found in a large multicenter Canadian trial that the 28-day mortality rate and targeted antimicrobial use were identical among patients randomly assigned to an invasive versus a clinical diagnostic approach. This study has been criticized for its exclusion of subjects at high risk for infection with antimicrobial-resistant pathogens.[448] In the absence of definitive data demonstrating superior outcomes with invasively obtained specimens or quantitative cultures, the 2016 Infectious Disease Society of America/American Thoracic Society HAP/VAP guidelines recommended that noninvasive sampling with semiquantitative culture be used to diagnose HAP and VAP rather than invasive sampling with quantitative cultures or noninvasive sampling with quantitative cultures.[409] The guideline panel acknowledged that there was potential for invasive sampling with quantitative cultures to lead to less antibiotic exposure if growth below the defined thresholds was used as a trigger to discontinue antibiotics.[409]

Risk Factors

A number of independent risk factors have been shown to increase the likelihood of developing VAP (Table 47.11).[140,436] In general, these risk factors can be categorized as (1) factors that increase the likelihood or duration of mechanical ventilation, (2) factors that increase colonization of the oropharynx and gastric mucosa, (3) factors that increase the likelihood of aspiration, and (4) host factors that increase susceptibility to infection.

Prolonged mechanical ventilation, reintubation, or both are the most powerful predictors of developing VAP. Cunnion and colleagues[449] found that mechanical ventilation in excess of 24 hours was associated with a 12-fold increased risk of developing VAP, and Trouillet and associates found that ventilation longer than 7 days was associated with a sixfold increased risk.[450] Emergent reintubation also carries a high risk of aspiration and was associated with a sixfold increased risk of VAP in a retrospective study.[451]

TABLE 47.11 Independent Risk Factors for Ventilator-Associated Pneumonia in Multivariate Analysis of Data From Published Studies

Host Factors	Intervention Factors
Serum albumin, <2.2 g/dL	Histamine H_2-receptor blockers ± antacids
Age ≥60 years	Paralytic agents, continuous intravenous sedation
Acute respiratory distress syndrome	Receipt of >4 units of blood
Chronic obstructive pulmonary disease or other chronic pulmonary diseases	Intracranial pressure monitoring
Coma or impaired consciousness	Mechanical ventilation in excess of 48 hours
Burns, trauma	Positive end-expiratory pressure
Organ failure	Frequent ventilator circuit changes
Advanced severity of illness	Reintubation
Large-volume gastric aspiration	Nasogastric tube
Gastric colonization and high gastric pH	Supine head position
Upper respiratory tract colonization	Transport out of the intensive care unit
Sinusitis	Prior antibiotic therapy

Modified from Chastre J, Fagon JY. Ventilator-associated pneumonia. *Am J Respir Crit Care Med.* 2002;165:867–903.

Poor dental hygiene increases the bacterial burden in the oropharynx and is an independent risk factor for nosocomial pneumonia.[452] Likewise, a high gastric pH (>5) is associated with greatly increased bacterial colonization of the gastric contents,[453] as well as an increased risk of VAP.[454] A number of studies have found that exposure to antacids or H_2-blockers is associated with an increased risk of VAP,[60] although this has not been a universal finding.[455]

Depressed levels of consciousness, nasogastric tubes, and endotracheal tubes are ubiquitous in the ICU and all increase a patient's risk of aspiration. That an altered level of cognition is associated with an increased risk of aspiration is supported by surveillance data showing increased rates of VAP in trauma and neurosurgical ICUs.[25] Joshi and colleagues[456] found that the use of a nasogastric tube was an independent predictor of VAP in a multivariate analysis (OR 6.5, 95% CI 2.1–19.8). Finally, as noted, endotracheal tubes allow pooling of hypopharyngeal secretions that can leak around the cuff directly into the trachea, and a supine position appears to increase the risk of aspiration around the cuff.[457]

Host factors also contribute to an increased risk of developing VAP (see Table 47.11). Conditions such as advanced age, increased severity of illness, and the postsurgical state are rarely modifiable. However, poor nutritional status,[423] oversedation,[458] transfusion therapy,[459] and exposure to broad-spectrum antimicrobials[450] are associated with an increased risk of VAP and are under the control of the clinician.

Treatment

Treatment of VAP is discussed in the Therapy section of Chapter 40.

Prevention

With an understanding of pathogenesis and epidemiology in hand, clinicians caring for mechanically ventilated patients can implement

preventive strategies that can materially reduce the risk of VAP (Table 47.12). Both the CDC HICPAC and Canadian Critical Care Trials Group offer evidence-based guidelines for the prevention of VAP.[140,460] Their recommendations are very similar. The Canadian guideline focuses exclusively on specific interventions for the prevention of VAP,[460] whereas the HICPAC guideline incorporates additional guidance for the prevention of nosocomial influenza, legionellosis, and invasive filamentous fungal infections in the hospital.[140] Recommendations from both guidelines can be divided into general, nonpharmacologic, and pharmacologic preventive measures (see Table 47.12).[461] The general measures used to reduce VAP, including education, infection control, hand hygiene, and reliable disinfection and sterilization of respiratory care equipment, are discussed elsewhere in this chapter.

Nonpharmacologic Preventive Measures

Avoiding prolonged intubation and reintubation—if avoiding intubation altogether is not feasible—offers the greatest promise for reducing an individual patient's risk of developing VAP.[451] The use of noninvasive ventilation to avoid endotracheal intubation has been shown to be successful in reducing rates of nosocomial pneumonia in a number of studies[462,463] and may abrogate the need for reintubation in selected patients who prematurely extubate themselves.[140] The implementation of .weaning protocols has also been shown to significantly reduce the duration of mechanical ventilation,[464,465] health care costs,[464,465] and institutional rates of VAP.[466,467] The effect of daily sedation interruption has shown conflicting results in meta-analyses.[468,469] Early tracheostomy—within 1 week of intubation—has been advocated as a method for reducing

TABLE 47.12 Recommendations for the Prevention of Ventilator-Associated Pneumonia

Preventive Measure	HICPAC Grade[a]	CCCTG Recommendation
General Measures		
• Educate all health care workers involved with the care of mechanically ventilated patients on the risks and methods of preventing ventilator-associated pneumonia.	IA	—
• Perform adequate hand hygiene between patient contacts.	IA	—
• Use gloves for handling respiratory secretions or objects contaminated with respiratory secretions.	IB	—
• Conduct surveillance for bacterial pneumonia in ICU patients using NNIS definitions. Include data on causative organisms and their antimicrobial susceptibility patterns. Express data as rates to assist intrahospital comparisons.	IB	—
• Do not routinely perform cultures of patients, equipment, or environment in the absence of an outbreak.	II	—
• Thoroughly clean all devices to be sterilized and disinfected.	IA	—
• Use steam sterilization or wet heat pasteurization for reprocessing of heat-stable semicritical devices and low-temperature sterilization for heat- or moisture-sensitive devices.	IA	—
• Use sterile water for rinsing reusable semicritical devices.	IB	—
• Change ventilator circuits only when they become soiled.	IA	Recommended
• Periodically drain and discard condensate from ventilator circuits.	IB	—
• Clean, disinfect, rinse with sterile water, and dry in-line nebulizers between treatments on the same patient.	IB	—
• When possible, use aerosolized medications in single-use vials.	IB	—
Nonpharmacologic Measures to Reduce Pneumonia		
• Oral (non-nasal) intubation	IB	Recommended
• Remove nasogastric and endotracheal tubes as soon as clinically feasible.	IB	—
• Avoid unnecessary reintubation.	II	—
• When feasible, use noninvasive ventilation to avoid the need for intubation or reintubation.	II	—
• Early tracheostomy	—	No recommendation
• Semirecumbent positioning of the patient	II	Recommended
• Implement a comprehensive oral hygiene program for mechanically ventilated patients.	II	—
• If feasible, use an endotracheal catheter that allows for continuous or frequent subglottic suctioning.	II	Consider
• Humidification with HME	NR	Recommended[b]
• Closed multiuse catheters for airway secretion suctioning	NR	Recommended
• Kinetic bed therapy	NR	Consider

TABLE 47.12 Recommendations for the Prevention of Ventilator-Associated Pneumonia—cont'd

Preventive Measure	HICPAC Grade[a]	CCCTG Recommendation
Pharmacologic Measures to Reduce Pneumonia		
• Immunize all patients at risk for pneumococcal infection.	IA	—
• Immunize all patients at risk for influenza.	IA	—
• Routine use of chlorhexidine oral rinse	NR	—
• Targeted use of chlorhexidine oral rinse in post–cardiac surgery patients	II	—
• Oral decontamination with topical antimicrobial agents	NR	—
• Preferential use of sucralfate for stress bleeding prophylaxis	NR	Not recommended
• Selective digestive decontamination	NR	Not recommended[c]
• Acidification of gastric feedings	NR	—
• Systemic antimicrobials to prevent development of pneumonia	NR	Not recommended[c]
• Cycling of antibiotic classes to reduce resistance in the ICU	NR	—

[a]From the CDC/HICPAC system of weighting recommendations based on scientific evidence: *IA,* strongly recommended for implementation and supported by well-designed experimental, clinical, or epidemiologic studies. *IB,* Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale. *IC,* required by state or federal regulations, rules, or standards. II, Suggested for implementation and supported by suggestive clinical or epidemiologic trials or a theoretic rationale. Unresolved issue, an unresolved issue for which evidence is insufficient or no consensus regarding efficacy exists. *NR,* No recommendation for or against at this time.

[b]Recommended in patients without hemoptysis or high minute ventilation. Exchanger should be replaced weekly.

[c]Topical or systemic antimicrobial agents alone are not recommended. Insufficient evidence on antibiotic resistance and cost-effectiveness exists to recommend combination topical and systemic therapy.

the risk of VAP in patients likely to require prolonged mechanical ventilation. However, randomized trials, admittedly of limited power, have not found significant benefit with this approach[470] and early tracheostomy is not currently recommended by most authorities.[140,460]

As noted earlier, supine positioning of the mechanically ventilated patient's head has been shown to increase the risk of gastroesophageal-pharyngeal aspiration.[457] A simple solution to this threat is to elevate the head of the patient's bed 35 to 45 degrees. Drakulovic and colleagues[471] found that patients whose torso and head were kept elevated at 45 degrees had much lower rates of microbiologically confirmed pneumonia compared with patients cared for in a 0-degree supine position (5% vs. 23%, P = 0.018).[471] In reality, maintaining elevation of the head in excess of 45 degrees on a consistent basis is actually quite difficult and uncommonly achieved in practice. A randomized study that sought to maintain head elevation above 45 degrees for 85% of the study period found that head elevation in the intervention arm averaged only 28.1 degrees.[472] Perhaps as a result of failure to successfully achieve adequate elevation, no reductions in the rate of VAP were seen.

Although data on the effect of comprehensive oral care on the risk of infection are limited,[473] maintaining adequate dental hygiene is considered an important component of VAP prevention.[140] Binkley and colleagues[474] found that although a majority of nurses caring for patients undergoing mechanical ventilation appreciated the importance of dental hygiene, the methods used to provide this varied considerably. Until more data are available on specific dental hygienic practices, it is recommended that mechanically ventilated patients have their teeth brushed daily, undergo oral cleansing every 2 to 4 hours, undergo routine suctioning to reduce accumulation of fluids in the oropharynx, and have a mouth moisturizer applied to their lips to prevent cracking.[475] The periodic instillation of a topical oral antiseptic solution is an additional promising intervention[475] and is discussed in "Pharmacologic Preventive Measures" later.

The use of a modified endotracheal tube with a separate ventral drainage tube for continuous or intermittent suctioning of subglottic secretions has been evaluated in a number of studies.[476,477] Subglottic suctioning reduced the rate of VAP significantly in all but one of these studies.[477] However, in the study by Kollef et al. the time to onset of VAP was delayed significantly (5.9 days vs. 2.9 days, P = 0.006),[477] and recent evidence-based guidelines have recommended the use of endotracheal tubes that allow for suctioning of subglottic secretions.[140,460] Nevertheless, the use of an endotracheal tube that allows for subglottic suctioning did not reduce the duration of mechanical ventilation or rate of ICU mortality in the studies done, which, coupled with the increased cost of the tube and propensity of the suction lumen to occlude, has limited wider adoption of this technology in practice.[478]

The evidence that heat and moisture exchangers (HMEs) are associated with a reduced risk of VAP is mixed. Only one of six published trials found a statistically significant reduction in VAP with use of HMEs (RR 0.41, 95% CI 0.20–0.86, P = 0.02).[479] However, pooling data from a recent systematic review[480] and a subsequently published randomized trial[481] shows that HMEs reduce the risk of VAP by 38% (RR 0.62, 95% CI 0.43–0.89, P = 0.012). The use of HMEs has been recommended by authors of a systematic review[482] and is currently recommended by the Canadian Critical

Care Trials Group.[460] However, HICPAC made no recommendation for the use of HMEs because five of six published trials failed to demonstrate a statistically significant reduction in the rate of VAP.[140] Heat exchange moisturizers become readily occluded in patients with airway hemorrhage and can increase airway resistance. As a result, they should not be used in patients with hemoptysis or those requiring high minute ventilation.[460] Finally, the membranes of HMEs can become colonized with bacteria and should be replaced weekly, according to current guidelines.[460]

The availability of in-line multiuse suction catheters abrogates the need to open and manipulate the endotracheal circuit, theoretically reducing the risk of exogenous contamination.[483] Despite their theoretical benefit, prospective studies have not consistently shown that in-line suction catheters are associated with a reduced risk of VAP.[484–486] Although in-line suction catheters do not appear to increase the risk of VAP, they are more time efficient for nursing personnel and respiratory therapists and are more cost-effective than open suction catheters.[460] Kollef and colleagues[487] found that rates of VAP were identical in patients random assigned to as-needed changes of their inline suction catheter versus those who had their catheter changed every 24 hours (14.7% vs. 14.8%). As a result, there is no compelling evidence that in-line suction catheters should be periodically changed, unless clinically indicated.

Pharmacologic Preventive Measures

Antacids and H_2-blockers have been used extensively in the ICU setting to prevent stress ulcer bleeding but have been associated with an increased risk of developing VAP because they lead to bacterial overgrowth of the gastric contents.[60] Sucralfate prevents stress ulcer bleeding without reducing gastric pH but is more difficult to administer and is less effective than acid-reducing agents.[455] The results of clinical trials examining these two competing strategies for preventing gastrointestinal hemorrhage in the ICU have been mixed, with earlier trials favoring the use of sucralfate.[60] However, additional published trials suggest only a small incremental increased risk of VAP with H_2-blockers,[455,488,489] and most experts feel that this risk is more than offset by their superior capacity to prevent stress ulcer bleeding.[140,460]

Selective digestive decontamination (SDD) is one of the most extensively studied preventive interventions in critical care medicine, yet the role for SDD continues to generate vigorous debate as to its overall benefit.[490,491] A more detailed discussion on the risks and benefits of this intervention is provided later in this chapter. Most U.S. experts believe that SDD has the potential to increase infection caused by multiresistant bacteria, particularly in settings with high rates of endemic antimicrobial resistance.[492,493] Until well-designed multicenter trials are done, proving that SDD does not adversely affect the ICU ecology in settings where multiresistant bacteria are common, it is likely that North American guidelines will continue to discourage its use.[140,460]

The use of parenteral antimicrobials as a single measure for prevention of VAP has not met with much success,[492] but selective antimicrobial decontamination of the oropharynx, without the use of enteral or systemic agents, reduced the risk of VAP nearly 70% (RR 0.33, 95% CI 0.16–0.67, P = 0.001) in one trial.[431] This study reemphasized the primary role of oropharyngeal colonization in the pathogenesis of VAP but engendered the same concerns as SDD over its potential for promoting antimicrobial resistance. However, it has facilitated the idea that topical decolonization of the oropharynx with nonantimicrobial agents might be able to materially reduce the risk of VAP without the potential for emergence of antimicrobial resistance. A meta-analysis of seven randomized trials that enrolled 914 mechanically ventilated patients found that topical chlorhexidine applied to the oropharynx reduced the risk of VAP by nearly 30% (RR 0.74, 95% CI 0.56–0.96, P = 0.02), although there was no significant impact on mortality.[433] The beneficial effects of chlorhexidine appear to be most pronounced in post––cardiac surgery patients,[494,495] prompting HICPAC to recommend its use in this subpopulation.[140]

Catheter-Associated Urinary Tract Infection

Incidence and Impact

Each year, urinary catheters are inserted in more than 5 million patients in acute-care hospitals and extended-care facilities.[496] Catheter-associated urinary tract infection (CAUTI) is one of the most common infections in ICUs, and incidence rates are highest in burn, neurologic, neurosurgical, and trauma ICUs, with intermediate risk in surgical and medical ICUs, and lowest risk in coronary care units (see Table 47.1).[25]

Nosocomial bacteriuria or candiduria develops in up to 25% of patients requiring a urinary catheter for more than 7 days, with a daily risk of 5%.[496] CAUTI is the second most common cause of nosocomial BSI[497]; some studies have also found increased mortality rates associated with CAUTI.[498] Although most CAUTIs are asymptomatic,[499] rarely extend hospitalization, and add only $500 to $1000 to the direct costs of acute-care hospitalization,[500] asymptomatic infections commonly precipitate unnecessary antimicrobial-drug therapy.[501] And CAUTIs comprise perhaps the largest institutional reservoir of nosocomial antibiotic-resistant pathogens, the most important of which are multidrug-resistant Enterobacteriaceae other than E. coli such as Klebsiella, Enterobacter, Proteus, and Citrobacter; P. aeruginosa; enterococci and staphylococci; and Candida spp.[502]

Pathogenesis

Excluding rare hematogenously derived pyelonephritis, caused almost exclusively by S. aureus, most microorganisms causing endemic CAUTIs derive from the patient's own colonic and perineal microbiomes or from the hands of health care personnel and gain access to the patient's urinary tract during catheter insertion or manipulation of the collection system.[283] Organisms gain access in one of two ways. Extraluminal contamination may occur early, by direct inoculation when the catheter is inserted, or later, by organisms ascending from the perineum by capillary action in the thin mucous film between the external catheter surface and the urethral wall. Intraluminal contamination occurs by reflux of microorganisms gaining access to the catheter lumen from failure of closed drainage or contamination of urine in the collection bag. Recent studies suggest that CAUTIs most frequently stem from microorganisms gaining access to the bladder extraluminally,[503] but both routes are important.

Most infected urinary catheters are covered by a thick biofilm containing the infecting microorganisms embedded in a matrix of host proteins and microbial exoglycocalyx.[504] A biofilm forms on the intraluminal or extraluminal surface of the implanted catheter, or both, usually advancing in a retrograde fashion. The role of the biofilm in the pathogenesis of CAUTI has not been established. However, anti-infective–impregnated and silver-hydrogel catheters, which inhibit adherence of microorganisms to the catheter surface, significantly reduce the risk of CAUTI,[505] particularly infections caused by gram-positive organisms or yeasts, which are most likely to be acquired extraluminally from the periurethral flora. These data suggest that microbial adherence

to the catheter surface is important in the pathogenesis of many, but not all, CAUTIs. Infections in which the biofilm does not play a pathogenic role are probably caused by mass transport of intraluminal contaminants into the bladder by retrograde reflux of microbe-laden urine when a catheter or collection system is moved or manipulated.

Prevention

Several catheter-care practices are universally recommended to prevent or at least delay the onset of CAUTI[283]: most important are avoiding unnecessary catheterizations; considering use of a condom catheter in a male or a suprapubic catheter; having trained professionals insert catheters aseptically; removing the catheter as soon as no longer needed; maintaining uncompromising closed drainage; ensuring dependent drainage as much as possible; minimizing manipulations of the system; and separating catheterized patients geographically on the patient care unit.

As noted earlier, technologic innovations to prevent nosocomial infection are most likely to be effective if they are based on a clear understanding of the pathogenesis and epidemiology of the infection. Novel technologies must be designed to block CAUTI by either the extraluminal or intraluminal routes, or both. Medicated catheters, which reduce adherence of microorganisms to the catheter surface, may confer the greatest benefit for preventing CAUTI. Two catheters impregnated with anti-infective solutions have been studied in randomized trials, one impregnated with the urinary antiseptic nitrofurazone[506] and the other with a broad-spectrum antimicrobial drug combination, minocycline and rifampin.[507] Both catheters showed a modest reduction in bacterial CAUTIs; however, the studies were small, and the risk of selection of antimicrobial drug–resistant uropathogens was not satisfactorily resolved. Silver compounds have also been studied for coating urinary catheters. A meta-analysis of eight randomized trials comparing silver oxide or silver alloy catheters with standard nonimpregnated catheters found that silver alloy, but not silver oxide, catheters were associated with a reduced risk of CAUTI.[508] Recommendations for the prevention of CAUTI are summarized in Table 47.13.[138]

TABLE 47.13 CDC/HICPAC Guideline Recommendations for Prevention of Catheter-Associated Urinary Tract Infection

Recommendation	Strength[a]
Appropriate Urinary Catheter Use	

• Insert catheters only for appropriate indications:
  • Appropriate indications (based primarily on expert consensus) include acute urinary retention or bladder outlet obstruction; measurement of urinary output in critically ill patients; perioperative use for selected surgical procedures—remove as soon as possible; promoting healing of open sacral wounds in incontinent patients; prolonged immobilization from multiple traumatic injuries; and improved comfort for end-of-life care.
  • Inappropriate indications (based primarily on expert consensus) include substitute for nursing care of the patient with incontinence; obtaining urine for diagnostic tests when patient can void; and prolonged postoperative use without appropriate indications.
	IB

• Promptly remove catheter when no longer needed.	• IB
• Consider alternatives to use of indwelling urethral catheters in select patients (e.g., external catheters in cooperative male patients without urinary retention or bladder outlet obstruction; intermittent catheterization in spinal cord injury patients or patients with bladder emptying dysfunction).	• II
• Further research is needed regarding use of suprapubic catheters as alternative to indwelling urethral catheters.	NR
Urinary Catheter Insertion	
• Perform hand hygiene before and after insertion or manipulation of catheter.	IB
• Only properly trained personnel should insert and maintain catheters.	IB
• Insert catheter using aseptic technique and sterile equipment (sterile gloves, drape, antiseptic or sterile solution for periurethral cleaning).	IB
• Properly secure catheter to prevent movement and urethral traction.	IB
• Use smallest-bore catheter possible that allows for good drainage to minimize bladder neck and urethral trauma.	II
Urinary Catheter Maintenance	
• Maintain a closed drainage system; if break in aseptic technique, disconnection, or leakage occurs, replace catheter and collecting system.	IB
• Maintain unobstructed urine flow (e.g., keep collecting bag below level of bladder at all times; keep catheter and collecting tube free from kinking; empty collecting bag regularly).	IB
• Use standard precautions, including the use of gloves and gown as appropriate, during any manipulation of catheter or collecting system.	IB
• Do not change catheters or drainage bags at routine, fixed intervals.	II
• Do not use systemic antimicrobials to prevent CAUTI.	IB
• Do not clean periurethral area with antiseptics; routine hygiene is appropriate (e.g., cleansing meatal surface during bathing).	IB

TABLE 47.13 CDC/HICPAC Guideline Recommendations for Prevention of Catheter-Associated Urinary Tract Infection—cont'd`

Recommendation	Strength[a]
• Unless obstruction is anticipated, bladder irrigation is not recommended.	II
• If obstruction occurs, change catheter.	IB
• Irrigation of bladder with antimicrobials and instillation of antiseptic or antimicrobial solutions into drainage bags are not recommended.	II
• Obtain urine samples aseptically.	IB
• If CAUTI rate is not decreasing after implementing a comprehensive strategy to reduce CAUTI rates, consider using antimicrobial/antiseptic-impregnated catheters.	IB
• Further research is needed on use of bacterial interference (i.e., bladder inoculation with a nonpathogenic bacterial strain) to prevent CAUTI.	NR
• Further research is needed regarding spatial separation of patients with catheters to prevent transmission of pathogens colonizing urinary drainage systems.	NR
Other Measures	
• Implement quality improvement strategies to enhance appropriate use of catheters and to reduce the risk of CAUTI.	IB
• Ensure that health care personnel are given periodic training regarding catheter insertion, maintenance, and removal; CAUTI; and alternatives to indwelling catheters.	IB
• Consider surveillance for CAUTI when indicated.	II
• Do not routinely screen catheterized patients for asymptomatic bacteriuria.	II

[a]Recommendations: *IA*, strong recommendation supported by high- to moderate-quality evidence suggesting net clinical benefit or harm. *IB*, Strong recommendation supported by low-quality evidence suggesting net clinical benefit or harm or an accepted practice (e.g., aseptic technique) supported by low- to very-low-quality evidence. *IC*, Strong recommendation required by state or federal regulation. *II*, Weak recommendation supported by any-quality evidence suggesting a trade-off between clinical benefit and harm. No recommendation/unresolved issue *(NR)*, unresolved issue for which there is low- to very-low-quality evidence with uncertain tradeoffs between benefit and harm.

Control of Antibiotic Resistance

Between 1940 and 1962, more than 20 new classes of antimicrobials were marketed. Since then, only two new classes have reached the market.[508a] In the 1960s, public health officials confidently declared that the war against infectious diseases was almost over. Unfortunately, it is not clear which side will be victorious. Although the greatest strides in our struggles with infectious diseases have resulted from improvements in hygiene and social conditions, the growing losses of our antibiotic armamentarium as a result of surging bacterial resistance could ultimately be disastrous for ICU patients if the tide is not stemmed.

Evolution of Antibiotic Resistance in ICUs

Antimicrobial resistance has evolved through several phases. In the 1970s and 1980s, resistance of aerobic gram-negative bacilli was the major concern, and P. aeruginosa, with its broad range of intrinsic and acquired resistances, was the quintessential nosocomial pathogen. By the 1990s, the availability of antibiotics from a variety of distinct classes—aminoglycosides, broad-spectrum penicillins (e.g., piperacillin), monobactams (e.g., aztreonam), carbapenems (e.g., imipenem), β-lactam–β-lactamase inhibitors (e.g., piperacillin-tazobactam), trimethoprim-sulfamethoxazole, and fluoroquinolones—promised a respite from concerns about resistance in aerobic gram-negative bacilli. During this period, however, gram-positive cocci gained prominence, and MRSA, β-lactam–resistant coagulase-negative staphylococci, and VRE became the major problem nosocomial pathogens. Co-emerging as nosocomial pathogens with MRSA have been methicillin-resistant coagulase-negative staphylococci, which have become the leading cause of IVD-related BSI and prosthesis-related surgical site infections.

In the early 1990s VRE burst onto the hospital and ICU scene in the United States and within a few years became entrenched in most tertiary medical centers. Heavy use of vancomycin, often as empiric treatment in response to concerns about MRSA, has been cited as an initial factor driving the emergence of VRE. In most settings, however, exposure to cephalosporins and antimicrobials with antianaerobic activity has emerged as the greatest risk factors for nosocomial colonization or infection by VRE. The mid-1990s witnessed growing problems with resistance in fungi and shifts to non–Candida albicans species, representing the effects of heavy empirical use of azoles such as fluconazole in hospitals during this period.

Multidrug-resistant gram-negative bacilli have also emerged as a serious threat, including multidrug-resistant P. aeruginosa and Acinetobacter, ESBL-producing Enterobacteriaceae in the 1980s, carbapenemase-producing Enterobacteriaceae in the 1990s, and AmpC β-lactamase–producing bacteria, with some of these pathogens resistant to all available antibiotics.[48]

Forces Driving Resistance in ICUs

To a large extent, the emergence of antimicrobial resistance reflects the combined effects of genetic selection, antibiotic pressures, and the frequency of cross-infection in ICUs.[48] For some resistance mechanisms (e.g., ESBL that confers resistance to third-generation cephalosporins such as ceftazidime), a shift of a single amino acid

in existing resistance genes can lead to new, inactivating enzymes. For other resistant bacteria, such as penicillin-resistant pneumococci, multiple resistance genes must be cobbled together in a specific, exacting sequence, which may take years to evolve, emerge, and spread.

Antibiotic pressures provide the necessary Darwinian forces that amplify these genetic changes.[509] Usually, resistance emerges to a specific agent that is used most heavily and, hence, provides the greatest pressure. In some instances, genetic linkage of resistance mechanisms to unrelated classes of antimicrobials results in the capacity of heavy use of one drug class to select for resistance to a different class. For example, use of trimethoprim-sulfamethoxazole has been associated statistically with the emergence of ceftazidime-resistant E. coli and K. pneumoniae as a result of linkage on a single plasmid of genes that encode production of ESBL and trimethoprim-sulfamethoxazole resistance. A large proportion of extended-spectrum β-lactamase–producing gram-negative bacilli are also resistant to fluoroquinolones.[510,511]

In epidemiologic and clinical studies of antibiotic resistance, there is always a proportion of patients in whom resistance is found without exposure to the problem antibiotic. These patients usually have other important risk factors, such as increased severity of underlying disease, extremes of age, presence of invasive devices, recent surgery, or proximity to patients who are infected or colonized with antibiotic-resistant bacteria. In these cases the presence of antibiotic-resistant strains is most often the consequence of patient-to-patient spread, usually on the contaminated hands of HCWs; occasionally, spread results from a contaminated common source, such as an inadequately cleaned piece of equipment. Studies of HCW hand hygiene show that rates of handwashing between patient contacts range from 25% to 50%, at best, and are inadequate to control resistance, especially in ICUs, where the staff are extremely busy and less likely to be attentive to hand hygiene.[177]

Controlling Antimicrobial Resistance in the ICU

Stemming the tide of antimicrobial resistance requires a multifaceted approach, especially in ICUs, where antibiotic pressures and lapses in hospital hygiene are usually greatest. First, active surveillance for resistant bacteria is essential to provide an understanding of local problems and needs. To support surveillance and treatment, cultures must be obtained from suspected sites of infection before empiric antibiotic therapy is initiated. The benefit of routine surveillance cultures (e.g., periodic cultures of sputum specimens or rectal swabs) for assessing rates of colonization by resistant bacteria in ICUs will depend on how such cultures are used.

Second, when rates of resistance begin to increase, molecular typing, such as by pulsed-field gel electrophoresis or more recently by whole genome sequencing, can differentiate spread of a single strain (clonal expansion)—usually the result of indirect person-to-person spread on the inadequately cleaned hands of HCWs or common source transmission—from spread of multiple strains (polyclonal expansion), which suggests emergence of resistance in individual patients as a result of antibiotic pressures or exogenous introduction of multiple resistant strains. Often, these problems—clonal and polyclonal—coexist.

Third, the importance of hand hygiene must be stressed at all times. Aggressive hand hygiene campaigns, with adherence monitoring and feedback of ward and even individual results, may achieve compliance rates as high as 70%. For some situations (e.g., when there is extensive patient colonization by antibiotic-resistant bacteria), these levels of adherence may not be sufficient to control cross-infection. Response to this problem has been to encourage "universal gloving," in addition to wider use of alcohol-based hand rubs (a "belt-and-suspender" approach) to bridge the gap left by incomplete attention to hand hygiene even in the best of circumstances. Use of universal gloving has been successful in controlling the spread of aminoglycoside-resistant gram-negative bacilli in ICUs and C. difficile–related diarrhea.[245,250] Because patients' intact skin and the environment in patient rooms may be a source of resistant bacteria, such as VRE, we recommend that disposable examination gloves be worn for all contact with ICU patients or their environment. Because gloves are not a total barrier, they must be removed and hands disinfected by an alcohol hand rub between patient contacts.

Fourth, antimicrobial stewardship is essential (Table 47.14).[277] See "Antibiotic Stewardship" earlier for an introduction to antimicrobial stewardship. The primary goal of antimicrobial stewardship is to optimize clinical outcomes while minimizing unintended consequences of antimicrobial use, such as toxicity, emergence of resistance, and C. difficile infection.[268,274,277] Because antimicrobial use drives antimicrobial resistance, the frequency of inappropriate antimicrobial use can be used as a surrogate marker for antimicrobial resistance. Both antimicrobial stewardship and a comprehensive infection control program are essential to limiting the emergence and transmission of antimicrobial-resistant pathogens. Many studies assessing the utility of antimicrobial stewardship have focused on adults in ICUs, where the burden of antimicrobial resistance is greatest.

A comprehensive evidence-based stewardship program to combat antimicrobial resistance is typically a multifaceted, multidisciplinary program; the size and complexity of the management team and the specific measures applied to optimize prescribing vary on the basis of local antimicrobial use patterns, resistance trends, and available resources. The two core strategies that provide the foundation for a successful antimicrobial stewardship program are (1) audits, with intervention and feedback, and (2) formulary restriction and preauthorization.[268,274,277]

Several studies have shown that real-time audits of antimicrobial use with intervention and feedback are an effective means of reducing inappropriate antimicrobial use.[512,513] In a randomized trial conducted at a 600-bed tertiary teaching hospital, inpatients receiving parenteral antimicrobial therapy were randomly assigned to an intervention group that received suggestions for optimal antimicrobial use from an infectious disease physician or to no interventions. Physicians in the intervention group implemented 85% of the suggestions they received, which resulted in 1.6 fewer days of parenteral therapy and $400 savings per patient. Similar results have been noted in trials undertaken in community hospitals.[512] If daily review of antimicrobial use is not feasible, review of antimicrobial usage 3 days a week may still have a significant impact. Effective auditing with intervention and feedback can be undertaken most easily with automated computer surveillance of antimicrobial use, allowing the targeting of specific units where the problems are greatest.

Formulary restriction and preauthorization requirements for specific agents are now common in most hospitals. Antimicrobial restriction is unequivocally the most effective method of controlling antimicrobial use.[514,515] However, it is unclear whether antimicrobial restriction achieves the more important outcome, reducing antimicrobial resistance. Several studies of outbreaks of C. difficile–associated diarrhea have shown abrupt cessation of the outbreak following restriction (and greatly reduced use) of one or more key antimicrobials such as clindamycin or third-generation cephalosporins.[514] However, other studies have documented

TABLE 47.14 Recommendations for Developing an Institutional Program to Enhance Antimicrobial Stewardship

Recommendation	Level of Evidence[a]
• Create a multidisciplinary antimicrobial stewardship team, including an infectious disease physician and a clinical pharmacist with infectious disease training.	A-II
• Include, if possible, a clinical microbiologist, an information systems specialist, an infection control professional, and the hospital epidemiologist.	A-III
• Foster collaboration between the antimicrobial stewardship team and the hospital infection control committee.	A-III
• Create a climate of support and collaboration between the antimicrobial stewardship team and the hospital administration and medical staff leadership.	A-III
• Develop infrastructure to measure antimicrobial use, and track use on ongoing basis.	A-II
• Use a system of prospective audit of antimicrobial use with direct interaction and feedback to the prescriber by an infectious disease physician or a clinical pharmacist with infectious disease training.	A-I
• Use formulary restrictions and preauthorization requirement to reduce antimicrobial use and cost.	A-II
• Provide education to health care providers regarding stewardship strategies.	A-III
• Education must be combined with active interventions to improve antimicrobial prescribing practices.	B-II
• Develop evidence-based multidisciplinary guidelines incorporating local microbiology and resistance patterns to improve antimicrobial utilization.	A-I
• No recommendation can be made regarding antimicrobial cycling as a means of preventing or reducing antimicrobial resistance.	C-II
• Use antimicrobial order forms as a component of antimicrobial stewardship.	B-II
• No recommendation can be made regarding the routine use of combination therapy to prevent emergence of resistance.	C-II
• Streamline or de-escalate antimicrobial therapy on the basis of culture results.	A-II
• Optimize antimicrobial dosing on the basis of individual patient characteristics, causative organisms, site of infection, and pharmacokinetic and pharmacodynamic characteristics of the drug.	A-II
• Use health care information technology. such as electronic medical records, computerized physician order entry, and clinical decision support, to improve antimicrobial prescribing.	B-II
• Use computer-based surveillance for more efficient targeting of antimicrobial interventions, tracking of resistance patterns, and identification of nosocomial infections and adverse drug reactions.	B-II
• Engage the clinical microbiology laboratory to participate in antimicrobial stewardship by providing patient-specific culture and susceptibility data and by assisting infection control efforts in the surveillance of resistant organisms and in the molecular epidemiologic investigation of outbreaks.	A-III
• Determine the impact of antimicrobial stewardship by measuring process and outcomes.	B-III

[a]Based on the Infectious Diseases Society of America grading system for ranking recommendations in clinical guidelines. *A,* Good evidence to support a recommendation for use. *B,* Moderate evidence to support a recommendation for use. *C,* Poor evidence to support a recommendation for use. *I,* Evidence from more than1 properly randomized, controlled trial. *II,* Evidence from more than 1 well-designed clinical trial, without randomization, from cohort or case-controlled analytic studies, or from multiple time-series. *III,* Evidence from expert opinion.

Modified from Dellit TH, Owens RC, McGowan JE Jr, et al. Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America guidelines for developing an institutional program to enhance antimicrobial stewardship. *Clin Infect Dis.* 2007;44:159–177.

inexorably rising resistance rates in nosocomial pathogens despite a rigorous program of antimicrobial restriction.[516] One explanation for this increase in resistance may be the compensatory increase in usage of broad-spectrum antimicrobials other than the restricted agent, thus counteracting any benefit of restriction. Furthermore, restricting the use of a single drug to reduce antimicrobial resistance may be ineffective because cross-resistance in bacterial species to more than one class of antimicrobials is the rule in nosocomial organisms.

One or both of the core strategies—audits with intervention and formulary restriction—should be adopted and supplemented by close collaboration of an antimicrobial stewardship team, infection control personnel, health care providers, and hospital administration.

Beyond the two core mechanisms of antimicrobial stewardship, other elements that should be incorporated into an institutional antimicrobial stewardship program include education of health care providers; however, passive educational efforts, such as conference presentations, teaching sessions, and provision of guidelines, are only marginally effective in the absence of other active interventions.[517] Clinical practice guidelines are being introduced with increasing frequency; however, the impact of these guidelines on

provider behavior and clinical outcomes has been difficult to measure. Guidelines tailored to local antimicrobial resistance patterns and antimicrobial use trends may have more impact than a generic clinical pathway. Finally, technologies that offer rapid identification of organisms in blood cultures are a promising new application that has improved time to escalation of antimicrobial therapy, and also de-escalation of antimicrobial therapy but only with involvement of the antimicrobial stewardship team (see "Role of the Microbiology Laboratory").[157,158]

Interest has been sparked in ICUs by the reborn concept of antibiotic cycling.[518,519] Switch therapy[520] has been evaluated for empiric antibiotic use, rather than actual cycling, and has shown beneficial reductions in resistance among gram-negative bacilli[521] and in the prevalence of VRE. Such approaches, as well as true cycling through different antimicrobial classes, may be effective over limited periods in closed environments such as ICUs, by transiently reducing selection pressure and thus resistance to the restricted agent. Yet studies have thus far not shown a consistent long-term benefit with cycling, and mathematical models do predict that cycling will not be an effective measure to reduce antimicrobial resistance.[522]

Antimicrobial order forms with automatic stop orders and the requirement for physician justification reduce antimicrobial usage.[523] Streamlining or de-escalation of therapy based on culture data is an essential component of appropriate antimicrobial use, with studies showing substantial reductions in days of antimicrobial use and cost savings.[524,525]

Computer order entry provides needed information at the moment in a neutral, nonjudgmental, fact-based format; this system is efficient, well accepted, and holds the promise to change prescribing behaviors materially.[526,527]

Effective antimicrobial stewardship programs can be financially self-supporting and improve patient care. Studies have shown reductions in antimicrobial usage from 22% to 36%, with annual savings of $200,000 to $900,000 in larger teaching hospitals and community hospitals. Guidelines from the Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America provide detailed recommendations for developing institutional programs of antimicrobial stewardship, which are summarized in Table 47.14.[277]

Avant Garde Infection Control Measures

Selective Digestive Decontamination

Intense interest has arisen in Europe and the United States[485–487] over the use of (SDD) for the prevention of bacterial pneumonia and other nosocomial infections in mechanically ventilated ICU patients. This novel therapy is based on the premise that the upper respiratory tract flora exists in a continuum with the gastrointestinal flora and that these mucosal microorganisms make up the major reservoir of pathogens causing pneumonia and many other nosocomial infections, especially in mechanically ventilated patients. Most ventilated ICU patients have a nasogastric tube that provides a direct conduit for reflux of microorganisms from the heavily colonized stomach to the oropharynx, from which organisms gain access to the lower respiratory tract.

SDD consists of four components: (1) a broad-spectrum parenteral antibiotic given for approximately 3 days to treat infections incubating at the time of admission to the ICU; (2) topical antimicrobials (usually polymyxin E, tobramycin, and amphotericin B) periodically applied to the oropharynx and instilled into the gut for a variable period, usually for the entire duration of ICU stay, to reduce the mucosal burden of gram-negative bacteria and yeasts while preserving the anaerobic flora; (3) a reemphasized adherence to hand hygiene to prevent nosocomial transmission of bacteria, and in some European centers, empiric barrier isolation; and (4) serial surveillance cultures of the oropharynx and rectum to monitor the efficacy of the treatment.[528,529]

Twelve meta-analyses assessing the efficacy of SDD for reducing infection and mortality rates have been published (Table 47.15).[530–541] All have found a reduction in pneumonia. Some, but not all, have found a reduced mortality rate. However, a review showed that the results of the meta-analyses were inversely related to study design,[542] which in the case of SDD may overestimate its efficacy. Most studies and meta-analyses of SDD did not make a distinction between parenteral and topical SDD; the few meta-analyses that undertook subgroup analyses found that topical antibiotics alone reduced infection but not the mortality rate.[535] In a large clinical trial of SDD and selective oropharyngeal decontamination in 5939 ICU patients, a large reduction in ICU-acquired bacteremia caused by gram-negative bacilli and S. aureus was seen, and an estimated reduction in the mortality rate of 3.5 percentage points with SDD and 2.9 percentage points with selective oropharyngeal decontamination was seen, providing further evidence of the efficacy of SDD.[543]

However, the greatest deterrent to widespread acceptance of SDD is the fear that it will promote the emergence and spread of antimicrobial-resistant microorganisms. Antibiotic pressure is without question the single most powerful force driving the selection of resistant microorganisms, and any strategy for prevention of infection in the ICU that has the potential to increase infections caused by multiresistant organisms must be approached very cautiously. A number of studies underlie the concern of promoting antimicrobial resistance with SDD. Numerous studies have documented major shifts in the microbial ecology of the ICU with the use of SDD.[544–547] In a study by Lingnau and colleagues,[544] 4.5 years of SDD with ciprofloxacin led to a marked increase in MRSA infection from 17% to 81% and of ciprofloxacin-resistant S. aureus from 33% to 80%. The number of infections caused by other multiresistant bacteria such as Acinetobacter was also increased by SDD.[544]

A distinction must also be made between the risk to an individual receiving SDD of infection caused by a resistant pathogen and the institutional risk of an increased prevalence of antimicrobial-resistant organisms related to the use of SDD. Although both consequences are undesirable, given the skyrocketing rates of endemic nosocomial MRSA and VRE infections worldwide, any—however small—potential for increased antimicrobial resistance must be taken seriously.[548] To better address this issue, well-designed, cluster-randomized trials that use multilevel modeling and specifically address the effects of SDD on antimicrobial resistance across the entire spectrum of microbial pathogens at the institutional level are necessary. Until such data are available, we believe that continued North American concerns about the effects of SDD on antimicrobial resistance are justified, particularly in institutions where MRSA and VRE are endemic, which encompasses virtually all larger hospitals. Given that other effective measures for the prevention of nosocomial infection exist, we believe that SDD should be restricted to select patients, such as certain trauma patients, or as a potential adjunctive control measure for a nosocomial outbreak caused by multiply resistant organisms.[549]

Randomized trials have identified several novel measures for prevention of VAP such as semirecumbent positioning[471] and subglottic suction endotracheal tubes.[550] We believe that these approaches are ecologically more attractive control measures for

ventilated ICU patients than prophylactic topical and systemic antibiotics.

Preemptive Barrier Isolation

Having fewer patients in a room, improving the facilities for handwashing, and using cohort nursing (i.e., assigning each nurse to designated patients) have reduced the incidence of endemic nosocomial infection in neonatal and pediatric ICUs.[181,551] Complicated forms of protective isolation have reduced the high rates of nosocomial infection in patients with profound granulocytopenia[552] or full-thickness burns.[181,264] Moreover, the routine use of gowns and gloves on a special pediatric unit was associated with a marked decline in the incidence of nosocomial infection with respiratory syncytial virus,[78] and the routine use of gloves for all patient contacts was shown to reduce the incidence of nosocomial C. difficile infection nearly fivefold in a large veterans hospital.[250]

Unfortunately, the few studies that have prospectively evaluated protective isolation of ICU patients have been performed in newborns and pediatric patients and have yielded conflicting and generally disappointing results[553–556]; however, most of these studies had major weaknesses in design.[557] More recently, several studies have shown that preemptive use of barrier precautions can effectively reduce the spread of multiresistant organisms such as MRSA or VRE in epidemic[558,559] and endemic settings (Table 47.16).[78,250,554,560–567] If colonization by nosocomial organisms could be prevented or at least delayed until invasive devices are removed, the incidence of infection might be significantly reduced.

One major prospective trial that assessed the efficacy of simple protective isolation—which we prefer to call preemptive barrier precautions—to reduce the incidence of nosocomial infection during pediatric intensive care studied 70 high-risk children over 30 months who were not immunosuppressed but who required prolonged mechanical ventilatory support and exposure to invasive devices in a pediatric ICU and were randomly assigned to receive standard care without any special precautions or preemptive barrier isolation, with the use of disposable nonwoven polypropylene gowns and nonsterile latex gloves for all patient contacts.[560] Risk factors predisposing patients to infection were comparable in the two groups. Nosocomial colonization occurred later among isolated patients (median 12 vs. 7 days) and was associated with subsequent infection in 2 patients, as compared with 12 patients given standard care. Among children who were isolated, the interval before the first infection was significantly longer (median, 20 vs. 8 days), the daily infection rate was twofold lower (86 vs. 44 infections per 1000 ICU days), and there were 50% fewer days with fever. The benefit of isolation was most notable after 7 days of ICU care. Isolation was well tolerated by patients and their families. Unannounced monitoring showed that children in each group were touched and handled comparably often by hospital personnel and families.

The study concluded that the use of disposable high-barrier gowns and gloves for the care of select high-risk children who require prolonged ICU care can substantially reduce the incidence of nosocomial infection, is well tolerated, and does not compromise the delivery of care. Simple forms of protective isolation as a general control measure would also seem preferable to attempts to suppress

nosocomial colonization with SDD. Further studies are necessary to determine the cost-effectiveness of prophylactic barrier precautions in the ICU and especially the efficacy of protective isolation in adult surgical ICUs, where the incidence of nosocomial infection is as high as 35%. Studies should also determine the relative importance of wearing a gown, as compared with wearing gloves alone.

Patients with prolonged severe granulocytopenia or those who are receiving high dosages of corticosteroids, usually as part of immunosuppressive regimens to prevent transplant rejection, are at risk for invasive pulmonary infection caused by Aspergillus species, mucormycosis, and other filamentous airborne fungi, which is associated with a high mortality rate.[41–43,568] The risk of invasive infection appears to be directly related to the likelihood of airborne fungi, and numerous outbreaks have been linked to building construction or failure of air-control systems. Studies have shown that the isolation of vulnerable patients in positive-pressure rooms with spore-free HEPA-filtered air greatly reduces the risk of invasive infection.[41,43] HEPA-filtered ICU rooms should be available for the care of patients who have received bone marrow or solid organ transplants and who require intensive care, especially in the early post-transplant period or during the treatment of rejection, when dosages of immunosuppressive drugs are high.

Preemptive use of barrier isolation precautions (e.g., universal gloving or gowns and gloves) and providing dedicated patient care items such as stethoscopes and sphygmomanometers in all high-risk patients from the time of admission is a simple and effective strategy to prevent HCWs from acquiring hand contamination by multiresistant organisms when having contact with patients with unrecognized colonization or infection and to block transmission to other as yet uncolonized patients.

Approach to a Nosocomial Epidemic

See the online supplement for Approach to a Nosocomial Epidemic.

Protection of Health Care Workers in the Intensive Care Unit

HCWs in general, but especially those working in ICUs who are exposed daily to critically ill patients, many of whom have contagious but undiagnosed infections, are at increased risk of acquiring occupationally related infections, including tuberculosis; herpes

Approach to a Nosocomial Epidemic

As noted earlier, most recognized nosocomial epidemics now occur in ICUs. If an epidemic is suspected, the epidemiologic approach must be methodical and thorough yet expeditious, directed toward establishing the bona fide nature of the putative epidemic infections (i.e., ruling out "pseudoinfections"[331]); confirming the existence of an epidemic (i.e., ruling out a "pseudoepidemic"[331]); defining the reservoirs and modes of transmission of the epidemic pathogens; and most importantly, controlling the epidemic quickly and completely. Control measures are predicated on accurate delineation of the epidemiology of the epidemic pathogen.

Each hospital, through its infection control committee, must be prepared administratively to conduct an investigation and implement needed control measures. The essential steps in dealing with a suspected outbreak of nosocomial BSI are summarized in Box 47.e1 [151] To illustrate the approach to a nosocomial epidemic, the epidemiologic investigation of an unusual and complicated outbreak of infusion-related bacteremia[329] is reviewed.

During a 2-week period in late March 1985, three patients in a university hospital developed primary nosocomial bacteremia with a similar nonfermentative gram-negative bacillus. All three patients had had open-heart surgery between March 11 and March 25 (Fig. 47.e2) and became bacteremic 48 to 148 hours after the operation.

The bloodstream pathogen in each case was shown to be Pseudomonas pickettii biovariant 1. The organism was also cultured from the IV fluid of two of the patients at the time because, serendipitously, during the outbreak most adult patients in the hospital receiving IV fluids were participating in a study of IV catheter dressings[569]: As part of the study protocol, specimens were routinely obtained from patients' IV fluid when the catheter was removed. Review of nearly 1000 cultures of IV fluid from the infusions of participants in the study since its outset 3 months earlier showed that three additional surgical patients operated on in March had had IV fluid cultures positive for P. pickettii biovariant 1 (see Fig. 47.e2), even though none had shown clinical signs of bacteremia. Molecular subtyping by restriction enzyme digestion and pulsed-field electrophoresis to delineate restriction polymorphism patterns showed all six isolates to be the clonal. Three more patients who had been operated on in January had had IV fluid that cultured positive for a similar nonfermentative gram-negative bacillus; although the three isolates were no longer available, the results of screening by AP-20E biochemical panel (API Analytab Products, Inc., Plainville, NY) at the time were identical to those of the six patients with P. pickettii contamination of IV, with or without associated bacteremia.

All three septic patients had had multiple positive blood cultures and were clinically in septic shock. P. pickettii had not been isolated from any local site of infection such as the urinary tract, lower respiratory tract, or surgical wound in any of the patients.

Review of nosocomial bacteremias over the past 7 years showed that P. pickettii had not previously been identified in any positive blood cultures from the institution, indicating that the cluster of three cases and six instances of contaminated infusate without bacteremia represented a true epidemic, and with the results of the subtyping, a common source epidemic.

The CDC and the manufacturer were contacted: none of more than 70 NNIS hospitals had reported P. pickettii bacteremias in the past year, and the manufacturer had never identified contamination with P. pickettii in quality-control microbiologic sampling of fentanyl before distribution, or received any complaints from users about suspected contamination of their fentanyl. Moreover, survey of surrounding [Wisconsin] hospitals that also used the manufacturer's fentanyl revealed none experiencing nosocomial [bacteremias] with P. pickettii.

A case-control study comparing the 9 cases, all of whom had had recent surgery, with 19 operated patients who had had negative IV fluid cultures in the IV dressing study (Table 47.e2), showed that all 9 cases but only 9/19 operated controls had received fentanyl intravenously in the operating room ($P = 0.05$; the mean total dose given to the 9 cases was far greater than that given to control-patients who received the drug, 3080 μg vs. 840 μg, $P < 0.001$).

In the hospital at the time, fentanyl was used [only in the operating rooms as part of balanced anesthesia]. The drug was

• BOX 47.E1 Evaluation of a Suspected Epidemic of Nosocomial Infections

Administrative Preparedness

Immediately retrieve putative epidemic isolates for confirmation of identity through species and subtyping by one or more methods:

- Biotyping
- Antimicrobial susceptibility pattern (antibiogram)
- Serotyping
- Phage typing
- Bacteriocin typing
- SDS-PAGE protein electrophoresis
- Immunoblot pattern
- Multifocus enzyme electrophoresis
- Restriction enzyme digestion and restriction fragment polymorphism patterns
- DNA probes
- Whole genome sequencing

Preliminary Evaluations and Control Measures

- Identify and characterize individual cases in time, place, risk factors.
- Strive to identify source of infections.
- Ascertain whether cases represent a true infection rather than a "pseudoinfection."
- Ascertain whether cases represent a true epidemic, rather than a "pseudoepidemic."
- Develop and implement provisional control measures.
- Intensify surveillance to detect each new case.
- Review general infection control policies and procedures.
- Determine the need for assistance, especially extramural (local, state, CDC).

Epidemiologic Investigations

- Clinicoepidemiologic studies, especially case-control studies
- Microbiologic studies

Definitive Control Measures and Follow-up

- Develop and implement definitive control measures.
- Confirm control of epidemic by intensified follow-up surveillance.

Reporting/Publishing Findings

Report the findings:

- Intramurally
- State health department, CDC

Publish the report.

received in 20-mL ampules from the manufacturer and each week one of three pharmacy technicians, by rotation, pre-drew into sterile syringes all fentanyl likely to be needed the following week in the operating rooms. Each day, one of the technicians delivered enough pre-drawn syringes to the operating rooms]to meet the needs of the cases being done that day. Cultures of pre-drawn fentanyl in syringes in the central pharmacy, prompted by the findings of the case-control study, showed that 20/50 (40%) 30-mL syringes sampled were contaminated by P. pickettii in a concentration of $>10^4$ CFUs/mL; none of 35 5- or 2-mL syringes showed contamination (P = 0.001).

Extensive culturing within the central pharmacy was negative for evidence of environmental contamination by P. pickettii with one exception: P. pickettii biovariant 1, with an identical antimicrobial susceptibility pattern and restriction enzyme fragment pattern to the epidemic strain recovered from blood cultures or patients' intravenous infusions, was cultured in a concentration of 28 to 80 CFUs/mL from five specimens of distilled water drawn from a tap in the central pharmacy. The epidemic strain was shown to multiply well in the fentanyl solution, attaining concentrations exceeding 10^4 CFUs/mL within 48 hours.

A second case-control study suggested strongly that the epidemic was caused by theft of fentanyl from 30-mL syringes by one pharmacy staff member and replacement by distilled water that the individual thought was sterile but which, unfortunately, was contaminated by P. pickettii. The pharmacy member resigned early in the investigation and no longer works in the hospital. On April 29, 1985, the hospital's system for providing fentanyl and other narcotics to the operating rooms was changed; narcotics are no longer predrawn into syringes in the central pharmacy but are delivered to the operating rooms in unopened vials or ampules, and anesthesiologists' orders for narcotics are filled by a staff pharmacist assigned to the operating room. No further bacteremias with P. pickettii have occurred since March 25, 1985 (see Fig. 47.e2), and cultures of more than 6000 samples of hospitalized patients' intravenous fluid in research studies since then have shown no further contamination by P. pickettii.

This outbreak illustrates the power of genetic subtyping[155] and case-control analyses to identify the cause of an epidemic. It further illustrates the potential for contamination of parenteral drugs or admixtures and the extraordinary range of epidemiologic mechanisms of nosocomial BSI deriving from such contamination.[114]

If epidemiologic or microbiologic studies suggest or indicate intrinsic contamination of a widely distributed commercial product or device, the local and state health authorities, U.S. Food and Drug Administration, CDC, and manufacturer should be informed immediately. Remaining products should be quarantined and retained for evaluation by the public health authorities.

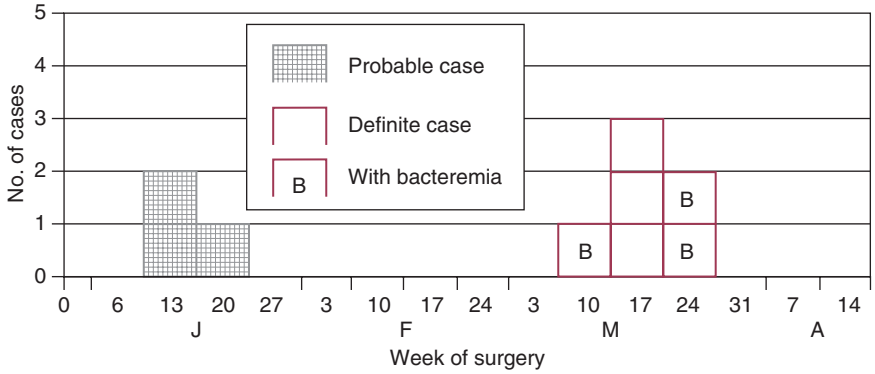

Fig. 47.e2 Epidemic curve for an outbreak of *Pseudomonas pickettii* bacteremias and contaminated intravenous infusions traced to contaminated fentanyl given intravenously. Isolates from blood or intravenous fluid of six definite cases (March 1985) were available for reconfirmation and subtyping as *P. pickettii* biovariant 1; isolates from intravenous fluid of three probable cases (January 1985) were not available for retesting but were considered likely to have also been *P. pickettii* biovariant 1 on review of the results of 20 biochemical tests common to these three and the six confirmed isolates. simplex virus infection; chickenpox; cytomegalovirus infection; hepatitis A, B, or C; HIV infection; influenza; measles; rubella; mumps; pertussis; and viral conjunctivitis.[570–572]

Fortunately, the risk posed by many of these infections can be eliminated by immunization of the HCW,[573] and recommendations from the Advisory Committee on Immunization Practices (ACIP) for the vaccination of HCWs were recently published in 2011.[574] However, a considerable number of occupational infections exist for which there are currently no vaccines. Because this is an area of active research, careful review of current guidelines is recommended, such as from the CDC.[575]

See the online supplement for additional material on Protection of Health Care Workers in the Intensive Care Unit.

Goals for the Future

Clearly, nosocomial infection is one of the most important causes of iatrogenic morbidity and death in patients who require prolonged life support care in an ICU. Much has been learned over the past three decades about the relative risks and especially the pathogenesis and epidemiology of these infections, information that has provided the scientific underpinnings for preventive strategies that have proved effective. However, there is an urgent need for better research to prevent nosocomial infection in ICU patients (Box 47.4),[627] particularly with respect to strategies to prevent colonization by multiresistant microorganisms, and to prevent infection when colonization has already occurred.[28]

Most of our understanding of the epidemiology of nosocomial infection, especially in ICUs, is based on studies of epidemics. Well-designed studies are necessary to better define the epidemiology of endemic nosocomial infections, especially those caused by resistant staphylococci, enterococci and gram-negative bacilli, and yeasts. The importance of hand carriage of pathogens by hospital personnel, the role of airborne and water-borne transmission in the ICU, and the relevance of contamination of the inanimate hospital environment by resistant pathogens all need to be better delineated, as well as the factors influencing nosocomial colonization and superinfection by resistant bacteria and yeasts.

In addition, larger and more sophisticated studies, using multivariate techniques of statistical analysis to define risk factors for the major forms of nosocomial infection in the ICU and whole genome sequencing of study pathogens to differentiate clonal from polyclonal spread, are necessary to guide allocation of infection control resources and to target future research efforts.

Considering that the period of greatly increased susceptibility to infection of ICU patients is limited—until the invasive devices have been removed—a major commitment must be made to devise and evaluate strategies for blocking transmission of organisms between patients and preventing, or at least delaying, nosocomial colonization.

One of the oldest yet most important infection control measures—hand hygiene—is still done almost indifferently by HCWs in most hospitals including within ICUs. Innovative approaches are necessary to improve the frequency and the quality of handwashing after patient contacts likely to result in acquisition of nosocomial organisms. Exactly how should hands be washed for maximal benefit and with what agents? The question can be posed: Could very frequent handwashing, which approaches 40 times per 8-hour shift in neonatal ICUs, increase the potential for transmission of microorganisms, such as methicillin-resistant coagulase-negative staphylococci? Should the frequency of handwashing, as well as the agents used, be critically reexamined? Beyond a certain frequency, more may not necessarily be better. Should handwashing machines, which substantially augment degerming,[628,629] be adopted widely? Could regular application of chlorhexidine-containing evaporative lotions, used without water, replace some of the conventional handwashing or at least compensate for the suboptimal handwashing currently practiced?[242,630,631] Large clinical trials, ideally in multiple centers, are necessary to ascertain the efficacy or lack of efficacy of innovative approaches to hand degerming in reducing infections in high-risk patients, particularly in nurseries and ICUs.

Whereas SDD with topical nonabsorbable antibiotics has shown promise for the prevention of nosocomial respiratory infection in ICU patients, as noted, the potential effect on the microbial ecology

• BOX 47.4 Directions for Future Research in Nosocomial Infection Control

Studies to Better Define the Epidemiology of Endemic Nosocomial Infections:

- Especially those caused by resistant staphylococci, gram-negative bacilli, and *Candida*
- The relevance of hand carriage of pathogens by hospital personnel
- The role of airborne transmission
- The relative importance of contamination of the inanimate hospital environment, especially with methicillin-resistant *Staphylococcus aureus, Clostridium difficile,* and other resistant organisms
- The biologic factors influencing colonization by nosocomial organisms
- The factors governing superinfection by resistant bacteria and *Candida*
- Better understanding of risk factors predisposing to infection, especially in the ICU, to guide allocation of resources in infection control and focus research efforts

Innovative Strategies to Prevent Nosocomial Colonization and Interrupt Cross-Infection, Especially in ICUs:

- New approaches to improving compliance with and improving the effectiveness of handwashing between patients
- Various types of barrier precautions (forms of protective isolation)
- The true efficacy and cost-benefit ratio of selective digestive decontamination, with careful assessment of the ecologic effects of long-term use
- Dedicated device care teams
- Large, randomized clinical trials of the various cutaneous antiseptics available, with infection, rather than colonization, as the index of comparison, for handwashing by personnel, site disinfection with invasive devices, patient bathing, and decolonization

Research on Devices:

- Innovative designs to implicitly reduce contamination
- Colonization-resistant polymers, possibly incorporating antimicrobials onto the surface or into the polymer itself
- Better techniques of use to enhance safety
- Cost-effective "needleless" systems to protect health care personnel
- Improved laboratory tests to identify infection more accurately and rapidly, especially tracheobronchitis and pneumonia, to reduce unnecessary antibiotic therapy yet permit early therapy to avert progression to life-threatening sepsis
- Measures to restrict and improve the use of antibiotics, especially in ICUs
- Expanded, more effective approaches to education in infection control for health care personnel, especially physicians, with respect to handwashing, use of isolation, invasive devices, and use of antibiotics

General Precautions Against Biohazardous Exposure

All hospitals, as mandated by The Joint Commission,[31] must have an employee health service and written protocols for the management of biohazardous exposures (Box 47.e2).[133,576] Such protocols permit expeditious and comprehensive evaluation and timely administration of postexposure prophylaxis (PEP) with antiretrovirals after HIV exposure, immune serum globulin or hepatitis B immune globulin after exposure to hepatitis A or B, or antimicrobial prophylaxis after exposure to contagious bacterial pathogens such as Neisseria meningitidis or Bordetella pertussis.

The single greatest measure a hospital can take to reduce the risk of biohazardous exposures is to implement a comprehensive program that actively monitors occupational exposures,[577] educates HCWs about the consequences and ways to prevent exposures,[578] and advocates for and rigorously evaluates new safety technologies as a means of reducing exposures further.[579]

The importance of uncompromising compliance with universal precautions to protect HCWs from unknowing exposure to HIV and other blood-borne viruses has been discussed. Importantly, the greatest emphasis in training on universal precautions should be placed on measures to prevent needle sticks and other sharps injuries,[576] prohibition of recapping used needles, and making impervious needle disposal containers[580] available at the bedside of each ICU patient.[581] The use of engineered controls such as needleless systems holds the greatest promise for effecting a material reduction in hazardous sharps injuries.[579]

• BOX 47.E2 Guidelines for Prevention and Management of Biohazardous Injuries in the Hospital[a]

1. Hospital personnel must be made more personally aware of the potential catastrophic sequelae of sharps injuries and other biohazardous exposures and of guidelines for prevention. This must be conveyed in initial orientation programs for all new personnel, including physicians, and by periodic updates on each patient care unit and presentations at staff conferences. The topic also can be periodically reviewed in the hospital's newsletter for personnel. Prominently placed posters warning of the hazards of sharps injuries and listing simple precautions to avert such injuries, especially in areas where sharps are heavily used, also may be of value.
2. Sharps disposal units should be made widely and conveniently available throughout the hospital, especially in locations that facilitate their immediate use: in individual patient rooms, nursing stations, pharmacy units, and utility rooms; in all clinical laboratories; on anesthesia carts; and in each operating room. Receptacles should be made of impervious material such as plastic or metal and should be emptied according to an established routine by personnel who have been properly instructed in the correct procedure. Disposal units should consist of impervious receptacles into which a used needle and syringe or other sharps can be immediately dropped without handling it further. If it is necessary to remove a used needle from a syringe or Vacutainer, an instrument should always be used.
3. Recapping or resheathing of used needles must be strongly discouraged except when rare circumstances do not permit immediate disposal, in which case capping must be done using a "one-handed technique" or special sheath.
4. Medical or nursing personnel must be apprised of the importance of obtaining adequate assistance when administering injections or infusion therapy to patients who may not be able to cooperate.
5. Personnel must be apprised of the need to use extreme care in cleaning up after procedures that involve needles or other sharps, such as lumbar punctures, thoracentesis, or central venous catheter placement.
6. A strong institutional commitment to the continuous evaluation and selective adoption of technology-based approaches to prevention of sharps injuries will have the greatest impact.
7. With accidental sharps injuries, unless the injury occurred with a clean sharp not used on a patient, the injury should be immediately reported to the employee health service, where work-related injuries in general can be evaluated and managed most consistently and inexpensively and surveillance of all work-related injuries can be assisted. A mechanism to ensure prompt management of biohazardous injuries 24 hours a day (including during nights and weekends by emergency department personnel who have been trained in the institutional biohazardous injury protocol) must be available.

   All hospital personnel who render care or services to patients, including all staff physicians, house officers, and health care students, should be covered by this institutional service to ensure consistent reporting and treatment of injuries.

   Employee health service personnel should meet with each employee who sustains a biohazardous injury, ascertain the exact reason for the accident, and review how to prevent a similar injury in the future. Particular attention should be given to those health care workers who have sustained repeated injuries to identify accident-prone activities or individuals or high-risk work situations that should be modified.
8. Institutions should carry out continuous surveillance and reporting of all biohazardous injuries, which can form the basis for preventive programs and determine their effectiveness. Risk management personnel should include sharps injury reduction as a major institutional priority.
9. Management of sharps injuries: A comprehensive protocol for management of sharps injuries would be beyond the scope of these guidelines; however, it is imperative that all hospitals have a protocol that provides unambiguous guidelines for management, specifically the following:
   a. Clear definitions of biohazardous injuries
   b. Procedures for immediate care of the injury at the time of occurrence (e.g., squeezing the puncture wound to induce bleeding, disinfection with a virucidal agent, such as an iodophor)
   c. Procedures to determine expeditiously the magnitude of risk (i.e., screening the source patient for evidence of active infection by hepatitis B virus; hepatitis C virus; and human immunodeficiency virus [HIV]). With regard to HIV screening, the protocol must be in compliance with state statutes governing HIV testing.
   d. The responsibilities of the injured health care worker; the worker's supervisor; the employee health service; and, after working hours, the emergency department
   e. Guidelines for postexposure immunoprophylaxis and drug therapy, especially with exposures to the following:
      Hepatitis A, B, and C
      HIV infection
      Jakob-Creutzfeldt disease
      Syphilis
      Malaria
      Bacteremia
   f. Follow-up evaluation of the exposed health care worker, especially after exposures to HIV and hepatitis B and C virus
   g. Administrative follow-up evaluation of all injuries to minimize recurrences, and institutional surveillance of biohazardous injuries
   h. Periodic review of the protocol, with revision as indicated

Vaccine-Preventable Diseases

Hepatitis B

Percutaneous exposure of an unvaccinated HCW to blood from a patient who is positive for hepatitis B surface antigen (HBsAg) carries considerable risk of seroconversion (23%–37%) and development of clinical disease (1%–6%).[133] This risk is greatly magnified if the source patient is hepatitis B e antigen (HBeAg) positive: the risk of seroconversion is 37% to 62%, and the risk of developing clinical disease is 22% to 31%.[133] The introduction of the recombinant hepatitis B vaccine in 1986 has greatly reduced the risk of occupationally acquired disease, and it is recommended that all HCWs receive a complete three-dose hepatitis B vaccine series.[574,582] Furthermore, ACIP recommends that all HCWs have documentation of protective serum titers (hepatitis B surface antibody [HBsAb] serum titer ≥10 mIU/mL) 1 to 2 months after completion of their primary series. Those HCWs who do not mount protective titers should be revaccinated with a second complete three-dose series, followed by HBsAb testing 1 to 2 months after the third dose.[574] HCWs exposed to hepatitis B who have not developed protective titers after a primary or secondary immunization series or who have not completed a primary immunization series should be given postexposure prophylaxis (PEP) as detailed by the U.S. Public Health Service[133] or ACIP.[574] In light of universal vaccination of all newborns, at least for those raised in the United States, the proportion of HCWs already vaccinated against hepatitis B will increase over time.

Measles, Mumps, and Rubella

Reported cases of measles, mumps, and rubella (MMR) have declined steadily in the United States since the introduction of mandatory childhood immunizations.[583–585] However, epidemics of measles and, more recently, mumps continue to be a problem in many parts of the country.[586–588] Severe measles in susceptible HCWs who themselves exposed additional patients while in the incubation phase of infection have been well described in the literature.[88,589] As a result, it is recommended that all HCWs born after 1956 have evidence of immunity to measles, mumps, and rubella by any of the following: (1) laboratory evidence of a protective titer; (2) laboratory confirmation of disease; or (3) written documentation of appropriate vaccination.[574] When nonimmune HCWs are exposed to measles, PEP with MMR vaccination has been shown to reduce the likelihood of developing fulminant disease.[574,590] Measles immunoglobulin is another PEP option for nonimmune HCWs who have a contraindication to immunization—pregnancy—but it provides only temporary protection.[574,590] When nonimmune HCWs are exposed to mumps, PEP with MMR vaccine is not recommended for prophylactic purposes because antibody response is not believed to develop soon enough to provide effective prophylaxis; however, the first dose of MMR vaccine should be offered as soon as possible.[574] PEP for rubella with vaccine or immune globulin is not effective.[574]

Varicella

Occupational acquisition of varicella-zoster virus is well described, with transmission rates among susceptible HCWs ranging from 2% to 16% in published studies.[573,591] Infected HCWs pose a threat for transmission to other susceptible patients, and HCWs, when compared with persons who acquire varicella during adolescence, often experience more severe disease,[592] particularly if pregnant.[593] All HCWs should have evidence of immunity to varicella, which includes any of the following: (1) laboratory evidence of immunity or laboratory confirmation of disease; (2) written documentation of vaccination with two doses of varicella vaccine; or (3) diagnosis or verification of a history of varicella disease or herpes zoster by a health care provider.[574,582,594] HCWs without evidence of immunity to varicella should be given two doses of varicella vaccine administered 4 to 8 weeks apart.[574,594]

HCWs, particularly if they are pregnant, without evidence of immunity to varicella should not care for patients with suspected or confirmed varicella or zoster infections.[574] In the event of an accidental exposure, HCWs without evidence of immunity to varicella should be given PEP with varicella vaccine as soon as possible, and preferably within 3 to 5 days of exposure on the basis of studies demonstrating a reduced risk of developing clinical infection and attenuated clinical disease.[574,594] For HCWs without evidence of immunity to varicella, who have been exposed to varicella or herpes zoster, and who are at high risk for severe disease and complications and for whom varicella vaccine is contraindicated (e.g., pregnant women, immunocompromised patients), varicella-zoster immune globulin is recommended as soon as possible after exposure, but can be given up to 10 days after exposure.[574,594,595]

Influenza

Influenza is responsible for 226,000 hospitalizations and 36,000 deaths in the United States each year.[596] Nosocomial outbreaks of influenza are common and put HCWs at considerable risk of acquiring and transmitting influenza to others.[574,597,598] These outbreaks impose considerable economic burden on health care institutions and increase adverse events among HCWs and patients alike.[599] Influenza immunization of HCWs has significantly reduced days of febrile illness and sick leave in randomized controlled trials,[600,601] and surveys suggest that HCWs tend to view influenza immunization as a means of protecting themselves from illness.[602,603] However, accumulating evidence suggests that influenza immunization of HCWs also significantly reduces rates of influenza-related morbidity and mortality among potentially exposed patients in a variety of health care settings.[604–606] Moreover, expanding immunization rates of HCWs has been shown to be cost-saving from an institutional perspective.[607] Despite this evidence and the recommendation that all HCWs receive annual influenza vaccination,[574] voluntary immunization rates among U.S. HCWs remain disappointingly low—in the range of 40%.[608] For these reasons, some experts are beginning to call for mandatory influenza immunization of HCWs (i.e., a condition of employment) in much the same way that hepatitis B and MMR vaccinations are mandatory for HCWs in most hospitals.[609]

Pertussis

HCWs are at increased risk of developing pertussis as a result of waning immunity in adulthood,[574,610] and numerous pertussis epidemics among HCWs have been reported in recent years.[611,612] Pertussis outbreaks are associated with considerable economic consequences,[612,613] and studies have shown that routinely providing a pertussis booster to HCWs in the form of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis adsorbed vaccine (Tdap) is cost-effective.[612] The ACIP recommends that all HCWs receive a single dose of Tdap as soon as feasible if they have not previously received Tdap and regardless of the time since their most recent tetanus-diphtheria vaccination.[574] Despite this recommendation, Tdap vaccination coverage among HCWs in the United States remains low and was only 17% in 2009.[574]

Non–Vaccine-Preventable Diseases of Major Interest

Herpetic Whitlow

Primary HSV paronychia has long been an occupational hazard of being an ICU nurse or physician[614,615] and is usually associated with a great deal of pain and discomfort, fever, and lymphadenitis. Leave from work for 2 to 3 weeks is not uncommon. One of the most compelling reasons for ICU HCWs to routinely wash their hands after contact with an ICU patient and to wear gloves during any contact with a patient's airway—including gloves on both hands during tracheal suctioning—is to protect themselves from this miserable condition.

Tuberculosis

Numerous reports of tuberculosis outbreaks in hospitals and other health care settings in the early and mid-1990s reminded the health care community of the risk associated with the care of patients with active pulmonary tuberculosis.[85–87,257] The feature common to most of these outbreaks was failure to recognize patients with active pulmonary tuberculosis. The most important measure for preventing the transmission of tuberculosis is to (1) rapidly identify and isolate patients with suspected tuberculosis and (2) promptly initiate appropriate therapy when tuberculosis is confirmed to reduce the duration of infectiousness.[616] Guidelines for the prevention of nosocomial tuberculosis have been published that stress the importance of administrative, environmental, and personal respiratory protection controls.[134] Implementation of these recommendations has led to remarkable reductions in nosocomial transmission rates.[258]

Hepatitis C

Nearly 4 million persons in the United States are infected with hepatitis C virus (HCV), which is responsible for 8000 to 10,000 deaths every year.[617] Although the already high and rising prevalence of HCV infection in the population potentially exposes HCWs to occupationally acquired infection, most studies have failed to find a higher seroprevalence to HCV among HCWs than in the general population.[618] However, at least one study found that a previous history of a needle stick injury is associated with an increased risk of HCV infection,[619] and pooled analyses of published studies suggest that the seroconversion rate after a percutaneous injury involving HCV-positive persons is about 0.5%, a risk that is similar to that seen with percutaneous injuries involving needle stick exposures to HIV.[618] Guidelines from the U.S. Public Health Service for the management of HCWs exposed to HCV recommend serologic testing and measurement of serum alanine aminotransferase levels, with or without HCV PCR testing, at baseline and again 4 to 6 months later, and do not recommend PEP with human immune globulin preparations or antiviral agents.[133] More recent guidelines from the Infectious Diseases Society of America and American Association for the Study of Liver Diseases do not recommend postexposure prophylaxis with antiviral therapy.[620] Although direct-acting antiviral-based regimens have shown very high efficacy for chronic HCV infection, there are no data regarding the efficacy or cost-effectiveness of direct-acting antiviral-based regimens for postexposure prophylaxis of HCV infection.[620] Furthermore, there is a 20% to 50% chance of spontaneous resolution of acute HCV infection; therefore monitoring HCV ribonucleic acid for at least 12 to 16 weeks is recommended to allow for spontaneous clearance, before considering starting treatment.[620]

Human Immunodeficiency Virus

Although the risk of occupationally acquired HIV infection is low, it is not zero. As of 2002, there had been 57 probable and an additional 139 possible cases of occupationally acquired HIV in the United States.[621] The vast majority involved percutaneous injuries from hollow-bore needles contaminated with blood.[618] Other types of sharps injuries are less likely to transmit HIV, and only a single documented case of occupational HIV transmission caused by a body fluid exposure other than blood—bloody pleural fluid—has been reported in the literature.[622] Although no randomized trials exist, there are considerable data from animal[623] and observational studies[624] to suggest that PEP with antiretrovirals can significantly reduce the likelihood of HIV transmission after a high-risk exposure. For this reason, the U.S. Public Health Service has issued detailed recommendations on occupational HIV PEP with the choice and number of drugs driven by characteristics of the HCW, type of exposure, and characteristics of the source patient.[625] Additionally, a PEP hotline is available through the University of California, San Francisco, Clinician Consultation Center (phone: 888-448-4911).[626]

of the ICU must be viewed with caution, and the cost-benefit and long-term effects of SDD need better clarification. The uses of simple barrier precautions to prevent colonization and infection have shown promise and warrant further study, especially in ICUs.

Universal decolonization (e.g., daily bathing with chlorhexidine) may become routine for all ICU patients. In a study involving 74,256 patients among 74 ICUs, patients were randomly assigned to one of three strategies: (1) universal decolonization (i.e., daily bathing with chlorhexidine-impregnated cloths for the entire ICU stay along with twice-daily intranasal mupirocin for 5 days), (2) targeted decolonization (i.e., MRSA nares screening and if positive, contact precautions implemented along with twice-daily intranasal mupirocin for 5 days), or (3) screening and isolation (i.e., MRSA nares screening and if positive, contact precautions implemented).[632] Universal decolonization of ICU patients was the most effective strategy and reduced positive MRSA clinical cultures, but not MRSA BSI. Universal decolonization also reduced BSIs from any pathogen.

Studies have shown that the use of dedicated IV therapy teams, consisting of trained nurses or technicians to ensure a high level of aseptic technique during catheter insertion and in follow-up care of the catheter, has been associated with greatly reduced rates of catheter-related infection and appears to be cost-effective.[346,347,633] The use of teams of trained ICU personnel to insert all urethral catheters and provide follow-up care for these catheters, all IVDs, and percutaneous tubes in the ICU deserves study.

Remarkably, there have been few comparative clinical trials of the various chemical antiseptics available for disinfecting skin before inserting IVDs or assisting in surgery or studies of antiseptic handwashing agents. Large, randomized clinical trials, ideally in multiple centers, are necessary in which infection, rather than cutaneous colonization or positive cultures, is used as the index of comparison.

Considerable evidence indicates that the material used in construction of an implanted device plays an important role in the pathogenesis of device-related infection—namely, whether the material provides an attractive surface for adherence by pathogenic microorganisms such as coagulase-negative staphylococci. Studies are necessary to delineate fully the molecular mechanisms of microbial adherence to prosthetic surfaces to develop new materials intrinsically resistant to colonization for use with implantable devices and to design devices that intrinsically deny microbial access.

Increased use of diagnostic tests has greatly increased awareness of infectious diseases. Improved laboratory techniques to identify infection more accurately and rapidly, especially methods to reliably distinguish colonization of the lower respiratory tract from early infection that merits antimicrobial therapy, could greatly reduce unnecessary antimicrobial therapy yet detect infections earlier, before they progress to sepsis with multiple-organ failure.

Antimicrobials are not used optimally in most ICUs, and there is much overuse in hospitals, particularly of extended-spectrum penicillins and cephalosporins, carbapenems, vancomycin, and fluoroquinolones. Antibiotic pressure has had a powerful effect on the hospital microbial ecology and, as noted previously, on the profile of nosocomial infection, especially in ICUs. We must and can do better.

Last, but certainly not least, many physicians remain remarkably oblivious to the most basic precepts of infection control, and nurses are in general far better informed and are a more effective force for ensuring compliance with infection control practices. More effective ways to communicate essential information on nosocomial infection control to hospital personnel, especially with regard to handwashing, aseptic use of devices, and antibiotic therapy, and to apply it more consistently in all hospitals, would have vast immediate benefits.

Key Points

- Patients in modern-day ICUs experience rates of nosocomial infection three to five times higher than non-ICU hospitalized patients. Rates of primary bacteremia and nosocomial pneumonia are up to 10 times higher.
- Patients who are severely immunocompromised or who are critically ill and have high severity of illness scores have a substantially increased risk of nosocomial infection. However, most nosocomial infections in the ICU appear causally to be most directly related to lifesaving technology, particularly invasive devices such as endotracheal tubes and mechanical ventilatory support, urethral and intravascular catheters, and intraventricular catheters, which facilitate colonization by nosocomial organisms and greatly increase vulnerability to infection.
- The major reservoir of bacterial nosocomial pathogens, and possibly Candida as well, in the ICU is the colonized or infected patient. Most infections begin with nosocomial colonization by organisms acquired from the inadequately cleaned hands of noncolonized HCWs. Increasing evidence suggests that antibiotic-resistant organisms, particularly MRSA, resistant enterococci, and C. difficile, may also be acquired from the inanimate environment immediately surrounding the patient. Some pathogens (e.g., respiratory viruses, influenza, S. pneumoniae) are spread by large droplet nuclei that travel 3 to 6 feet from the source. Other pathogens (e.g., Mycobacterium tuberculosis, varicella-zoster virus, measles), are transmitted by the airborne route.
- ICUs are uniquely conducive to the epidemic spread of nosocomial organisms of all types, especially antibiotic-resistant bacteria and even Candida; more than half of all detected hospital epidemics occur in ICUs.
- An active, visible institutional infection control program can prevent up to one-third of nosocomial infections. Surveillance of infection, whether total or focused, and education of all personnel are the most essential components of the program.
- The regular use of waterless alcohol-based handrubs or a chlorhexidine-containing agent for handwashing between patients will reduce endemic nosocomial infections in the ICU by at least 30%.
- Stringent attention to isolation precautions, especially use of disposable gloves and a gown for contacts with patients known to be infected or colonized by resistant organisms, is mandatory to minimize cross-infection and prevent outbreaks. It is essential to monitor for misuse of gloves as part of universal gloving to avoid a paradoxical increase in the risk of nosocomial infection.
- Modern-day ICUs must have adequate numbers of special negative-pressure isolation rooms for the care of patients with suspected or proven pulmonary tuberculosis and other airborne infections such as varicella-zoster virus.

- Patients who have undergone recent bone marrow transplants or who have received intensive chemotherapy and are experiencing prolonged severe granulocytopenia should receive ICU care in special HEPA-filtered positive-pressure isolation rooms to protect them from devastating deep Aspergillus and other filamentous fungal infection.
- Meticulous attention to aseptic technique and the use of maximal barrier precautions—long-sleeved sterile surgical gown, mask, and head cover, as well as sterile gloves—during the insertion of CVCs; the use of 2% chlorhexidine solutions for cutaneous antisepsis; avoiding insertion into the femoral veins when possible; and prompt removal of catheters as soon as they are no longer necessary can reduce the incidence of catheter-related BSI at least threefold.
- Several studies have demonstrated that the use of gloves for all patient contacts (i.e., universal gloving), decreases ICU infection rates, as have some studies of prophylactic use of simple barrier precautions. Universal gloving and protective isolation are more appealing ecologically than the use of SDD.
- Measures to avert needle sticks and other sharps injuries are the most important aspect of universal precautions; these measures are necessary to protect the HCWs from HIV and other bloodborne viruses.
- A crisis of antibiotic resistance exists in ICUs. The progressive increase in antibiotic resistance of nosocomial staphylococci (methicillin), gram-negative bacilli (aminoglycosides, expanded-spectrum β-lactams, and carbapenems) and enterococci (vancomycin or ampicillin), and the sixfold increase in Candida infections during the past two decades indicates that it is of highest priority to reduce antimicrobial pressure within ICUs.
- Novel technology holds the greatest promise for prevention of nosocomial infection in general, particularly the development of medical devices that are intrinsically resistant to infection.
- Identifying more effective ways to communicate knowledge of infection control to hospital personnel, especially with regard to handwashing, aseptic use of devices, and antibiotic therapy, and to apply it consistently in all hospitals would have vast immediate benefits.
