Preface

Few fields in medicine have grown, evolved, and changed as rapidly as critical care medicine over the past 40 years. From its origins in the postoperative recovery room and the coronary care unit, the modern intensive care unit (ICU) represents the ultimate example of medicine's ability to supply the specialized personnel and technology necessary to sustain and restore seriously ill persons to productive lives. In more recent years critical care has extended beyond the walls of the ICU to the emergency department where partnerships between intensivists and emergency medicine physicians have been forged. Critically ill patients now may be held for significant time periods in the emergency department, the post-operative recovery room or special critical care holding areas while awaiting an ICU bed. While the field continues to evolve rapidly, sufficient principles, knowledge, and experience have accumulated in the past few decades to warrant the production of a textbook dedicated to adult critical care medicine. We chose to limit the subject matter of our book to the critical care of *adult* patients to allow the production of a comprehensive textbook in a single volume.

This book was envisioned to be multidisciplinary and multi-specialty, authored by acknowledged leaders in the field, and aimed primarily at practicing critical care physicians who spend the better part of their time caring for patients in an ICU. Thus the book would be appropriate for critical care internists as well as for surgical or anesthesia critical care specialists. The goal was to produce the acknowledged "best practice" standard in critical care medicine.

The first edition of the textbook was published in 1995, co-edited by Joe Parrillo and Roger Bone. The book sold exceedingly well for a first edition text. After the untimely death of Roger Bone in 1997, Phil Dellinger joined Joe Parrillo as the co-editor for the second, third, fourth, and now this fifth edition. As co-editors, we have labored to produce a highly readable text that can serve equally well for comprehensive review and as a reference source. We felt that it was important for usability and accessibility to keep the book to a single volume. This was a challenge, because critical care knowledge and technology have expanded significantly during the past decade. By placing emphasis on clear, concise writing and keeping the focus on critical care medicine for the adult, this goal was achieved.

Our view of critical care medicine is mirrored in the organization of the textbook. Modern critical care is a multidisciplinary specialty that includes much of the knowledge and technology contained in many disciplines represented by the classic organ-based subspecialties of medicine, as well as the specialties of surgery and anesthesiology. The book begins with a section consisting of chapters on the technology, procedures, and pharmacology that are essential to the practicing critical care physician. This section is followed by sections devoted to the critical care aspects of cardiovascular, pulmonary, infectious, renal, metabolic, neurologic, gastrointestinal, and hematologic-oncologic diseases. Subsequent chapters are devoted to important social, ethical, and other issues such as psychiatric disorders, severity of illness scoring systems, and administrative issues in the ICU. This fifth edition has significant content additions and revisions, including new chapter authors for approximately a third of our chapters. Online videos are also available featuring a variety of content areas, including echocardiograms and bedside ultrasounds from a variety of exam sites. Further, a series of questions and answers with rationale for correct and incorrect answers are provided for each chapter to assist readers in board review and to reinforce the important content of each chapter.

Each chapter is designed to provide a comprehensive review of pertinent clinical, diagnostic, and management issues. This is primarily a clinical text, so the emphasis is on considerations important to the practicing critical care physician; also presented, however, are the scientific (physiologic, biochemical, and molecular biologic) data pertinent to the pathophysiology and management issues. We have aimed for a textbook length that is comprehensive but manageable. Substantial references (most now online) are provided for readers wishing to explore subjects in greater detail. We have identified key points and key references to highlight the most important issues within each chapter. Continued popular features of this fifth edition include a color-enhanced design and clinically useful management algorithms.

We have been fortunate to attract a truly exceptional group of authors to write the chapters for *Critical Care Medicine: Principles of Diagnosis and Management in the Adult.* For each chapter, we have chosen a seasoned clinician-scientist actively involved in critical care who is one of a handful of recognized experts on his or her chapter topic. We have continued the international flavor of our authorship. To provide uniformity in content and style, one or both of us have edited and revised each chapter.

We wish to thank the highly dedicated people who provided us with the assistance needed to complete a venture of this magnitude. Our thanks go to Ellen Lawlor, for her administrative assistance; and to the excellent editorial staff at Elsevier, including Anne Snyder, Nancy Duffy, and Rachel McMullen.

Video Contents

Chapter 8

Standard Normal Imaging Planes

Video 8.1. PLAXNL. Normal parasternal long-axis view *(PLAX)*. *Ao,* Aorta; *AV,* aortic valve; *LA,* left atrium; *LV,* left ventricle; *MV,* mitral valve; *RV,* right ventricle.

Video 8.2. PSAXNL. Normal parasternal short-axis *(PSAX)* of the left ventricle *(LV)*. The inferoposterior wall, the anterolateral wall, and the ventricular septum *(IVS)* are noted. *RV,* Right ventricle.

Video 8.3. Sax Base. Normal PSAX at the level of the aortic *(Ao)* valve. *Arrow,* Atrial septum; *LA*, left atrium; *PA,* main pulmonary artery; *PV,* pulmonary valve; *RA,* right atrium; *RV,* right ventricle; *TV,* tricuspid valve.

Video 8.4. AP4CH NL. Apical four-chamber view. *LA*, Left atrium; *LV,* left ventricle; *MV,* mitral valve; *RA,* right atrium; *TV,* tricuspid valve.

Video 8.5. AP2CH NL. Apical two-chamber view. *LA*, Left atrium; *LV,* left ventricle; *MV,* mitral valve.

Video 8.6. APLAX NL. Apical long-axis view. *LA*, Left atrium; *LV,* left ventricle; *MV,* mitral valve.

Video 8.7. Subcostal View. *LA*, Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Video 8.8. Inferior Vena Cava. Subcostal view demonstrating normal caliber and collapse of the inferior vena cava *(IVC)*.

Miscellaneous Disease

Video 8.9. AP4CH ASD. AP4CH view demonstrating typical secundum atrial septal defect *(ASD)* (indicated by *asterisk*). *LA*, Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Video 8.10. AP4CH ASD/Color. AP4CH view demonstrating L>R color flow *(arrow)* across atrial septal defect *(ASD)*. *RA,* Right atrium; *RV,* right ventricle.

Video 8.11. AP4CH ASD/PFO. AP4CH view demonstrating atrial septal aneurysm *(ASD) (arrow*) and positive bubble study. *RA,* Right atrium; *RV,* right ventricle.

Video 8.12. AP4CH PFO. AP4CH view demonstrating strongly positive (R>L) saline solution bubble study in another patient. *LA*, Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

Video 8.13. AP4CH PFO Device/Saline Solution. AP4CH view demonstrates persistent R>L shunt after placement of PFO occluder device in same patient as Video 8.12. *LA*, Left atrium; *PFO,* patent foramen ovale; *RA,* right atrium.

Video 8.14. TEE Device Color. Transesophageal images of device in same patient as Video 8.12 demonstrating residual R>L color flow crossing occluder device. *LA*, Left atrium; *RA,* right atrium; *SVC,* superior vena cava; *wire*, pacemaker wire.

Video 8.15. TEE Device Saline Solution. Transesophageal image of same patient as Video 8.12 demonstrating persistent strongly positive bubble study after device placement. *LA*, Left atrium; *RA,* right atrium.

Imaging Enhancement

Video 8.16. AP4CH Without Contrast. Poor-quality apical four-chamber view. *LA*, Left atrium; *LV,* left ventricle; *MV,* mitral valve.

Video 8.17. AP4CH With Contrast. Same patient as Video 8.16 after administration of a commercially available contrast agent to enhance endocardial border definition.

Myocardial Disease/Complications of Myocardial Infarction

Video 8.18. PLAX Inf Infarct. PLAX demonstrating inferior infarct with scar (denoted by *asterisk*).

Video 8.19. PSAX Inf Infarct. PSAX of same patient as Video 8.18 demonstrating inferior wall thinning and scar (denoted by *asterisk*). *LV,* Left ventricle.

Video 8.20. AP4CH Inf Infarct. AP4CH view of same patient as Video 8.18 demonstrating marked right ventricular *(RV)* systolic dysfunction consistent with extension of inferior infarct.

Video 8.21. AP4CH Ap Aneurysm. Apical four-chamber view demonstrating true left ventricular *(LV)* apical aneurysm *(aneur)*. *LA*, Left atrium; *RA,* right atrium; *RV,* right ventricle.

Video 8.22. AP4CH Thrombus. AP4CH view of left ventricular *(LV)* apical layered thrombus *(arrow)*. *RV,* Right ventricle.
Video 8.23. Zoom AP4CH Thrombus. Zoom of apical thrombus seen in Video 8.22.
Video 8.24. PLAX Inf PSAn. PLAX demonstrates inferior pseudoaneurysm *(PSAn)* (the asterisk denotes the neck). *Arrow* points to layered thrombus within PSAn. *LA*, Left atrium; *LV,* left ventricle.
Video 8.25. AP4CH PSAn. AP4CH view demonstrates severe left ventricular *(LV)* systolic dysfunction and apical pseudoaneurysm *(PSAn)*. The *arrow* points to the narrow neck of the PSAn. *LA*, Left atrium; *LV,* left ventricle; *MV,* mitral valve.
Video 8.26. PLAX Rup PM. PLAX demonstrates hyperdynamic left ventricle *(LV)* and ruptured papillary muscle. *Ao,* Aorta; *LA*, left atrium.
Video 8.27. Zoom PLAX Rup PM. Zoom of same patient as Video 8.26 demonstrating flail papillary muscle head *(arrow)*.
Video 8.28. TEE Rup PM w/MR. TEE of same patient as Video 8.26 demonstrating severe mitral regurgitation and the prolapsing ruptured papillary head. *Ao,* Aorta; *LA*, left atrium; *LV,* left ventricle.
Video 8.29. AP4CH VSD. AP4CH view demonstrating apical infarct and apical akinesis (denoted by the *asterisk*).
Video 8.30. PSAX Apex VSD. PSAX of the left ventricle *(LV)* at the level of the apex in same patient as Video 8.29 demonstrating akinesis of apical septum *(arrow)*. *RV,* Right ventricle.
Video 8.31. PSAX VSD/Color. PSAX of the left ventricle *(LV)* apex in same patient as Video 8.29 demonstrating serpiginous post-infarct ventricular septal defect *(arrow)*. *RV,* Right ventricle.
Video 8.32. PLAX HCM. PLAX demonstrating the typical asymmetric septal hypertrophy and systolic anterior motion of the mitral valve *(SAM)* seen in hypertrophic cardiomyopathy. *LA*, Left atrium; *LV,* left ventricle.
Video 8.33. PLAX CMP. PLAX of dilated cardiomyopathy. *Ao,* Aorta; *LA*, left atrium; *LV,* left ventricle; *MV,* mitral valve; *RV,* right ventricle.
Video 8.34. PSAX CMP. PSAX of dilated cardiomyopathy. *LV,* Left ventricle; *RV,* right ventricle.
Video 8.35. AP4CH CMP. Apical four-chamber view of dilated cardiomyopathy. *LA*, Left atrium; *LV,* left ventricle; *MV,* mitral valve; *RA,* right atrium; *RV,* right ventricle.
Video 8.36. AP4CH CMP w/MR. Apical four-chamber view of same patient as Video 8.35 demonstrating significant mitral regurgitation.
Video 8.37. AP4CH Pre. Apical four-chamber view demonstrating vigorously normal left ventricular *(LV)* systolic function. The patient is 12 hours after Whipple procedure and is tachycardic. *LA,* Left atrium.
Video 8.38. AP4CH Takotsubo. Apical four-chamber view of the same patient as Video 8.37 obtained 36 hours later demonstrating profound apical akinesia. The patient had emergent cardiac catheterization with normal coronary arteries, suggesting the diagnosis of apical ballooning syndrome (Takotsubo). *LA,* Left atrium; *LV,* left ventricle.

Pulmonary Embolus

Video 8.39. PSAX Phtn. Short-axis view of the left ventricle *(LV)* demonstrating flattening of the interventricular septum in diastole, resulting in "D-shaped" appearance of the LV in the setting of pulmonary hypertension. *RV,* Right ventricle.
Video 8.40. AP4CH McConnell 1. AP4CH view demonstrating marked enlargement and hypokinesia of the right ventricle *(RV)* after pulmonary embolus. The *arrow* points to RV apical motion typical of McConnell's sign. *LV,* Left ventricle; *RA,* right atrium.
Video 8.41. AP4CH McConnell 2. AP4CH view demonstrating another example of McConnell's sign *(arrow)*. *LV,* Left ventricle; *RV,* right ventricle.
Video 8.42. SAX Base PE. PSAX at the base of the heart demonstrating residual trapped thrombus *(arrow)* traversing the atrial septum at the level of the fossa ovalis in a patient after a massive pulmonary embolus. *Ao,* Aorta; *LA*, left atrium; *RA,* right atrium; *RV,* right ventricle.
Video 8.43. AP4CH PEIT. AP4CH of same patient as Video 8.42, demonstrating marked dilatation of the right ventricle *(RV)* and thrombus trapped in the atrial septum *(arrow)*. *LA*, Left atrium; *LV,* left ventricle; *RA,* right atrium.

Valvular Disease

Video 8.44. PLAX AS. PLAX of aortic valve *(AoV)* stenosis. The valve is calcified *(arrow)* and the left atrium *(LA)* is dilated. *LV,* Left ventricle.
Video 8.45. Zoom PLAX Mveg. Zoomed PLAX view of a large pedunculated vegetation *(arrow)* on the atrial surface of the mitral valve. *Ao,* Aorta; *LA*, left atrium; *LV,* left ventricle.
Video 8.46. AP4CH Mveg. AP4CH view of same patient as Video 8.45. The *arrow* points to the vegetation. *LA*, Left atrium; *LV,* left ventricle.
Video 8.47. AP4CH Mveg/Color. AP4CH view of same patient as Video 8.45 demonstrating multiple jets of severe mitral regurgitation.
Video 8.48. Tveg. Right heart inflow tract view demonstrating large pedunculated vegetation

on the tricuspid valve *(TV, arrow)*. Note the failure of the leaflets to coapt. *RA,* Right atrium; *RV,* right ventricle.

Pericardial Effusion

Video 8.49. PLAX Posterior Eff. PLAX view of large predominantly posterior postoperative pericardial effusion *(Eff)*. The *arrow* points to small anterior collection of fluid. *Ao,* Aorta; *Dao,* descending aorta; *RV,* right ventricle.

Video 8.50. PSAX Posterior Eff. PSAX view demonstrates very large posterior effusion *(Eff)* in the same patient as Video 8.49. *LV,* Left ventricle.

Video 8.51. Subcostal Peri Eff. Subcostal view demonstrating large inferoposterior accumulation of fluid *(Eff)* in the same patient as Video 8.49.

Video 8.52. PLAX Circ Eff. PLAX demonstrating large circumferential pericardial effusion with right ventricular *(RV)* collapse *(arrow)* suggesting tamponade. *Ao,* Aorta; *DA,* descending aorta; *LV,* left ventricle.

Video 8.53. PSAX Circ Eff. PSAX of the same patient as Video 8.52 demonstrating large pericardial effusion *(Eff)* and right ventricular *(RV)* collapse *(arrow)*. *LV,* Left ventricle.

Video 8.54. Subcostal Circ Eff. Subcostal view of same patient as Video 8.52 demonstrating large circumferential effusion *(Eff)*.

Video 8.55. Dilated IVC/Eff. The inferior vena cava *(IVC)* in the same patient as Video 8.52 is dilated and nonreactive. *Ple,* Pleural effusion.

Video 8.56. Massive Eff. Massive pericardial effusion *(Eff)* secondary to bacterial pericarditis. The image on the left is subcostal; the image on the right is apical four-chamber view, which demonstrates frank collapse of right heart chambers *(arrows)*. *LV,* Left ventricle.

Video 8.57. Massive Eff/IVC. Same patient as Video 8.56 demonstrating dilated nonreactive inferior vena cava *(IVC)*. *Eff,* Pericardial effusion; *LV,* left ventricle.

Video 8.58. PLAX p/op Eff. Massive pericardial effusion *(Eff)* in this postoperative patient, demonstrating almost no filling of either ventricle secondary to fluid compression. The *arrow* shows right ventricle *(RV)* collapse. *LA*, Left atrium; *LV,* left ventricle.

Video 8.59. PLAX p/op Eff 2. Same patient as Video 8.58 demonstrating near cardiac standstill while the operator is struggling to prepare for emergent pericardiocentesis. The *arrow* points to the aortic valve.

Video 8.60. PLAX p/op Eff Tap. Same patient as Video 8.58 demonstrating ventricles beginning to fill as fluid is tapped. *Eff,* Pericardial effusion; *LV,* left ventricle.

Video 8.61. PLAX p/op Eff Tap 2. Same patient as Video 8.58 after more than 1400 mL of bloody pericardial fluid has been drained and ventricles appear at near-normal volume. The patient eventually succumbed of prolonged hypoxia. *Ao,* Aorta; *LV,* left ventricle; *RV,* right ventricle.

Video 8.62. Subcostal Myxedema Eff. Subcostal views of large circumferential effusion *(Eff)* in a patient with myxedema. The image on the right demonstrates collapse of the inferior vena cava *(IVC),* suggesting a chronic effusion. The heart rate and blood pressure were normal.

Video 8.63. Eff/Tap. Off-axis apical views of patient sitting upright in the catheter laboratory during pericardiocentesis of malignant effusion. The *arrow* points to the needle in pericardial space. *LV,* Left ventricle; *MV,* mitral valve.

Video 8.64. Eff/Tap Saline Solution. Injection of agitated saline solution *(blue arrow)* in the same patient as Video 8.63 during pericardiocentesis confirms correct location of the needle *(white arrow)* in the pericardial space.

Video 8.65. SAX Base Hematoma. PSAX view at the level of the aortic valve *(Ao)* demonstrates large mediastinal (not pericardial) hematoma *(H)* after blunt injury to the chest. In this view it can be difficult to distinguish a pericardial from a mediastinal process.

Video 8.66. AP4CH Hematoma. Apical four-chamber view of same patient as Video 8.65 demonstrates hematoma *(H)* in pleural space and trivial pericardial effusion (indicated by the *asterisk*). *LV,* Left ventricle.

Video 8.67. Subcostal Hematoma. Subcostal view of same patient as Video 8.65 demonstrating no pericardial effusion. This was a very useful view in this patient. *LV,* Left ventricle; *RV,* right ventricle.

Video 8.68. AP4CH RA Coll. Apical four-chamber view demonstrating right atrial *(RA)* collapse but no significant pericardial fluid. *Dao,* Descending aorta; *RV,* right ventricle.

Video 8.69. AP4CH RA/IVC Coll. Subcostal view in same patient as Video 8.68 *(right image)* demonstrating complete collapse of the inferior vena cava *(IVC),* consistent with hypovolemia.

Video 8.70. PLAX Fat Pad. PLAX of the left ventricle *(LV)*. The arrow points to an epicardial fat pad, demonstrating "linear streaking," suggesting tissue planes c/w fat, in the typical anterior plane over the right ventricle *(RV)*. *RA,* Right atrium.

Video 8.71. Subcostal Fat Pad. Subcostal view of the same patient as Video 8.70, demonstrating epicardial fat *(arrow),* which moves with the epicardial surface and demonstrates tissue planes. *LV,* Left ventricle; *RA,* right atrium; *RV,* right ventricle.

Diseases of the Aorta

Video 8.72. PLAX Diss. PLAX of markedly dilated proximal aorta demonstrating dissection flap *(arrow)*. It is less common to identify dissections with transthoracic imaging. *AoV,* Aortic valve; *LA*, left atrium; *LV,* left ventricle.

Video 8.73. AP4CH Diss. Apical four-chamber view in same patient as Video 8.72 demonstrates marked dilatation of proximal ascending aorta and dissection flap *(arrow)*. *AoV,* Aortic valve.

Video 8.74. AP4CH Diss/Color. Apical four-chamber view in same patient as Video 8.73 demonstrates proximal dissection flap *(arrow)* and severe aortic regurgitation.

Video 8.75. AP4CH/Myxoma. Typical left atrial myxoma *(M)* seen from apical four-chamber view, prolapsing through the mitral valve in diastole. *LA*, Left atrium; *LV,* left ventricle.

Video 8.76. TEE Ao Debris. Gr5 mixed atheromatous debris *(arrow)* in aorta as seen on TEE.

Video 8.77. TEE Ao Debris 2. TEE image of proximal descending aorta (Prox Desc Ao) demonstrating Gr5 atheromatous debris *(arrow)*.

Cardiac Arrest and Cardiopulmonary Resuscitation

BRIAN W. ROBERTS, TAPAN KAVI, AND STEPHEN TRZECIAK

CHAPTER OUTLINE

Epidemiology and General Principles

Cardiopulmonary Resuscitation
- Chest Compressions
- Defibrillation
- Rescue Breathing

Advanced Cardiac Life Support
- Vasopressors
- Antiarrhythmic Drugs
- Other Drug Therapies
- End-Tidal Carbon Dioxide
- Extracorporeal CPR
- Reversible Causes

Postresuscitation Care
- General Approach
- Hemodynamic Support
- Oxygenation and Ventilation
- Seizures
- Cardiac Catheterization
- Targeted Temperature Management
- Neurologic Prognostication

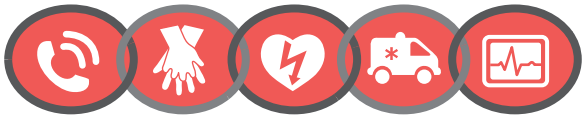
Epidemiology and General Principles

Sudden cardiac arrest is defined as the cessation of effective cardiac mechanical activity as confirmed by the absence of signs of circulation. Sudden cardiac arrest is the most common fatal manifestation of cardiovascular disease and a leading cause of death worldwide. The exact incidence of sudden cardiac arrest is unclear, but in the United States alone, it has been estimated to be as high as 450,000 persons annually.[1] Approximately 21% to 25% of sudden cardiac arrest events are due to pulseless ventricular arrhythmias (i.e., ventricular fibrillation [VF] or pulseless ventricular tachycardia [VT]), whereas the rest can be attributed to other cardiac rhythms (i.e., asystole or pulseless electrical activity [PEA]).[2,3] Patients who suffer cardiac arrest due to VF or VT have a much higher chance of surviving the event compared with patients who present with PEA/asystole.[4] The prognosis is better in patients with ventricular arrhythmias because (1) ventricular arrhythmias are potentially treatable with defibrillation (i.e., "shockable" initial rhythm) to restore circulation, whereas the other initial rhythms are not, and (2) ventricular arrhythmias are typically a manifestation of a cardiac etiology of cardiac arrest (e.g., acute myocardial infarction), whereas the other initial rhythms are more likely to be related to a noncardiac etiology and perhaps an underlying condition that is less treatable. Clinical outcomes for cardiac arrest are poor. Approximately 11% of out-of-hospital cardiac arrest (OHCA)[5] and 20% of in-hospital cardiac arrest (IHCA) patients survive to hospital discharge.[6]

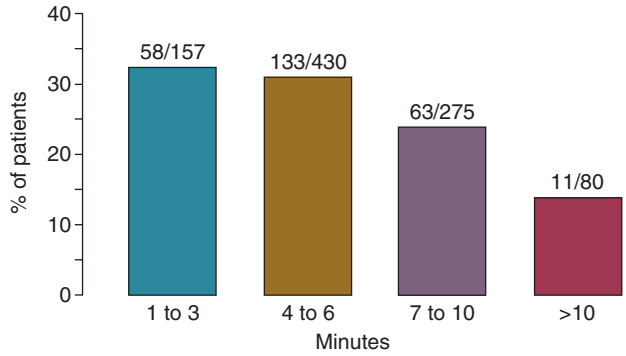
The basic principles of resuscitation are an integral part of training for many health care providers (HCPs). Because timely interventions for cardiac arrest victims have the potential to be truly lifesaving, it is especially important for critical care practitioners to have a sound understanding of the evaluation and management of cardiac arrest. A number of critical actions (*chain of survival*) must occur in response to a cardiac arrest event. The chain of survival paradigm (Fig. 1.1) for the treatment of cardiac arrest remained unchanged in the 2015 American Heart Association (AHA) Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care from 2010 and is similar to other cardiac arrest guidelines. The chain of survival paradigm consists of five separate and distinct elements: immediate recognition that cardiac arrest has occurred and activation of the emergency response system; application of effective cardiopulmonary resuscitation (CPR); early defibrillation (if applicable); advanced cardiac life support; and initiation of postresuscitation care (e.g., targeted temperature management).[7–9] When the chain of survival is implemented effectively survival for VF, OHCA can exceed 45%.[3]

Cardiopulmonary Resuscitation

For CPR to be effective in restoring spontaneous circulation, it must be applied immediately at the time of cardiac arrest. Therefore immediate recognition that a cardiac arrest has occurred and activation of the emergency response system are essential. Patients become unresponsive at the time of cardiac arrest. Agonal gasps may be observed in the early moments after a cardiac arrest event, although normal breathing ceases. Pulse checks (i.e., palpation of femoral or carotid arteries for detection of a pulse) are often



• **Fig. 1.1** The American Heart Association chain of survival paradigm.[89] This figure represents the critical actions needed to optimize the chances of survival from cardiac arrest. The links (from left to right) include (1) immediate recognition of cardiac arrest and activation of the emergency response system; (2) early and effective cardiopulmonary resuscitation; (3) defibrillation (if applicable); (4) advanced cardiac life support; and (5) post–cardiac arrest care (including target temperature management if appropriate). (From Travers AH, Rea TD, Bobrow BJ, et al. Part 4: CPR overview: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2010;122(18 suppl 3):S676–S684.)



• **Fig. 1.2** Relationship between the time interval before attempted defibrillation and the proportion of patients discharged from the hospital alive after out-of-hospital cardiac arrest. (Modified from Weaver WD, Cobb LA, Hallstrom AP, et al. Factors influencing survival after out-of-hospital cardiac arrest. *J Am Coll Cardiol*. 1986;7:752–757.)

unreliable, even when performed by experienced HCPs.[10] Because delays in initiating CPR are associated with worse outcome, and prolonged attempts to detect a pulse may result in a delay in initiating CPR, prolonged pulse checks are to be avoided. CPR should be started immediately if the patient is unresponsive and either has agonal gasps or is not breathing.[7]

Chest Compressions

In CPR, chest compressions are used to circulate blood to the heart and brain until a pulse can be restored. High-quality chest compressions are vital for successful resuscitation. The mechanism by which chest compressions generate cardiac output is through an increase in intrathoracic pressure plus direct compression of the heart. As in 2010, the 2015 AHA guidelines recommend HCPs initiate the CPR sequence with chest compressions instead of rescue breaths (i.e., compressions-airway-breathing [C-A-B] vs. airway-breathing-compressions [A-B-C]) to minimize the time to chest compressions.[7] With the patient lying in the supine position, the rescuer applies compressions to the lower half of the patient's sternum. The heel of one hand is placed over the lower half of the sternum and the heel of the other hand on top in an overlapping and parallel fashion. In addition to manual CPR, there has been an increase in the use of mechanical CPR devices. Studies have not demonstrated a difference in patient outcomes between manual and mechanical CPR.[8,11]

The recommended compression depth in adults is at least 2 inches (5 cm) while avoiding chest compression depths greater than 2.4 inches (6 cm).[7–9] The recommended rate of compression per the 2010 AHA guidelines was *at least* 100 compressions per minute.[12] The 2015 AHA guidelines now recommend a rate of 100 to 120 compressions per minute.[7] These new AHA guidelines are in line with the 2010 and 2015 European Resuscitation Council guidelines for resuscitation, as well as the 2015 International Liaison Committee on Resuscitation recommendations.[8,9,13] In addition, incomplete recoil of the chest impairs the cardiac output that is generated. Incomplete recoil occurs when HCPs lean on the chest wall between compressions; thus HCPs should avoid leaning to allow the chest wall to recoil completely between compressions. Owing to rescuer fatigue, the quality of chest compressions predictably decreases as the time providing chest compressions increases, and the persons providing chest compressions (even experienced HCPs) may not perceive fatigue or a decrease in the quality of their compressions.[14] Therefore it is recommended that rescuers performing chest compressions rotate every 2 minutes.[7,9]

The quality of CPR is a critical determinant of surviving a cardiac arrest event.[15] Minimization of interruptions in chest compressions is imperative. Interruptions in chest compressions during CPR have been quite common historically, and the "hands off" time has been shown to comprise a substantial amount of the total resuscitation time.[15] The proportion of time chest compressions are performed during a cardiac arrest has been termed chest compression fraction. A higher chest compression fraction has been associated with increased survival in VF cardiac arrest,[16] and increased return of spontaneous circulation (ROSC) in non-VF cardiac arrest.[17] Guidelines recommend a chest compression fraction as high as possible, with a goal of at least 60%.[7,9] A chest compression fraction of 80% is likely ideal and achievable in many settings.[18] Potential reasons for decreased chest compression fraction include pulse checks, rhythm analysis, switching compressors, procedures (e.g., airway placement), and pauses before defibrillation ("preshock pause"). All of these potential reasons for interruptions should be minimized. Pauses related to rotating compressors, pulse checks, and delivering rescue breaths should take no longer than 10 seconds.[7,9] Eliminating (or minimizing) preshock pauses has been associated with a higher likelihood of ROSC and improved clinical outcome.[19,20]

Defibrillation

The next critically important action in the resuscitation of patients with cardiac arrest caused by pulseless ventricular arrhythmias (i.e., VF or pulseless VT) is rapid defibrillation. Delays in defibrillation are clearly deleterious, with a sharp decrease in survival as the time to defibrillation increases.[21] With the advent of automatic external defibrillators and their dissemination into public places, both elements of effective CPR (effective chest compressions and rapid defibrillation) can be performed by lay rescuers in the field for patients with OHCA. Fig. 1.2 shows the importance of rapid defibrillation, with decreasing success of resuscitation with increasing time to defibrillation. Thus defibrillation should be performed as soon as possible. The amount of energy for defibrillation should be based on the specific manufacturer's guidance. To increase the chest compression fraction, chest compressions should resume immediately after defibrillation for adult cardiac arrest in any setting.[7,9]

Rescue Breathing

Recommendations regarding ventilation during CPR depend on the rescuer (i.e., trained HCPs vs. layperson).[7,9] For trained HCPs, the recommended ventilation strategy is a cycle of 30 chest compressions to 2 breaths until an endotracheal tube is placed, and then continuous chest compressions with 1 breath every 6 seconds after the endotracheal tube is placed. Excessive ventilations can be deleterious from a hemodynamic perspective owing to increased intrathoracic pressure and reduction in the cardiac output generated by CPR and thus should be avoided during resuscitation.[22] Excessive ventilation could also potentially result in alkalemia. For OHCA is it reasonable for emergency medicine service providers to delay positive-pressure ventilation while providing up to 3 cycles of 200 continuous chest compressions with passive oxygenation.[7]

For laypersons who are attempting CPR in the field for a victim of OHCA, rescue breathing is no longer recommended. Rather, the recommended strategy is compression-only (or hands-only) CPR.[7,9] The rationale is that compression-only CPR can increase the number of effective chest compressions that are delivered to the patient (i.e., minimizes interruptions for rescue breaths), and does not require mouth-to-mouth contact. Mouth-to-mouth contact is one of the perceived barriers to CPR in the field. By removing this element, the hope is that an increase in attempts at bystander CPR will result. Hands-only CPR has been found to be noninferior to conventional CPR including rescue breaths for victims of OHCA[23–25]; thus hands-only CPR has become the preferred technique to teach lay rescuers. Fig. 1.3 displays the AHA algorithm for adult basic life support.

Advanced Cardiac Life Support

There are several additional elements of resuscitation that are intended specifically for trained HCPs (e.g., advanced cardiac life support [ACLS]), and specifically this includes pharmacologic therapy. Fig. 1.4 displays the AHA algorithm for ACLS.[26]

It is notable that the impact of recommended ACLS therapies on outcome from cardiac arrest remains a matter of debate. Some studies have shown that ACLS interventions did not improve clinical outcomes when compared to basic life support alone.[27]

Vasopressors

The primary goal of pharmacologic interventions is to assist the achievement and maintenance of spontaneous circulation. The mainstay of pharmacologic interventions is vasopressor drugs. It is reasonable to administer epinephrine (1 mg) by intravenous (IV) or intraosseous (IO) route every 3 to 5 minutes during CPR until ROSC is achieved.[8,26,28] If IV/IO access cannot be established, epinephrine could be administered via an endotracheal tube, but at a higher dose (2–2.5 mg). The optimal timing of epinephrine administration is currently unclear; however, observational studies have demonstrated that early administration of epinephrine is associated with improved outcomes in nonshockable rhythms.[29,30]

Vasopressin as a substitute for epinephrine was removed from the 2015 AHA guidelines. One study found the use of intracardiac arrest vasopressin (20 IU/CPR cycle), epinephrine (1 mg/CPR cycle), and methylprednisolone (40 mg during first CPR cycle) followed by postcardiac arrest hydrocortisone (300 mg daily for 7 days maximum and gradual taper) increased the probability of successful ROSC and discharge with good neurologic outcome[31]; however, the evidence for this practice is not currently strong enough to recommend its routine use.[26]

Antiarrhythmic Drugs

Amiodarone is the preferred antiarrhythmic agent for refractory VF/VT cardiac arrest.[8] Refractory VF/VT refers to VF or pulseless VT that persists or recurs after one or more defibrillation attempts. It is unlikely that antiarrhythmic drug therapy itself will convert refractory VT/VF; rather, the goal of antiarrhythmic drug therapy is to aid in reestablishing and maintaining an organized perfusing rhythm in conjunction with subsequent defibrillation. The recommended dose of amiodarone is 300 mg IV/IO for the first dose, 150 mg IV/IO for the second dose.[26,28] Of note, antiarrhythmic drug therapy has not been demonstrated to improve survival or neurologic outcomes after VF/VT cardiac arrest.

Other Drug Therapies

The use of atropine for PEA/asystole was removed from the ACLS guidelines in 2010. Along these lines, there is also insufficient evidence to recommend routine administration of sodium bicarbonate or calcium during CPR.[28,32] In the setting of confirmed or suspected pulmonary embolism, limited evidence suggests that systemic thrombolysis administration during ongoing CPR is associated with ROSC and short-term survival,[33] with earlier administration associated with greater benefit.[34] However, in the setting of presumed cardiac etiology of cardiac arrest there is currently no evidence to support clinical benefit.[35] The decision to administer systemic thrombolytics during cardiac arrest may be considered in cases with a strong suspicion for pulmonary embolism, or cardiac etiology without immediate access to percutaneous coronary intervention.

End-Tidal Carbon Dioxide

End-tidal carbon dioxide ($ETCO_2$) may reflect cardiac output and pulmonary blood flow. $ETCO_2$ can be measured during CPR to monitor the quality of chest compressions in intubated patients. An $ETCO_2$ less than 10 mm Hg after 20 minutes of high-quality CPR has been demonstrated to be predictive of mortality,[36,37] whereas an $ETCO_2$ greater than 20 mm Hg was associated with survival to hospital discharge.[36] Although predictive of outcome, a low $ETCO_2$ should not be used alone to discontinue CPR efforts. It is also important to realize a low $ETCO_2$ could be a result of bronchospasm, plugging or kinking of the endotracheal tube, hyperventilation, or an air leak in the airway.[26] A sudden, sustained increase in $ETCO_2$ (i.e., >40 mm Hg) during chest compressions can be an indication of ROSC.[26,28,38] $ETCO_2$ monitoring in nonintubated patients may not accurately reflect the true $ETCO_2$ level and should not be used as an adjunct prognostication tool.

Extracorporeal CPR

Extracorporeal CPR (ECPR) refers to venoarterial extracorporeal membrane oxygenation and cardiopulmonary bypass during cardiac arrest. In theory ECPR could be used as a bridge to allow physicians time to treat reversible causes of cardiac arrest. To date there has not been a randomized control trial comparing ECPR to conventional CPR for prolonged resuscitations. The limited case reports and observational studies do not provide sufficient evidence to recommend the routine use of ECPR; however, it may be reasonable

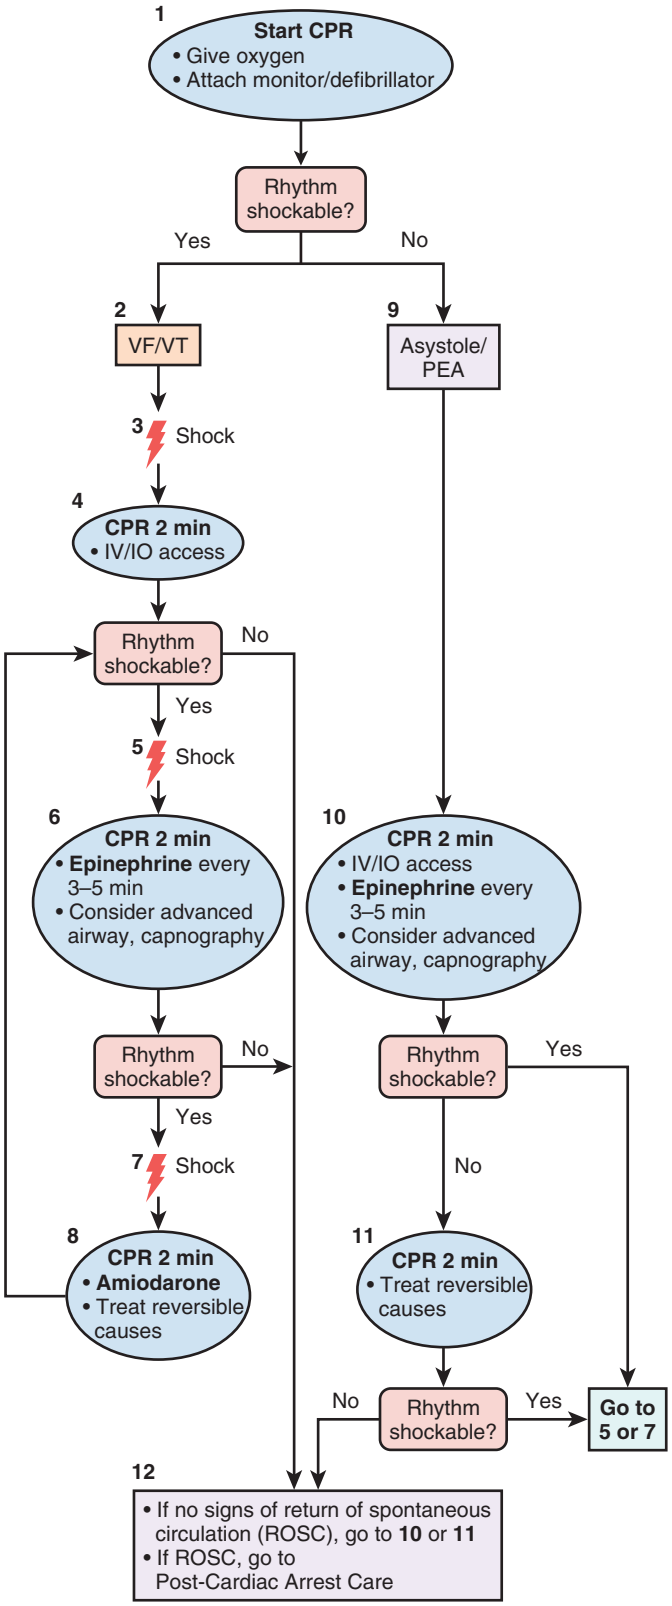
to consider ECPR for specific patients with a potentially reversible etiology of cardiac arrest.[26,28]

Reversible Causes

When managing a cardiac arrest it is important to consider the potential etiologies of the arrest. In many situations it is not possible to maintain an organized perfusing rhythm until the underlying cause of the cardiac arrest is reversed. A frequently used pneumonic for common potential reversible causes involves the "Hs and Ts."[28] The "Hs" include hypoxia, hypovolemia (including hemorrhage), hyperkalemia, hypokalemia, hypoglycemia, hydrogen ions (i.e., metabolic acidosis), and hypothermia. The "Ts" include thrombosis (i.e., coronary occlusion and pulmonary embolism), tension pneumothorax, cardiac tamponade, and ingestion of therapeutic or toxic substances. Once the etiology of the cardiac arrest is identified (or strongly presumed), treatment should be aimed at reversing the specific cause.



CPR Quality
- Push hard (2 inches [5 cm]) and fast (100–120/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 min or sooner if fatigued
- If no advanced airway, 30:2 compression-ventilation ratio
- Quantitative waveform capnography
  - If P_{ETCO_2} <10 mm Hg, attempt to improve CPR quality
- Intra-arterial pressure
  - If relaxation phase (diastolic) pressure <20 mm Hg, attempt to improve CPR quality

Shock Energy for Defibrillation
- **Biphasic:** Manufacturer recommendation (e.g., initial dose of 120–200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered
- **Monophasic:** 360 J

Drug Therapy
- **Epinephrine IV/IO Dose:** 1 mg every 3–5 min
- **Amiodarone IV/IO Dose:** First dose: 300 mg bolus Second dose: 150 mg

Advanced Airway
- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 s (10 breaths/min) with continuous chest compressions

Return of Spontaneous Circulation (ROSC)
- Pulse and blood pressure
- Abrupt sustained increase in P_{ETCO_2} (typically ≥40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible Causes
- **H**ypovolemia
- **H**ypoxia
- **H**ydrogen ion (acidosis)
- **H**ypo-/hyperkalemia
- **H**ypothermia
- **T**ension pneumothorax
- **T**amponade, cardiac
- **T**oxins
- **T**hrombosis, pulmonary
- **T**hrombosis, coronary

Postresuscitation Care

Even if ROSC is achieved with CPR and defibrillation, cardiac arrest victims are at extremely high risk of dying in the hospital, and many who survive sustain permanent crippling neurological sequelae. Approximately 50% to 60% of patients successfully resuscitated from OHCA do not survive. After ROSC global ischemia/reperfusion (I/R) injury results in potentially devastating neurologic disability. The primary cause of death among postresuscitation patients is brain injury. However, clinical trials have shown that targeted temperature management (TTM) after ROSC can improve outcomes. These landmark clinical trials have dramatically transformed the classical thinking about anoxic brain injury after cardiac arrest; this condition is, in fact, *treatable*. Early therapeutic interventions such as TTM initiated in the post-ROSC period can improve the trajectory of the long-term disease course. Accordingly, the postresuscitation care is now considered to be a crucial fifth link in the chain of survival paradigm (see Fig. 1.1).[7–9]

General Approach

Post–cardiac arrest syndrome is a heterogeneous disease process with varying precipitating factors and underlying etiologies. As such, post–cardiac arrest management must be tailored on a case-by-case basis for each specific patient. For patients resuscitated from cardiac arrest, admission to a critical care unit with the following capabilities should be considered[39]:

- Critical care support to optimize cardiovascular indices and vital organ perfusion, and prevent repeat cardiac arrest (or provide rapid treatment of rearrest if it occurs)
- Interventional cardiac catheterization for possible percutaneous coronary intervention (PCI) if needed
- TTM for at least 24 hours in attempts to prevent permanent neurologic injury
- Systematic application of an evidence-based approach to neurologic prognostication to refrain from inappropriately early final determinations of poor neurologic prognosis (i.e., to prevent inappropriately early withdrawal of life support before the neurologic outcome can be known with certainty).

Hemodynamic Support

I/R triggers profound systemic inflammation. In clinical studies, ROSC has been associated with sharp increases in circulating cytokines and other markers of the inflammatory response. Accordingly, some investigators have referred to the post–cardiac arrest syndrome as a "sepsis-like" state. The clinical manifestations of the systemic inflammatory response may include marked hemodynamic derangements such as sustained arterial hypotension similar to septic shock. Hemodynamic instability occurs in approximately 50% of patients who survive to intensive care unit admission after ROSC, and thus the need for aggressive hemodynamic support (e.g., continuous infusion of vasoactive agents and perhaps advanced hemodynamic monitoring) should be anticipated.[40]

In addition to a systemic inflammatory response, an equally important contributor to post-ROSC hemodynamic instability is myocardial stunning. Severe, but potentially reversible, global myocardial dysfunction is common after ROSC. The etiology is thought to be I/R injury, but treatment with defibrillation (if applied) could also contribute. Although the myocardial dysfunction occurs in the absence of an acute coronary event, myocardial ischemia may be an ongoing component of myocardial depression if an acute coronary syndrome caused the cardiac arrest. Severe myocardial stunning may last for hours, but it often improves by the 24-hour mark after ROSC. An echocardiogram may be helpful in hemodynamic assessment after ROSC to determine if global myocardial depression is present, as this may affect decisions on vasoactive drug support (e.g., dobutamine) or mechanical augmentation (e.g., intraaortic balloon counterpulsation) until the myocardial function recovers. However, when needed, clinicians should be aware that β-adrenergic agents may increase the likelihood of dysrhythmia.

Observational studies have demonstrated postresuscitation arterial hypotension to be associated with sharply lower survival,[40,41] and a post-ROSC mean arterial blood pressure greater than 70 mm Hg to be associated with improved neurologic outcome at hospital discharge.[42] However, it is currently unclear whether a specific blood pressure target or other hemodynamic goals are beneficial.[43] Expert opinion (and clinical intuition) suggests that hemodynamics and organ perfusion should be optimized, and rapidly reversing and preventing hypotensive after ROSC is recommended.[44,45] Whether or not postresuscitation hypotension has a cause-and-effect relationship with worse neurologic injury or is simply a marker of the severity of the I/R injury that has occurred remains unclear.

Oxygenation and Ventilation

Given the ongoing I/R injury during the early period after ROSC, hypoxia should be avoided in all post–cardiac arrest patients. Exposure to hyperoxia (excessively high partial pressure of arterial oxygen [PaO_2]) has also been associated with poor clinical outcome among adult patients resuscitated from cardiac arrest and admitted to an intensive care unit.[46] These data corroborate the findings of numerous laboratory studies in animal models in which hyperoxia exposure after ROSC worsens brain histopathologic changes and neurologic function.[47–51] A paradox may exist regarding oxygen delivery to the injured brain, where inadequate oxygen delivery can exacerbate cerebral I/R injury, but excessive oxygen delivery can accelerate formation of oxygen free radicals and subsequent reperfusion injury. Although the results of observational studies of hyperoxia are mixed[52,53] and no interventional studies have been performed, expert opinion advocates initially using the highest available oxygen concentration after ROSC to prevent hypoxia, and once the arterial oxygen saturation or PaO_2 can be measured, the fraction of inspired oxygen can be titrated down as much as possible while maintaining an arterial oxygen saturation of at least 94% to limit unnecessary exposure to an excessively high postresuscitation PaO_2.[45,54]

Post-ROSC partial pressure of arterial carbon dioxide ($PaCO_2$) levels have been demonstrated to be associated with clinical outcomes. Specifically, hypocapnia is associated with worse neurologic outcome.[55–57] It is possible that hypocapnia induces cerebral vasoconstriction and decreased cerebral blood flow, resulting in worsening cerebral ischemia. The effects of hypercapnia on clinical outcomes are currently unclear.[58] Current recommendations advocate maintaining normocapnia (i.e., $PaCO_2$ 35–45 mm Hg) after cardiac arrest.[54]

Seizures

Seizures are not uncommon after anoxic brain injury. Routine seizure prophylaxis is not currently recommended in post–cardiac arrest syndrome. However, it is important to be vigilant in clinical assessment for any motor responses that could represent seizure

activity so that it can be treated promptly with anticonvulsant medications. Patients with status epilepticus may not have clinically detectable signs of seizure. Therefore continuous electroencephalography monitoring (if available) can be useful, especially if continuous administration of neuromuscular blocking agents becomes necessary for any reason.[45,54]

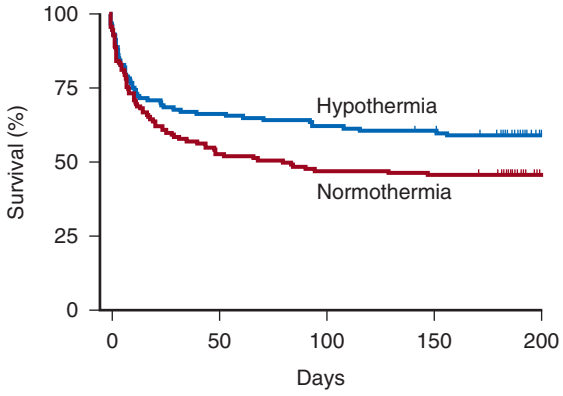
Cardiac Catheterization

Acute coronary syndrome is the most common etiology of sudden cardiac arrest. Clinicians should have a high clinical suspicion of acute myocardial ischemia as the inciting event for the cardiac arrest when no other obvious etiology of cardiac arrest is apparent. Although ST-segment myocardial infarction is an obvious indication for PCI, other subtler electrocardiogram abnormalities may indicate that an acute ischemic event caused the cardiac arrest. In patients with no obvious noncardiac etiology of cardiac arrest, a clinical suspicion of coronary ischemia, and an abnormal electrocardiogram after ROSC, consultation with an interventional cardiologist is encouraged and coronary angiography should be considered.[54] There is insufficient evidence to recommend PCI based on the presenting cardiac arrest rhythm (i.e., VF vs. non-VF). Recent studies and experience indicate that inducing TTM simultaneously with emergent percutaneous coronary intervention is feasible.

Targeted Temperature Management

TTM, previously referred to as therapeutic hypothermia or mild therapeutic hypothermia, is a treatment strategy of rapidly reducing the patient's body temperature after ROSC for the purposes of protection from neurologic injury. The body temperature is typically reduced to 32°C to 36°C for at least 24 hours. After ROSC the severity of the reperfusion injury can be mitigated, despite the fact that the initial ischemic injury has already occurred. Reperfusion injury refers to tissue and organ system injury that occurs when circulation is restored to tissues after a period of ischemia, and is characterized by inflammatory changes and oxidative damage that are in large part a consequence of oxidative stress. Neuronal cell death after I/R injury is not instantaneous, but rather a dynamic process. In animal models of cardiac arrest, brain histopathologic changes may not be found until 24 to 72 hours after cardiac arrest.[59] This indicates that a distinct therapeutic window of opportunity exists. In theory, TTM may protect the brain by attenuating or reversing all of the following pathophysiologic processes: disruption of cerebral energy metabolism, mitochondrial dysfunction, loss of calcium ion homeostasis, cellular excitotoxicity, oxygen free radical generation, and apoptosis.

The two original clinical trials of TTM targeting 32°C to 34°C were published in 2002.[60,61] These trials showed improved outcomes with TTM targeting 32°C to 34°C for comatose survivors of witnessed OHCA with VF as the initial rhythm. The survival data for the largest of these clinical trials (i.e., the Hypothermia After Cardiac Arrest Study Group) appear in Fig. 1.5. For patients with OHCA and a non-VF initial rhythm or IHCA, there are no randomized clinical trials and observational data have conflicting results. In 2013, a randomized control trial of 939 unconscious adults with OHCA of presumed cardiac etiology found no difference between neurologic outcomes and survival at 6 months when temperature was controlled at 36°C versus 33°C (Table 1.1).[62] It is currently unclear if certain subpopulations of post–cardiac arrest patients benefit from lower or higher temperatures.



No. at risk					
Hypothermia	137	92	86	83	11
Normothermia	138	74	66	64	9

• **Fig. 1.5** Cumulative survival in the normothermia and hypothermia groups from a randomized trial of therapeutic hypothermia in comatose survivors of out-of-hospital cardiac arrest due to ventricular fibrillation. Censored data are indicated by tick marks. (From Hypothermia After Cardiac Arrest Study Group. Mild therapeutic hypothermia to improve the neurologic outcome after cardiac arrest. *N Engl J Med* 2002;346(8):549–556.)

The current AHA guidelines for CPR and Emergency Cardiovascular Care recommend at least 24 hours of TTM targeting 32°C to 36°C for comatose survivors of OHCA caused by VF or pulseless VT, as well as non-VF/pulseless VT and IHCA.[54] These recommendations for non-VF/pulseless VT and IHCA are stronger than the 2010 AHA recommendations, the 2015 European Resuscitation Council and European Society of Intensive Care Medicine Guidelines for Post-resuscitation Care, and the 2015 International Liaison Committee on Resuscitation recommendations, which state that TTM may be considered for victims of IHCA and other arrest rhythms.[8,45,63]

Appropriate selection of candidates for TTM is clearly important. If a patient does not follow verbal commands after ROSC is achieved, this indicates that the patient is at risk for brain injury and TTM should be strongly considered. If a patient is clearly following commands immediately after ROSC, then significant brain injury is less likely and it is probably reasonable to withhold TTM. There are multiple potential methods for inducing TTM, including specialized external or intravascular cooling devices for TTM, or a combination of conventional cooling methods such as ice packs, cooling blankets, and cold (4°C) intravenous saline infusion. Compared with the use of specialized cooling devices, overshoot (body temperature <31°C) is a not uncommon occurrence with use of ice packs, cooling blankets, and cold saline.[64] Regardless of which method is used, effective achievement of target temperature may be aided by the use of a uniform physician order set for TTM induction.[65] The current recommendation is to maintain TTM for at least 24 hours.[8,45,54] Whether or not a longer duration of therapy could be beneficial is currently unknown.

Shivering with TTM induction is very common and should be anticipated regardless of which target temperature is chosen.[62] Shivering can be detrimental to the patient by making goal temperature more difficult (or impossible) to achieve. Therefore immediate recognition and treatment of shivering is imperative. Adequate sedation and analgesics are an essential component of TTM, especially during the induction phase, and often the administration of additional sedative and/or opioid agents will be

TABLE 1.1 Neurologic Outcome and Mortality at 6 Months With Temperature Control in Comatose Survivors of Cardiac Arrest[a]

Outcome	33°C Group No./total No. (%)	36°C Group No./total No. (%)	Hazard Ratio or Risk Ratio (95% CI)[b]	*P* Value
Primary outcome: deaths at end of trial	235/473 (50)	225/466 (48)	1.06 (0.89–1.28)	0.51
Secondary outcomes:				
Neurologic function at follow-up[c]				
CPC of 3–5	251/469 (54)	242/464 (52)	1.02 (0.88–1.16)	0.78
Modified Rankin scale score of 4–6	245/469 (52)	239/464 (52)	1.01 (0.89–1.14)	0.87
Deaths at 180 days	226/473 (48)	220/466 (47)	1.01 (0.87–1.15)	0.92

[a]The study shows the 6-month outcome and mortality for a randomized trial of temperature control at 33°C vs. 36°C in comatose survivors of out-of-hospital cardiac arrest with presumed cardiac etiology.
[b]The hazard ratio is shown for the primary outcome, and risk ratios are shown for the secondary outcomes.
[c]The neurologic follow-up was specified in the protocol to be performed at 180 days ± 2 weeks, but the time to follow-up was in some cases several weeks longer for logistic reasons. The Cerebral Performance Category (CPC) scale ranges from 1 to 5, with 1 representing good cerebral performance or minor disability, 2 moderate cerebral disability (function is sufficient for independent activities of daily life), 3 severe cerebral disability, 4 coma or vegetative state, and 5 brain death. Scores on the modified Rankin scale range from 0 to 6, with 0 representing no symptoms, 1 no clinically significant disability despite some symptoms, 2 slight disability (patient is able to look after own affairs without assistance), 3 moderate disability (patient requires some help but is able to walk unassisted), 4 moderately severe disability (patient is unable to attend to own bodily needs), 5 severe disability (patient is bedridden), and 6 death.
CI, Confidence interval.
From Nielsen N, Wetterslev J, Cronberg T, et al. Targeted temperature management at 33 degrees C versus 36 degrees C after cardiac arrest. *N Engl J Med.* 2013;369(23):2197-2206.

sufficient to ameliorate shivering. Magnesium sulfate can also be used to reduce the shivering threshold.[66] If shivering persists despite sedatives or opioid agents and magnesium, neuromuscular blocking agents may be required. If neuromuscular blocking agents are used, they are often necessary only in the induction phase of TTM when the temperature is dropping at a fast rate. Once the target temperature is achieved, patients often stop shivering. It is prudent to try to limit neuromuscular blocking agents to the induction phase of TTM, and they likely can be withheld thereafter. Unnecessarily prolonged neuromuscular blockade should be avoided because prolonged neuromuscular weakness may persist after discontinuation, and this could potentially make the patient's neurologic assessment at a later time point more challenging. When using neuromuscular blocking agents for the induction of TTM, their administration may be titrated to the resolution of shivering rather than complete paralysis, which may result in the administration of a much lower dose of neuromuscular blocker.

A number of potential complications are possible with TTM, including bradycardia, a "cold diuresis" resulting in hypovolemia and electrolyte derangements, hyperglycemia, coagulopathy, and perhaps increased risk of secondary infection. However, these potential complications are often not severe when they do occur, and in terms of risk-benefit determinations, the risk of anoxic brain injury usually greatly outweighs the risks of complications. Specifically, bradycardia is a normal response to hypothermia. It is typically not recommended to treat bradycardia during TTM as long as the blood pressure, lactate, mixed venous saturation, and urine output are sufficient, even with heart rates less than 40 beats/min.[45] In the TTM trial 33°C was associated with a lower heart rate, increased need for vasopressor support, and increased incidence of hypokalemia compared with 36°C.[41,62] There was no difference in the rate of bleeding complications, infection, other cardiac arrhythmias (i.e., atrial fibrillation/flutter, tachycardia, bradycardia requiring pacing, and VT/VF), or other electrolyte derangements (i.e., hypomagnesemia, hypophosphatemia, and hypoglycemia).[62]

Fever is not uncommon in the post–cardiac arrest population because of the intense proinflammatory response to ischemia/reperfusion. The development of hyperthermia after completion of TTM (i.e., rebound hyperthermia) is associated with mortality and poor neurologic outcome.[67] Fever is clearly detrimental in brain-injured patients because it increases the cerebral metabolic rate; it should be treated aggressively after completion of TTM and in patients who do not receive TTM with antipyretic therapies and other techniques (e.g., cooling blankets).

Neurologic Prognostication

Neurologic prognostication after cardiac arrest is challenging, especially with the advent of TTM. Recovery of brain function—and correspondingly the findings on neurologic examination—are delayed with TTM. This delay is likely because of modulation of brain injury and slowed metabolism of sedative medications.[68] Neurologic prognostication immediately (e.g., first 24 hours) after resuscitation from cardiac arrest is especially unreliable. Among patients who are initially comatose after ROSC, 25% to 48% could potentially have a favorable outcome, especially if TTM is used.[62] In general, the recommended approach is to wait a minimum of 72 hours after ROSC before neurologic prognostication.[8,45,54] For neurologic examination findings to be used for neuroprognostication, and specifically for the determination of poor neurologic prognosis, the "false-positive rate" (FPR) (i.e., prognostication of a poor outcome that ultimately proves not to be poor), should approach zero. The reason it is imperative for a neurologic examination finding to show an FPR approaching zero is to prevent premature discontinuation of life support for patients who are potentially salvageable. Neurologic examination findings by themselves may not have an FPR of zero. Hence, a multimodal approach using a combination of clinical examination, neuroimaging, neurophysiologic tests, and biomarkers may be helpful for neurologic prognostication.[69]

Clinical Examination

Motor responses to pain, brainstem reflexes, and myoclonus remain the standard of clinical assessment even after TTM.[69] Bilateral absence of pupillary reflexes at 72 hours after cardiac arrest is

highly predictive of poor neurologic outcome with or without TTM with an FPR of about 0.5%.[70–73] The bilateral absence of corneal reflexes at 72 hours is also predictive of poor neurologic outcome, but with a higher FPR (5%) compared with pupillary reflexes.[70,72] The utility of absent or extensor motor response to pain at 72 hours for the determination of poor prognosis is diminished with TTM.[70,73] Similarly, the use of early post–anoxic myoclonus as a predictor of poor neurologic outcome after TTM is not sufficiently reliable, with recent reports of patients recovering well despite early myoclonus.[74–76] Myoclonus accompanied by malignant electroencephalogram findings is a more reliable predictor of poor neurologic outcome.[77]

Neuroimaging

Loss of gray-white matter differentiation on a computed tomography (CT) scan of the brain has been shown to be a reliable predictor of poor outcome, with an FPR of zero in multiple studies, but the sensitivity of this CT finding remains very low.[78,79] Although it is a higher-resolution study, magnetic resonance imaging has not been shown to be more useful than CT with respect to prognostication. Abnormalities on diffusion and apparent diffusion coefficient sequence of brain magnetic resonance imaging have been evaluated across multiple studies with variable results regarding utility in neuroprognostication.[69] In general, data on the use of neuroimaging for neuroprognostication are few compared with clinical and neurophysiologic testing; thus clinical and neurophysiological testing are considered more reliable.[72]

Neurophysiological Testing

EEG findings such as low voltage or suppressed background, burst suppression pattern, or discontinuous background are suggestive of poor outcome with FPR approaching zero.[80,81] Absence of reactivity on EEG and epileptiform discharges after TTM have been shown to be predictive of a poor outcome with an FPR of 7% and 9%, respectively.[82] Upper extremity somatosensory evoked potential, through stimulation of the median nerve and recording of response at the sensory cortex, is well studied and validated, both with and without TTM. The absence of bilateral cortical responses (N20s) have been shown to be highly predictive of poor outcome (FPR of 0% in multiple studies), but the presence of cortical response does not predict good outcome.[72,83]

Biomarkers

Serum neuron-specific enolase, a marker of neuronal damage, has been the most extensively studied biomarker as a prognostic tool after cardiac arrest. Before the advent of TTM, serum neuron-specific enolase concentration of more than 33 μg/mL was found to be highly predictive of poor outcome (FPR of 0%) when measured between 24 and 72 hours after cardiac arrest.[84] Now in the TTM era, the serum concentration cutoff value seems more difficult to determine because multiple studies have shown high FPR even with higher cutoffs.[70,77,85–87]

New Studies

Long-latency somatosensory evoked potentials, a measurement of cerebral oxygenation and several new blood biomarkers, are among the upcoming promising modalities to improve prognostication after cardiac arrest. At this time, these modalities are considered investigational.

One of the major limitations of all studies regarding neuroprognostication after cardiac arrest is the problem of self-fulfilling prophecy—that is, the presence of the neurologic finding or positive test influences clinician perception of severe anoxic injury and poor prognosis, leading to a withdrawal of care. Hence, instead of using a single modality to determine prognosis, a multimodal approach to neurologic prognosis seems most prudent. Waiting sufficient time (e.g., 72 hours or more in most cases) after cardiac arrest before making a definite prognosis, and paying particular importance to repeated neurologic examination without sedation, are the most important components of this multimodal approach. A multidisciplinary approach involving an intensivist, neurologist, and most importantly the patient's family members is the key to making decisions about goals of care based on neurologic prognosis and the minimally acceptable quality of life for the patient.

Key Points

- The quality of CPR (especially in the quality of and minimization of interruptions in chest compressions) is probably the single most important treatment-related determinant of outcome from cardiac arrest.
- Cellular damage from ischemia/reperfusion injury is a dynamic process, and a therapeutic window exists after resuscitation from cardiac arrest in which the effects can be attenuated.
- TTM is the first proven therapy to improve neurologic outcome after resuscitation from cardiac arrest, indicating that brain injury related to cardiac arrest is in fact a treatable condition.
- Neurologic prognostication can be very challenging in the early period after resuscitation from cardiac arrest, and in most cases attempts at prognostication should be withheld until at least the 72-hour mark from ROSC.

Review Questions

1. The recommended chest compression rate during cardiopulmonary resuscitation is (compressions/min):
   a. >100
   b. >120
   c. 100–120
   d. 100–140
   Answer: c. 100–120 compressions/min is the current recommended chest compression rate.[7–9]
2. During cardiopulmonary resuscitation, once a definitive airway is placed (i.e., endotracheal tube) the recommended ventilation strategy is:
   a. 1 breath every 3 seconds
   b. 1 breath every 6 seconds
   c. 2 breaths for every 30 chest compressions
   d. 2 breaths for every 15 chest compressions
   Answer: b. Once a definitive airway is placed the recommended ventilation strategy is 1 breath every 6 seconds.[7–9]
3. The preferred antiarrhythmic agent for refractory ventricular fibrillation/pulseless ventricular tachycardia cardiac arrest is:
   a. Amiodarone
   b. Lidocaine
   c. Procainamide
   d. β-Blocker
   Answer: a. Amiodarone is the current recommended antiarrhythmic agent for refractory ventricular fibrillation/pulseless ventricular tachycardia.[8,26,28]
4. During cardiopulmonary resuscitation, which of the following end-tidal carbon dioxide ($ETCO_2$) levels would be predictive of mortality?
   a. 25 mm Hg immediately after return of spontaneous circulation
   b. 25 mm Hg after 20 minutes of high-quality chest compressions
   c. 9 mm Hg immediately after return of spontaneous circulation
   d. 9 mm Hg after 20 minutes of high-quality chest compressions
   Answer: d. An $ETCO_2$ less than 10 mm Hg following 20 minutes of high-quality chest compressions can be predictive of mortality. However, this criterion should not be used alone to decide to terminate resuscitation efforts.[36,37]
5. After successful resuscitation from cardiac arrest the recommended temperature range and duration for targeted temperature management is:
   a. 32°C–36°C for 12–24 hours
   b. 34°C–36°C for 12–24 hours
   c. 32°C–36°C for at least 24 hours
   d. 34°C–36°C for at least 24 hours
   Answer: c. The recommended temperature range and duration for targeted temperature management is 32°C–36°C for at least 24 hours.[45,54,88]
6. After successful resuscitation from cardiac arrest a definite indication for emergent coronary angiography is:
   a. Electrocardiogram (ECG) consistent with ST-segment elevation myocardial infarction (STEMI)
   b. Ventricular fibrillation/pulseless ventricular tachycardia as the presenting cardiac arrest rhythm
   c. Out-of-hospital cardiac arrest
   d. Pulseless electrical activity as the presenting cardiac arrest rhythm
   Answer: a. Only ECG findings consistent with STEMI are a definite indication for emergent coronary angiography. There is currently insufficient evidence to recommend routine coronary angiography based on initial cardiac arrest rhythm or location of cardiac arrest. For cardiac arrest patients without STEMI the decision to proceed with emergent coronary angiography should be made in conjunction with an interventional cardiologist.[54]
7. The following is true regarding SSEPs when used for neuroprognostication after cardiac arrest:
   a. The absence of bilateral cortical responses (N20s) has not been shown to be predictive of poor outcome, but the presence of cortical response predicts good outcome.
   b. The absence of bilateral cortical responses (N20s) has been shown to be predictive of poor outcome, but the presence of cortical response does not predict good outcome.
   c. The absence of bilateral cortical responses (N20s) has been shown to be predictive of poor outcome, and the presence of cortical response is predictive of good outcome.
   d. Neither the absence nor the presence of bilateral cortical responses (N20s) has been shown to be predictive of outcome
   Answer: b. The absence of bilateral cortical responses (N20s) has been shown to be highly predictive of poor outcome (false-positive rate of 0% in multiple studies), but the presence of cortical response does not predict good outcome.[72,83]

Human Factors

Common Problems in Airway Management

Appropriate management of the airway is the cornerstone of good resuscitation. It requires judgment (airway assessment), skill (airway maneuvers), and constant reassessment of the patient's condition. Although complex airway procedures have a high profile and are sometimes lifesaving, the timely use of simple airway maneuvers is often very effective and may avoid the need for further intervention.

Structure and Function of the Normal Airway

Knowledge of the structure and function of the airway is required to manage the various conditions that may affect it. The airway begins at the nose and oral cavity and continues as the pharynx and larynx, which lead to the trachea (beginning at the lower edge of the cricoid cartilage) and finally the bronchial tree. The airway provides a pathway between the atmosphere and the lungs for gas/vapor; facilitates filtering, humidification, and heating of ambient air/gas before it reaches the lower airway; prevents nongaseous material from entering the lower airway; and allows phonation by controlling the flow of air through the larynx and oropharynx.[1–6]

The Nose

Key to the respiratory function of the nose are the lateral walls, which on each side lie medial to the orbit, the ethmoid, and maxillary sinuses. Each lateral wall has three horizontal bony projections covered by highly vascular mucosa—the superior, middle, and inferior nasal conchae that greatly increase the surface area. The (nonolfactory) sensory innervation of the nasal mucosa is supplied by two divisions of the trigeminal nerve.

The Oral Cavity and Pharynx

The teeth form the lateral wall of the oral cavity, while the floor is the tongue—a mass of horizontal, vertical, and transverse muscle bundles attached to the mandible and the hyoid bone. The anterior two-thirds of the tongue has sensory innervation from the lingual nerve with taste sensation from the chordae tympani, whereas the posterior one-third has a sensory supply from the glossopharyngeal nerve. All intrinsic and extrinsic muscles of the tongue are supplied by the hypoglossal nerve, except the palatoglossus, which is supplied by the vagus nerve.

The adult pharynx is a midline structure, running anterior to the cervical prevertebral fascia, from the base of the skull to the level of the sixth cervical vertebra (approximately 14 cm), and continuing as the esophagus. It is a muscular tube with three portions: the nasopharynx, oropharynx, and laryngopharynx (or

hypopharynx). It contains three groups of lymphoid tissue: the adenoids, the pharyngeal tonsil (on the posterior wall), and the palatine (lingual) tonsils as well as the inner opening of the eustachian tube on each lateral wall. The vagus nerve supplies all but one of the pharyngeal muscles. Sensory supply is via branches of the glossopharyngeal and vagus nerves. The pharynx is a common pathway for the upper alimentary and respiratory tracts and is concerned with swallowing and phonation.

The Larynx

The larynx sits anteroinferior to the laryngopharynx, anterior to the fourth to the sixth cervical vertebrae, and posterior to the infrahyoid muscles, the deep cervical fascia, and the subcutaneous fat and skin that cover the front of the neck. Laterally lie the lobes of the thyroid gland and carotid sheath. The larynx acts as a sphincter at the upper end of the respiratory tract and is the organ of phonation. The skeleton of the larynx consists of the epiglottis, thyroid, cricoid, and paired arytenoid, cuneiform, and corniculate cartilages, together with the interconnecting ligaments, and has a volume of 4 mL. Two pairs of parallel horizontal folds project into the lumen of the larynx—the false vocal cords (lying superiorly) and the true vocal cords (inferiorly). The opening between the true cords is called the glottis. The larynx communicates above with the laryngopharynx and below with the trachea, which begins at the lower edge of the cricoid ring.

The superior aspect of the epiglottis is innervated by the glossopharyngeal nerve, whereas the inferior surface of the epiglottis and the larynx is innervated by the vagus, via its superior laryngeal nerve (SLN) and recurrent laryngeal nerve (RLN) branches. The external (motor) branch of the SLN supplies the cricothyroid muscle, and the internal branch is the sensory supply to the larynx down to the vocal cords. The RLN supplies all intrinsic laryngeal muscles and is the sensory supply to the larynx below the cords.

In health, the laryngeal abductor muscles contract early in inspiration, separating the vocal cords and facilitating airflow into the tracheobronchial tree. Movements of the thyroid and arytenoid cartilages alter the length and tension of the vocal cords, and sliding and rotational movements of the arytenoid cartilages can alter the shape of the glottic opening between the vocal cords. Fine control of the muscles producing these movements allows vocalization as air passes between the vocal cords in expiration. The sound volume is increased by resonance in the sinuses of the face and skull.

Injury to the SLN causes hoarseness secondary to a loss of tension in the ipsilateral vocal cord. Complete unilateral RLN palsy (loss of function) inactivates both ipsilateral adductor and abductor muscles, but the vocal cord remains adducted (at/near the midline) owing to action of the unopposed SLN-innervated cricothyroid muscle. In bilateral RLN palsy, both cords are in adduction. On inspiration, the adducted vocal cords then act like a Venturi device, generating a negative pressure that pulls the cords even more tightly together, producing inspiratory stridor—the characteristic sign of upper airway obstruction. Sudden complete adduction of the vocal cords caused by muscle spasm (laryngospasm) is a life-threatening form of airway obstruction that may be triggered by mechanical stimulation of the larynx or by cord irritation caused by aspiration of oral secretions, blood, or vomitus.

The Tracheobronchial Tree

The trachea is a midline fibrous tube, 2 cm in diameter, beginning at the level of the sixth cervical vertebra and extending 10 to 14 cm to the level of the fourth thoracic vertebra before dividing into the right and left main bronchi (carina). The tracheal walls include 15 to 20 incomplete cartilaginous rings limited posteriorly by fibroelastic tissue and smooth muscle. The bronchial tree has a similar wall structure to the trachea.

In the neck the trachea lies anterior to the esophagus, with the RLN in the groove between the two. Anteriorly lie the cervical fascia, infrahyoid muscles, isthmus of the thyroid, and the jugular venous arch. Laterally lie the lobes of the thyroid gland and the carotid sheath. In the thorax, the trachea is traversed anteriorly by the brachiocephalic artery and vein (which may be damaged or eroded by the tracheostomy tube). To the left are the common carotid and subclavian arteries and the aortic arch. To the right are the vagus nerve, the azygos vein, and the pleura. The bifurcation of the trachea (carina) lies anterior to the esophagus and behind the pulmonary trunk.

The two main bronchi diverge from the carina, the right main bronchus being shorter, wider, and more vertical and running close to the pulmonary artery and the azygos vein. The left main bronchus passes under the arch of the aorta, anterior to the esophagus, thoracic duct, and descending aorta.[7]

Overview of Airway Function

In the nose, inspired gas is filtered, humidified, and warmed before entering the lungs. Resistance to gas flow through the nose is twice that of the mouth, explaining the need to mouth-breathe during exercise when the required gas flows are high. Warming and humidification continue in the pharynx and tracheobronchial tree. Between the trachea and the alveolar sacs, the airways divide 23 times, thus increasing the cross-sectional area for the gas exchange.

Particles in inspired air with diameters greater than 10 μm are trapped by hairs on the nasal mucosa. Particles less than 2 μm in diameter may reach the alveoli, where they are ingested by macrophages. Particles 2 to 10 μm in diameter fall on the mucus-covered bronchial walls (as airflow slows), initiating reflex bronchoconstriction and coughing. Such particles are moved upward away from the lungs at a rate of 16 mm/min by cilia that beat at a frequency of 1000 to 1500 cycles/min. Ciliated columnar epithelium lines the respiratory tract from the nose to the respiratory bronchioles (except at the vocal cords). Smoking and some inherited disorders (e.g., Kartagener syndrome) cause defective ciliary motility and a failure of this "mucus escalator." This may allow more particles to reach the alveoli, thereby predisposing the patient to chronic pulmonary inflammation.[8]

The larynx prevents food and other foreign bodies from entering the trachea. Reflex closure of the glottic inlet occurs during swallowing and periods of increased intrathoracic (e.g., coughing, sneezing) or intraabdominal (e.g., vomiting, micturition) pressure. In unconscious patients, these reflexes are lost, so glottic closure may not occur, increasing the risk of pulmonary aspiration.

Assessing Adequacy of the Airway

Adequacy of the airway should be considered in four aspects:

- *Patency.* Partial or complete obstruction compromises ventilation of the lungs and likewise gas exchange.
- *Protective reflexes.* These reflexes help maintain patency and prevent aspiration of material into the lower airways.
- *Inspired oxygen concentration.* Gas entering the pulmonary alveoli must have an appropriate oxygen concentration.

- *Respiratory drive.* A patent, secure airway is of little benefit without the movement of gas between the atmosphere and the pulmonary alveoli. This is achieved by the processes of inspiration and expiration.

Patency

Airway obstruction is most frequently due to reduced muscle tone, allowing the tongue to fall backward against the postpharyngeal wall, thereby blocking the airway. Loss of patency by this mechanism typically occurs in an obtunded or anesthetized patient lying supine. Other causes include the presence of blood, mucus, vomitus, or a foreign body in the lumen of the airway or edema, inflammation, swelling, or enlargement of the tissues lining or adjacent to the airway.

Upper airway obstruction has a characteristic presentation in the spontaneously breathing patient: noisy inspiration (stridor), poor expired airflow, intercostal retraction, increased respiratory distress, and paradoxical rocking movements of the thorax and abdomen.[9] These resolve quickly if the obstruction is removed. In total airway obstruction, sounds of breathing are absent entirely, owing to complete lack of airflow through the larynx. Airway obstruction may occur in patients with an endotracheal tube (ET) or tracheostomy tube in situ as the result of mucous plugging or kinking of the tube or the patient's biting down on a tube placed orally. Spontaneously breathing patients with airway obstruction have the symptoms and signs described earlier, whereas patients supported by assisted (positive-pressure) breathing modes exhibit high inflation pressures, decreased tidal and minute volumes, increased end-tidal carbon dioxide ($ETCO_2$) levels, and decreased arterial oxygen saturation.

Protective Reflexes

The upper airway shares a common pathway with the upper gastrointestinal tract. Protective reflexes, which exist to safeguard airway patency and to prevent foreign material from entering the lower respiratory tract, involve the epiglottis, the vocal cords, and the sensory supply to the pharynx and larynx.[10] Patients who can swallow normally have intact airway reflexes, and normal speech makes absence of such reflexes unlikely. Patients with a decreased level of consciousness (LOC) should be assumed to have inadequate protective reflexes.

Inspired Oxygen Concentration

Oxygen demand is elevated by the increased work of breathing associated with respiratory distress[11] and by the increased metabolic demands in critically ill or injured patients. Often, higher inspired oxygen concentrations are required to satisfy tissue oxygen demand and to prevent critical desaturations during maneuvers for managing the airway. A cuffed ET, connected to a supply of oxygen, is a sealed system in which the delivered oxygen concentration also is the inspired concentration. A patient wearing a face mask, however, inspires gas from the mask and surrounding ambient air. Because the patient will generate an initial inspiratory flow in the region of 30 to 60 L/min, and the fresh gas flow to a mask is on the order of 5 to 15 L/min, much of the tidal inspiration will be "ambient air" entrained from around the mask. The entrained air can dilute the concentration of oxygen inspired to less than 50%, even when 100% oxygen is delivered to the mask. This unwelcome reduction in inspired oxygen concentration can be mitigated by (1) using a mask with a reservoir bag, (2) ensuring that the mask is fitted firmly to the patient's face, (3) using a high rate of oxygen flow to the mask (15 L/min), and (4) supplying a higher oxygen concentration if not already using 100%.

Respiratory Drive

A patent, protected airway will not produce adequate oxygenation or excretion of carbon dioxide without adequate respiratory drive. Changing arterial carbon dioxide tension (PCO_2) by changing the hydrogen ion (H^+) concentration in cerebrospinal fluid stimulates the respiratory center, which in turn controls minute volume and therefore arterial PCO_2 (negative feedback). This assumes that increased respiratory drive can produce an increase in minute ventilation (increased respiratory rate or tidal volume, or both), which may not occur if respiratory mechanics are disturbed. Brain injury and drugs such as opioids, sedatives, and alcohol are direct-acting respiratory center depressants.

Ventilation can be assessed qualitatively by looking, listening, and feeling. In a spontaneously breathing patient, listening to (and feeling) air movement while looking at the extent, nature, and frequency of thoracic movement provides an impression of ventilation. These parameters may be misleading, however. Objective assessment of minute ventilation requires PCO_2 measurement in arterial blood or monitoring of $ETCO_2$, which can be used as a real-time measure of the adequacy of minute ventilation. If respiratory drive or minute ventilation is inadequate, positive-pressure respiratory support may be required, and any underlying factors should be addressed if possible (e.g., depressant effect of sedatives or analgesics).

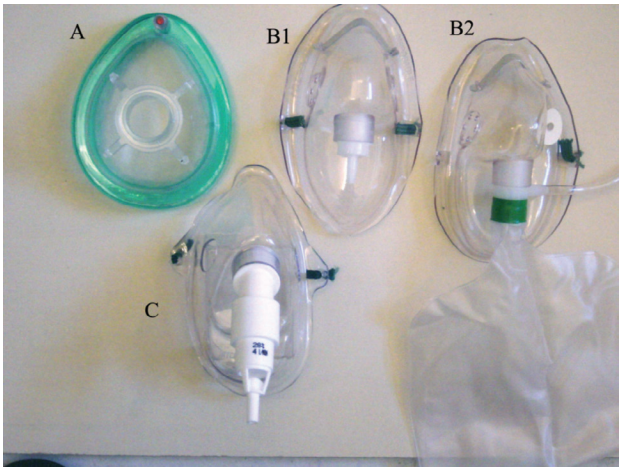
Management of the Airway

The aims of airway management are to provide an adequate inspired oxygen concentration; to establish a patent, secure airway; and to support ventilation if required.

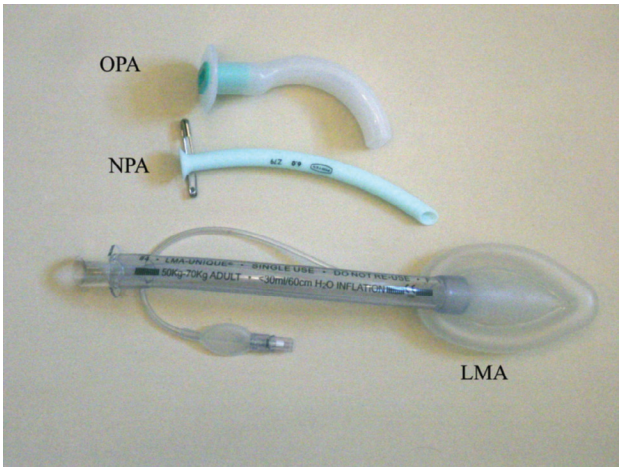
Providing an Adequate Inspired Oxygen Concentration

Although oxygen can be administered via nasal cannula, this method does not ensure delivery of more than 30% to 40% oxygen (at most). Other disadvantages include lack of humidification of gases, patient discomfort with use of flow rates greater than 4 to 6 L/min, and predisposition to nasal mucosal irritation and potential bleeding. Therefore despite being more intrusive for patients, face masks are superior for oxygen administration. The three main types of face masks are shown in Fig. 2.1:

- The anesthesia-type face mask (mask A in Fig. 2.1) is a solid mask (with no vents) with a cushioned collar to provide a good seal. It is suitable for providing very high oxygen concentrations (approaching 100%) because entrainment is minimized and the anesthetic circuit normally includes a reservoir of gas. These masks become unacceptable for many *awake* patients within a few minutes because of the association with heat, moisture, and claustrophobia.
- The simple face mask has vents that allow dissipation of heat or humidity but that also entrain room air. These masks have no seal and are relatively loose-fitting. Such masks may have a reservoir bag (approximately 500 mL) sitting inferior to the mask (B2 in Fig. 2.1) or may not (B1 in Fig. 2.1). Using the latter, it is difficult to reliably deliver an inspired oxygen



• **Fig. 2.1** Face masks: anesthesia mask (A); simple face mask (B1); simple face mask with reservoir bag (B2); Venturi mask (C).



• **Fig. 2.2** Artificial airways: oropharyngeal airway *(OPA)*; nasopharyngeal airway *(NPA)*; laryngeal mask airway *(LMA)*.

concentration in excess of 50% even with tight application and 100% oxygen flow to the mask. Under the same conditions, a simple mask with a reservoir bag can produce an inspired oxygen concentration of about 80%.

- The Venturi mask (C in Fig. 2.1) has vents that entrain a known proportion of ambient air when a set flow of 100% oxygen passes through a Venturi device. Thus the inspired oxygen concentration (usually 24% to 35%) is known.

Establishing a Patent and Secure Airway

Establishing a patent and secure airway can be achieved using simple airway maneuvers, further airway adjuncts, tracheal intubation, or a surgical airway.

Airway Maneuvers

Simple airway maneuvers involve appropriate positioning, opening the airway, and keeping it open using artificial airways if needed.

Positioning for Airway Management

In the absence of any concerns about cervical spine stability (e.g., with trauma, rheumatoid arthritis, or severe osteoporosis), raising the patient's head slightly (5–10 cm) by means of a small pillow under the occiput can help in airway management. This adjustment extends the atlantooccipital joint and moves the oral, pharyngeal, and laryngeal axes into better alignment, providing the best straight line to the glottis ("sniffing" position).

Clearing the Airway

Acute airway obstruction in the obtunded patient is often due to the tongue or extraneous material—liquid (saliva, blood, gastric contents) or solid (teeth, broken dentures, food)—in the pharynx. In the supine position, secretions can be cleared under direct vision using a laryngoscope and a rigid suction catheter.[12] In some cases, a flexible suction catheter, introduced through the nose and nasopharynx, may be the best means of clearing the airway. A finger sweep of the pharynx may be used to detect and remove larger solid material in unconscious patients without an intact gag reflex. During all airway interventions, if cervical spine instability cannot be ruled out, relative movement of the cervical vertebrae must be prevented—most often by manual inline immobilization.[12,13]

Triple Airway Maneuver

The triple airway maneuver often is beneficial in obtunded patients if it is not contraindicated by concerns about cervical spine instability. As indicated by its name, this maneuver has three components: head tilt (neck extension), jaw thrust (pulling the mandible forward), and mouth opening.[14] The operator stands behind and above the patient's head. Then the maneuver is performed as follows:

- Extend the patient's neck with the operator's hands on both sides of the mandible.
- Elevate the mandible with the fingers of both hands, thereby lifting the base of the tongue away from the posterior pharyngeal wall.
- Open the mouth by pressing caudally on the anterior mandible with the thumbs or forefingers.

Artificial Airways

If the triple airway maneuver or any of its elements reduces airway obstruction, the benefit can be maintained for a prolonged period by introducing an artificial airway into the pharynx between the tongue and the posterior pharyngeal wall (Fig. 2.2).

The oropharyngeal airway (OPA) is the most commonly used artificial airway. Simple to insert, it is used temporarily to help facilitate oxygenation or ventilation before tracheal intubation. The OPA should be inserted with the convex side toward the tongue and then rotated through 180 degrees. Care must be taken to avoid pushing the tongue posteriorly, thereby worsening the obstruction. The nasopharyngeal airway has the same indications as for the OPA but significantly more contraindications[15] (Box 2.1). It is better tolerated than the OPA, making it useful in semiconscious patients in whom the gag reflex is partially preserved. These artificial airways should be considered as a temporary adjunct—to be replaced with a more secure airway if the patient's condition fails to improve rapidly to the point at which an artificial airway no longer is needed. Such airways should not be used in association with *prolonged* positive-pressure ventilation.

Advanced Airway Adjuncts

Advanced airway adjuncts fill the gap between simple airway maneuvers and the insertion of a tracheal tube or surgical airway. These devices can be used to facilitate safe reliable airway management and manual ventilation in the prehospital or emergency

• BOX 2.1 Contraindications to Insertion of Oropharyngeal and Nasopharyngeal Airways

Contraindications to Oropharyngeal Airways

Inability to tolerate (gagging, vomiting)
Airway swelling (burns, toxic gases, infection)
Bleeding into the upper airway
Absence of pharyngeal or laryngeal reflexes
Impaired mouth opening (e.g., with trismus or temporomandibular joint dysfunction)

Contraindications to Nasopharyngeal Airways

Narrow nasal airway in young children
Blocked or narrow nasal passages in adults
Airway swelling (burns, toxic gases, infection)
Bleeding into the upper airway
Absence of pharyngeal or laryngeal reflexes
Fractures of the midface or base of skull
Clinical scenarios in which nasal hemorrhage would be disastrous

resuscitation setting, often without expert medical presence. The number of supraglottic airways (SGAs) available has increased dramatically in the past 2 decades. They may be used to maintain airway maintenance during low-risk surgery and have utility in airway management in obese patients, in airway rescue after failed intubation, and during an anticipated difficult airway.[16]

The laryngeal mask airway (LMA) is a small latex mask mounted on a hollow plastic tube.[17,18] The airway is placed "blindly" in the lower pharynx overlying the glottis. The inflatable cuff helps wedge the mask in the hypopharynx, sitting obliquely over the laryngeal inlet. Although the LMA produces a seal that allows ventilation with gentle positive pressure, it does not definitively protect the airway from aspiration. Indications for use of the LMA in critical care are (1) as an alternative to other artificial airways, (2) the difficult airway, particularly the "cannot intubate–cannot ventilate" scenario, and (3) as a conduit for bronchoscopy. It is possible to pass a 6.0-mm ET through a standard LMA into the trachea, but the LMA must be left in situ. The intubating LMA, which was developed specifically to aid intubation with a tracheal tube, has a shorter steel tube with a wider bore, a tighter curve, and a distal silicone laryngeal cuff. A bar present near the laryngeal opening is designed to lift the epiglottis anteriorly. The intubating LMA allows the passage of a specially designed size 8.0 ET.

There is increasing evidence that many of the newer SGAs have better performance characteristics that may improve efficacy compared with the original LMA device. They are often easier to insert, with better oropharyngeal seal pressures, and may reduce the risk of aspiration.[19,20]

Tracheal Intubation

If the foregoing interventions are not effective or are contraindicated, tracheal intubation is required. This modality provides (1) a secure, potentially long-term airway; (2) a safe route to deliver positive-pressure ventilation if required; and (3) significant protection against pulmonary aspiration.

Orotracheal intubation is the most widely used technique for clinicians practiced in direct laryngoscopy (indications and contraindications in Box 2.2). Normally, anesthesia with or without neuromuscular blockade is necessary for this procedure, which is summarized in Box 2.3.

• BOX 2.2 Orotracheal Intubation: Indications and Relative Contraindications

Indications

Long-term correction or prevention of airway obstruction
Securing the airway and protecting against pulmonary aspiration
Facilitating positive-pressure ventilation
Enabling bronchopulmonary toilet
Optimizing access to pharynx, face, or neck at surgery

Contraindications (Relative)

Possibility of cervical spine instability
Impaired mouth opening (e.g., trismus, temporomandibular joint dysfunction)
Potential difficult airway
Need for surgical immobilization of maxilla or mandible (wires, box frame)

• BOX 2.3 Procedure: Orotracheal Intubation

- Position patient and induce anesthesia ± neuromuscular blockade (if needed).
- Perform manual ventilation using triple airway maneuver and oropharyngeal airway.
- Hold laryngoscope handle (left hand) near the junction with blade.
- Insert the blade along the right side of the tongue—moving tongue to the left.
- Advance tip of the blade in the midline between tongue and epiglottis.
- Pull upward and along the line of the handle of the laryngoscope.
- Lift the epiglottis upward and visualize the vocal cords.
- Do *not* use the patient's teeth as a fulcrum when attempting to visualize the glottis.
- Stop advancing tube when cuff is 2 to 3 cm beyond the cords.
- Connect to a bag-valve system and pressurize it by squeezing bag.
- Inflate cuff until audible leak around tube stops.
- Check correct tube position (auscultation) and assess cuff pressure.
- Check end-tidal carbon dioxide trace.

TABLE 2.1 Drugs Used to Facilitate Tracheal Intubation

Drug	Dose (Intravenous)
Induction Agent	
Propofol	1–2.5 mg/kg
Opioids	
Fentanyl	1.0–1.5 μg/kg
Morphine	0.15 mg/kg
Nondepolarizing Agents	
Atracurium	0.4–0.5 mg/kg
Vecuronium	0.1 mg/kg
Rocuronium	0.45–0.6 mg/kg
Depolarizing Agent	
Succinylcholine (suxamethonium)	1.0–1.5 mg/kg

Tracheal intubation requires lack of patient awareness (as in the unconscious state or with general anesthesia) and the abolition of protective laryngeal and pharyngeal reflexes. The drugs commonly used to achieve these states are shown in Table 2.1. Anesthesia is achieved using an intravenous induction agent, although intravenous

sedatives (e.g., midazolam) theoretically may be used. Opioids often are used in conjunction with induction agents because they may reduce the cardiovascular sequelae of laryngoscopy and intubation (tachycardia and hypertension) and may contribute to the patient's unconsciousness.

Abolition of protective laryngeal and pharyngeal reflexes may be achieved by inducing a deep level of unconsciousness using one or more of the aforementioned agents, followed by inhalation of high concentrations of a volatile anesthetic agent (e.g., sevoflurane, isoflurane). This technique sometimes is used in the anticipated difficult airway scenario to obtain conditions suitable for tracheal intubation in a patient who is still breathing spontaneously.

More often, a muscle relaxant is used to abolish the protective reflexes, abduct the vocal cords, and facilitate tracheal intubation. In the elective situation, nondepolarizing neuromuscular blocking agents are used. These drugs have the disadvantage of requiring several minutes to exert their effect, during which the patient must receive ventilation via a mask, thus allowing the possibility of gastric dilation and pulmonary aspiration. In patients at high risk of the latter (e.g., nonfasting patients), a depolarizing muscle relaxant (succinylcholine) can be used because it produces suitable conditions for intubation within 15 to 20 seconds, and mask ventilation is not required. Succinylcholine has several side effects—among them hyperkalemia, muscle pains, and (rarely) malignant hyperpyrexia. Alternatively, the ability to antagonize the effects of rocuronium rapidly with sugammadex may be an advantage. If rapid antagonism of rocuronium with sugammadex is part of the failed intubation plan, then the appropriate dose (16 mg/kg) must be readily available.

Nasotracheal intubation shares the problems and contraindications associated with the NPA. The technique usually is used when there are relative contraindications to the oral route (e.g., anatomic abnormalities, cervical spine instability). Nasotracheal intubation may be achieved under direct vision or (if spontaneously breathing) with the use of a blind technique, either with the patient under general anesthesia or in the awake or lightly sedated patient with appropriate local anesthesia (Box 2.4). If orotracheal or nasotracheal intubation is required but cannot be achieved, then a surgical airway is required (see later text).

With a need for isolation of one lung from another, a double-lumen tube (having one cuffed tracheal lumen and one cuffed bronchial lumen fused longitudinally) can be used.[21] The main indications are (1) to facilitate some pulmonary or thoracic surgical procedures; (2) to isolate a lung containing contaminated fluid (e.g., in lung abscess) or blood, thereby preventing contralateral spread; and (3) to enable differential or independent lung ventilation. Intermitted lung ventilation allows each lung to be treated separately—for example, to deliver positive-pressure ventilation with high positive end-expiratory pressure to one lung while applying low levels to the other. Such a strategy may be advantageous in cases of pulmonary air leak (bronchopleural fistula, bronchial tear, or severe lung trauma) or in severe unilateral lung disease requiring ventilatory support.[21,22]

• BOX 2.4 Procedure: Nasotracheal Intubation (Blind and Under Direct Vision)

Preparation and Assessment of the Patient

1. Use a nasal decongestant such as phenylephrine to reduce bleeding.
2. Provide local anesthesia to the nasal mucosa.
3. Examine each nostril for patency and deformity.
4. Choose the most patent nostril, and use an appropriate-size ET.
5. After induction of anesthesia, position the head and neck as for oral intubation.

Blind Nasotracheal Intubation

- Keep patient breathing spontaneously.
- Insert well-lubricated ET into the nostril (concavity forward, bevel lateral).
- While passing ET along nasal floor, listen for audible breathing through the tube.
- Advance ET, rotating as needed to maintain clear breath sounds.
- ET will pass through cords, and patient may cough.
- Technique takes time, so it is not suitable for a patient experiencing desaturation.
- Do not force passage of ET, because this could cause bleeding.

Nasotracheal Intubation (Direct Vision)

- Patient may be apneic with or without relaxants.
- Gently advance ET through the nose.
- When ET tip is in oropharynx, perform laryngoscopy.
- Visualize ET in pharynx and advance toward glottis.
- Advance ET through cords into trachea, under direct vision if possible.
- Use Magill forceps if required to guide tip while advancing ET.
- Try to avoid damaging cuff if using forceps to help passage through cords.

ET, *Endotracheal tube.*

Providing Ventilatory Support

If a patient has no (or inadequate) spontaneous ventilation, then a means of generating gas flow to the lower respiratory tract must be provided. Negative pressure, mimicking the actions of the respiratory muscles, occasionally is used in some patients who require long-term ventilation. In acute care, however, ventilation is achieved using positive pressure, which requires an unobstructed airway; in the nonintubated patient, this is best achieved by proper positioning, the triple airway maneuver, and use of an OPA or NPA. In a patient without an ET in place, particularly if some degree of airway obstruction exists, positive-pressure ventilation often causes gastric distention and (potentially) regurgitation and pulmonary aspiration.

Bag-Valve-Mask Ventilation

Ventilation with a mask requires an (almost) airtight fit between mask and face. This is best achieved by firmly pressing the mask against the patient's face using the thumb and index finger (C-grip) while pulling the mandible upward toward the mask with the other three fingers. The other hand is used to squeeze the reservoir bag, generating positive pressure. Excessive pressure from the C-grip on the mask may lead to backward movement of the mandible with subsequent airway obstruction, or a tilt of the mask with leakage of gas. If a proper seal is difficult to attain, placing a hand on each side of the mask and mandible is advised, with a second person manually compressing the reservoir bag (four-handed ventilation). Bag-valve-mask systems have a self-reinflating bag, which springs back after compression, thereby drawing gas in through a port with a one-way valve. It is important to have a large reservoir bag with a continuous flow of oxygen attached to this port to achieve a high inspired oxygen concentration.[23,24] Bag-valve-mask ventilation usually is a short-term measure in urgent situations or is used in preparation for tracheal intubation.

Prolonged Ventilation Using a Sealed Tube in the Trachea

Ventilation of the lungs with a bag-valve-mask arrangement is difficult and potentially dangerous if required for more than a few

minutes or if the patient needs to be transported. In these instances, ventilation through a sealed tube in the trachea is indicated. Orotracheal or nasotracheal intubation, surgical cricothyrotomy, and tracheostomy all achieve the same result: a cuffed tube in the trachea, allowing the use of positive-pressure ventilation and protecting the lungs from aspiration.

Apneic Oxygenation

Apneic oxygenation is achieved using a narrow catheter that sits in the trachea and carries a flow of 100% oxygen. The catheter may be passed into the trachea via an ET or under direct vision through the larynx. This apparatus can be set up as a low-flow open system (gas flow rate of 5 to 8 L/min) or as a high-pressure (jet ventilation) system[25] and can be used to maintain oxygenation with a difficult airway either at intubation or at extubation (see later text).

Physiologic Sequelae and Complications of Tracheal Intubation

Laryngoscopy is a noxious stimulus that, in an awake or lightly sedated patient, would provoke coughing, retching, or vomiting and laryngospasm. In clinical practice, however, laryngoscopy and tracheal intubation usually are performed after induction of anesthesia, and in emergency situations, the patient often is hypoxic and hypercarbic, with increased sympathetic nervous system activity. Thus the physiologic effects of laryngoscopy and tracheal intubation tend to be masked.

Laryngoscopy and intubation cause an increase in circulating catecholamines and increased sympathetic nervous system activity, leading to hypertension and tachycardia. This represents an increase in myocardial work and myocardial oxygen demand, which may provoke cardiac dysrhythmias and myocardial hypoxia or ischemia. Laryngoscopy increases cerebral blood flow and intracranial pressure—particularly in patients who are hypoxic or hypercarbic at the time of intubation.[26] This rise in intracranial pressure will be exaggerated if cerebral venous drainage is impeded by violent coughing, bucking, or breath-holding.

Coughing and laryngospasm occur frequently in patients undergoing laryngoscopy and intubation when muscle relaxation and anesthesia are inadequate. Increased bronchial smooth muscle tone, which increases airway resistance, may occur as a reflex response to laryngoscopy or may be due to the physical presence of the ET in the trachea; in its most severe form, termed bronchospasm, this increased tone causes audible wheeze and ventilatory difficulty.

The cross-sectional area of the ET is less than that of the airway and therefore causes increased resistance to gas flow. This difference usually is unimportant with positive-pressure ventilation but causes a significant increase in work of breathing in spontaneously breathing patients. Resistance is directly related to $1/r^4$ (where r is the radius of the ET) and will be minimized by use of a large-bore ET.

Laryngoscopy and intubation may cause bruising, abrasion, laceration, bleeding, or displacement or dislocation of the structures in and near the airway (e.g., lips, teeth or dental prostheses, tongue, epiglottis, vocal cords, laryngeal cartilages). Dislodged structures such as teeth or dentures may be aspirated, blocking the airway more distally. Less common complications include perforation of the airway with the potential for the development of a retropharyngeal abscess or mediastinitis. Over time, erosions resulting from pressure and ischemia may develop on the lips or tongue (or external nares and anterior nose in patients with a nasotracheal tube) and in the larynx or upper trachea. These lesions result in a breach of the mucosa with the potential for secondary infection. In the case of the lips and tongue, such lesions are (temporarily) disfiguring and painful and may inhibit attempts to talk or swallow.

The mucosa of the upper trachea (subglottic area) is subjected to the pressure of the cuff of the ET. This pressure reduces perfusion of the tracheal mucosa and, combined with the mechanical movement of the tube (from patient head movements, nursing procedures, or rhythmic flexion with action of the ventilator), tends to cause mucosal damage and increase the risk of superficial infection. These processes may lead to ulceration of the tracheal mucosa, fibrous scarring, contraction, and ultimately stenosis, which can be a life-limiting or life-threatening problem.

Any tube in the trachea has a significant effect on the mechanisms protecting the airway from aspiration and infection. The mucus escalator may be inhibited by mucosal injury and by the lack of warm humidified airflow over the respiratory epithelium.[27] The disruption of normal swallowing results in the pooling of saliva and other debris in the pharynx and larynx above the upper surface of the tube's inflatable cuff, which may become the source of respiratory infection if the secretions become colonized with microorganisms, or may pass beyond the cuff into the lower airways—that is, pulmonary aspiration (silent or overt).[28,29] The former may occur as a result of (1) colonization of the gastric secretions and the regurgitation of this material up the esophagus to the pharynx or (2) transmission of microorganisms from the health care environment to the pharynx via medical equipment or the hands of hospital staff or visitors (cross-infection).[29–32]

The presence of a tube traversing the larynx and sealing the trachea makes phonation impossible. The implications of this limitation for patients and their families often are ignored. If patients cannot tell caregivers about pain, nausea, or other concerns, they may become frustrated, agitated, or violent. This may result in the excessive use of sedative or psychoactive drugs, which prolong the time ventilation is used and the stay in the intensive care unit (ICU), with the risk of infection increased accordingly.[33] The inability to communicate may therefore be a real threat to patient survival. Potential solutions involve the use of letter and picture boards, "speaking valves" (with tracheostomy), laryngeal microphones, or computer-based communication packages. The involvement and innovations of disciplines such as the speech and language center may be advantageous.

The Difficult Airway

The difficult airway has been defined as "the clinical situation in which a conventionally trained anesthetist experiences difficulty with mask ventilation of the upper airway, tracheal intubation, or both."[34] It has been a commonly documented cause of adverse events, including airway injury, hypoxic brain injury, and death under anesthesia.[35–41] The frequency of difficulty with mask ventilation has been estimated to be between 1.4% and 7.8%,[42–44] whereas tracheal intubation using direct laryngoscopy is difficult in 1.5% to 8.5% and impossible in up to 0.5% of general anesthetics.[40,45] The incidence of failed intubation is approximately 1:2000 in the nonobstetric population and 1:300 in the obstetric population.[46] In the critical care unit, up to 20% of all critical incidents are airway related,[47–49] and such incidents may occur at intubation, at extubation, or during the course of treatment (as with the acutely displaced or obstructed ET or tracheostomy tube).

Recognizing the Potentially Difficult Airway

Many conditions are associated with airway difficulty (Table 2.2), including anatomic abnormalities, which may be associated with an unusual appearance, thereby alerting the examiner. The goal is to identify the potentially difficult airway and develop a plan to secure it. Factors including age older than 55 years, body mass index greater than 26 kg/m^2, presence of a beard, lack of teeth, and a history of snoring have been identified as independent variables predicting difficulty with mask ventilation—in turn associated with difficult tracheal intubation.[43,50]

Mallampati[51] developed a grading system (subsequently modified[46]) that predicted ease of tracheal intubation at direct laryngoscopy. The predictive value of the Mallampati system has been shown to be limited[52,53] because many factors that have no influence on the Mallampati classification—mobility of head and neck, mandibular or maxillary development, dentition, compliance of neck structures, and body shape—can influence laryngeal view.[35,48,54,55] A study of a complex system including some of these factors found the rate of difficult intubation to be 1.5%, but with a false-positive rate of 12%.[56] A risk index based on the Mallampati classification, a history of difficult intubation, and five other variables lacked sufficient sensitivity and specificity.[57] Airway management should be based on the fact that the difficult airway cannot be reliably predicted.[58,59] This is a particularly important consideration in the critical care environment.

TABLE 2.2 Conditions Associated With Difficult Airway

Causative Factors	Associated Conditions/Disorders
Abnormal anatomy/development	Small mouth or large tongue Dental abnormality Prognathia Obesity Advanced pregnancy Acromegaly Syndromic child[a]
Inability to open mouth	Masseter muscle spasm (dental abscess) Temporomandibular joint dysfunction Facial burns Postradiotherapy fibrosis Scleroderma
Cervical immobility/abnormality	Short neck/obesity Poor cervical mobility (e.g., ankylosing spondylitis) Previous cervical spine surgery Presence of cervical collar Postradiotherapy fibrosis
Pharyngeal or laryngeal abnormality	High or anterior larynx Deep vallecula: inability to reach base of epiglottis with blade of scope Anatomic abnormality of epiglottis or hypopharynx (e.g., tumor) Subglottic stenosis
Injury	Traumatic debris Obstructing foreign bodies Basilar skull fracture Bleeding into airway or adjacent swelling/hematoma Fractured maxilla/mandible Cervical spine instability (confirmed or potential) Laryngeal fracture or disruption
Infections	Epiglottitis Abscess Croup, bronchiolitis Laryngeal papillomatosis Tetanus/trismus
Connective tissue/inflammatory disorders	Rheumatoid arthritis: temporomandibular joint or cervical spine involvement, cricoarytenoid arthritis Ankylosing spondylitis Scleroderma Sarcoidosis
Endocrine disorders	Goiter: airway compression or deviation Hypothyroidism, acromegaly: large tongue

[a]For example, Klippel-Feil syndrome (limited neck extension); Beckwith-Weidemann syndrome (restricted TM joint mobility and large tongue); Pierre Robin Syndrome (limited submandibular space)

The Obstructed Airway

Although the most common reason for an obstructed airway in the unintubated patient is posterior displacement of the tongue in association with a depressed LOC, it is the less common causes that provide the greatest challenges. It is important to quickly elucidate the level at which the obstruction occurs and, if possible, the nature of the obstructing lesion: infection or edema (epiglottitis, pharyngeal or tonsillar abscess, mediastinal abscess), neoplasm (primary malignant or benign tumor, metastastic spread, direct extension from nearby structures), thyroid enlargement, vascular lesions, trauma, or foreign body or impacted food.

Airway lesions above the level of the vocal cords are considered to lie in the upper airway and commonly manifest with stridor.[60] If breathing is labored and associated with difficulty breathing at night, rather than just noisy breathing, then the narrowing probably is more than 50%. Patients with these lesions usually fall into one of two groups: (1) those who can be intubated, usually under inhalational induction, with an otorhinolaryngologist or other qualified surgeon/physician immediately available to perform rigid bronchoscopy or tracheostomy if required, or (2) those who require a tracheostomy performed while under local anesthesia. In patients with midtracheal obstruction, computed tomography imaging usually is necessary to discover the exact level and nature of the obstruction and to allow planning of airway management for nonemergency clinical presentations.[60] Tracheostomy often is not beneficial because the tube may not be long enough to bypass the obstruction. In such instances, fiberoptic intubation often may be useful. Lower tracheal obstruction often is due to space-occupying lesions in the mediastinum and necessitates multidisciplinary planning involving otorhinolaryngology, cardiothoracic surgery, anesthesia, and critical care team members.

Trauma and the Airway

Airway management in the trauma victim provides additional challenges because the victim often has other life-threatening conditions and preparation time for management of the difficult airway is limited. Approximately 15% of severely injured patients have maxillofacial involvement, and 5% to 10% of patients with blunt trauma have an associated cervical spine injury (often associated with head injury).[61]

Problems encountered in trauma patients include presence in the airway of debris or foreign bodies (e.g., teeth), vomitus, or regurgitated gastric contents; airway edema; tongue swelling; blood and bleeding; and fractures (maxilla and mandible). Patients must be assumed to have a full stomach (requiring bimanual cricoid pressure and a rapid-sequence induction for intubation), and many will have pulmonary aspiration before the airway is secured. An important consideration in most cases is the need to avoid movement of the cervical spine at laryngoscopy or intubation.[12,13] Direct injury to the larynx is rare but may result in laryngeal disruption, producing progressive hoarseness and subcutaneous emphysema. Tracheal intubation, if attempted, requires great care and skill because it may cause further laryngeal disruption. With Le Fort fractures, airway obstruction or compromised respiration requiring immediate airway control is present in 25% of cases.[62] Postoperative bleeding after operations to the neck (thyroid gland, carotid, larynx) may compress or displace the airway, leading to difficulty in intubation.

The Airway Practitioner and the Clinical Setting

Although airway difficulties often are due to anatomic factors as discussed, it is important to recognize that the inability to perform an airway maneuver also may be due to a practitioner's inexperience or lack of skill.[63–68] Expert opinion and clinical evidence also identify lack of skilled assistance as a factor in airway-related adverse events.[69–72] As might be expected, inexperience and lack of suitable help may contribute to failure in optimizing the conditions for laryngoscopy (Box 2.5). Airway and ventilatory management performed in the prehospital setting or in the hospital but outside an operating room (OR) carries a higher frequency of adverse events and a higher mortality rate compared with those performed using anesthesia in an OR.[73–77] In the critical care unit, all invasive airway maneuvers are potentially difficult.[78] Positioning is more difficult on an ICU bed than on an OR table. The airway structures may be edematous after previous laryngoscopy or presence of an ET. Neck immobility or the need to avoid movement in a potentially unstable cervical spine may be other contributing factors.[79–81] Poor gas exchange in ICU patients reduces the effectiveness of preoxygenation and increases the risk of significant hypoxia before the airway is secured.[82] Cardiovascular instability may produce hypotension or hypoperfusion, or it may lead to misleading oximetry readings (including failure to record any value at all), a further confounding factor for the attending staff.[83,84]

• BOX 2.5 Common Errors Compromising Successful Intubation

Poor patient positioning
Failure to ensure appropriate assistance
Faulty light source in laryngoscope or no alternative scope
Failure to use a longer blade in appropriate patients
Use of inappropriate tracheal tube (size or shape)
Lack of immediate availability of airway adjuncts

Managing the Difficult Airway

Management of the difficult airway can be considered in the framework of three possible clinical scenarios with progressively increasing risks for the patient: (1) the anticipated difficult airway; (2) the unanticipated difficult airway; and (3) the difficult airway resulting in a can't intubate–can't ventilate situation.

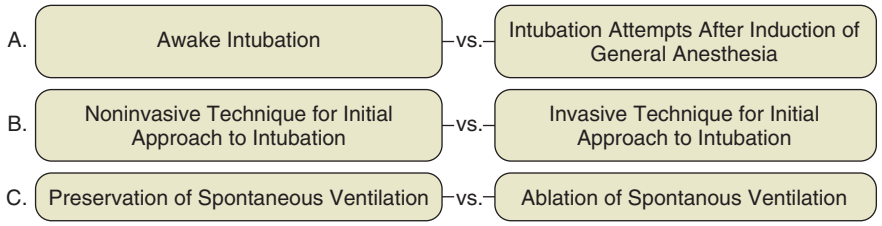
Requirements for clinicians involved in airway management include the following:

- Expertise in recognition and assessment of the potentially difficult airway. This involves the use of the assessment techniques noted previously and a "sixth sense."[58]
- The ability to formulate a plan (with alternatives).[34]
- Familiarity with algorithm(s) that outline a sequence of actions designed to maintain oxygenation, ventilation, and patient safety. The American Society of Anesthesiologists guidelines[34] and the composite plan from the Difficult Airway Society (DAS)[85] are shown in Figs. 2.3 through 2.5. Fig. 2.4 summarizes four airway plans (A–D), available from the DAS website (www.das.uk.com).
- The skills and experience to use a number of airway adjuncts, particularly those relevant to the unanticipated difficult airway.

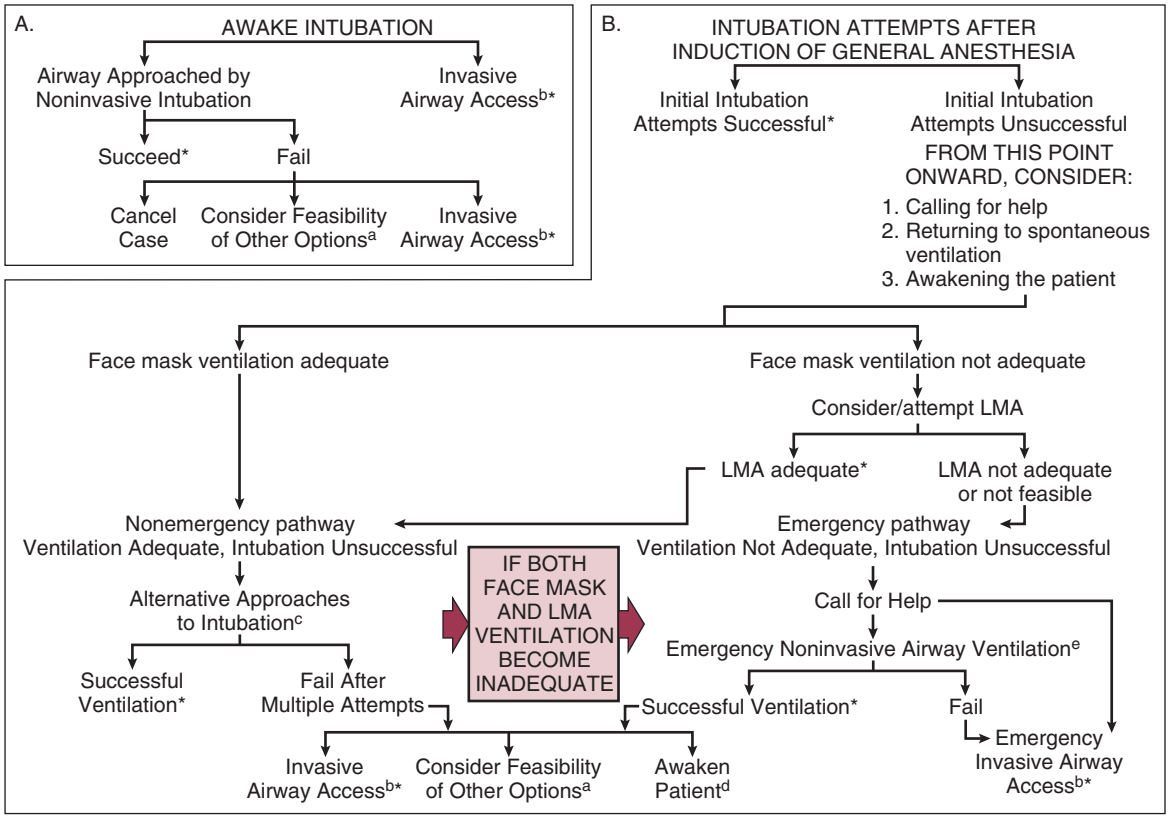
Basic preparation for management of a difficult airway includes (1) the availability of the correct equipment to hand the clinician, (2) informing the patient with a known or suspected difficult airway, (3) assigning an appropriately skilled individual to provide assistance during the procedure, (4) preanesthetic preoxygenation

DIFFICULT AIRWAY ALGORITHM

1. Assess the likehood and clinical impact of basic management problems:
   - Difficult ventilation
   - Difficult intubation
   - Difficulty with patient cooperation or consent
   - Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:



4. Develop primary and alternative strategies:



* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2.

[a] Other options include (but are not limited to) surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration, and regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

[b] Invasive airway access includes surgical or percutaneous tracheostomy and cricothyrotomy.

[c] Alternative noninvasive approaches to difficult intubation include (but are not limited to) use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

[d] Consider repreparation of the patient for awake intubation or canceling surgery.

[e] Options for emergency noninvasive airway ventilation include (but are not limited to) rigid bronchoscope, esophageal-tracheal Combitube ventilation, and transtracheal jet ventilation.

by mask, and (5) administration of supplemental oxygen throughout the process.

The Anticipated Difficult Airway

The anticipated difficult airway is the "least lethal" of the three scenarios—with time to consider strategy, optimize patient status, and obtain appropriate adjuncts and personnel. The key questions are as follows:

1. Should the patient be kept awake or be anesthetized for intubation?
2. Which technique should be used for intubation?

Awake Intubation

Awake intubation is more time-consuming, requires experienced personnel, is less pleasant for the patient (compared with intubation under anesthesia), and may have to be abandoned as a result of the patient's inability or unwillingness to cooperate. Because spontaneous breathing and pharyngeal/laryngeal muscle tone are maintained, however, it is significantly safer. The techniques available are fiberoptic and retrograde intubation. It also may be used in patients judged to be at risk for a difficult airway, whereupon an initial direct laryngoscopic view allows intubation.

Fiberoptic Intubation. Fiberoptic intubation is a technique in which a flexible endoscope with a tracheal tube loaded along its length is passed through the glottis. The tracheal tube is then pushed off the endoscope and into the trachea, and the endoscope is withdrawn. An informed patient, trained assistance, and adequate preparation time make fiberoptic intubation less stressful. The nasotracheal route is used most often and requires the use of nasal vasoconstrictors. Nebulized local anesthetic is delivered to the airway via face mask. Sedation may be given, but ideally the patient should

remain breathing spontaneously and responsive to verbal commands. The procedure often is time-consuming and tends to be used in elective situations[86] (Box 2.6).

Retrograde Intubation. For retrograde intubation,[87] local anesthesia is provided and the cricothyroid membrane is punctured by a needle through which a wire or catheter is passed upward through the vocal cords. The wire is visualized in the pharynx, brought out through the mouth, is used to guide the ET through the vocal cords, and then is withdrawn. This technique also can be used to guide a fiberoptic scope through the vocal cords. Owing to time constraints, it is not suitable for emergency airway access and is contraindicated in the presence of an expanding neck hematoma or coagulopathy.

Intubation Under Anesthesia

It may be decided, despite the safety advantage of awake intubation, to anesthetize the patient before attempted intubation. Preparation of the patient, equipment, and staff is paramount (Box 2.7). Adjuncts such as those described later should be available, either to improve the chances of intubation or to provide a safe alternative airway if intubation cannot be achieved.

Unanticipated Airway Difficulty

The DAS guidelines[85] focus on the unanticipated difficult airway, an unpredictable clinical problem. More focus is placed on the need to be prepared and accountable and to optimize conditions and reduce patient morbidity in this situation. Those involved in the airway management of critically ill individuals must be familiar with alternative airway devices and techniques, including when to perform emergency invasive airway access. The unanticipated difficult airway allows only a short period to solve the problem if significant hypoxemia, hypercarbia, and hemodynamic instability are to be avoided. The patient usually is anesthetized, may be apneic, and may have received muscle relaxants, and previous initial attempt(s) at intubation may have been unsuccessful. If appropriate equipment, assistance, and experience are not immediately at hand, little time is available to obtain them. Nevertheless, it is essential to maintain oxygenation and avoid hypercarbia if possible—commonly by mask ventilation with 100% oxygen. The four-handed technique often is used. Restoration of ventilation is the priority by either an SGA, an invasive intervention, or by wakening the patient if possible. The new DAS guidelines favor the use of second-generation SGAs as they have been designed to provide a better seal and reduce the risk of aspiration.

If the practitioner is inexperienced, if the patient has had no (or a relatively short-acting) muscle relaxant, and if ventilation is not a problem, it may be appropriate to let the patient recover consciousness. An awake intubation can then be planned either after a short period of recovery or on another occasion. With an experienced practitioner, it may be appropriate to continue using techniques to improve the chances of visualizing and intubating the larynx. As discussed next, various adjuncts may be useful in this situation and also in the anticipated difficult airway when it has been decided to intubate with the patient under anesthesia.

The U.K. Royal College of Anaesthetists Fourth National Audit Project (NAP4) provided significant insight into contemporary airway management by identifying several deficiencies that increase the risk of adverse outcomes relating to the airway in critically ill patients.[88] Failure to plan (ahead) appeared to be a common causative factor in a large number of poor airway outcomes. This was sometimes due to (1) poor assessment (no recognition that there was a potential problem needing a plan), (2) failure to plan even when potential problems were recognized, and (3) failure to have alternative plan(s) (in the event that "plan A" was not successful). Many poor outcomes are the result of repeated use of an approach that has already (sometimes repeatedly) failed. NAP4 revealed a number of scenarios or patient-related factors that seemed to predispose to poor airway outcomes. These predictors are summarized in Box 2.8.

• BOX 2.6 Indications for Fiberoptic Intubation

Anticipated difficult intubation
Avoidance of dental damage in high-risk patient
Direct laryngeal trauma
Other need for awake intubation

• BOX 2.7 Checklist for Anticipated Difficult Intubation of Patient Under General Anesthesia

- Prepare and assess the patient.
- Prepare and test the equipment.
- Ensure skilled assistance with knowledge of BURP/bimanual laryngoscopy.
- Have the following available:
  - A range of laryngoscopes including specialized blades and handles
  - Videolaryngoscope
  - A range of tracheal tubes lubricated and cuffs tested for patency (*women:* 7.0–7.5 mm in internal diameter; *men:* 7.5–9.0 mm in internal diameter)
  - Gum-elastic bougie or tracheal tube stylet
  - Supraglottic airways (LMA, ILMA)
  - Flexible fiberoptic intubation equipment
  - Equipment suitable for emergency invasive airway access
  - An exhaled carbon dioxide monitor
- Check battery and bulb function.
- Check functioning of suction devices.
- Use optimal patient position.
- Preoxygenation with 100% oxygen for 3 to 5 minutes if possible

BURP, B*ackward, upward, and rightward pressure.*

Strategies to Improve First-Attempt Success at Intubation in Critical Illness

Airway management in critically ill patients is high risk owing to both anatomic and physiologic characteristics that increase risk of complications, including aspiration, hypoxemia, hemodynamic compromise, hypoxic brain injury, and death.[89,90]

• BOX 2.8 Predictors for Poor Airway Outcomes

Use of a supraglottic airway (only) in patients with a recognized airway difficulty
Cases in which awake fiberoptic intubation was indicated, but not used
Failure to use capnography or failure to interpret capnography trace correctly
Airway maneuvers in obese patients, in the emergency department, or in the intensive care unit
Use of emergency cannula cricothyrotomy (60% failure rate)
Displacement of a tracheostomy tube
Events related to emergence, recovery, and extubation

Preoxygenation

The process of preoxygenation replaces the nitrogen-rich air in the alveoli with oxygen. Optimization of this may be suboptimal in critically ill patients who may have physiologic derangements, including high oxygen requirements, shunt physiology, and lack of cooperation, all of which may increase the possibility of hypoxemia. In addition to oxygen supplementation, 20-degree elevation of the head can improve preoxygenation and increase apnea time.[91] Noninvasive ventilation has also been used to improve preoxygenation before intubation in patients with obesity and shunt physiology.[92] A high-flow nasal cannula can provide humidified high-flow oxygen up to 70 L/min. It is being used increasingly in preoxygenation of patients and also in extubated patients.[93]

Bimanual Laryngoscopy

Application of pressure on the cricoid area or the upper anterior tracheal wall, or both, by the laryngoscopist (a technique sometimes termed bimanual laryngoscopy) may improve laryngeal view.[94,95] When the view is optimized by the laryngoscopist, an assistant maintains the pressure and thus the position of the larynx, freeing the hand of the laryngoscopist to perform the intubation. The use of "blind" cricoid pressure, or BURP (backward, upward, and rightward pressure), by an assistant may impair laryngeal visualization.[94,96,97] The use of cricoid pressure in the difficult intubation scenario has not been extensively studied and opinions remain divided on its effectiveness.

Stylet ("Introducer") and Gum Elastic Bougie

The *stylet* is a smooth, malleable metal or plastic rod that is placed inside an ET to adjust the curvature—typically into a J- or hockey-stick shape to allow the tip of the ET to be directed through a poorly visualized or unseen glottis. The stylet must not project beyond the end of the ET to avoid potential laceration or perforation of the airway.

The *gum elastic bougie* is a blunt-ended, malleable rod that during direct laryngoscopy may be passed through the poorly or nonvisualized larynx by putting a J-shaped bend at the tip and passing it blind in the midline upward beyond the base of the epiglottis. Then, keeping the laryngoscope in the same position in the pharynx, the ET can be "railroaded" over the bougie, which is then withdrawn. For many critical care practitioners, it is the first-choice adjunct in the difficult intubation situation.[95,98]

Different Laryngoscope or Blade

More than 50 types of curved and straight laryngoscope blades are available; the most commonly used is the curved Macintosh blade. Using specific blades in certain circumstances has been both encouraged and discouraged. In patients with a large lower jaw or "deep pharynx," the view at laryngoscopy is often improved significantly by using a size 4 Macintosh blade (rather than the more common adult size 3). This ensures the tip of the blade can reach the base of the vallecula to lift the epiglottis. Other blades, such as the McCoy, may be advantageous in specific situations.

Lighted Stylet

A lighted stylet (light wand) is a malleable fiberoptic light source that can be passed along the lumen of an ET to facilitate blind intubation by transillumination. It allows the tracheal lumen to be distinguished from the (more posterior) esophagus on the basis of the greater intensity of light visible through anterior soft tissues of the neck as the ET passes beyond the vocal cords.[99] In elective anesthesia, the intubation time and failure rate with light wand–assisted intubation were similar to those with direct laryngoscopy,[100] and in a large North American survey, the light wand was the preferred alternative airway device in the difficult intubation scenario.[101] A potential disadvantage is the need for low ambient light, which may not be desirable (or easily achieved) in a critical care setting.

Video Laryngoscopy

Guidelines for unanticipated difficult intubation emphasize the importance of the first attempt at laryngoscopy with the aim of plan A to maximize the likelihood of success at the first attempt or, failing that, to limit the duration and number of attempts at laryngoscopy. The role of video laryngoscopes in difficult intubation has been recognized by the DAS 2015 guidelines[85] and it is recommend that all anesthetists be trained in and have immediate access to them. Videolaryngoscopes provide a better view of the larynx than with a standard Macintosh blade (direct laryngoscopy).[102] The improved laryngeal view is a result of two factors: for videolaryngoscopes with Mactintosh-shaped blades, a camera on the distal end of the blade provides an increased field of view compared with direct laryngoscopy, whereas for videolaryngoscopes with extra curved blades, there is an increased capacity to "see around the corner" and gain a view normally beyond the standard Macintosh blade. They are proposed to have advantages as being less traumatic to the airways and having a higher rate of successful intubation when used as a rescue device if direct laryngoscopy fails.[103] They may be particularly useful in patients with cervical instability, either by providing a better glottic view or by a reduction in upper cervical movement during intubation.[104] However, an improved laryngeal view does not always equate to a successful intubation. Intubation time can also be prolonged with the videolaryngoscope, especially in inexperienced hands.[105]

Videolaryngoscopes may have training advantages—the trainer can observe the screen while the trainee performs a procedure and can help optimize blade position and advise the trainee in real time.

Fiberoptic Intubation

The fiberoptic bronchoscope can be used in the unanticipated difficult airway if it is readily available and the operator is skilled.[40,106,107] With an anesthetized patient, the technique may be more difficult. Loss of muscle tone tends to allow the epiglottis and tongue to fall back against the pharyngeal wall. This can be counteracted by lifting the mandible.

Cannot Intubate–Cannot Ventilate

A cannot intubate–cannot ventilate scenario is an uncommon but life-threatening situation best managed by adherence to an appropriate algorithm.[34,85] Fig. 2.5 presents a flow sheet summarizing the appropriate actions.[108]

All personnel involved will be pressured (and motivated) by the potential for severe injury to the patient. Efficient teamwork is more likely in an environment that is relatively calm. Although it may be difficult, shouting, impatience, anger, and panic should be avoided in such situations, whereas effective communication may be lifesaving (see "Human Factors").

Confirming Tube Position in the Trachea

A critical factor in the difficult airway scenario, potentially leading to death or brain injury, is failure to recognize misplacement of the ET. Attempted intubation of the trachea may result in esophageal

intubation. This alone is not life-threatening unless it goes unrecognized.[78] Thus confirmation of ET placement in the trachea is essential.

Visualizing the ET as it passes between the vocal cords into the trachea is the definitive means of assessing correct tube positioning. This may not always be possible, however, owing to poor visualization. In addition, the laryngoscopist may be reluctant to accept that the ET is not in the trachea. Several clinical observations support the presence of the ET in the trachea.

Chest wall movement with positive-pressure ventilation (manual or mechanical) is usual but may be absent in patients with chronic obstructive pulmonary disease, obesity, or decreased compliance (e.g., in severe bronchospasm). Although condensation of water vapor in the ET suggests that the expired gas is from the lungs, this also may occur with esophageal intubation. The *absence of water vapor* usually is indicative of esophageal intubation. *Auscultation of breath sounds* (in both axillae) supports correct tube positioning but is not absolute confirmation.[109] Apparent inequality of breath sounds heard in the axillae may suggest intubation of a bronchus by an ET that has passed beyond the carina. Of note, after emergency intubation and clinical confirmation of the ET in the trachea, 15% of ETs may still be inappropriately close to the carina.[110]

The use of capnography to detect $ETCO_2$ is the most reliable objective method of confirming tube position.[111] False-positive results may be obtained initially when exhaled gases enter the esophagus during mask ventilation[112] or (rarely) when the patient is generating carbon dioxide in the gastrointestinal tract (as with recent ingestion of carbonated beverages or bicarbonate-based antacids).[113] A false-negative result (ET in trachea but no carbon dioxide gas detected) may be obtained when pulmonary blood flow is minimal, as in cardiac arrest.[114] Visualizing the trachea or carina through a *fiberoptic bronchoscope,* which may be readily available in critical care, also will confirm correct placement of the ET.

Surgical Airway

The indication for a surgical airway is inability to intubate the trachea in a patient who requires it, and the techniques available are cricothyrotomy and tracheostomy.

Cricothyrotomy

Cricothryotomy may be performed as a percutaneous (needle) or open surgical procedure (Box 2.9). The indication for both these techniques is the cannot intubate–cannot ventilate situation. Although needle cricothyrotomy is an emergency airway procedure, the technique is similar to that for "mini-tracheostomy," which is performed electively. Unlike the other surgical airway techniques, a needle cricothyrotomy does *not* create a definitive airway. It will not allow excretion of carbon dioxide but will produce satisfactory oxygenation for 30 to 40 minutes. It can be viewed as a form of apneic ventilation (see later discussion). There are several methods of connecting the intravenous cannula to a gas delivery circuit with the facility to ventilate, using equipment and connections readily available in the hospital. The appropriate method thus should be thought out in advance with equipment available on the difficult airway trolley or bag. New commercial kits that come preassembled also are available.

A surgical cricothyrotomy allows a cuffed tube to be inserted through the cricothyroid membrane into the lower larynx or upper trachea. This allows positive-pressure ventilation for considerable periods and also protects against pulmonary aspiration.

• BOX 2.9 Procedure: Needle and Surgical Cricothyrotomy

The cricothyroid membrane is diamond-shaped and lies between the thyroid and the cricoid cartilages. Inject subdermal lidocaine and epinephrine (adrenaline) for local anesthesia.

Needle Cricothyrotomy

- Identify the cricothyroid membrane and the midline.
- Insert a 14-gauge intravenous cannula and syringe through the skin and membrane.
- Continuously apply negative pressure until air enters the syringe.
- Stop at this point and push the cannula off the needle into the trachea.
- The insertion of the cannula into the trachea allows apneic (low-pressure) ventilation or jet (high-pressure) ventilation.

Surgical Cricothyrotomy

- Make a 1.5-cm skin incision over the cricothyroid membrane.
- Incise the superficial fascia and subcutaneous fat.
- Divide the cricothyroid membrane (short blade, blunt forceps, or the handle of a scalpel often is used).
- Insert (size 6.0) cuffed tracheostomy tube through membrane between the thyroid and cricoid cartilages.

• BOX 2.10 Tracheostomy: Indications and Contraindications

Indications for Tracheostomy

Inability to maintain a patent airway
Suspected cervical spine instability (percutaneous technique only)
Prevention of damage to vocal cords and (possibly) subglottic stenosis
Abnormal anatomy (percutaneous only)
Upper airway obstruction
Requirement for tracheobronchial toilet with suctioning
Part of larger surgical procedure (e.g., laryngectomy)

Contraindications to Tracheostomy

Local inflammation
Bleeding disorder (relative)
Arterial bleeding in neck/upper thorax

Tracheostomy

A tracheostomy is an opening in the trachea—usually between the second and third tracheal rings or one space higher—that may be created surgically or made percutaneously.[115,116] The indications for and contraindications to tracheostomy are summarized in Box 2.10. Compared with long-term orotracheal or nasotracheal intubation, tracheostomy often contributes to a patient who is less agitated, requires less sedation, and who may be weaned from ventilation more easily.[33,117] This increased ability to wean is sometimes attributed to reduced anatomic dead space. The potential reduction in sedation after tracheostomy, however, is a much greater advantage to weaning than the small reduction in dead space. The benefits and complications of tracheostomy are listed in Box 2.11. Percutaneous tracheostomy is normally carried out by medical staff in the ICU (Box 2.12).

• BOX 2.11 Tracheostomy: Benefits and Complications

Benefits

Comfort
Reduced need for sedation
Improved weaning from ventilation
Improved ability to suction trachea
Prevention of ulceration of lips and tongue or healing of such ulcers
Reduced upper airway injury
Potential for speech and oral nutrition

Complications

Misplacement of tube
Primary hemorrhage
Pneumothorax or tension pneumothorax; hemothorax
Surgical emphysema
Infection
Late hemorrhage—erosion of innominate (or other) vessels
Tracheoesophageal fistula

• BOX 2.12 Procedure: Bronchoscopy-Assisted Percutaneous Tracheostomy

- Withdraw endotracheal tube until the cuff lies at or just below the cords.
- Pass a flexible bronchoscope down endotracheal tube to distal end.
- Make a 1.5- to 2-cm transverse incision at midpoint between cricoid cartilage and suprasternal notch.
- Strip away tissue down to pretracheal fascia using blunt dissection (forceps).
- Under direct vision, use a 14-gauge cannula to puncture anterior tracheal wall (in midline).
- Advance cannula into trachea, aspirate air, and insert Seldinger guidewire.
- Dilate around guidewire using dilator(s) or special forceps.
- Pass tracheostomy tube over guidewire into trachea.
- Pass bronchoscope through tracheostomy to check position.

Although no consensus exists on the definition of prolonged tracheal intubation, or when tracheostomy should be performed,[118] most ICUs convert the intubated airway to a tracheostomy after 1 to 3 weeks, with earlier tracheostomy increasingly favored in some patient subgroups.[119]

Conventional wisdom states that the procedure for tracheostomy is more complex and time-consuming than a surgical cricothyrotomy and should be performed only by a surgeon. Studies in the elective ICU situation suggest that cricothyrotomy is simpler and (at worst) has a similar complication rate.[120,121] Although needle cricothyrotomy has long been advocated as a lifesaving emergency intervention,[122] work suggests that surgical cricothyrotomy is the more advantageous procedure.[123] In patients with unfavorable anatomy, surgical cricothyrotomy is a viable alternative to elective tracheostomy.[120] Surgical cricothyrotomy has been viewed as a temporary airway that should be converted to tracheostomy within a few days, but it may be used successfully as a definitive (medium-term) airway,[124,125] thereby avoiding conversion from cricothyrotomy to tracheostomy, which can cause significant morbidity.[126,127]

Extubation in the Difficult Airway Patient (Decannulation)

The patient with a difficult airway still poses a problem at extubation, because reintubation (if required) may be even more difficult than the original procedure. Between 4% and 12% of surgical ICU patients require reintubation[128] and may be hypoxic, distressed, and uncooperative at the time of reintubation. The presence of multiple risk factors for difficult intubation,[81] as well as acute factors such as airway edema and pharyngeal blood and secretions, makes reestablishing the airway in such patients challenging. Before extubation of any critical care patient, the critical care team should have formulated a strategy that includes a credible plan for reintubation.

Tube Displacement in the Critical Care Unit

Endotracheal Tube

ET displacement in the ICU is a life-threatening emergency that may result in significant morbidity.[129] Although tube dislodgment sometimes is viewed as unavoidable, often preventable factors are involved.[130–132] Changes in patient posture or head position cause significant movement of the tube within the trachea.[133] The frequency of tube displacement can be reduced by good medical and nursing practice,[134] attention to the arrangements and ergonomics around the bed, achieving appropriate sedation levels, and ensuring adequate ICU nurse staffing.[135,136] Experience and the ability to anticipate possible glitches constitute an important part of prevention. The management of ET displacement starts with an assessment of whether the patient can manage without the ET.[132] If replacement is required, preparations for a potentially difficult reintubation are indicated.

Tracheostomy Tube

Adverse events with tracheostomy tubes are quite common.[132,137] Displacement may be a life-threatening event,[138] especially if the tube has been in place less than 5 to 7 days (before a well-defined tract between skin and trachea is formed) or if the procedure has been performed percutaneously (so that the external opening of the tract may not easily admit a new tube of the same size). The option to leave the patient without a tube should be considered, and if this option is pursued, the tracheostomy opening should be dressed to make it (to some degree) "airtight"—thus facilitating effective coughing. If the patient needs a tube but replacing the tracheostomy is not possible, then oral reintubation should be performed, after which the tracheostomy should be dressed. With a more mature tracheostomy (>7 days old), it usually is possible to insert a new tube through the mature tract between skin and trachea.

Tracheostomy tubes may be displaced from the lumen of the trachea but appear to be normal when viewed externally. Difficulty with breathing, ventilation, or tracheal suctioning or the presence of a pneumothorax, pneumomediastinum, or surgical emphysema may be due to tracheostomy tube displacement. Fiberoptic assessment of the tube position and patency may be very useful. Assessing tracheostomy tube position on the chest x-ray film is of no value.

Human Factors

Many challenging airway scenarios are predictable and are successfully managed using a plan drawn up by the clinician(s) involved.

Sometimes, however, the problem is unrecognized until the situation is potentially life-threatening, or the airway management plan does not deliver the expected outcome/solution. In such crises, a successful outcome depends not only on the knowledge and skill of the clinicians but also on the human factors influencing the entire clinical team.

Human factors (sometimes termed *ergonomics*) is the scientific discipline concerned with understanding the interactions of humans, environment, and other elements of a system. We can enhance clinical performance through an understanding of the effects of teamwork, tasks, equipment, workspace, culture, and organization on human behavior and abilities and applying that knowledge in clinical settings.[139] The outcome of all emergency situations may be influenced significantly by the behaviors of the entire team with success depending on factors such as situational awareness, authority gradient, and (avoiding) cognitive overload. The well-documented case of Elaine Bromiley[140,141] shows how unfavorable human factors can lead to a bad outcome despite the presence of well-trained, highly motivated, and caring professionals. Successful management of all challenging clinical problems, including the difficult airway, starts by building a team culture of openness, mutual respect, and collective leadership. Although this takes time, failure to do so will result in a team that is unlikely to perform at its best under pressure.

Common Problems in Airway Management

• PROBLEM 2.1 Ineffective (Spontaneous) Breathing Despite Artificial Airway

Underlying Causes

1. Obstructed airway
2. Depressed respiratory drive (influence of drugs)
3. Inefficient respiratory effort (e.g., from fractured ribs or diaphragmatic injury)
4. Pulmonary pathologic process (pneumonitis, contusion, collapse, consolidation)

Action

Attempt to deliver 100% oxygen. Check airway. When airway obstruction has been corrected or ruled out, the patient's respiratory status should improve unless another underlying pathologic process is present. If no improvement is obtained, manually ventilate the patient. If the respiratory status still fails to improve, proceed to tracheal intubation with manual or mechanical ventilation. Investigate and treat any underlying condition.

• PROBLEM 2.2 Ineffective Manual Ventilation Despite Artificial Airway

Potential Causes

1. Obstructed airway
2. Poor seal or poor technique with mask or manual ventilation
3. Pulmonary pathologic process (pneumonitis, contusion, collapse, consolidation)

Action

Attempt to deliver 100% oxygen at 15–20 L/min. Check and readjust airway and patient head position. When airway obstruction has been corrected or ruled out, use a two-handed approach for mask and airway with an assistant squeezing the bag. If no improvement is obtained, check for availability of someone with more airway experience. If no such person is available, proceed to tracheal intubation with manual or mechanical ventilation. Investigate and treat any underlying condition.

• PROBLEM 2.3 Unilateral Chest Movements in the Intubated Ventilated Patient

Potential Causes

1. Bronchial intubation
2. Bronchial obstruction
3. Lung collapse, pneumothorax
4. Hemothorax, pleural effusion
5. Consolidation, absent lung (pneumonectomy)

Action

If bronchial intubation is suspected, deflate the tracheal tube cuff and slowly withdraw the tube 1–2 cm. Reinflate the cuff, and manually ventilate the patient while auscultating both sides of the chest. Is air entry present and equal on both sides? Be suspicious if the tube has to be withdrawn more than 3–4 cm or if the tube length at the teeth is much less than the expected correct length; another underlying cause may be involved. In an adult, the average distance from the vocal cords to the carina is 12 cm. The tip of a size 8.0 (adult) tracheal tube typically is 6.5 cm below the upper surface of the balloon, which must sit below the vocal cords. Therefore if the upper surface of a cuff is only 3 cm below the vocal cords, the tip will be within 2–3 cm of the carina. It is easy to inadvertently intubate a bronchus or leave the tip of the tube close enough to enter the bronchus with head movement or when moving the patient. In adults with normal bronchial anatomy, the tube tip usually will pass into the right main bronchus.

• PROBLEM 2.4 Sudden Airway or Ventilatory Compromise in Ventilated Patient With Orotracheal Tube

A ventilated patient with an orotracheal tube in place may suddenly develop dyspnea, hypoxemia, hypercarbia, and a seesaw respiratory pattern. The mechanical ventilator alarm will sound.

Potential Causes

1. Failure of oxygen or air supply to the ventilator
2. Ventilator disconnection or obstruction in ventilator circuit
3. Obstructed tracheal tube
   - Plugged by mucus or clot
   - Kink in tracheal tube
   - Biting on tube (previous biting may have narrowed the tube)
   - Obstruction of tube tip by side wall of lower airways or carina
4. Patient's fighting against ventilator
5. Respiratory fatigue (e.g., with weaning from mechanical support or new infection)
6. Pneumothorax or tension pneumothorax
7. Rapid development of large hemothorax or pleural effusion

Action

Disconnect the patient from the ventilator and ventilate through the tracheal tube manually. Have the ventilator and circuit checked by another appropriate staff member. High resistance or inability to inflate the lungs suggests tube obstruction or an intrathoracic problem. The (recent) inability to pass a suction catheter down the lumen is suggestive of tube obstruction. If the patient's condition is stable or improving, a small fiberoptic bronchoscope or laryngoscope (if readily available) may be passed down the tube. An obstruction may be removed by suction catheter, or removal of the tube and use of mask ventilation (to reverse hypoxemia and hypercarbia) followed by reintubation, may be required. If no answer to the problem is found, consider whether the patient's condition could be due to a tension pneumothorax. If appropriate, use needle decompression. Otherwise, order an emergency chest film and continue either manual or mechanical ventilation as appropriate.

• PROBLEM 2.5 Sudden Airway or Ventilatory Compromise in Ventilated Patient With Tracheostomy

A ventilated patient with a tracheostomy may suddenly develop dyspnea, hypoxemia, hypercarbia, and a seesaw respiratory pattern. The mechanical ventilator alarm will sound.

Potential Causes

Causes may include all those listed for Problem 2.4.

Action

Appropriate interventions are the same as for Problem 2.4, with an appreciation of the fact that tracheostomy tubes are shorter, more curved, and more rigid than tracheal tubes. They rarely kink but may become blocked with secretions or blood.[31,178] Suctioning the tube may resolve this. Double-skinned tracheostomy tubes may be unblocked by removing the inner tube (containing the obstruction) for washing, leaving the outer tube in place to maintain a clear airway. Such double-skinned tubes are safer for patients discharged to general wards. Tracheostomy tubes also may become obstructed when the distal opening is blocked by a mucosal flap, the side wall of the trachea, or (rarely) the carina.

Key Points

- The difficult airway may be unanticipated despite expert preassessment. All critical care physicians should be familiar with unanticipated difficult intubation guidelines.
- Use of the appropriate size and type of laryngoscope blade in conjunction with other adjuncts and techniques is an important element of successful tracheal intubation—particularly with the unanticipated difficult airway.
- Airway difficulty in critical care is common and may be precipitated long after intubation by acute events such as tube dislodgment or obstruction.
- Tube dislodgment in critical care is potentially avoidable and may be influenced by staffing levels, sedation policy, and other bedside factors.
- Surgical cricothyrotomy is a relatively simple procedure and may be used to establish a medium-term airway, avoiding the need for tracheostomy.
- In critical care, removal of a tracheal tube may precipitate an acute difficult airway scenario. A protocol for handling a difficult reintubation should always be in place.
- Knowledge and application of human factors are an important element of managing the difficult airway.

Review Questions

1. A 36-year-old female is admitted via the emergency department with a severe headache and altered level of consciousness. On your arrival, she vomits, becomes obtunded, and is unable to protect her airway. Which one of the following statements is most correct?

a. Removal of vomit can only be performed using a flexible suction catheter via the nose and nasopharynx.
b. The triple airway maneuver is the most appropriate airway intervention if there are concerns regarding the stability of the cervical spine.
c. A finger sweep of the pharynx can be useful in clearing the airway in a patient with an intact gag.
d. The triple airway maneuver consists of head tilt/neck extension, jaw thrust/pulling mandible forward and opening the mouth

Answer: d. Vomitus can be removed using a rigid suction catheter and a laryngoscope if required. The triple airway maneuver should *not* be used if there are concerns regarding cervical instability, and an approach that maintains in-line immobilization approach should be used. A finger sweep is recommended only in patients with an impaired gag reflex. The triple airway maneuver can be beneficial in the early management of the airway in an obtunded patient.

2. Which one of the following is *not* a contraindication to an oropharyngeal airway?

a. Airway swelling
b. Vomiting
c. Fracture of the base of skull
d. Inhalation injury

Answer: c. Contraindication to an oropharyngeal airway includes inability to tolerate, which includes vomiting and any cause of airway swelling. Fracture of the base of skull is a contraindication to a *naso*pharyngeal airway (see Box 2.1).

3. It is decided that tracheal intubation is required as the patient's condition continues to deteriorate. Initial laryngoscopy views are suboptimal. Which of the following statements is most correct?

a. Neuromuscular blockade may be detrimental.
b. Appropriate oxygenation and anesthesia must be maintained.
c. Four attempts at direct laryngoscopy should be attempted.
d. A bougie is contraindicated in the difficult airway.

Answer: b. Appropriate oxygenation and anesthesia are vital in the management of an unanticipated difficult tracheal intubation. Lack of full neuromuscular blockade may be a cause of suboptimal view at laryngoscopy. Three attempts at direct laryngoscopy are recommended according to the Difficult Airway Society guidelines. A bougie can be a helpful tool in these circumstances (see Fig. 2.5).

4. An endotracheal tube is inserted. What method is best routinely to ascertain that the tube is in the correct position?

a. Chest wall movement with positive-pressure ventilation
b. End-tidal carbon dioxide ($ETCO_2$) monitoring
c. Visible condensation in the endotracheal tube
d. Auscultation of breath sounds bilaterally

Answer: b. $ETCO_2$ monitoring is the most objective reliable way of confirming tube positon. Bronchoscopy via the tracheal tube can be used but is not always available and may be time-consuming. Chest wall movement with positive-pressure ventilation is not reliable in certain lung conditions, including pneumothorax. There may be no condensation in the endotracheal tube even if appropriately placed. Breath sounds may be diminished with a pleural effusion, collapse, or pneumothorax.

Assessment of Cardiac Filling and Blood Flow

MARTIN GEISEN, MAURIZIO CECCONI, AND ANDREW RHODES

CHAPTER OUTLINE

Cardiac Filling
- Preload
- Contractility
- Afterload
- Clinical Limitations of Systemic Vascular Resistance and Pulmonary Vascular Resistance
- Clinical Interpretation of Indicators of Preload

Hemodynamic Status and Blood Flow
- Measurement of Cardiac Output
- Assessment of Adequacy of the Circulation

Conclusions

The accurate assessment and manipulation of the circulation are important parts of the management of critically ill patients. The principal objective of cardiorespiratory manipulation is to ensure optimal oxygen delivery. Adequate cellular respiration, adequate delivery of substrates and pharmaceuticals, and improved organ function is possible only when this has been achieved. This chapter deals with the physiologic principles governing the cardiovascular system and discusses interpretation of hemodynamic data in a clinical context. With the increasing number of medical devices available to monitor the circulation, this chapter also outlines the principles underlying the design and function of these devices, as well as their uses and limitations (Tables 3.1–3.4).

Cardiac Filling

One of the fundamental concepts in optimizing the circulation of a critically ill patient is the manipulation of cardiac output as a major determinant of blood flow and oxygen delivery. Cardiac output is defined as the product of stroke volume (SV) and heart rate (HR). Although options to control HR are limited, clinical studies have largely focused on interventions to increase SV. The SV of the heart is determined by the complex interaction of three components: preload, contractility, and afterload. A thorough understanding of the physiology and pathophysiologic principles that define these components is essential for the clinician to successfully control and improve cardiovascular dynamics.

Our current understanding of the relationship between preload and contractility and their effect on SV is based on the experiments of Dario Maestrini, Otto Frank, and Ernest Starling, culminating in Starling's "law of the heart," which states that the force of myocardial contraction is directly proportional to the end-diastolic myocardial fiber length (or "preload"), as determined by the ventricular end-diastolic volume (EDV).[1,2] It is this relationship, commonly known as the Frank-Starling mechanism, that matches venous return to cardiac output (Fig. 3.1).

The most common intervention used by clinicians to improve SV—the administration of fluids—is aimed at increasing venous return as a main determinant of EDV. In this regard, two factors are important to consider: the position of an individual heart on the Frank-Starling curve and the expected response to fluid administration, as well as giving the right amount of fluid in an appropriate time frame to achieve a hemodynamic response. The dynamics of venous return have been extensively described by Arthur Guyton, whose theories contribute to our current understanding of the circulation and may help to optimize venous return.[3,4]

Preload

Based on Ernest Starling's observations, preload is defined as the tension developed by the stretch of the myocardial fibers. An increase in venous return leads to an increase in EDV, which in turn increases myocardial sarcomere length, resulting in an increase of contractility and a rise in SV and cardiac output. Conversely, a decrease in venous return will reduce EDV, resulting in a decreased SV and cardiac output. This mechanism matches the mechanical activity of both ventricles under changing physiologic conditions and functions independent of nervous supply to the flow of blood back to the heart from the venous system (venous return).

Preload is determined by the following factors:

- Circulating blood volume
- Venous capacitance (i.e., sympathetic stimulation resulting in venoconstriction, mechanical compression)
- Posture: The Trendelenburg position (supine, head down) increases venous return. Clinically, a passive leg-raising test may be performed to assess volume responsiveness by autotransfusion of approximately 300 mL of blood from the splanchnic and lower limb compartments to the central circulation, increasing preload.
- Intracavitary pressures: Abdominal hypertension and increased intrathoracic pressures (i.e., during positive-pressure ventilation

TABLE 3.1 Primary Measured Hemodynamic Data

Parameter/Formula	Normal Range
Arterial blood pressure (BP)	
Systolic (SBP)	90–140 mm Hg
Diastolic (DBP)	60–90 mm Hg
Mean arterial pressure (MAP): [SBP + (2 × DBP)]/3	70–105 mm Hg
Right atrial pressure (RAP)	2–6 mm Hg
Right ventricular pressure (RVP)	
Systolic (RVSP)	15–25 mm Hg
Diastolic (RVDP)	0–8 mm Hg
Pulmonary artery pressure (PAP)	
Systolic (PASP)	15–25 mm Hg
Diastolic (PADP)	8–15 mm Hg
Mean pulmonary artery pressure (MPAP): [PASP + (2 × PADP)]/3	10–20 mm Hg
Pulmonary artery occlusion pressure (PAOP)	6–12 mm Hg
Left atrial pressure (LAP)	6–12 mm Hg
Cardiac output (CO): HR × SV/1000	4.0–8.0 L/min

HR, Heart rate; *SV,* stroke volume.

TABLE 3.2 Derived Hemodynamic Data

Derived Parameter/Formula	Normal Range
Cardiac index (CI): CO/BSA	2.5–4.0 L/min per m^2
Stroke volume (SV): CO/HR × 1000	60–100 mL/beat
Stroke volume index (SVI): CI/HR × 1000	33–47 mL/m^2 per beat
Systemic vascular resistance (SVR): 80 × (MAP – RAP)/CO	1000–1500 dyne • s/cm^5
Systemic vascular resistance index (SVRI): 80 × (MAP – RAP)/CI	1970–2390 dyne • s/cm^5 per m^2
Pulmonary vascular resistance (PVR): 80 × (MPAP – PAOP)/CO	<250 dyne • s/cm^5
Pulmonary vascular resistance index (PVRI): 80 × (MPAP – PAOP)/CI	255–85 dyne • s/cm^5 per m^2

BSA, Body surface area; *CO,* cardiac output; *HR,* heart rate; *MAP,* mean arterial pressure; *MPAP,* mean pulmonary artery pressure; *RAP,* right atrial pressure; *PAOP,* pulmonary artery occlusion pressure.

TABLE 3.3 Hemodynamic Parameters: Adults

Parameter/Formula	Normal Range
Left ventricular stroke work (LVSW): SV × (MAP – PAOP) × 0.0136	58–104 g-m/beat
Left ventricular stroke work index (LVSWI): SVI × (AP – PAOP) × 0.0136	50–62 g-m/m^2 per beat
Right ventricular stroke work (RVSW): SV × (MPAP – RAP) × 0.0136	8–16 g-m/beat
Right ventricular stroke work index (RVSWI): SVI × (MPAP – RAP) × 0.0136	5–10 g-m/m^2 per beat
Coronary artery perfusion pressure (CPP): Diastolic BP – PAOP	60–80 mm Hg
Right ventricular end-diastolic volume (RVEDV): SV/EF	100-160 mL
Right ventricular end-systolic volume (RVESV): EDV – SV	50–100 mL
Right ventricular ejection-fraction (RVEF): SV/EDV	40%–60%

BP, Blood pressure; *EDV,* end-diastolic volume; *EF,* ejection fraction; *MAP,* mean arterial pressure; *MPAP,* mean pulmonary artery pressure; *PAOP,* pulmonary artery occlusion pressure; *RAP,* right atrial pressure; *SV,* stroke volume; *SVI,* stroke volume index.

and application of positive end-expiratory pressure [PEEP]) can oppose venous return.
- Ventricular compliance: Ventricular compliance determines the relationship between EDV and end-diastolic pressure (i.e., diastolic dysfunction or impaired relaxation as in ventricular hypertrophy).
- HR: The filling time influences EDV.
- Atrial contraction: Atrial contraction contributes to EDV and may be impaired (i.e., in atrial fibrillation).

Indicators of Preload

In vivo measurement of sarcomere length is not possible. To assess this variable in the clinical setting, ventricular end-diastolic pressures have been traditionally used as surrogate parameters to estimate EDV. Although EDV can be assessed by echocardiography, continuous monitoring of this parameter is usually not possible. Static indices of preload include traditional parameters assessing filling pressures or volumes as well as parameters derived from techniques based on thermodilution (see later text), which have been classified as volumetric indices of preload. In addition, parameters based on the cyclic changes in intrathoracic pressure during mechanical ventilation have been described as estimates of preload responsiveness under certain circumstances, although they do not measure preload per se. These dynamic indices of preload can play a role in predicting an increase of SV after an increase of preload, or in other words, the "fluid responsiveness" of the ventricle.

Static Indicators of Preload

These parameters give an estimate of preload, but their ability to predict a response to fluid administration is limited. Static preload indices have been defined for both sides of the heart:

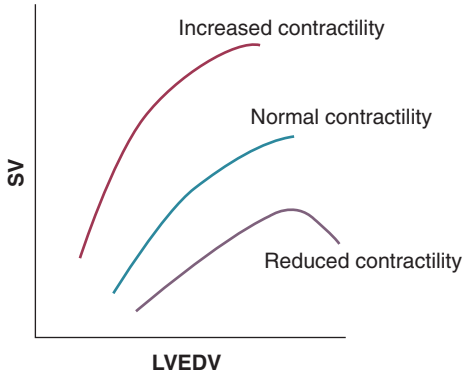
Static indices of the left side of the heart:
- Left ventricular end-diastolic volume (LVEDV)
- Left ventricular end-diastolic pressure (LVEDP)
- Left atrial pressure (LAP)
- Pulmonary artery occlusion or "wedge" pressure (PAOP or PAWP)

Static indices of the right side of the heart:
- Right ventricular end-diastolic volume (RVEDV)
- Right ventricular end-diastolic pressure (RVEDP)
- Right atrial pressure (RAP)
- Central venous pressure

TABLE 3.4 Oxygenation Parameters: Adults

Parameter/Formula	Normal Range
Partial pressure of arterial oxygen (Pao_2)	80–100 mm Hg
Partial pressure of arterial carbon dioxide ($Paco_2$)	35–45 mm Hg
Bicarbonate (HCO_3^-)	22–28 mEq/L
pH	7.38–7.42
Arterial oxygen saturation (Sao_2)	95%–100%
Mixed venous oxygen saturation (Svo_2)	60%–80%
Arterial oxygen content (Cao_2): (0.0138 × Hb × Sao_2) + (0.0031 × Pao_2)	17–20 mL/dL
Venous oxygen content (Cvo_2): (0.0138 × Hb × Svo_2) + (0.0031 × Pvo_2)	12–15 mL/dL
Arteriovenous oxygen content difference [$C(a-v)o_2$]: $Cao_2 - Cvo_2$	4–6 mL/dL
Oxygen delivery (Do_2): $Cao_2 \times CO \times 10$	950–1150 mL/min
Oxygen delivery index (Do_2I): $Cao_2 \times CI \times 10$	500–600 mL/min per m^2
Oxygen consumption (Vo_2): $C(a-v)o_2 \times CO \times 10$	200–250 mL/min per m^2
Oxygen consumption index (Vo_2I): $C(a-v)o_2 \times CI \times 10$	120–160 mL/min per m^2
Oxygen extraction ratio (O_2ER): [($Cao_2 - Cvo_2$)/Cao_2] × 100	22%–30%
Oxygen extraction index (O_2EI): [($Sao_2 - Svo_2$)/Sao_2] × 100	20%–25%

CI, Cardiac index; *CO,* cardiac output; *Cvo_2,* mixed venous oxygen content; output; *Hb,* hemoglobin.



• **Fig. 3.1** Graph demonstrating the Frank-Starling principle: the effect of preload on stroke volume in three different myocardial contractility states. *LVEDV,* Left ventricular end-diastolic volume; *SV,* stroke volume.

It is generally postulated that EDVs correspond to myocardial sarcomere length just before ventricular contraction and that end-diastolic pressures correspond with EDVs.

For the left side of the heart these relationships are as follows:

$$PAOP = LAP = LVEDP \approx LVEDV$$

For the right side of the heart these relationships are as follows:

$$CVP = RAP = RVEDP \approx RVEDV$$

It is important to note that these assumptions do not hold true in most clinical conditions and all parameters are influenced by physiologic and technologic factors. Ventricular pressures and volumes are both influenced by ventricular compliance, so there is only a poor relationship between the two, and the traditional assumption that CVP, RAP, PAOP, and LAP estimate LVEDP as an indicator of LVEDV is usually not valid. PAOP reflects left ventricular function only if the vascular system between the catheter tip and the left ventricle is free from any pathologic condition that could influence the pressures detected by the catheter.

PAOP *overestimates* LVEDP in the following conditions:

- Chronic mitral stenosis
- PEEP
- Left atrial myxoma
- Pulmonary hypertension

PAOP *underestimates* LVEDP in the following conditions:

- Poorly compliant left ventricle
- LVEDP greater than 25 mm Hg

PAOP readings are accurate only if the tip of the pulmonary artery catheter (PAC) is appropriately wedged in West lung zone 3, corresponding to the lower third of the lung where continuous blood flow can be assumed.

The PAOP does not predict preload and bears little or no relationship to the subsequent response to a volume challenge. It is important to realize, however, that pressure is one of the driving forces responsible for edema formation in the lungs. In this regard, the PAOP may function as more of a safety limit rather than as a guide to therapy.[5]

The CVP reflects RAP and has been traditionally used as a marker of right ventricular preload and, assuming a relationship among CVP, RVEDP, and RVEDV, of left ventricular preload. However, CVP does not accurately reflect left ventricular preload and has been shown to correlate poorly with blood volume. The main clinical value of measuring CVP is to provide information about the right side of the heart, as in cases of right ventricular failure or in assessing the right ventricular response to pulmonary hypertension. A low CVP in the setting of clinical signs of tissue hypoperfusion may be predictive of a benefit from fluid administration, and a rapid significant rise of CVP during a fluid challenge may indicate that the heart is not fluid responsive.[6]

Volumetric Indicators of Preload

Based on cardiac output measurements using thermodilution and incorporating indicator passage times, volumetric preload parameters have been introduced as an alternative to conventional "static" parameters and have become available with thermodilution-based monitoring techniques marketed by a number of companies. The continuous end-diastolic volume index is a surrogate of RVEDV. Global end-diastolic volume index, intrathoracic blood volume index, and extravascular lung water index are parameters provided by devices that require transpulmonary thermodilution for the measurement of cardiac output based on pulse pressure analysis. The global end-diastolic volume index represents the total intracardiac volume, and the volume of the descending aorta has been shown to be a better indicator of preload than CVP.[7]

Dynamic Indicators of Preload (or Preload Responsiveness)

Based on the study of heart-lung interactions a number of so-called dynamic preload indicators have been described. Although these

parameters are not measures of preload per se, they play an important role in the prediction of the hemodynamic response (i.e., by an increased cardiac output) to an increase in preload (preload or "volume" responsiveness). Generally, these parameters are based on the observation that transient changes in preload occur during mechanical ventilation.[8,9]

Stroke Volume Variation

During mechanical ventilation each positive-pressure breath induces a decrease in venous return. In conditions of decreased volume status, when the right ventricle is responsive to an increase in preload, a reduction in right ventricular outflow will occur and result in a decrease of left ventricular preload after the number of cardiac cycles it takes to pump blood through the lung (pulmonary transit time). If the left ventricle is preload responsive as well, a transient decrease in SV will occur. This cyclic variation in SV (stroke volume variation, SVV) can indicate volume responsiveness if it reaches a certain degree and may describe the response to a volume challenge in relation to changes in cardiac output.

Pulse Pressure Variation

Similar to SVV, a marked respiratory variation of the arterial pulse pressure (pulse pressure variation, PPV) has been found to accurately predict volume responsiveness.

SVV, PPV, and systolic pressure variation (SPV) can be automatically calculated by an array of cardiac output monitors.

Plethysmographic Variability Index

The pulse oximeter plethysmographic waveform has been shown to display respiratory variations during mechanical ventilation, which can be predictive of volume responsiveness. Calculation of the plethysmographic variability index (PVI) is performed by measuring changes of the perfusion index (PI = pulsatile infrared signal/nonpulsatile infrared signal × 100) over at least one respiratory cycle.[9]

Indices Derived by Echocardiography

Finally, respiratory variations of the inferior vena cava diameter as measured by transthoracic echocardiography or the superior vena cava (SVC) diameter as measured by transesophageal echocardiography (TEE) have been shown to accurately predict volume responsiveness.

It is important to note that these variables are reliable only during controlled mechanical ventilation. Other conditions in which the use of these parameters cannot be advised are as follows:

- Cardiac arrhythmias
- Application of low tidal volumes (i.e., <8 mL/kg)
- Open chest conditions
- Right ventricular failure

Contractility

Ventricular contractility, or inotropy, describes the strength of ventricular contraction. It is defined as the tension developed by myocardial fibers at a given preload and afterload and the velocity of the shortening of the myocardial sarcomeres. It represents the intrinsic ability of the myocardium to generate a force independent of filamental stretch or ventricular loading conditions. Contractility is influenced by the following factors:

Factors that *increase* myocardial contractility:

- Circulating catecholamines
- Drugs (inotropes, digoxin, calcium solutions)
- Metabolic state (i.e., hyperthermia)
- Sympathetic nervous system activity
- Increased HR

The following factors *reduce* myocardial contractility:

- Hypoxia or hypercapnia
- Metabolic state (acidosis, hypothermia, hyperkalemia, hypocalcemia)
- Drugs (e.g., β-adrenergic receptor antagonists, digoxin)
- Acute and chronic cardiomyopathies
- Parasympathetic nervous system activation

Contractility is difficult to assess in the clinical setting. The temporal rate of change of ventricular pressure (dP/dt) and its maximum value (peak dP/dt) can be derived invasively (i.e., in the cardiac catheterization laboratory) or estimated less invasively with varying accuracy by echocardiography and some cardiac output monitoring devices. This parameter has been shown to be related to ventricular function in clinical studies. Echocardiography provides additional functional assessment of ventricular wall motion and blood velocity kinetics. Parameters such as the fractional area change and ejection fraction (EF) are not accurate measures of contractility but are related to the contractile state of the myocardium and can be used to guide therapy.[10]

Afterload

The afterload of the heart may be considered as the ventricular wall tension required to eject the SV during systole. According to the law of Laplace, afterload relates to the stress within the wall of the ventricle developing during systolic ejection:

$$T = (P \times r)/2,$$

where T is tension, P is intraventricular pressure, and r is the intraventricular radius. In this equation, afterload is mainly dependent on wall thickness and ventricular radius. At a given pressure, an increase in ventricular radius (i.e., dilatation of the ventricle) will increase afterload. An increase in wall thickness (i.e., ventricular hypertrophy) will reduce afterload.

Afterload for the left ventricle is increased by the following factors:

- Anatomic obstruction (e.g., aortic valve stenosis, subvalvular obstruction)
- Raised systemic vascular resistance (SVR)
- Decreased elasticity of the aorta and great vessels
- Increased ventricular volume

Afterload for the right ventricle is increased by the following factors:

- Anatomic obstruction (e.g., pulmonary valve stenosis)
- Raised pulmonary vascular resistance (PVR) (e.g., pulmonary hypertension, pulmonary embolism, hypoxia, and hypercarbia)
- Increased ventricular volume

The *Anrep effect* describes an intrinsic regulatory mechanism of the heart in response to an acute increase in afterload, which results in an initial reduction in SV followed by an increase in EDV, which restores the SV toward near-normal values.

Indicators of Afterload

SVR and PVR are the most commonly used indicators of afterload in the clinical setting for the left and right ventricle, respectively. Vascular resistance can be described as the mechanical property of the vascular system opposing flow of blood into a vascular bed. There are two main components of vascular resistance:

- *Flow component*—frictional opposition to blood flow through the vessels, with blood viscosity being the major determinant. Vascular resistance increases with an increase in viscosity.
- *Frequency-dependent or "reactive" component*—related to the compliance of the vessel walls and the inertia of the ejected blood. A low vascular compliance increases vascular resistance.

SVR and PVR cannot be measured directly and thus are calculated from Ohm's law:

$$V = I \times R,$$

where V is voltage, I is current, and R is resistance. Applied to cardiovascular physiology this principle looks as follows:

$$\Delta P = CO \times R,$$

in which ΔP is the pressure gradient, CO (cardiac output) is "flow," and R is the resistance.

SVR is calculated as follows:

$$SVR\left(\text{dyne} \bullet \frac{s}{cm^5}\right) = 80 \times \frac{MAP - RAP}{CO},$$

where MAP is mean arterial pressure (mm Hg), RAP is right atrial pressure (mm Hg), and CO is cardiac output. To convert from mm Hg to dyne × s/cm^5 the multiplication by 80 is necessary. Normal values for SVR range from 800 to 1200 dyne × s/cm^5. If standardized to body surface area, SVR is quoted as SVRI (SVR index) with normal values for SVRI ranging from 1900 to 2400 dyne × s/cm^5 per m^2.

The following factors affect SVR:

- *Vessel diameter:* According to the law of Hagen-Poiseuille resistance is inversely related to the fourth power of the radius. This means that a decrease in vessel diameter during vasoconstriction will result in a significant increase in SVR. Vasodilation decreases SVR.
- *Compliance* of the systemic circulation
- *Blood viscosity and hematocrit*

In the same way as SVR, PVR may be calculated using the pressure differential across the pulmonary vasculature, between the mean pulmonary artery pressure (MPAP) and PAOP:

$$PVR\left(\text{dyne} \times \frac{s}{cm^5}\right) = 80 \times \frac{MPAP - PAOP}{CO}$$

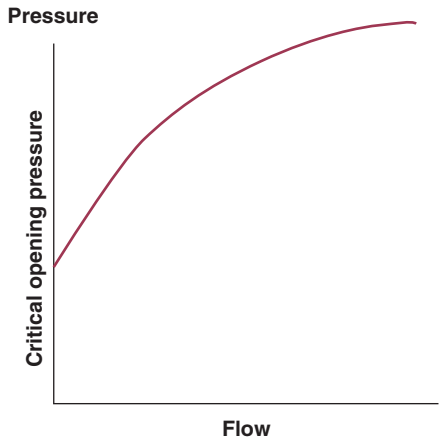
Values for PVR are normally below 250 dyne × s/cm^5. Again, PVR is often quoted as the PVR index (PVRI) with a normal range between 255 and 285 dyne × s/cm^5 per m^2.

The following factors affect PVR:

- *Vessel diameter:* Pulmonary vasoconstriction increases PVR (i.e., during hypoxia), and vasodilation reduces PVR.
- *Positive-pressure ventilation* increases PVR.
- *Established pulmonary hypertension* increases PVR.
- *Compliance* of the pulmonary circulation affects PVR.
- *Blood viscosity and hematocrit* affect PVR.

Clinical Limitations of Systemic Vascular Resistance and Pulmonary Vascular Resistance

Although the concept of vascular resistance permits an intuitive understanding of the circulation, a number of limitations make it unreasonable to use SVR and PVR to guide therapy. First, because SVR and PVR are derived variables, errors inherent in the measurement of their components (i.e., filling pressures) are multiplied, making the derived number less accurate. Further, these calculations assume a linear relation between pressure and flow, which does not exist in vivo (Fig. 3.2). It is therefore wise to use these parameters with caution and consider their limitations in clinical practice.



• **Fig. 3.2** Relationship among pressure, flow, and resistance. The critical opening pressure reflects the pressure in the vasculature at zero flow. The important point to recognize is that this is not at the origin of the graph. This means that even when the flow is zero, a baseline pressure exists. Estimating systemic vascular resistance by calculating the gradient of pressure and flow for any given point will therefore be inaccurate, because the "line" is actually nonlinear and does not go through the zero origin.

Clinical Interpretation of Indicators of Preload

It has already been stressed that accurate assessment of the preload status of the heart is important as it allows for the application of interventions that may improve cardiovascular dynamics. However, without knowing whether the heart will respond to an increase of a certain status of volume or preload, this information is of limited value. This concept—the individual response of cardiac output to a volume challenge—has become known as *volume responsiveness.*[8] Intravascular volume expansion is often the initial intervention in patients with circulatory failure. However, only approximately 50% of patients given a fluid challenge will respond by increasing cardiac output. The ability to distinguish fluid-responsive patients from nonresponders is important to avoid inappropriate and potentially harmful fluid challenges in situations in which other interventions (i.e., inotropes or vasopressors) should be preferentially used. Consequences of inappropriate fluid therapy include pulmonary edema, deterioration in gas exchange, and cardiac failure.

There are currently a number of parameters available with different monitoring modalities that can be used as estimates of preload and may predict volume responsiveness under defined conditions.

Static Indicators of Preload

Conventional static markers of cardiac preload, such as CVP and PAOP, are poor predictors of fluid responsiveness. CVP and PAOP reflect intracavitary pressures that frequently show poor correlation with transmural pressures, which are actually related to EDV through chamber compliance. Therefore EDV is overestimated (i.e., under the application of PEEP) or underestimated (i.e., in concentric left ventricular hypertrophy) in many clinical situations.

Furthermore, static parameters do not determine the position of the heart on the "individual" Frank-Starling curve as contractile function is not taken into the account. A patient may not respond to a fluid challenge because of ventricular dysfunction or poor ventricular compliance (see Fig. 3.1). It is important to realize, however, that pressure is one of the driving forces responsible for edema formation in the lungs. Thus, although the PAOP is considered to have limited utility for predicting and guiding fluid challenges, it does have a role in determining how much volume should be administered to patients and may be regarded as more of a safety limit, rather than as a guide to therapy.[6]

Volumetric Indicators of Preload

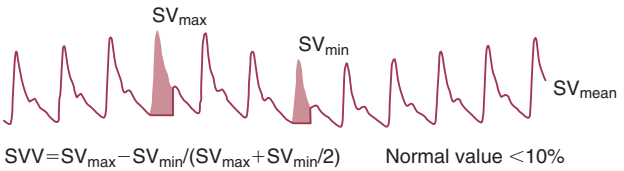
The continuous EDV, global EDV, and intrathoracic blood volume are computed by some monitoring systems. Although continuous and global EDVs seem to be better indicators of preload than static parameters, they are still poor predictors of a response to a fluid challenge in most situations. Extravascular lung water has been shown to help in the identification of noncardiogenic pulmonary edema and has the potential to increase the safety of fluid therapy in patients with structural lung disease or acute lung injury and acute respiratory distress syndrome.[11]

Dynamic Indicators of Preload

A number of dynamic parameters have been described that allow the clinician at the bedside to predict with some accuracy which patients will or will not respond to a fluid challenge. These parameters include the SVV, PPV, SPV, and the PVI and changes of vena cava diameters as derived by echocardiography. Generally, an SPV, PPV, SVV, or PVI variation greater than approximately 10% suggests that the patient will be volume responsive (Fig. 3.3). As stressed earlier in this chapter, these parameters require controlled mechanical ventilation and a tidal volume of at least 8 mL/kg of body weight to be maintained to remain reliable. Further, the presence of arrhythmias and severe tricuspid regurgitation precludes the safe use of these variables.[8]

The Passive Leg-Raising Test

Patients who are critically ill seldom fulfill criteria to allow for dynamic preload indices to be accurate predictors of volume responsiveness. The passive leg-raising test has been suggested to overcome these limitations. When traditionally performed by lifting the legs up at a 45-degree angle in a supine position, approximately 150 mL of blood can be recruited to increase venous return to predict a response of cardiac output to a noninvasive, endogenous fluid challenge. However, by starting the passive leg raising from a 45-degree semirecumbent position, a substantial increase of mobilized venous blood can be achieved by adding venous blood from the splanchnic compartment to that from the lower extremities, increasing the sensitivity of the maneuver for the prediction of fluid responsiveness. It is important to note that when performing the passive leg-raising test, the monitoring modality used must be able to track changes in cardiac output within a time frame of approximately 60 to 90 seconds.[8]



• **Fig. 3.3** Stroke volume variation *(SVV).* The arterial pressure trace can be used to generate stroke volume *(SV)* on a beat-to-beat basis. The variation in SV (SVV) with mechanical ventilation is a useful marker for identifying patients who are likely to respond to an increase in intravascular volume. This tracing demonstrates the fluctuations in SV in a patient with an increased SVV. *min,* Minimum; *max,* maximum.

The Diagnostic Fluid Challenge

In the care of critically ill patients situations do exist in which the preceding parameters are not reliable and a passive leg-raising test may be contraindicated owing to technical constraints or based on the patient's underlying illness, such as in brain injury with elevated intracranial pressure. In this scenario, the clinician may rely on the administration of fluids as a diagnostic intervention to indicate a potential benefit from further fluid therapy by assessing the response of various hemodynamic parameters, with SV being the parameter most widely used in studies investigating fluid responsiveness, with an increase of 10% to 20% indicating a positive response. Although the optimal volume to function as a fluid challenge has yet to be determined, it can be recommended in this situation to use the CVP as an indicator of a sufficient challenge of the right ventricle to ensure that an adequate preload has been achieved.[12]

It is important to recognize, however, that identification of a patient who is fluid responsive is not the same as saying that the patient should be given fluid without an appreciation of the clinical context. Most healthy patients will be volume responsive; however, few will benefit from volume challenges. In critically ill patients, other clinical factors need to be taken into account. Does the patient actually need a higher cardiac output? Or is cardiac output adequate, so that further increase may actually cause harm?

Hemodynamic Status and Blood Flow

Cardiac output (or blood flow) is an important variable to be considered in a critically ill patient. Although arterial pressure has been used as the target for therapy, this focus is perhaps related more to convenience in measurement than to a sound physiologic rationale. When patients become critically ill, it is extremely difficult to predict cardiac output from routine clinical assessment, so sensible and logical use of vasoactive therapy requires monitoring of both pressure and flow. Arterial blood pressure often is mistakenly used as a surrogate marker for blood flow; however, no direct relationship between pressure and flow exists. Moreover, clinical estimation of cardiac output can be difficult and inaccurate, although clinical assessment must not be ignored. Often these signs constitute the only tool that a clinician may have to estimate a patient's hemodynamic status before admission to a critical care unit. At this stage the response of clinical assessment to simple therapeutic maneuvers can give important information. If, however, the patient does not respond in a suitable fashion, monitoring of these variables becomes necessary to direct therapy.

Cardiac output is the volume of blood ejected by the left ventricle per minute. It is the product of HR and SV. It should be borne in mind that excessive HRs will reduce diastolic ventricular filling time, with a negative impact on SV. Heart rhythm also is essential in determining cardiac output, and in general any rhythm other than sinus rhythm will result in a reduction in SV. For example, the loss of atrial contribution to diastolic ventricular filling in atrial fibrillation results in a subsequent reduction in SV and hence cardiac output.

Cardiac output should not be considered in isolation from other relevant variables. The concept of oxygen delivery describes the relationship between cardiac output and arterial oxygen content:

$$\text{Oxygen delivery} = \text{Arterial } O_2 \text{ content} \times \text{Cardiac output}$$

Measurement of Cardiac Output

The ideal method of measuring cardiac output would be noninvasive, accurate, continuous, safe, easy to use, and operator independent; would provide rapid data acquisition; and would be cost-effective. None of the cardiac output monitoring devices currently available possesses all of these properties. Conventional thermodilution remains the clinical gold standard for accuracy in cardiac output measurement; however, newer, less (almost non) invasive monitoring methods that provide continuous cardiac output data are establishing a role in patients' hemodynamic management.[9,13]

The Fick Principle

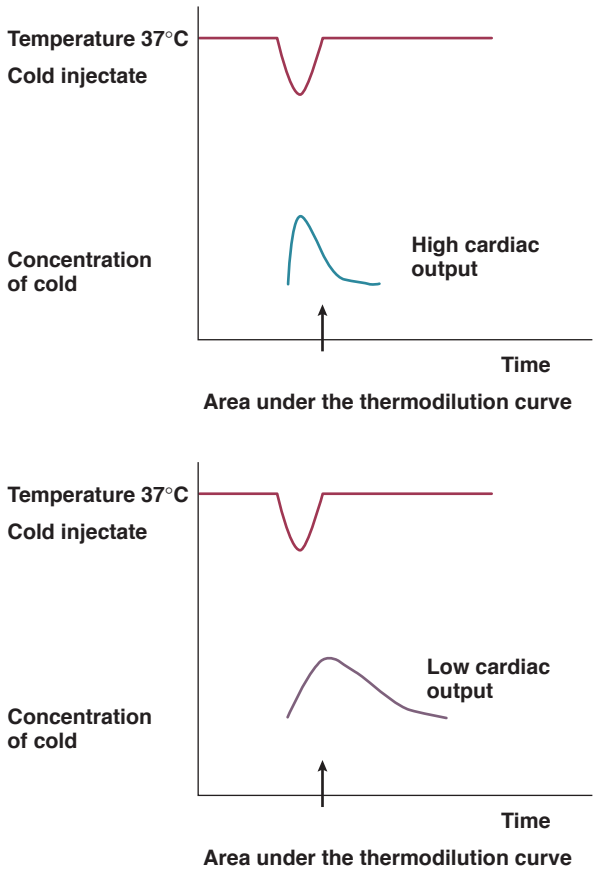
Fick described the following relationship in the nineteenth century: $Q = M/(A - V)$. That is, the uptake or release of a substance (M) by an organ is the product of the blood flow (Q) through that organ and the arteriovenous concentration difference (A − V) of the substance in question.

Applying the Fick principle to cardiac output measurement of the pulmonary blood flow over 1 minute may be achieved by measuring the arteriovenous oxygen content difference across the lungs and the rate of oxygen uptake. Oxygen uptake may be determined using spirometry by measuring the expired gas volume over a known time and calculating the difference in oxygen concentration between the expired gas and that of inspired gas. Accurate collection of the gas is difficult, unless the patient has an endotracheal tube, because of the leaks that occur around a face mask or mouthpiece. Analysis of the gas is straightforward if the inspired gas is air, but if it is oxygen-enriched air, two possible problems need to considered. (1) The addition of oxygen may fluctuate, producing an error owing to the nonconstancy of the inspired oxygen concentration. (2) Measurement of small changes in oxygen concentration at the top end of the scale is difficult. Blood oxygen content is measured via blood gas analysis. In the absence of intrapulmonary or intracardiac shunts, the pulmonary blood flow is equal to the systemic blood flow and thus cardiac output.

The technique just described based on the Fick principle may thus be used as an accurate and reliable static measure of cardiac output, but it remains a time-consuming and largely laboratory-based tool. Several variants of the basic method have been devised, but usually their accuracy is less reliable.

Thermodilution

Thermodilution from the PAC has traditionally been considered as the gold standard of cardiac output measurement for accuracy and acceptability in the clinical setting. Newer methods are routinely validated against the PAC thermodilution technique. A bolus of 5 to 10 mL of cold 0.9% sodium chloride or 5% dextrose is injected through the proximal port of a PAC into the right atrium. Temperature changes are measured by a distal thermistor in the pulmonary artery. A plot of temperature change against time gives a thermodilution curve from which cardiac output can be calculated from the Stewart-Hamilton equation (Fig. 3.4). Application of this equation assumes three major conditions: complete mixing of blood and indicator, no loss of indicator between place of injection and place of detection, and constant blood flow. For accurate results with this technique, it is important to ensure adherence to these conditions.



• **Fig. 3.4** Thermodilution curves show a plot of temperature change versus time after a bolus of cold injectate. Cardiac output is inversely proportional to the area under the thermodilution curve. With a large cardiac output, the bolus is pumped rapidly past the thermistor, so the area is small.

The degree of change in the temperature is inversely proportional to the cardiac output.

- Increased blood flow (and cardiac output) = minimal temperature change
- Decreased blood flow (and cardiac output) = pronounced temperature change

Modern PACs are able to provide a continuous reading of cardiac output. They contain an electrical heating coil that sits in the right atrium, which heats up the blood in a semirandom binary fashion. The pulsed heating bursts can be detected by the thermistor in the pulmonary artery, which after autocorrelation with the inputting signal can provide continuous cardiac output. It has to be noted, however, that this technique has a latency of 7 to 10 minutes.

Dye/Indicator Dilution

A number of techniques are available to measure cardiac output with the use of either a dye (indocyanine green) or an indicator (lithium). The concept is exactly the same as that for thermodilution: injection of a substance into the right side of the heart and detection of the same substance distally, either in the pulmonary artery or in the aorta. A curve is generated, which is replotted semilogarithmically to correct for recirculation of the dye. Cardiac output is

calculated from the injected dose, the area under the curve, and the duration of effect (short duration indicates high cardiac output) from the Stewart-Hamilton equation:

$$\dot{Q} = \frac{V(T_B - T_I)K_1K_2}{T_B(t)dt},$$

where $\dot{Q}$ is cardiac output, V is volume of injectate, T_B is blood temperature, T_I is injectate temperature, K_1K_2 are computer constants, and $T_B(t)dt$ is the change in blood temperature over time.

Arterial Pulse Pressure Analysis

Arterial pulse pressure analysis is a technique of measuring and monitoring SV on a beat-to-beat basis from the arterial pulse pressure waveform. This technique has several advantages over technologies such as the PAC, including its less invasive nature, as arterial access is available in most patients. Changes in both SV and cardiac output are then shown on an almost continuous basis. A fair number of less invasive cardiac output monitoring devices based on pulse pressure analysis are now commercially available and have resulted in a decreased use of the pulmonary catheter in most institutions.

The fluctuations of blood pressure around its mean value occur as a specific volume of blood—the SV—is forced into the aorta by each cardiac contraction. The magnitude of this pressure change, the pulse pressure, is a function of the magnitude of the SV. On a beat-to-beat basis, the only factor that determines changes in pulse pressure is change in SV, owing to the relatively slow nature of reactive vascular changes. To translate the pressure waveform into an accurate SV, however, an estimate of the arterial compliance and resistance must be made. The greater the compliance, the less will be the vascular resistance to the pulsatile increase in the arterial pressure, and the less will be the pressure required to distend the vessel to accommodate a given SV.

The need to incorporate arterial compliance and resistance into the measurement system has hindered this technology for many years. The origins of the pulse contour method for estimation of beat-to-beat SV are based on the Windkessel model described by Otto Frank in 1899. Only recently have methods been described that can compensate or correct for these compliance or resistance changes to provide an accurate determination of SV. Different technologies address this by different methods. Both lithium dilution and thermodilution techniques have been validated to calibrate pulse pressure tracking systems. Other devices are being marketed with the ability to self-calibrate after identifying vascular compliance and resistance directly from the pressure waveform.

Transesophageal Doppler

The esophageal Doppler cardiac output monitor, described in the early 1970s, provides a safe and minimally invasive means of continuously monitoring the circulation.[14,15] Compared with suprasternal probes, esophageal probes have the advantage of less positional variety owing to the smooth muscle tone of the esophagus and less signal interference from bone, soft tissue, and lung owing to the close proximity of the aorta to the esophagus. The esophageal Doppler monitor measures blood flow velocity in the descending thoracic aorta using a flexible ultrasound probe. When these data are combined with the aortic cross-sectional area, other hemodynamic variables including SV and cardiac output can be calculated, providing minimally invasive, continuous cardiac output assessment. Abrupt changes in cardiac output are much better followed with Doppler systems than with the PAC-based continuous cardiac output systems.

Despite several potential sources of error, good correlation has been observed between measures of cardiac output made simultaneously with the esophageal Doppler monitor and with conventional thermodilution. Esophageal Doppler ultrasonography has been used for intravascular volume optimization both in the perioperative period and in the critical care setting. One of the main advantages of the technique is the capability of rapid data acquisition after esophageal probe insertion.

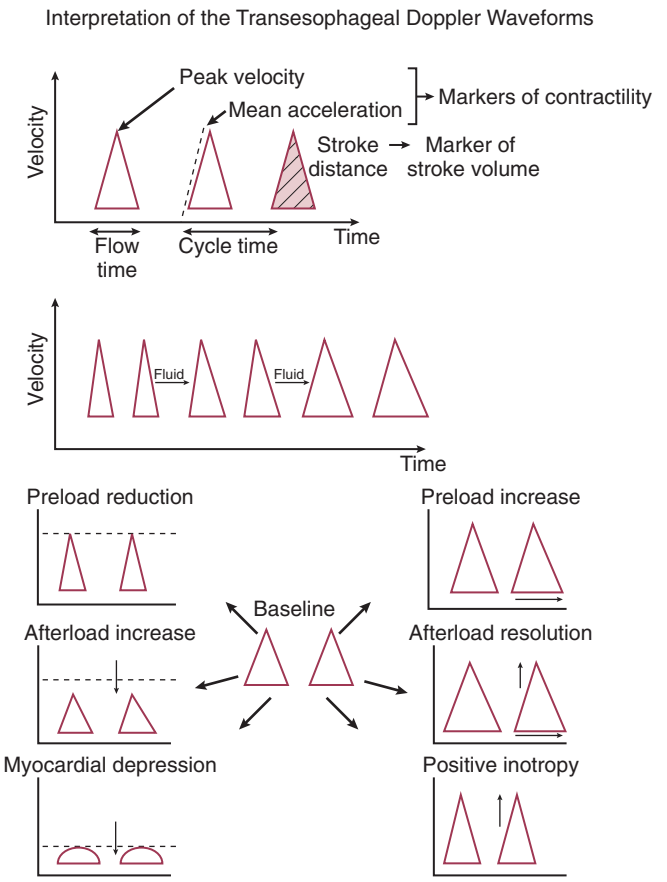
Identification of the descending aortic waveform is essential for the correct use of the esophageal Doppler cardiac output monitor. Waveforms from other structures, such as the pulmonary artery, azygos vein, or celiac axis, may be encountered, leading to misinterpretation. After the characteristic descending aortic waveform is acquired, the signal is optimized before data acquisition by movement of the probe a centimeter up or down until the waveform indicates the best possible velocity and color intensities, followed by rotation of the probe to optimize the signal further if possible. The "peak velocity" display is used as a reference to the highest identified wave.

Esophageal Doppler waveform analysis has been increasingly evaluated as a method for determining optimal cardiac preload. The key preload parameter of interest is the flow time (FT)—the time required from the start of the waveform upstroke to return to baseline. FT represents the duration of left ventricular systole and makes up one-third of the cardiac cycle (cycle time). Because the FT is HR dependent, it typically is corrected (FTc) to a rate of 60 beats/min to compensate for the change in duration of systole. The FTc reflects the afterload status of the circulation. Decreased levels commonly are seen in hypovolemic patients, but caution in interpretation is advised because this pattern also can be seen with profound vasoconstriction. A more sensible use of this device is in following the effects of a fluid challenge. Because SV can be determined on a beat-to-beat basis, it is easy to see the effects on the circulation of a small fluid bolus. Diagrammatic representations of characteristic Doppler waveform patterns are shown in Fig. 3.5.

Echocardiography

Transthoracic echocardiography and TEE both are evolving tools in the critical care setting, and particularly TEE has become a standard of care for intraoperative monitoring in patients undergoing cardiac valvular replacement or repair.[6] TEE has been used for a number of years for acute hemodynamic monitoring and diagnostic purposes in the cardiothoracic critical care setting, and its use in the general critical care setting is now becoming commonplace.

Echocardiography provides a dynamic assessment of cardiac function, allowing visualization of cardiac chamber dimensions, functional assessments such as estimation of ventricular ejection fractions, detection of regional and global wall motion abnormalities, detection of valvular abnormalities, and exclusion of pericardial effusion. It also can be used to derive cardiac output from measurement of blood flow velocity by recording the Doppler shift of ultrasound signals reflected from the red blood cells. The time-velocity integral, which is the integral of instantaneous blood flow velocities during one cardiac cycle, is obtained for the blood flow in the left ventricular outflow tract (other sites can be used). This is multiplied by the cross-sectional area and the HR to give cardiac output. The results for cardiac output measured by this device in skilled hands are comparable to those obtained with use of the PAC.



• **Fig. 3.5** Diagrammatic representation of characteristic Doppler waveform patterns. The characteristic flow "triangles" generated in an esophageal Doppler study can be used to monitor cardiac output and stroke volume. The width of the base of the triangle (flow time) when corrected for heart rate provides an estimate of afterload. This diagram demonstrates the changes seen after a volume challenge in a variety of clinical conditions.

The main disadvantages of the method are that a skilled operator is needed, the probe is large and therefore heavy sedation or anesthesia is needed, the equipment is very expensive, and an expert user is needed to adjust the probe to provide continuous cardiac output readings. Nonetheless, echocardiography has an important and established clinical role. The modality is covered in detail in Chapter 8.

Assessment of Adequacy of the Circulation

Resuscitation of critically ill patients is a complex process. The rationale for most resuscitation maneuvers is that the delivery of oxygen to the tissues is inadequate, resulting in tissue hypoxia. Resuscitation is therefore aimed at increasing the oxygen delivery to a level at which enough oxygen is brought to the tissues to ensure efficient metabolism, so that normal cellular processes can occur. Part of this process entails measuring cardiac output and then increasing this variable to an "adequate" level. Unfortunately, this strategy is complicated as a result of the fact that all patients' cardiac output requirements differ—no "normal" level of flow can be specified for any patient in any given situation. To assess adequacy of perfusion, therefore, a number of surrogate markers need to be assessed that provide an estimate of the underlying metabolic status. The cardiac output then needs to be assessed in combination with these surrogate markers of metabolism to ensure that resuscitation is improving the clinical situation.

Clinical Assessment

The first step in the hemodynamic assessment must be a thorough clinical assessment. Pulse rate and quality, respiratory rate, skin temperature, capillary refill time, core-peripheral temperature gradient, level of consciousness, and urine output are strongly related to cardiovascular dynamics, and a change in these clinical parameters may indicate deterioration as well as a positive response to a hemodynamic intervention. Skin mottling, pallor, and diaphoresis are alarming signs that require immediate and appropriate intervention. Several studies have shown a strong relationship between clinical and microcirculatory parameters and underline their importance in hemodynamic assessment.[16,17]

Mixed Venous Oxygenation

Venous oxygen saturation (SvO_2) is the oxygen saturation of mixed venous blood in the pulmonary artery. It reflects the overall venous saturation after the blood has been fully mixed in the right side of the heart. SvO_2 is related to the balance between oxygen delivery (DO_2I) and the ability to extract oxygen, or the oxygen extraction ratio (O_2ER). Under normal circumstances, oxygen consumption is independent of supply until oxygen delivery falls below the anaerobic threshold. The normal O_2ER is approximately 25%, giving an SvO_2 of 75%. In the face of a reduction in oxygen delivery, the tissues maintain oxygen consumption by increasing oxygen extraction, so SvO_2 decreases. However, SvO_2 does not necessarily vary with cardiac output. Not all patients can increase their O_2ER if DO_2I falls. Clinically, the response of SvO_2 to an increase in cardiac output or oxygen delivery can aid hemodynamic manipulation. SvO_2 can be measured by sampling blood from the distal lumen of a PAC and then measuring oxyhemoglobin saturation by means of co-oximetry, or by using an oximetric PAC that is able to continuously display SvO_2. A flow diagram of a published protocol using PAC-derived parameters is shown in Fig. 3.6.

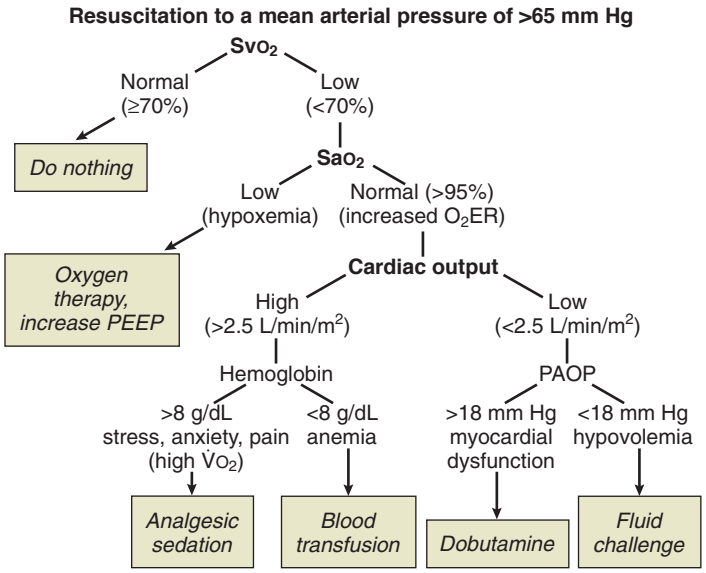
It has been suggested that SvO_2 should be monitored and the key variables manipulated to keep it within the normal range (65%–75%). In practice, this means ensuring that the hemoglobin concentration and arterial oxygen saturation are normal and then either increasing cardiac output or decreasing oxygen utilization (such as by sedation or cooling). Thus SvO_2 monitoring provides a means of assessing the adequacy of cardiac output for a given patient. This strategy has been used with success in patients who have undergone cardiac surgery and has been suggested for use in critically ill patients.[5]

Central Venous Oxygen Saturation

In patients without PACs in place, central venous oxygen saturation ($ScvO_2$) may be measured by sampling from the distal lumen of a central venous line in the SVC. This variable bears some relationship to the mixed SvO_2, although because the venous blood is not totally mixed in the SVC, the relationship should be considered as representing a guide rather than reflecting reality. In practice, the $ScvO_2$ should be used as a screening tool rather than as an accurate marker of adequacy. If the level is very low, then the inference can be made that the circulation is inadequate; however, near-normal levels do not preclude underlying problems.

Blood Lactate

Blood lactate levels represent the balance between lactate production and lactate metabolism. The liver is responsible for the major part



• **Fig. 3.6** Flow chart for the Pinsky-Vincent protocol. A diagnostic and treatment algorithm for the use of pulmonary artery catheter–derived variables. *O_2ER,* Oxygen extraction ratio; *PAOP,* pulmonary artery occlusion pressure; *PEEP,* positive end-expiratory pressure; *Sa_{O_2},* arterial oxygen saturation; *$\dot{V}_{O_2}$,* oxygen consumption. (Adapted from Pinsky MR, Vincent JL. Let us use the PAC correctly and only when we need it. *Crit Care Med.* 2005;33:1119–1122.)

of lactate metabolism. Inadequate oxygen delivery and tissue hypoxia, irrespective of the underlying cause, results in increased lactate generation. In critically ill patients, high blood lactate levels develop from a combination of inadequate oxygen delivery secondary to poor perfusion (in terms of both perfusion pressure and flow), impaired cellular oxygen utilization from mitochondrial damage, and reduced hepatic clearance of lactate. A resolving lactic acidosis along with clinical signs of improved perfusion is an important indicator of improving perfusion after resuscitation. Lactate levels and lactate clearance have been shown to predict mortality risk and morbidity, and studies investigating protocols aimed at decreasing lactate levels have shown the potential role of lactate as a treatment goal.[18]

Venous-to-Arterial Carbon Dioxide Difference (P_{CO_2} Gap)

Oxygen-derived parameters, namely S_{VO_2} and S_{cVO_2}, may falsely indicate adequate tissue perfusion in the presence of anaerobic metabolism owing to microcirculatory compromise. In this situation, a decrease in oxygen consumption ($\dot{V}_{O_2}$) may occur, either because of impaired oxygen delivery or reduced oxygen demand, resulting in normal levels of S_{VO_2} or S_{cVO_2}. In hypoxic conditions as the result of an impaired tissue perfusion, a rise in the partial pressure of carbon dioxide (P_{CO_2}) is usually seen, widening the gap between arterial and venous P_{CO_2}. Recent clinical studies have suggested that the venous-to-arterial CO_2 difference using a central venous and an arterial blood sample ($P(cv-a)CO_2$ or P_{CO_2} gap) may be used as a complementary tool to unmask inadequate tissue perfusion in patients who are apparently resuscitated to target goals—namely, an S_{cVO_2} of 70%. Further prospective clinical studies will show if this parameter has the potential to function as a treatment goal in the resuscitation of critically ill patients with hemodynamic compromise.[19]

Monitoring the Microcirculation

The goal of interventions that manipulate the macro-hemodynamics of a patient should be improving the microcirculation and tissue perfusion. Microcirculatory parameters have been shown to be associated with patients' outcomes in both medical and surgical patients.[20,21] Until recently, monitoring the microcirculation required complex and long offline analysis of images acquired at the bedside. The inability to use these techniques as real-time monitoring tools and the lack of evidence from trials using microcirculation targets as goals in clinical practice have prevented the mainstream use of these devices at the bedside. Recently, however, new devices with faster (almost real-time) software analysis have become available.[22] Validation and outcome studies in this new field are largely awaited.

Conclusions

Resuscitation of critically ill patients is a complex process. Several simple steps need to be taken to ensure delivery of an appropriate level of resuscitation. First, the patient should attain an optimal level of preload. This is best achieved by identifying the group of patients who are likely to benefit from volume loading and then providing this intervention, while at the same time not giving excess intravascular volume to patients who are unlikely to benefit from it. If it is impossible to predict which patients will benefit, then the fluid should be given under tightly controlled circumstances in the form of a fluid challenge with close monitoring of the circulation. After appropriate volume resuscitation, the circulation of some patients will still be inadequate for their metabolic demands. These patients may then benefit from either a reduction in oxygen requirements or an increase in oxygen delivery. This approach necessitates the monitoring of the circulation and the metabolic status.

Key Points

- Isolated measurements of either right atrial pressure or pulmonary artery pressure are not good markers for identifying patients who will respond to a fluid challenge.
- Dynamic measurements of pulse or stroke volume variation can predict volume responsiveness with a high degree of sensitivity and specificity.
- No "normal" cardiac output can be specified for any patient, so cardiac output must be compared with other markers of metabolic status.
- Cardiac output can be measured by a number of techniques. Less important than how it is measured is how this knowledge is applied.

Review Questions

1. Which of the following variables is best placed to predict the response to an increase in intravenous volume with regard to an improvement in cardiac output?
a. Central venous pressure
b. Pulmonary artery occlusion pressure
c. Pulse pressure variation
d. Heart rate
e. Urine output
Answer: c. Static measures of the circulation are very poor predictors of volume responsiveness. Functional parameters, such as the pulse pressure response to mechanical ventilation, when used appropriately are good predictors of the response to fluid.

2. Which of the following variables is *not* directly related to oxygen delivery?
a. Hemoglobin concentration
b. Mean arterial pressure
c. Cardiac output
d. Heart rate
e. Arterial oxygen saturation
Answer b. Oxygen delivery is the product of article oxygen capacity and cardiac output. Mean arterial pressure is not directly related to oxygen delivery.

3. Which of the following variables cannot be used to identify an adequate response to resuscitation of the cardiovascular system?
a. Cardiac output
b. Mixed venous oxygen saturation
c. Central venous oxygen saturation
d. Venous-to-arterial carbon dioxide (CO_2) difference (Pco_2 gap)
e. Arterial lactate concentration
Answer: a. There is no normal value of cardiac output for a patient and thus other markers need to be used to assess adequacy of resuscitation.

- Does the Use of a Pulmonary Artery Catheter Improve Outcome?

Arterial Catheters

What Do They Offer?

The placement of an arterial catheter permits (1) reliable and continuous monitoring of arterial pressure and (2) repeated blood sampling. Analysis of the arterial pulse pressure curve may also have other applications, including assessment of fluid responsiveness and estimation of cardiac output. The appearance of arterial pressure waves varies according to the site at which the artery is sampled. As the arterial pressure wave is conducted away from the heart, three effects are observed: the wave appears narrower, the dicrotic notch becomes smaller, and the perceived systolic and pulse pressures rise and the perceived diastolic pressure falls.

Arterial Pressure Measurement

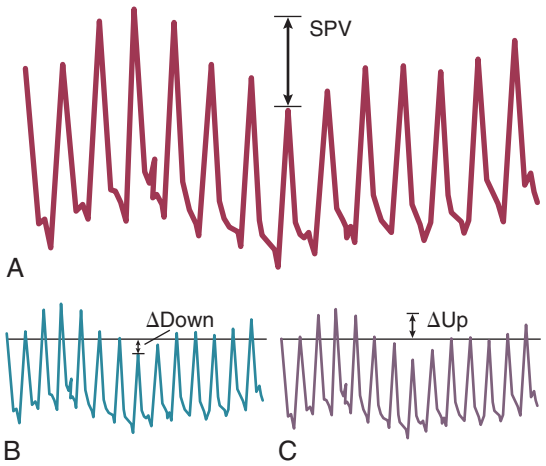
The optimal range of arterial pressure depends on individual patient characteristics, on underlying diseases, and also on treatment. Hence, it is impossible to give an optimal range of arterial pressure that is applicable in all patients. When arterial pressure needs to be evaluated accurately, oscillometric measurements become unreliable,[1] and insertion of an arterial catheter is indicated.

Four potential indications for insertion of an arterial catheter for measurement of arterial pressure are recognized:

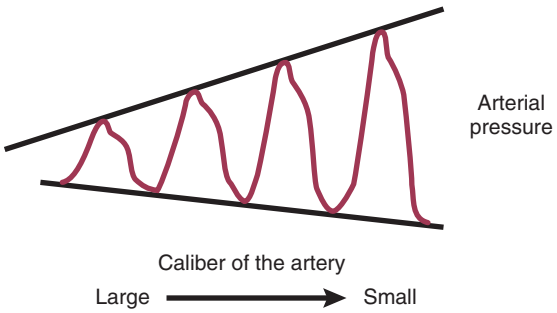
1. *Hypotensive states associated with (a risk of) altered tissue perfusion.* Hypotension that is resistant to fluid administration requires the administration of vasopressor agents, and invasive measurement of arterial pressure is then necessary to titrate this form of therapy. Norepinephrine is the vasopressor agent most commonly used in this setting. A mean arterial pressure (MAP) of 65 to 70 mm Hg is usually targeted, but this level must be adapted to the individual patient and the clinical scenario[2,3]; in particular, elderly patients with atherosclerotic disease may require higher levels than younger individuals with normal arteries.
2. *Intravenous vasodilator therapy.* Vasodilating therapy (e.g., nitrates and hydralazine) is a mainstay in the management of heart failure because it can increase cardiac output. Close monitoring of arterial pressure is essential to avoid excessive hypotension.
3. *Severely hypertensive states.* Extreme hypertension may result in organ impairment, especially of the brain and the heart. Calcium entry blockers or sodium nitroprusside usually are used to lower arterial pressure, and careful, accurate monitoring is essential to titrate the antihypertensive therapy.
4. *Induction of hypertension.* Hypertension is sometimes induced in patients with neurologic diseases. Severe cerebral edema with intracranial hypertension, in particular, requires vasopressor support to maintain cerebral perfusion pressure (the gradient between the MAP and the intracranial pressure); likewise, hypertension may be used to treat or prevent the development of vasospasm secondary to subarachnoid hemorrhage. Norepinephrine is usually used for this purpose.

Fluid Responsiveness

Variations in arterial pressure during positive-pressure ventilation have been used as a measure of fluid responsiveness. The transient increases in intrathoracic pressure influence venous return in patients who are likely to respond to fluid administration. This fluctuation



• **Fig. 4.1** The systolic pressure variation *(SPV)* is the difference between the maximum and the minimum systolic blood pressures during one ventilatory cycle (A). The SPV is the sum of the ΔDown (B) and the ΔUp (C). (From Perel A, Pizov R, Cotev S. Systolic blood pressure variation is a sensitive indicator of hypovolemia in ventilated dogs subjected to graded hemorrhage. *Anesthesiology.* 1987;67:498.)



• **Fig. 4.2** Schematic representation of an arterial pressure tracing showing that the pulse pressure increases as arterial size decreases.

in ventricular filling translates into fluctuations in arterial pressure a few beats later. Accordingly, the greater the degree of systolic arterial pressure, or pulse pressure, variation during the respiratory cycle, the greater the increase in cardiac output in response to fluid administration (Fig. 4.1). However, this observation is valid primarily in patients without spontaneous respiratory movements and without significant arrhythmias, and only when a sufficient tidal volume is applied.[4]

Cardiac Output Assessment

The pulse contour analysis also can serve to estimate cardiac output less invasively than with the pulmonary artery catheter (PAC). Because the only determinants of arterial pressure are the stroke volume and the resistance and compliance factors of the blood and arteries, analysis of the pulse contour trace can help to monitor cardiac output over time. This can be done with regular calibrations whenever changes in vascular tone or blood volume occur, or even in the absence of calibration. These measurements are still approximations, so further technological developments can be expected to improve accuracy.

Blood Sampling

The presence of an arterial catheter can greatly facilitate blood sampling, especially in terms of enabling easy access to the circulation for regular monitoring of blood gases, such as may be required in severe respiratory failure or with acute metabolic alterations. Sensors can measure blood gases continuously, but widespread use of such sensors is limited by their cost.

Access

The radial artery is usually used for placement of arterial catheters. The femoral artery can be easily cannulated and gives a better signal, but the presence of a femoral catheter interferes more with patient mobility and warrants concern about infection.[5] Use of other sites, such as the brachial or the axillary artery or even the dorsalis pedis artery, can be considered. An important point to remember is that the pulse pressure increases from the core to the periphery. In other words, the systolic pressure is overestimated in smaller arteries (Fig. 4.2). Hence, it may be better to rely more on mean values than on systolic or diastolic pressures.

Complications

The most feared complication with use of arterial catheters is ischemia. With any suspicion of ischemia, the catheter must be removed immediately. The Allen test, used to determine occlusive arterial lesions distal to the wrist, is unreliable and is no longer widely used. The accidental disconnection of arterial lines can be associated with severe hemorrhage and even exsanguination. Infectious complications are rare.

Central Venous Catheters

What Do They Offer?

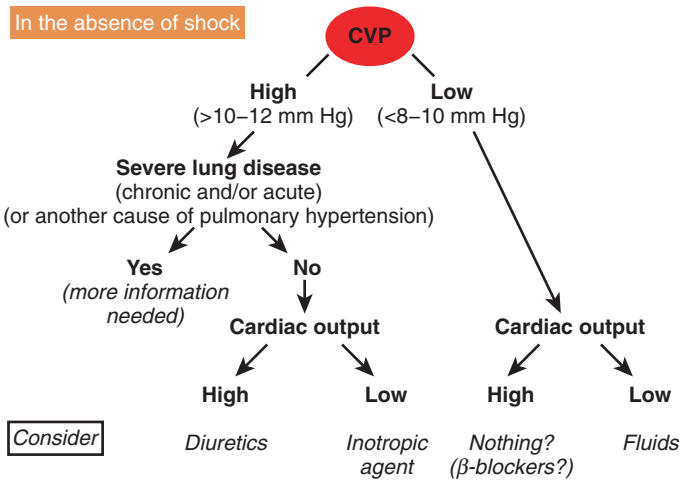
The central venous catheter can facilitate fluid administration. It also allows measurement of the central venous pressure (CVP) and enables access to central venous blood for sampling.

Trace Analysis

Analysis of the CVP waveform can provide some interesting information. In particular, a large y descent indicates a restrictive cardiac state, but not all restrictive patterns are associated with this finding.

Fluid Administration

The large-bore central venous catheter allows fluids to be administered fast and reliably in the presence of acute hemorrhage. Placement of a central catheter is therefore essential in patients with hemorrhage caused by polytrauma or with other forms of acute bleeding. It also allows irritant or hypertonic fluids to be administered, such as parenteral solutions, potassium-enriched solutions, and some therapeutic agents. Central venous lines also can be convenient in patients who need prolonged intravenous therapy when peripheral venous access becomes problematic.



• **Fig. 4.3** Interpretation of central venous pressure *(CVP)* must be made in conjunction with a measure of cardiac output.

Measurement of Central Venous Pressure

CVP is identical to right atrial pressure (RAP) (in the absence of vena cava obstruction) and to right ventricular (RV) end-diastolic pressure (in the absence of tricuspid regurgitation). It is thus equivalent to the right-sided filling pressure. CVP is determined by the interaction of cardiac function and venous return, which is itself determined by the blood volume and the compliance characteristics of the venous system. Hence, an elevated CVP can reflect an increase in blood volume as well as an impairment in cardiac function. The cardiac output must therefore be taken into consideration when interpreting a CVP value (Fig. 4.3). Because the CVP evaluates the right-sided filling pressures, CVP can be increased in the presence of pulmonary hypertension, even if left ventricular (LV) function is normal. The normal value in healthy persons is very low, not exceeding 5 mm Hg in the patient breathing spontaneously. Thus the CVP value may not be much lower than normal in the presence of hypovolemia. In general, a CVP below 10 mm Hg can be considered as indicative that the patient is more likely to respond to fluid resuscitation, but exceptions to this rule exist. A high CVP suggests a certain blood volume but does not guarantee sufficient LV filling.

Clinically, CVP can be assessed by evaluation of the degree of jugular distention or liver enlargement. An isolated CVP measurement is not very useful and is not a good indicator of a positive response to fluids; an increase in CVP without a concurrent increase in cardiac output is not only useless but also harmful, because it will lead to increased edema formation. Hence, changes in CVP during rapid fluid administration are important components of the fluid challenge.[6,7]

Access to Blood in the Superior Vena Cava

Measuring the central venous oxygen saturation ($ScvO_2$) is a surrogate for measurement of the true mixed venous oxygen saturation (SvO_2). Although absolute values of $ScvO_2$ are not identical to single SvO_2 values, trends in $ScvO_2$ over time may follow the same pattern as trends in SvO_2, making $ScvO_2$ a useful measure in patients who do not require a PAC.[8] $ScvO_2$ can be obtained either intermittently (by withdrawal of blood samples) or continuously (with the use of a catheter equipped with fiberoptic fibers). The so-called early goal-directed therapy in septic shock was initially proposed by Rivers et al.[9] and consisted of targeting an $ScvO_2$ of at least 70% in all patients with septic shock. This strategy did not result in improved outcomes in three large randomized controlled trials,[10–12] which included patients who were already resuscitated and already had normal $ScvO_2$ values. Nevertheless, monitoring $ScvO_2$ can still be useful in complex cases.[13]

Access

The central venous catheter generally is introduced via the internal jugular vein or the subclavian vein, although the risk of pneumothorax may be somewhat higher with this latter route.[14] Peripherally inserted central catheters (PICCs) can also be placed via the cephalic vein, basilic vein, or brachial vein. Introduction of a femoral catheter through the abdominal inferior vena cava to the right atrium can also yield reliable CVP measurements. The use of femoral catheters, however, is associated with a greater risk of infections and thrombophlebitis[14] and does not provide a true CVP (as the tip of the catheter is not located in the thorax).

Complications

Complications of central venous catheterization are related primarily to puncture of the central vein; hemothorax can be life-threatening, especially in the presence of severe respiratory failure. In the presence of unilateral pathology, the catheter must be introduced on the affected side. Arterial puncture resulting in a local hematoma is not uncommon, but hematoma formation usually is without major consequences. Bedside ultrasonography can help guide the introduction of the catheter into the vein. Excessive advancement of a long catheter in a small patient can result in arrhythmias; such arrhythmias have been described with advancement of the catheter tip into the right ventricle, but this problem can be identified by the presence of an RV trace on the monitor display.

Catheter-related infections constitute the major long-term complication. Adherence to basic hygiene guidelines can decrease the incidence of catheter-related sepsis. Triple-lumen catheters may be associated with a higher incidence of catheter-related infection,[15] primarily as a result of increased catheter manipulation. The use of antimicrobial-coated catheters may decrease the risk of infections,[16] but fears remain about the risks of development of resistant organisms.[17] Routine replacement of catheters after 3 to 7 days is not recommended.[18,19]

Pulmonary Artery Catheters

What Do They Offer?

PACs allow collection of data on right atrial, pulmonary artery, and pulmonary artery occlusive pressures (Fig. 4.4); flow (cardiac output); and oxygenation (SvO_2).

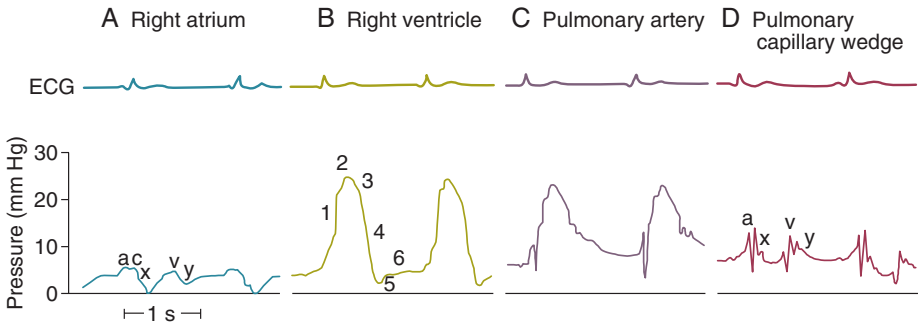
Pressures

Right Atrial Pressure

As indicated earlier, the RAP is identical to the CVP in the vast majority of cases.

Pulmonary Artery Occlusion Pressure

When the balloon on the catheter is inflated, it causes an obstruction (becomes wedged) in a small branch of the pulmonary artery, interrupting the flow of blood locally (but blood flow continues normally in the rest of the pulmonary circulation), so that (assuming the absence of an abnormal obstacle) a continuous column of



• **Fig. 4.4** Pressure waveforms. A, The normal right atrial (RA) tracing. The a wave is the RA pressure rise resulting from atrial contraction and follows the P wave of the electrocardiogram *(ECG)*. On simultaneous ECG and RA tracings it usually occurs at the beginning of the QRS complex. The c wave, caused by closure of the tricuspid valve, follows the a wave and is coincident with the beginning of ventricular systole. Atrial relaxation (x descent) is followed by a passive rise in RA pressure resulting from atrial filling during ventricular systole and occurs during the T wave of the simultaneously recorded ECG. The y descent reflects the opening of the tricuspid valve and passive atrial emptying. B, The normal right ventricular (RV) tracing. The sharp rise in RV pressure *(1)* is due to isometric contraction and is followed by a rapid pressure decrease *(2)* as blood is ejected through the pulmonary valve. This rapid ejection is followed by a phase of more reduced pressure decrease, which is often reflected in a small step in the downslope of the RV pressure waveform *(3)*. The subsequent sharp decline in RV pressure *(4)* occurs as a result of isometric relaxation and is noted once the RV pressure falls below the pulmonary artery (PA) pressure (with consequent closure of the pulmonary valve). As RV pressure falls below RA pressure, the tricuspid valve opens, and passive refilling *(5)* of the right ventricle occurs, followed by atrial contraction, causing a biphasic wave of ventricular filling to appear on the RV tracing *(6)*. C, The normal pulmonary arterial waveform. A pulmonary artery systolic elevation is caused by ejection of blood from the right ventricle, followed by a decline in pressure as RV pressure falls. As RV pressure falls below pulmonary artery pressure, the pulmonary valve closes, which causes a momentary rise in the declining pulmonary artery pressure. This is the dicrotic notch characteristic of the pulmonary arterial (and also the systemic arterial) waveform. The pulmonary artery systolic wave usually occurs in synchrony with the T wave of the ECG. Pulmonary artery diastolic pressure (PADP) does not fall below RA pressure and therefore is higher than right ventricular end-diastolic pressure; it is an approximation to left ventricular end-diastolic pressure (LVEDP). D, The normal pulmonary artery occlusion pressure (PAOP) waveform. The waveform of the pulmonary capillary wedge pressure (PCWP) is subject to the same mechanical variables as the RA waveform, but because of the damping that occurs through the pulmonary circulation, the waves and descents often are less distinct. Similarly, the mechanical events are recorded later in the cardiac cycle, as seen on the ECG. Thus the a wave is not seen until after the QRS complex, and the v wave occurs after the T wave of the ECG. The PCWP is a closer approximation to LVEDP than is PADP. (From Grossman W: Cardiac catheterization. In: Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine.* 3rd ed. Philadelphia: WB Saunders; 1992.)

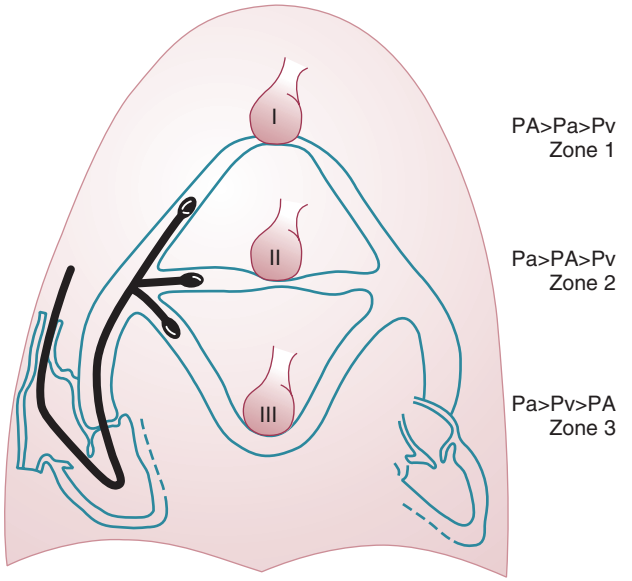
blood is present between the tip of the PAC and the left atrium. This pulmonary artery occlusion pressure (PAOP), or pulmonary artery wedge pressure, generally reflects the left atrial pressure well. Nevertheless, a number of steps must be taken to ensure the adequacy of the measurement.

A first question is whether the PAOP reflects the pressure in the pulmonary veins and not the alveolar pressure. The tip of the catheter should be in a West zone III position, where a continuous column of blood exists between the catheter tip and the left atrium (Fig. 4.5). These considerations are less important with fluid optimization and with today's lower positive end-expiratory pressures (PEEPs).

To exclude a possible influence of airway pressure on PAOP readings, the changes in PAOP can simply be compared with the changes in pulmonary artery pressure (PAP) during the respiratory cycle. If PAOP reflects the pressure within the pulmonary veins, these changes should be identical, because the pulmonary artery and vein should be subjected to identical changes in intrathoracic pressures. If, on the other hand, the catheter tip is not in a West zone III, the changes in PAOP will be more significant than the changes in PAP. In these latter conditions, either fluid administration or some reduction in the PEEP level may abolish the differences.

The next question is whether the measured pressure is truly a transmural pressure—that is, the pressure difference between the vascular structures and the environmental structures. In other words, will changes in surrounding intrathoracic pressures influence the pressures measured? In the case of intrathoracic pressures, the changes in pleural pressure are particularly relevant. Hence, all measurements should be performed at end-expiration, when the pleural pressure is closest to zero. A marked fall in intrapleural pressure, as with a Mueller maneuver (forced inspiration against resistance), may dramatically increase the transmural pressures. A more common problem in the intensive care unit (ICU) is the increase in pleural pressure owing to positive-pressure ventilation, sometimes with high PEEP levels.

One method of combating this problem could be to subtract the esophageal pressure from the measured PAOP, but this approach has a number of technological limitations. Simple disconnection of the respirator to measure PAOP after obtaining an equilibration state is not recommended, because the measured PAOP will not represent the real value when PEEP is applied. A better method consists of measuring the lowest (nadir) PAOP, within seconds after a very transient disconnection from the ventilator, to identify the true transmural pressure before a new equilibrium is reached.[20]



• **Fig. 4.5** The position of the pulmonary artery catheter tip in relation to the zones of the theoretical lung model described by West. For pulmonary artery occlusion pressure (PAOP) to be a valid estimate of "left heart" filling pressure, a continuous column of blood must exist between the catheter tip and the left atrium. In zones I and II, pulmonary vasculature is either totally or partially compressed by the intraalveolar pressure, and measurements of PAOP will be misleading. *PA,* Alveolar pressure; *Pa,* pulmonary artery pressure; *Pv,* pulmonary venous pressure. (From Marini JJ: *Respiratory Medicine and Intensive Care for the House Officer.* Baltimore: Williams & Wilkins; 1991.)

Such a maneuver suppresses the high intrathoracic pressure and eliminates the influence of the extramural pressure, but the values obtained may not be valid in the presence of intrinsic PEEP. Other methods have been suggested, some relatively sophisticated[21] and others more simple, involving subtraction of approximately one-third of the PEEP level from the measured PAOP, for example. The question is whether this is really so important because absolute PAOP values are not very helpful.

In respiratory failure, PAOP does not represent true capillary pressure, which may be somewhat higher. The true capillary pressure may be estimated from the measurement of the intersection point of the rapid and slow pressure decay curves recorded after a rapid interruption of the blood flow; such measurements of capillary pressure are possible from the pressure trace. This pressure is well correlated with extravascular lung water in animal experiments. The need to know these values is questionable, however, because the primary goal remains to keep these hydrostatic pressures as low as possible while maintaining adequate cardiac output.

PAOP may not adequately reflect LV end-diastolic pressure. It may be lower in patients with aortic regurgitation or higher in the presence of significant tachycardia or mitral valve disease. LV end-diastolic pressure may not even accurately predict LV end-diastolic volume. This was already demonstrated many years ago with radionuclide techniques.[22] Preload is more directly defined as the end-diastolic volume. A stiff, noncompliant ventricle can result in a relatively high end-diastolic pressure for a given end-diastolic volume. An evaluation of end-diastolic volumes can be obtained less invasively with echocardiographic techniques. Likewise, the use of transthoracic thermodilution techniques allows the estimation of intrathoracic blood volume and global end-diastolic volumes. However, these assessments of end-diastolic volumes do not provide additional information about the likelihood of fluid responsiveness.

In sum, then, a given level of cardiac filling pressures does not provide much information about fluid responsiveness, but monitoring can be very helpful to guide a fluid challenge.[6] During fluid administration, the goal is to obtain a significant increase in cardiac output (by the Frank-Starling mechanism), with the least increment in cardiac filling pressures, to minimize the risk of edema formation. The goal is not to keep the cardiac filling pressures within predefined arbitrary limits; rather, PAOP is a direct determinant of edema formation in the lungs. The key principle is to keep the PAOP as low as possible, provided that all of the other organs are happy.

Pulmonary Artery Pressures

Normally the pulmonary vasculature is a low-resistance circuit, so that the diastolic PAP should be equal to or only slightly higher than the PAOP. An increased pressure gradient between the diastolic PAP and the PAOP indicates active primary pulmonary hypertension related to pulmonary vascular changes (hypoxia) or diseases (primary pulmonary artery hypertension). Pulmonary hypertension may result in RV dilation with septal shifts that may compromise LV function.

Cardiac Output

The reference method for measurement of cardiac output is use of the Fick equation; however, this equation is difficult to apply in practice. The indicator dilution technique has been used instead. Indocyanine green clearance has been used for many years, but this method is time-consuming and quite difficult to perform. The thermodilution technique developed by Ganz is a convenient technique that today allows the almost continuous measurement of cardiac output. The presence of tricuspid insufficiency is the major limitation to this technique. Other techniques, including transpulmonary and lithium dilution techniques, have been developed but are somewhat less precise.

The thermodilution technique estimates cardiac output over several cardiac cycles, whereas other techniques, including those based on pulse contour analysis, may assess beat-to-beat variations. These techniques may be useful for estimating the influence of changes in intrathoracic pressures on the stroke volume variation, an estimate of fluid responsiveness.

Right Ventricular Volumes

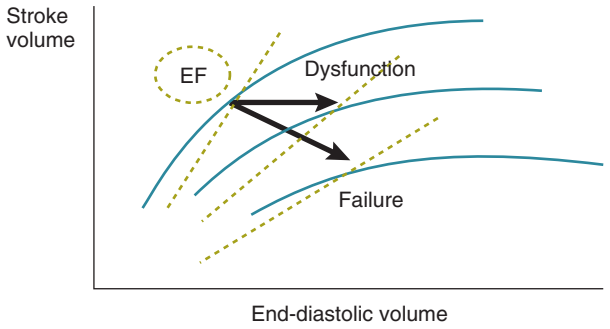
The use of a modified PAC equipped with a fast-response thermistor also allows evaluation of the right ventricular ejection fraction (RVEF) (Fig. 4.6). With knowledge of the stroke volume, it becomes easy to calculate the end-systolic and end-diastolic volumes. This measurement can be particularly useful in the presence of RV failure, but this also is a situation in which the measurement is least reliable: tricuspid regurgitation secondary to pulmonary hypertension.

Mixed Venous Oxygen Saturation

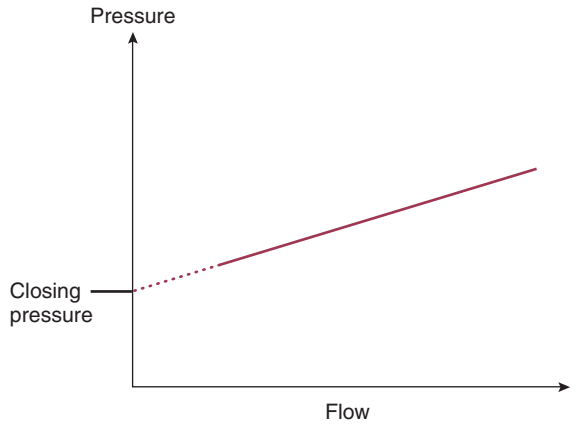
$S\bar{v}O_2$ represents the balance between oxygen consumption and oxygen supply. According to the Fick equation:

$$\dot{V}O_2 = \text{Cardiac output} \times (CaO_2 - C\bar{v}O_2)$$

where $\dot{V}O_2$ is oxygen uptake and CaO_2 and $C\bar{v}O_2$ are the arterial and mixed venous oxygen content, respectively. If the dissolved



• **Fig. 4.6** Ventricular function curve depicting the difference between ventricular dysfunction (decrease in the ventricular ejection fraction *[EF]* but preservation of stroke volume) and ventricular failure (defined as the inability of the heart to pump enough flow). The EF, the ratio between stroke volume and end-diastolic volume, is represented by the *dashed lines*; it is decreased in all cases.



• **Fig. 4.7** Relationship between pressure and blood flow, illustrating the limitations in the calculation of the vascular resistance. Note that the line defining that relationship does not go through the origin, because the pressure is not zero in the absence of blood flow.

oxygen in the blood is neglected for the purposes of calculation, then:

$$VO_2 = \text{Cardiac output} \times Hb\,(SaO_2 - SvO_2) \times C$$

and

$$SvO_2 = SaO_2 - (VO_2/\text{Cardiac output} \times Hb \times C),$$

where Hb is hemoglobin and C represents the oxygen-carrying capacity of saturated hemoglobin.

Accordingly, a decrease in SvO_2 can reflect either a decrease in SaO_2 (hypoxemia), anemia, or a relative inadequacy of cardiac output in relation to the oxygen demand of the tissues.

SvO_2 can be measured continuously using catheters equipped with fiberoptic fibers, and measurements are helpful to guide therapy. $ScvO_2$ has been proposed as a surrogate for SvO_2, but the relationship between $ScvO_2$ and SvO_2 is rather vague. Indeed, the $ScvO_2$ is lower than the SvO_2 in healthy conditions (as a result of the low O_2 extraction by the kidneys) but is higher than the SvO_2 in critically ill patients (because of relative increase in O_2 extraction in the kidneys and in the gut).[23] Moreover, O_2 extraction is high in the coronary circulation, and this is missed in the measurement of $ScvO_2$.

Derived Variables

Hemodynamic assessment can include a number of derived variables, including resistance, ventricular stroke work, oxygen transport, oxygen consumption, and venous admixture, as described next.

Resistance

In steady-flow conditions, Ohm's law indicates that resistance is the ratio between the pressure drop and the flow in the system. In the pulmonary circulation, the inflow pressure would be the mean PAP and the outflow pressure would be PAOP; for the systemic circulation, these would be the MAP and the CVP, respectively. In either case, flow would be cardiac output. This approach is limited, however, by the fact that the extrapolated intercept of the PAP–cardiac output relationship represents the average closing pressure of the small pulmonary arterioles, and the slope represents the upstream arterial resistance. Accordingly, the increased PAP in pulmonary hypertension can be explained by both an increase in pulmonary vascular closing pressure and an increase in vascular tone, and pulmonary vascular resistance is not a good reflection of vasomotor tone in the pulmonary vasculature. Pulmonary hemodynamics are therefore best assessed by altering blood flow to better evaluate this relationship (Fig. 4.7).

Calculation of systemic vascular resistance (SVR) is not very helpful either. It is better to base clinical decisions on primary variables. Simply stated, a relatively high cardiac output in relation to arterial pressure reflects a low SVR state, whereas a relatively low cardiac output reflects a high SVR state.

Ventricular Stroke Work

The work developed by the ventricles is determined by the ventricular work as derived from the product of flow and the pressure generated. The relationship between stroke work (SW) and the respective filling pressure represents a better assessment of contractility than does the stroke volume. LV stroke work index (LVSWI) can be calculated using the equation:

$$LVSWI = SVI\,(MAP - PAOP) \times 0.0136,$$

where SVI represents the stroke volume index.

Oxygen-Derived Variables

Oxygen delivery (DO_2) can be assessed as the product of cardiac output and the arterial oxygen content, according to the equation:

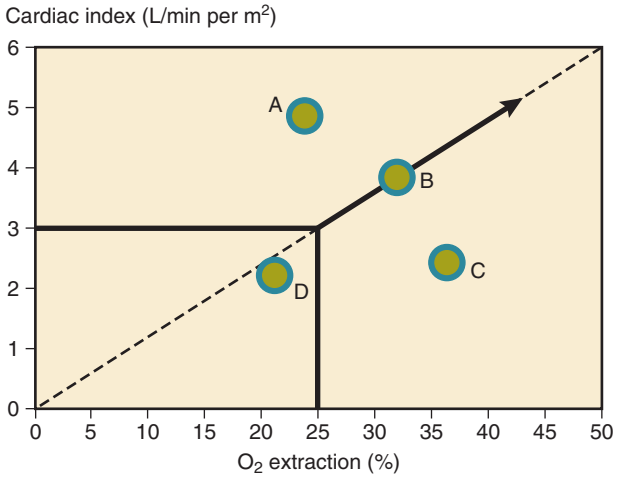
$$DO_2 = \text{Cardiac output} \times CaO_2$$
$$= \text{Cardiac output} \times ([Hb] \times SaO_2 \times 1.39) + 0.0031 \times PaO_2$$

Calculations of this variable benefit from combining measurements of cardiac output, hemoglobin, and SaO_2 but have the limitation that the corresponding oxygen demand is unknown. Some studies have suggested that maintaining supranormal DO_2 in the perioperative period in high-risk patients[24] or early after trauma may result in better outcomes.

Oxygen consumption also can be calculated from the product of cardiac output and the arteriovenous oxygen difference, according to the formula:

$$VO_2 = \text{Cardiac output} \times (CaO_2 - CvO_2),$$

where CvO_2 is calculated in the same way as for CaO_2, using the SvO_2 instead of the SaO_2.



• **Fig. 4.8** Diagram illustrating the relationship between cardiac index and oxygen (O_2) extraction. Four typical examples are given: hyperkinetic state (A), anemia (B), low cardiac output state (C), and profound anesthesia (D).

The difficulty is in evaluating the oxygen requirements (or the oxygen demand) of the body. VO_2 assessment may perhaps be useful to evaluate the caloric need of the critically ill patient.

The calculation of oxygen extraction (oxygen extraction ratio, or O_2ER) is accomplished by determining the ratio of VO_2 to DO_2, or in a simplified way:

$$O_2ER = VO_2/DO_2 = (CaO_2 - CvO_2)/CaO_2$$
$$= (SaO_2 - SvO_2)Hb/SaO_2 \times Hb$$
$$= (SaO_2 - SvO_2)/SaO_2$$

Accordingly, when SaO_2 is close to 100%, in the absence of hypoxemia, O_2ER mirrors SvO_2. Its calculation can be useful in the presence of hypoxemia, when SaO_2 is decreased. Also, the relationship between cardiac output and O_2ER can be helpful to compare the central and the peripheral components of oxygen delivery (Fig. 4.8). This relationship is independent of hemoglobin, so it can be helpful in evaluating the cardiovascular status in the presence of anemia.[25]

Venous Admixture

Venous admixture can be calculated by the Berggren equation:

$$Qs/Qt = (Cc'O_2 - CaO_2)/(Cc'O_2 - CvO_2),$$

where Qs is shunt flow, Qt is total pulmonary blood flow, and $Cc'O_2$ represents the capillary oxygen content (assuming an oxygen saturation of 100%). This may help to assess the effects of various interventions (PEEP or other respiratory conditions, administration of vasoactive agents) on pulmonary hemodynamics.

Complications

Complications of pulmonary artery catheterization can be divided into seven categories as listed in Box 4.1. Many of these can be prevented, and most are relatively uncommon.

Complications of the venous access are the same as for the insertion of a central venous catheter. Arrhythmias are common but usually are without major consequence, except in moribund patients. It has been suggested that lidocaine should be given prophylactically in predisposed patients, but this usually is not necessary. Likewise, complete atrioventricular block may develop in patients with left bundle branch block, but this is exceptional. Knot formation will be rare if the catheter is advanced carefully and if its presence in the pulmonary artery is confirmed before further advancement into the right ventricle. In particular, care should be taken not to advance the catheter by more than 30 to 35 cm into the right ventricle. Thrombotic complications have become rare with the development of heparin-coated catheters. The appearance of an infiltrate beyond the tip of the PAC on the chest film should suggest an evolving thrombotic event, which should lead to consideration of the withdrawal of the catheter. Endothelial lesions have been found at autopsy, but their clinical relevance is doubtful. Endocarditis is very rare. Valvular damage may occur as a result of improper handling of the catheter (in particular, its withdrawal with the balloon still inflated). Catheter-related infections remain a risk, but they do not seem to be any more common than with central venous catheters.

Pulmonary artery rupture is the most feared complication; although it is exceptionally rare, it is associated with a high mortality rate. The usual cause is overinflating the balloon in the presence of resistance to inflation, particularly in the presence of preexisting pulmonary artery hypertension. The cardinal sign of rupture is the development of hemoptysis. The reaction to this event should not be to completely pull out the catheter, but rather to withdraw it slightly and then inflate the balloon. If the hemorrhage does not stop, a thoracotomy may be necessary to repair the pulmonary artery.

• BOX 4.1 Complications of Pulmonary Artery Catheter Insertion

- Complicated vascular access (pneumothorax, hematoma)
- Arrhythmias (e.g., heart block, ventricular tachycardia/fibrillation)
- Catheter knotting
- Pulmonary thrombosis and infarction
- Endothelial or valvular damage
- Colonization and bacteremia
- Pulmonary artery rupture

Technical Limitations

Invasive measurements of pressures are based on fluid-filled systems with disposable transducers. The transducer includes a deformable membrane with a Wheatstone bridge modifying the electrical resistance and, correspondingly, the intensity of a current. Reliability is ensured by the excellent linearity between the pressure signal and the electrical signal generated by the transducer, in a range of frequency values largely exceeding the range of frequencies found in the human body.

Reliability is less secure in the intermediary system made of tubes and stopcocks along the extent of the pressure system. These can modify the morphology of the trace, resulting in damping. Motion artifacts can further complicate the tracings. The presence of air bubbles also may alter the signal. Use of fluid-filled catheters to measure pressures provides reliable estimates of mean vascular pressures.

To guarantee reliable measurements, it is essential to have appropriate zeroing, which is accomplished by opening the transducer to atmospheric pressure (taken as the zero value). All pressures must be measured with reference to an arbitrary reference point. This zero reference pressure level should ideally be where

it is least influenced by location on the body. In humans, it is thought to be at the level of the right atrium, so the reference level usually is placed in the midchest (midaxillary) position at the level of the fourth intercostal space. In healthy persons, the CVP referred to that region does not change with supine versus upright position. Obviously, errors in zeroing are relatively more important for measurements of cardiac filling pressures than for arterial pressure measurements, because the errors are quantitatively identical but proportionally greater. One should also ensure the good quality of the trace. Shaking the catheter should result in large pressure variations on the screen. A damped system underestimates systolic pressures. The liquid column should be continuous, without air bubbles in the system. Excessive tubing length, or multiple stopcocks and connectors, may decrease the resonant frequency, resulting in "whipped" traces. Likewise, the presence of bubbles must be carefully avoided. Transient flushing should be followed by an abrupt return of the pressure trace to its actual value.

Applications: Diagnosis Versus Monitoring

Today the PAC is more useful in guiding therapy rather than in identifying abnormalities; this latter role has largely been taken over by noninvasive, mainly echocardiographic techniques (Table 4.1). In the past, analysis of waveforms was used—for example, the abnormal v waves of mitral regurgitation. Likewise, an increase of all pressures to identical levels should suggest pericardial tamponade. These findings should still alert the clinician to possible abnormalities, but echocardiographic techniques have largely replaced the use of the PAC for identifying valvular disease. The use of echocardiographic techniques for monitoring, however, is hampered by the difficulty of keeping the probe in the esophagus for prolonged periods, and results are very operator dependent.

To illustrate the need to integrate different variables, rather than focusing on just one variable, some suggested applications follow:

- *Interpretation of a cardiac output value.* It is important to consider the four determinants of cardiac output (Fig. 4.9).[26] Interpretation should start by considering the stroke volume (cardiac output divided by heart rate) and relating this to an index of ventricular filling (PAOP) and an index of ventricular afterload (arterial and pulmonary artery pressures); an inotropic agent should be added only when preload and afterload have been optimized.
- *Fluid status.* Low cardiac filling pressures may be normal or reflect hypovolemia. The measurement of cardiac output and SvO_2 will help determine fluid needs. Indeed, hypovolemia typically is associated with a low cardiac output (Fig. 4.10) and a low SvO_2 (Fig. 4.11). By contrast, hypervolemia in the presence of normal cardiac function is manifested by high cardiac filling pressures associated with a relatively high cardiac output and normal or high SvO_2.
- *Hemodynamic versus nonhemodynamic pulmonary edema.* The distinction between hemodynamic and nonhemodynamic types of lung edema no longer requires pulmonary artery catheterization; the clinical history and less invasive (e.g., echocardiographic) measurements usually are sufficient to separate the two.
- *RV dysfunction versus failure.* A reverse gradient between RAP and PAOP (i.e., a higher RAP than PAOP) indicates RV dysfunction or failure and usually is secondary to pulmonary

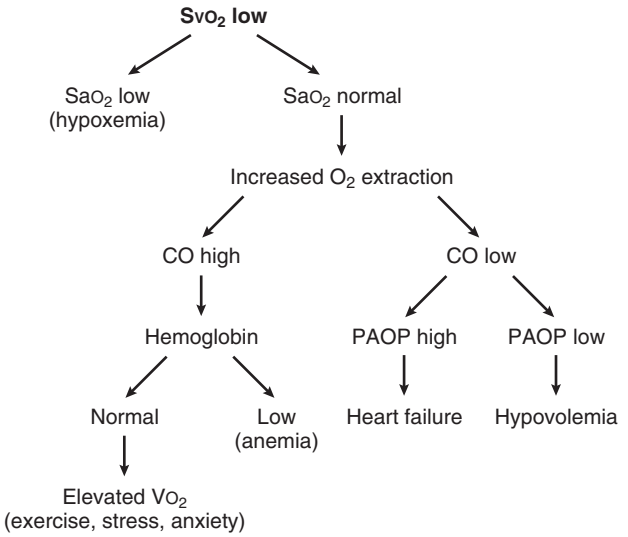
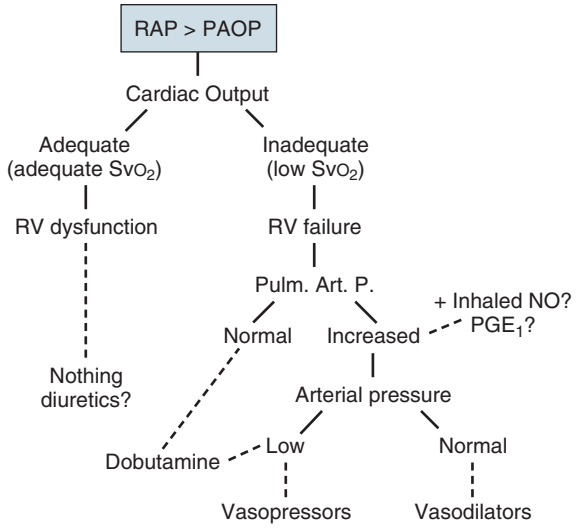
TABLE 4.1 Pulmonary Artery Catheterization Versus Echocardiographic Techniques for Management of Selected Disorders: Relative Value

	PA CATHETERIZATION		ECHOCARDIOGRAPHY	
Disorder	Diagnosis	Monitoring	Diagnosis	Monitoring
Tamponade	+	++	+++	+
Hypovolemia	++	+++	++	+
Valvular disease	+	++	+++	+
Heart failure	++	+++	++	+
Right ventricular failure	++	+++	+++	++
Septic shock	+	+++	+	+

PA, Pulmonary artery.



• **Fig. 4.11** Interpretation of a low SvO_2 (mixed venous oxygen saturation). *CO,* Cardiac output; *PAOP,* pulmonary artery occlusion pressure; *SaO_2,* arterial oxygen saturation; *VO_2,* oxygen uptake.



• **Fig. 4.12** Interpretation of a reversed gradient between the right atrial pressure *(RAP)* and the pulmonary artery occlusion pressure *(PAOP). NO,* Nitric oxide; *PGE_1,* prostaglandin E_1; *RV,* right ventricular; *SvO_2,* mixed venous oxygen saturation.

hypertension, as will be immediately apparent from the measurements of pulmonary artery pressures. RV dysfunction is manifested by RV dilation (and thus a decrease in RVEF) with no limitation on cardiac output. This is the most common situation in patients with acute respiratory distress syndrome, who usually maintain a hyperkinetic state. Rather, RV failure refers to a state in which cardiac output is no longer sustained at adequate levels. These different entities are illustrated in Fig. 4.12.

- *LV dysfunction versus failure.* Here the gradient between PAOP and RAP is higher than the typical 3 to 5 mm Hg. As with the right ventricle, in LV dysfunction the ventricular volumes may increase (so the ejection fraction will decrease), but the cardiac output may be simultaneously preserved; such a situation may exist in septic shock. LV failure is more common and is manifested by a decrease in cardiac output and SvO_2.

Assessing Effects of Interventions

The PAC can be used to monitor the effectiveness of various interventions:

- *Fluid challenge.* A fluid challenge technique is indicated whenever the benefit of fluid administration is in doubt.[6] Ideally, fluid administration results in increases in cardiac output and tissue perfusion without major increases in cardiac filling. An increase in PAOP in the absence of a significant change in cardiac output and SvO_2 indicates that fluid administration will only result in an increased risk of edema and should be discontinued.
- *Inotropic agents.* The use of inotropes aims to increase cardiac output and possibly decrease PAOP. Lack of an increase in cardiac output after administration of a β_1-adrenergic inotropic agent indicates a desensitization of the β-adrenergic receptors and is associated with a worse prognosis.[27]
- *Vasopressors.* The use of pure vasoconstrictors is expected to increase arterial pressure as well as cardiac filling pressures. An excessive increase in cardiac filling pressures with use of such an agent suggests the need for addition of an inotropic agent (e.g., dobutamine).
- *Vasodilators.* The administration of vasodilators may rapidly reduce arterial pressure so that continuous arterial pressure monitoring is usually indicated. Moreover, a reduction in vascular tone in the presence of hypovolemia may reduce venous return and thus cardiac output.

Clinical Indications for Pulmonary Artery Catheter Insertion

The improvement in noninvasive diagnostic techniques means that today the PAC is used primarily for monitoring. Potential indications include the following:

- *Severe circulatory shock.* The PAC can be used to help guide fluid challenges and titrate inotropic agents. Shock caused by hypovolemia (as in polytrauma or with other forms of massive bleeding) does not require insertion of a PAC because management of such patients generally is quite straightforward.
- *RV failure.* The PAC can be used to monitor pulmonary artery pressures, the gradient between RAP and PAOP, cardiac output, and SvO_2.
- *Acute respiratory failure caused by pulmonary edema.* Whether lung edema is hemodynamic or nonhemodynamic, the strategy should be to keep the hydrostatic pressures as low as possible, but this requires measurements of cardiac output and SvO_2 to ensure the systemic circulation is not compromised.
- *Complex fluid management in the presence of impending renal failure.* Sometimes it is difficult to evaluate the fluid status in oliguric patients, in whom hypovolemia may compromise renal function but hypervolemia obviously must be avoided.
- *Dynamic assessment of cardiac function in specific conditions.* The best example is that of the patient who is difficult to wean from mechanical ventilation, possibly owing in part to cardiac dysfunction.

Pulmonary Artery Occlusion Pressure and Partial Occlusion

Partial occlusion of the pulmonary artery in the presence of pulmonary hypertension may be difficult to recognize and can lead to significant overestimation of the PAOP. A useful clue to partial occlusion is occurrence of a substantial increase in the

PAOP without a concomitant change in the pulmonary artery diastolic pressure. If the pulmonary artery diastolic pressure minus the PAOP gradient is normal and the underlying disease process would predict increased pulmonary vascular resistance, partial occlusion should be suspected. Partial occlusion may occur if a catheter is either too proximal or too distal in the pulmonary artery, and appropriate repositioning may be corrective. The best PAOP may be obtained in some circumstances by further advancing the catheter with the balloon fully inflated and at other times by retracting the catheter to the original pulmonary artery position and attempting to occlude with 1.0 to 1.2 mL of air, instead of full inflation. It is imperative never to inflate against resistance.

Does the Use of a Pulmonary Artery Catheter Improve Outcome?

The use of the PAC has been challenged on the basis that it has not been shown to improve outcomes.[28] An improvement in outcome, however, has not been demonstrated with other monitoring techniques either. Moreover, a number of studies have indicated that the use of the PAC can influence therapy.[29] If use of a PAC does not result in better outcomes, important and challenging questions arise about the beneficial effects of many therapeutic interventions in the ICU. Some evidence suggests that the use of the PAC may improve outcomes in the most severely ill subsets of critically ill patients.[30] Errors in measurements from the PAC were identified many years ago,[31] and another consideration is the considerable interobserver variability in interpretation of PAC tracings.[32] Clearly, not all ICU patients need a PAC and insertion should be reserved for complex cases.[33,34] If a PAC is considered necessary, it is important to respect the three successive steps: to take adequate and full measurements; to interpret the results correctly; and to apply the gathered information for the patient's benefit. Unfortunately, potential errors are associated with each step. Some of these issues can be addressed with better teaching and improved basic knowledge of hemodynamics and basic physiology.

Key Points

- No simple guidelines for monitoring are available or applicable in all cases; monitoring should be tailored to each patient's needs.
- Each variable, taken individually, has limitations and is subject to error and difficulty in interpretation. Variables should be combined and integrated to provide a global picture of the clinical situation.
- A monitoring technique cannot improve outcome by itself; each of the three components of monitoring is important with any monitoring technique:
  - Accurate collection of data
  - Interpretation of the data
  - Application of the information obtained
- Cardiac output is an adaptive value that must constantly adjust to the oxygen requirements of the organs.
- Separation of the four determinants of cardiac output—heart rate, contractility, preload, and afterload—is useful to consider the various interventions that can be used to increase it.
- Measurements of mixed venous oxygen saturation are essential to interpret cardiac output measurements.
- The relationship between cardiac filling pressures and volumes is relatively weak. Pressure measurements are important, however, because pressures (rather than volumes) are the primary determinant of edema formation.
- The calculation of derived variables, such as vascular resistances, ventricular work, and oxygen-derived variables, is of limited usefulness.

Review Questions

1. Invasive arterial pressure measurement is required in all of the following *except*
a. Severe hypotension
b. Severe hypertension
c. Induced hypertension
d. Inotropic therapy
Answer: d. The aim of inotropic therapy is to increase cardiac output and oxygen delivery. It may influence arterial pressure somewhat but not sufficiently to require invasive monitoring (see the Arterial Pressure Measurement section).

2. How do the central venous pressure (CVP) and the right atrial pressure (RAP) correlate with each other?
a. The CVP is slightly higher than the RAP.
b. the CVP is slightly lower than the RAP.
c. The two values are identical.
d. It may vary depending on the respiratory conditions.
Answer: c (see the Measurement of Central Venous Pressure section).

3. A low SvO_2 can be explained by all of these *except*
a. Sedation
b. Anemia
c. Hypovolemia
d. Massive pulmonary embolism
Answer: a. Reduced oxygen demand is characterized by a normal or high SvO_2 (decreased oxygen extraction) (see the Mixed Venous Oxygen Saturation section).

5 Cardiac Pacing

GRANT R. SIMONS

CHAPTER OUTLINE

Electrocardiographic Considerations

Clinical Evaluation of AV Block

Management of Bradycardia and Indications of Temporary Pacing

Cardiac Pacing Techniques
- Esophageal and Transthoracic Pacing
- Transcutaneous Pacing
- Epicardial Pacing
- Transvenous Pacing
- Special Considerations in Temporary Pacing

Common Clinical Scenarios in Which Pacing Should Be Considered
- SN Dysfunction and AV Block
- Electrolyte and Metabolic Derangement
- Medication Side Effects
- Infectious Disease
- After Myocardial Infarction
- Torsades de Pointes

Conditions That Do Not Normally Require Pacing
- Hypothermia
- Hypothyroidism
- Obstructive Sleep Apnea
- Preoperative Considerations
- Seizure
- Spinal Cord Injury and Tracheal Suctioning

Permanent Pacing

Indications for Permanent Pacemaker Implantation
- Pacing Indications for Sinus Node Dysfunction
- Pacing Indications for Acquired AV Block
- Other Permanent Pacing Indications

Complications of Permanent Pacemaker Implantation
- Lead Dislodgement
- Pneumothorax
- Cardiac Perforation
- Bleeding and Hematoma
- Inadvertent Lead Placement in the Left Ventricle
- Arrhythmias
- Thrombosis
- Lead Failure
- Twiddler's Syndrome
- Pacemaker Syndrome
- Infection

Special Considerations in Permanent Pacing
- Intravenous Access
- Magnet Application
- Magnetic Resonance Imaging

Conclusions

Familiarity with the clinical management of patients who require cardiac pacing is essential in the critical care setting. The critical care physician should be proficient in the recognition of pathologic bradycardia and of electrocardiographic patterns that portend it, in temporary pacing, and in the management of patients with previously implanted cardiac rhythm devices. This chapter provides a practical review of these topics.

Electrocardiographic Considerations

Bradycardia may result from either sinus node (SN) dysfunction or atrioventricular (AV) block. Electrocardiographic recognition of SN dysfunction, which can present as sinus bradycardia, sinus pauses, junctional or wide-complex bradycardia without P waves, or postconversion pauses after termination of tachyarrhythmias

such as atrial fibrillation, is relatively straightforward and is not reviewed further here.

Electrocardiographic recognition of AV block is more complex, and proper classification is essential for communication among practitioners and for proper risk stratification and therapy.[1,2] AV block is classified as either first, second, or third degree. First-degree AV block is actually a misnomer, as there is no block, but rather delayed activation of the ventricles after atrial activation; this manifests electrocardiographically as a prolonged PR interval over 200 msec. First-degree AV block itself does not actually cause bradycardia as there is 1:1 AV conduction; however, in some patients it may indicate significant conduction system disease and a risk of progression to a higher degree of AV block and clinically significant bradycardia.

Second-degree AV block presents as *intermittent* failure of AV conduction in the form of nonconducted P waves. In type I second-degree AV block (also known as Mobitz I pattern or Wenckebach), there is a nonconstant PR interval followed by a *single* nonconducted P wave. Most commonly, the PR interval progressively prolongs before the blocked beat, after which there is resumption of a new cycle of gradual PR prolongation until the next blocked P wave. In type II second-degree AV block (also known as Mobitz II pattern), there are intermittent *single* nonconducted P waves with a constant PR interval among conducted beats. Importantly, diagnosis of type II second-degree AV block requires a constant P-P interval.[3]

The electrocardiographic distinction of Mobitz I versus II block, which can be challenging, requires at least two consecutive conducted P waves so that a determination can be made regarding whether there is a nonconstant PR interval prolongation prior to block.[3,4] Thus a third type of second degree AV block is 2:1 AV block, which cannot be classified further as either type I or type II because two consecutive conducted P waves are not present to allow for assessment of whether or not the PR interval is constant. The fourth and final type of second-degree AV block is high-degree AV block (also known as advanced AV block), in which two or more consecutive blocked P waves are present. High-degree AV block is described in terms of the AV ratio—for example, as 3:1 or 4:1 AV block. Significant semantic controversy exists regarding whether 2:1 AV block should be classified as either type I, type II, or advanced AV block[4–6]; however, it is clinically useful to describe it as a separate entity, as discussed below.

Third-degree AV block, which is also referred to as complete heart block, is a pattern in which there is no conduction from the atria to the ventricles. The electrocardiographic hallmark of third-degree AV block is a regular ventricular rate; among patients who are not in atrial fibrillation or flutter, the ventricular rate is faster than the sinus rate. If the ventricular rate is irregular, second-degree AV block is likely and should be strongly considered. Among patients in atrial flutter, it is sometimes challenging to distinguish high-degree AV block from complete heart block.

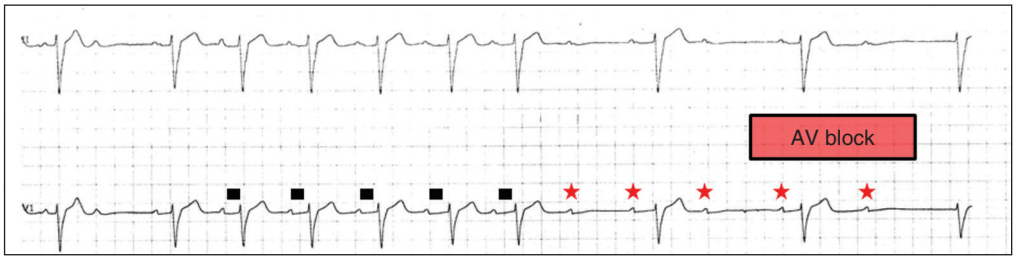
The "level" of AV block—whether within the AV node or below the AV node in the His-Purkinje system—is critical in determining the need for temporary or permanent pacing. A central concept in the assessment of AV block is that *AV nodal block is generally less perilous than block below the AV node (infranodal block)*. This is because AV nodal block is more likely to respond to pharmacologic interventions and because the escape rhythms observed after progression to complete heart block are usually faster and more stable. In contrast, AV block below the AV node, even if intermittent, may portend sudden progression to severe bradycardia or asystole unresponsive to intravenous medications. The pharmacologic responsiveness of the AV node results from its susceptibility to autonomic effects—specifically, parasympatholytic and adrenergic modulation, which is not a characteristic of His-Purkinje tissue. Thus, as a general rule, urgent temporary pacing should be considered for infranodal block, but it is rarely required for block within the AV node.

The most important clinical clue regarding level of block is the QRS width, which is considered to be wide when its duration is 120 msec or greater. Generally speaking, a narrow QRS complex is indicative of block at the level of the AV node, and a wide QRS complex suggests infranodal block. Another important clinical rule is that Mobitz II block is usually infranodal and more ominous than Mobitz I block, which is almost always the result of block at the level of the AV node. Thus a patient with Mobitz II second-degree block is likely to have underlying His-Purkinje disease and a bundle branch block electrocardiographic pattern; this should be recognized as potentially ominous, and there should be a low threshold for temporary pacing, even in the absence of symptoms. On the other hand, a patient with Mobitz I second-degree AV block is much lower risk, and temporary pacing is rarely required, although elective insertion of a permanent pacemaker for alleviation of symptoms may be appropriate. A 2:1 AV block is often "judged by the company it keeps"[5,6]; if Mobitz II infranodal block is also noted, the 2:1 block is likely to share the same mechanism.

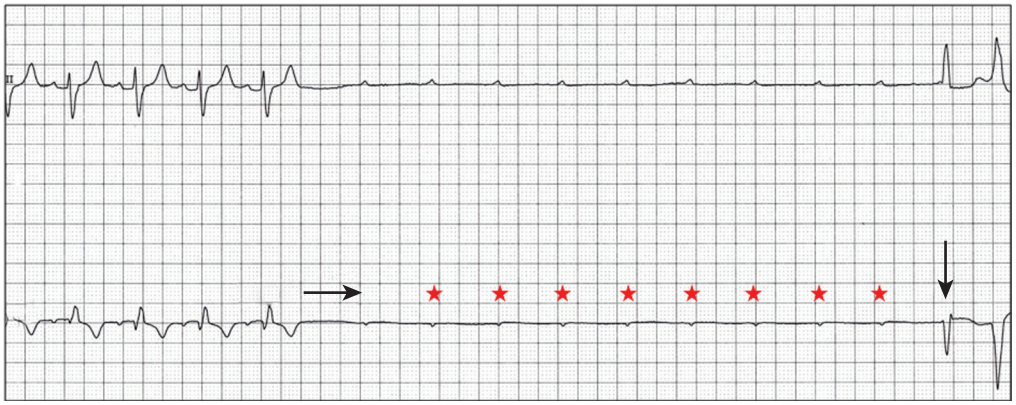
In the case of third-degree AV block, the considerations are similar. Infranodal block is associated with a slow and unreliable escape rhythm arising from the bundle branches or even ventricular myocardium, a wide and often bizarre QRS morphologic pattern, and a heart rate well below 40 beats/min.[7] A significant risk of sudden-onset, pharmacologically unresponsive asystole is present, and urgent intervention is usually required, even in the setting of hemodynamic stability. In contrast, complete heart block with a narrow escape rhythm does not typically require temporary pacing, unless it is medically unresponsive and accompanied by symptoms or significant hypotension. A history of syncope in a patient who presents with advanced second-degree AV block may portend a higher degree of AV block or pause-dependent torsades de pointes, and there should be a very low threshold for temporary pacing.[8]

Clinical Evaluation of AV Block

In the critical care setting, it is crucial to recognize vagally mediated AV block, which is usually clinically benign and rarely requires therapy. Vagally mediated AV block is common and results from causes such as sleep apnea, gastrointestinal distress, coughing, endotracheal suctioning, and sleep. It is frequently observed among asymptomatic young and/or athletic patients. It is due to *extrinsic* enhanced parasympathetic input and is characterized by progressive sinus slowing, progressive PR prolongation, Mobitz type I second-degree AV block immediately before the onset of complete heart block, and/or sinus slowing during the episode (Fig. 5.1). In particular, the finding of concomitant sinus slowing and AV block should be recognized as a *pathognomonic finding* for vagally mediated AV block. In contrast, AV block caused by an *intrinsic* failure of a diseased His-Purkinje system—also termed "paroxysmal" AV block—is characterized by a constant sinus rate, or even sinus acceleration during the episode (Fig. 5.2). Patients with paroxysmal AV block *usually* have a baseline conduction abnormality on their surface 12-lead electrocardiogram—most commonly, right bundle branch block—but this finding is not absolute. The hallmark of paroxysmal AV block is *immediate* transition from apparently normal conduction to complete AV block and ventricular asystole. This



• **Fig. 5.1** Telemetry strip demonstrating vagally mediated complete heart block. There is progressive PR prolongation *(black boxes)* and sinus slowing *(red stars)* just before the development of complete heart block, reflecting parasympathetic innervation of both the sinus and atrioventricular *(AV)* nodes.



• **Fig. 5.2** Telemetry strip demonstrating paroxysmal atrioventricular (AV) block. There is onset of AV block *(horizontal black arrow)* characterized by nonconducted P waves *(red stars)* with associated sinus acceleration, reflecting an intrinsic failure of AV nodal conduction. The nearly 7-second pause is eventually interrupted by a junctional escape complex *(vertical black arrow).*

is often triggered by a pause after a premature atrial or ventricular depolarization, but vagally mediated sinus slowing can have the same effect, complicating the interpretation of these events. Vagally mediated heart block is typically benign, is atropine responsive, and does *not* require temporary pacing. Paroxysmal AV block can be fatal and requires urgent temporary pacing until a permanent pacemaker can be placed.[9]

Management of Bradycardia and Indications of Temporary Pacing

Decisions regarding the need for temporary cardiac pacing are often required in the critical care setting. This decision-making process is in fact more central to critical care medicine than decisions regarding permanent pacing, which are commonly rendered by cardiology or cardiac electrophysiology consultants. Temporary pacing is indicated for hemodynamically significant or otherwise clinically significant bradycardia caused by either SN dysfunction or AV block that is not easily treated medically, for clinical syndromes that are likely to progress to severe bradycardia, and for rhythms that can serve as triggers for malignant ventricular tachyarrhythmias.

Pharmacologic intervention is a useful alternative to temporary pacing, particularly in cases of reversible bradycardia. Medical therapy to reduce vagal tone (e.g., atropine) or to increase sympathetic tone (e.g., dopamine, isoproterenol) may be sufficient in sinus bradycardia and in many cases of AV block. However, although the sinus node and the AV node are usually amenable to these autonomic interventions, the His-Purkinje system is generally not similarly responsive, as discussed previously. Block within the His-Purkinje system, which manifests as second- and third-degree block with a wide QRS complex and/or Mobitz II block, has a substantial likelihood of progression to severe bradycardia that is unresponsive to medical therapy; therefore immediate pacing is usually indicated.

The determination of whether bradycardia is clinically significant involves consideration of multiple parameters, including blood pressure, urine output, renal function, cardiac or other organ ischemia, congestive heart failure, and mental status. When these parameters are significantly deranged as a result of bradycardia, and pharmacologic intervention is not effective or practical, temporary pacing is indicated. It is not uncommon for temporary pacing indications to be reversible and not require subsequent permanent pacing after therapy. On the other hand, in many cases the underlying cause remains, and permanent pacemaker insertion is required before discontinuation of temporary pacing, which has served as a temporizing measure. Occasionally, there is clinical certainty that pathologic bradycardia is irreversible, and depending on staff and facility availability, referral for immediate permanent pacemaker insertion is appropriate in lieu of temporary pacing. Of note, with the exception of surgically placed epicardial electrodes, temporary atrial pacing is not feasible. Therefore temporary pacing is hemodynamically less advantageous than permanent dual-chamber pacing among patients with intact sinus node function caused by a lack of AV synchrony.

Cardiac Pacing Techniques

Esophageal and Transthoracic Pacing

For reasons of efficacy and patient comfort, esophageal pacing has fallen in disfavor in lieu of transcutaneous and transvenous pacing techniques. Transthoracic pacing with direct, percutaneous placement of a needle into the heart is obsolete.

Esophageal pacing and recording are of historical interest. The esophagus lies immediately posterior to the left atrium, and an esophageal pill electrode was historically used for diagnostic purposes. Esophageal recording easily identifies atrial activity, which can be useful in the differentiation of ventricular tachycardia from supraventricular tachycardia with aberrant conduction.[10] The presence of AV dissociation is virtually pathognomonic for ventricular tachycardia, but atrial activity is often difficult to recognize on the 12-lead electrocardiogram, particularly with fast, wide-complex arrhythmias. Nevertheless, straightforward algorithms allow for the rapid and relatively accurate electrocardiographic diagnosis of wide-complex rhythms, often regardless of whether atrial activity is apparent on the 12-lead electrocardiogram.[11,12]

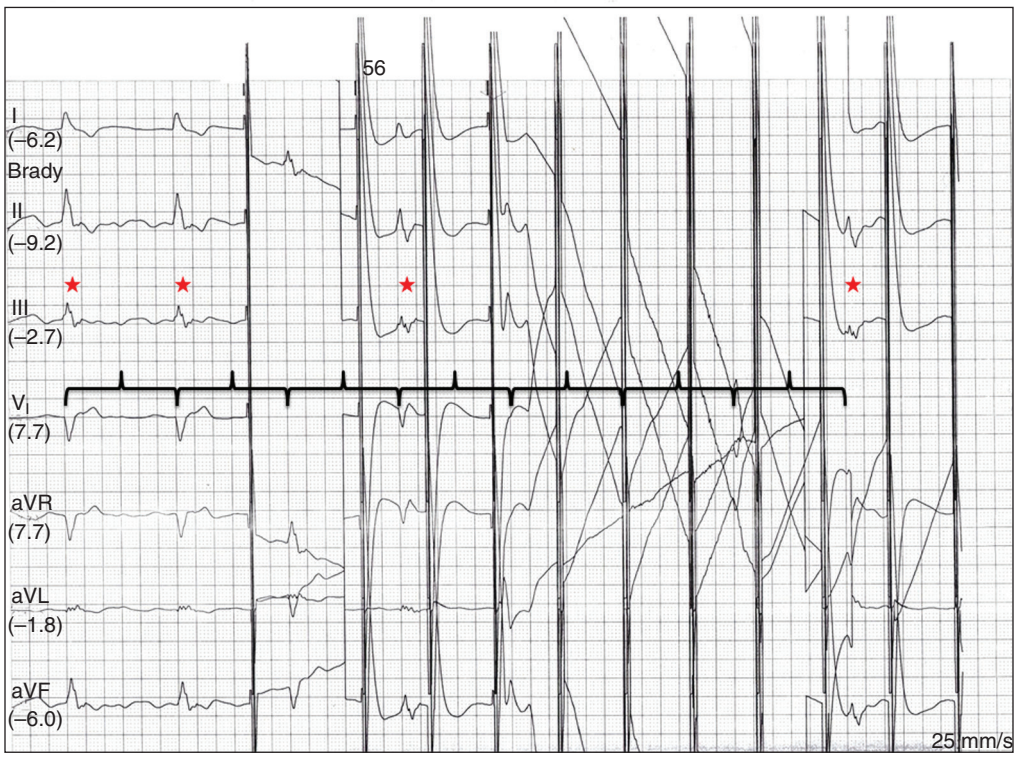
Transcutaneous Pacing

Background

First described by Paul Zoll in 1952 for the management of Stokes-Adams attacks, transcutaneous pacing involves the delivery of pacing stimuli though cutaneous patch electrodes.[13] It is the least technically challenging means of temporary pacing, and it can be initiated very rapidly. Most importantly, it does not introduce the risks associated with vascular access and transvenous pacing. The initial system required the subcutaneous insertion of 21-gauge needles and was limited by high pacing thresholds and significant pain. The technology has evolved over time, but transcutaneous pacing is still painful and generally requires the administration of sedation or analgesics. It is best tolerated in deeply anesthetized or unconscious patients, and it is most appropriate in situations in which pacing is required only briefly or intermittently, or as a bridging measure for placement of a transvenous system. Capture may be difficult to assess electrocardiographically because of saturation artifact from pacing stimuli, particularly if pacing outputs are high (Fig. 5.3).[14]

Methods

Commercially available external defibrillators have both pacing *and* defibrillating capability. The skin should be cleaned thoroughly with alcohol, but preferably not shaved, because the pain associated with pacing is typically localized to small abrasions and local salt deposits on the skin.[15] The patch electrodes should be arranged in an anteroposterior position with one patch over the mid-dorsal spine at the left paravertebral position, and the other over the point of maximal impulse. If abrasions are present, the patches can be positioned over an adjacent area of intact skin. The external generator should be turned on at the lowest pacing output and at a rate higher than the measured heart rate, and then increased in a stepwise fashion until reliable capture is observed on telemetry. It can be difficult to distinguish pacing artifact from capture, but



• **Fig. 5.3** Telemetry strip demonstrating ineffective transcutaneous pacing. There is an underlying junctional rhythm *(red stars)* that "marches through" the pacing artifact without any change in rate or rhythm, proving that transcutaneous pacing fails to capture the myocardium. The pacing artifact saturates the tracing and makes interpretation quite difficult.

the presence of a QRS complex and T wave—which represent cardiac depolarization and repolarization—is confirmatory. Capture can also be confirmed by the presence of a palpable or measurable pulse matching the paced rate. When in doubt, observation of the waveform of an arterial line or pulse oximeter is extremely helpful for confirmation of capture. The pacing output should be set slightly above capture threshold to minimize pacing artifact, pain, and risk of proarrhythmia.

Capture thresholds are predictably higher than with endocardial pacing, but most patients will capture at a pacing output of 40 to 70 mA. The capture threshold is proportional to the size of the patch electrode owing to the relationship between electrode size and current density—that is, larger electrodes require higher output for capture.[16] Higher impedance electrodes are preferred for pacing, but standard patch electrodes are more practical in daily practice. Hypoxia, acidosis, and prolonged periods of asystole may increase the pacing threshold.[17]

The pacing rate is dictated by the underlying rhythm and clinical indication. Pacing for a patient with complete heart block and hemodynamic instability should be at a rate of 60 to 90 beats/min until transvenous pacing can be established. Pacing for a patient with prolonged postconversion pauses or only intermittent heart block should be at a backup rate of 40 beats/min to minimize pacing. In general, the lowest possible rate should be chosen owing to patient discomfort.

Epicardial Pacing

Background

Most patients in the postcardiac surgery critical care setting have epicardial pacing wires. Eventual permanent pacing is required in roughly 2% of coronary artery bypass grafting and up to 7.7% of valve surgery cases,[18–20] but transient sinus node dysfunction (SND), fascicular block, bundle branch block, and AV block are common within the first few days after surgery.[21] Epicardial pacing offers a safe and well-tolerated "bridge" to recovery, avoiding the need for transcutaneous and transvenous pacing. It also allows for prevention, diagnosis, and management of postoperative atrial arrhythmias, and the optimization of hemodynamics in the critical care setting.

Methods

Epicardial wires are typically placed on the anterior right atrium and right ventricle at the conclusion of open heart surgery, then threaded through the right and left subcostal areas for attachment to an external pulse generator. Most surgeons routinely implant both atrial and ventricular leads because AV synchrony and native AV conduction is preferred whenever possible, particularly in patients with preexisting systolic dysfunction.[22,23]

Pacing and sensing thresholds typically deteriorate rapidly over 3 to 5 days owing to local inflammation,[24] and should be checked on a daily basis to ensure adequate safety margins, particularly in patients who are pacemaker-dependent. Thresholds below 5 mA are generally considered to be excellent, and thresholds above 10 mA warrant concern regarding an impending rapid rise in threshold and resultant inability to capture at the maximal external pulse generator output, which is 25 mA for most commercially available models. Of note, high outputs may only further exacerbate the local inflammation that produces high pacing thresholds.[25] Alternate locations—including the basal and lateral left ventricle—may be associated with more favorable pacing thresholds and cardiac performance.[26]

Prevention of Atrial Arrhythmias

Atrial fibrillation complicates 20% to 50% of cardiac surgery cases, resulting in increased length of stay, increased hospital costs, and higher morbidity and mortality rates.[27] The administration of β-adrenergic blockers and amiodarone constitutes first-line therapy, and there are data supporting the use of atrial pacing to prevent atrial fibrillation in the postoperative setting.[28,29] One small, prospective study demonstrated a 17% absolute risk reduction of postoperative atrial fibrillation through the use of "overdrive" atrial pacing (AAI mode at a minimum of 80 beats/min) for 24 hours on the second postoperative day, but longer-term follow-up was not reported in the study.[30] More recently, biatrial epicardial pacing has been demonstrated to be of potential benefit in the prevention of postoperative atrial fibrillation.[31] Overall, trials of epicardial pacing after cardiac surgery have been small and heterogeneous in design, but meta-analyses suggest an absolute reduction of 10% of postoperative atrial fibrillation with overdrive atrial pacing.[32,33] The beneficial effect of atrial pacing is probably synergistic with preventative pharmacologic intervention.

Treatment of Atrial Arrhythmias

Rapid, "burst" atrial pacing can be easily performed at the bedside using a standard external pulse generator. Typical atrial flutter and other macro-reentrant arrhythmias that involve the right atrium are often susceptible to pace termination owing to depolarization of the "excitable gap" of the flutter circuit. Pace termination is performed by pacing the atrium at a rate slightly faster than the arrhythmia and at a sufficiently high pacing output for atrial capture. One can begin pacing at 10 mA and 10 to 20 beats/min faster than the atrial rate for 5 to 10 seconds, but these parameters can be adjusted if initial attempts are unsuccessful. Because rapid ventricular pacing can easily precipitate ventricular fibrillation, it is essential to confirm that the epicardial system is connected appropriately before any pacing attempt, and to first test at a low rate to rule out incidental ventricular capture. Burst pacing may cause atrial flutter to degenerate into atrial fibrillation, which is often associated with a slower and better-tolerated heart rate.

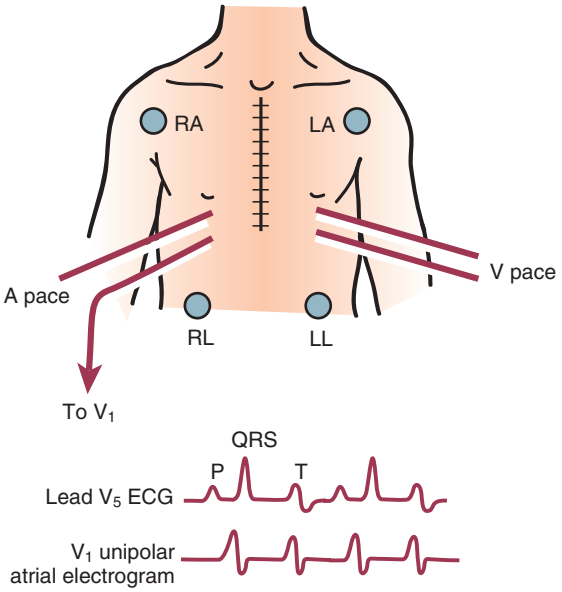
Diagnosis of Wide-Complex Arrhythmias

Atrial activity can be directly recorded by connecting the pin of an atrial epicardial wire to precordial lead V_1 of the 12-lead electrocardiogram, elucidating the mechanism of a tachycardia (Fig. 5.4). As discussed previously in the overview of esophageal recording, the presence of ventriculoatrial dissociation is diagnostic of ventricular tachycardia. AV association with an atrial:ventricular (A:V) ratio of 2:1 or higher is usually diagnostic of atrial tachycardia. Of note, the presence of a 1 : 1 ventriculoatrial relationship does not discriminate between tachycardia mechanisms because ventricular tachycardia may have 1 : 1 ventriculoatrial retrograde conduction.

Risks

Some centers argue against the routine placement of epicardial wires because of their cost and potential risk, but their use remains nearly ubiquitous. The frequency of complications is far less than 1%, but case reports have described the inadvertent laceration of saphenous vein grafts,[34,35] right atrium,[36] and right ventricular outflow tract[37] with development of either pericardial tamponade or hemothorax after wire removal, and infection attributed to

abandonment and bacterial colonization of the wires.[38,39] Epicardial wires should be removed with gentle traction, and their occasional abandonment generally does not constitute a risk to the patient. To minimize risks associated with pericardial bleeding, they should be removed in a monitored setting after discontinuation of anticoagulation therapy.



• **Fig. 5.4** Temporary atrial pacing wires used for arrhythmia diagnosis. Epicardial pacing wires can be used for arrhythmia diagnosis in postoperative coronary artery bypass graft patients when P waves cannot be clearly visualized on surface electrocardiography. One of the epicardial atrial wires is clipped to lead V_1 on the standard electrocardiogram machine. The unipolar atrial electrogram now appears on lead V_1 referenced to surface lead V_5 in this figure, demonstrating two P waves for every QRS complex, making the diagnosis of atrial flutter. *ECG,* Electrocardiogram; *LA,* left atrium; *LL,* left leg; *RA,* right arm; *RL,* right leg.

Transvenous Pacing

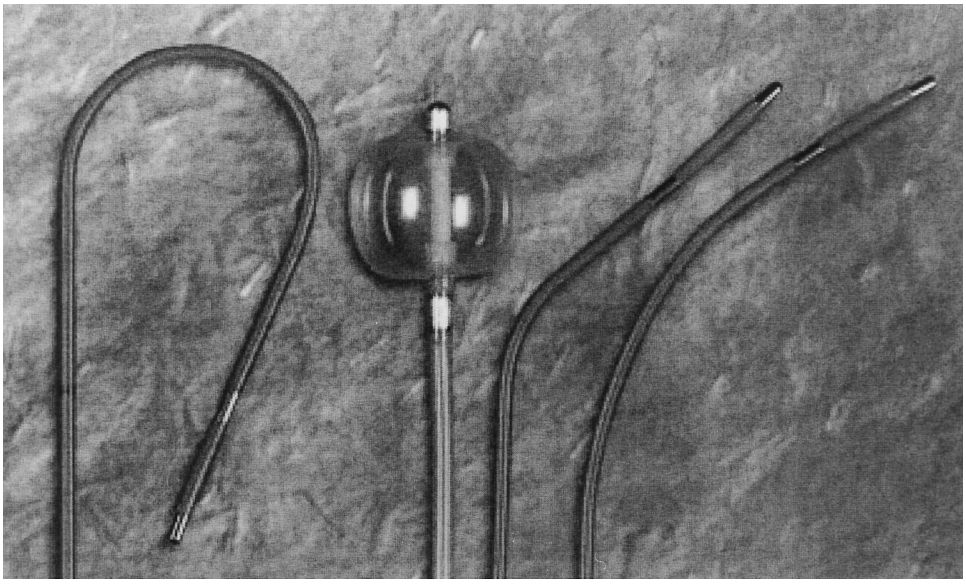
Background

Cardiac pacing with an endocardial electrode was first introduced in 1959 and quickly supplanted transcutaneous pacing as the method of choice for temporary pacing.[40] Transvenous pacing is more reliable and more comfortable than transcutaneous pacing, but it also takes more time to initiate and introduces procedural risk.

Methods

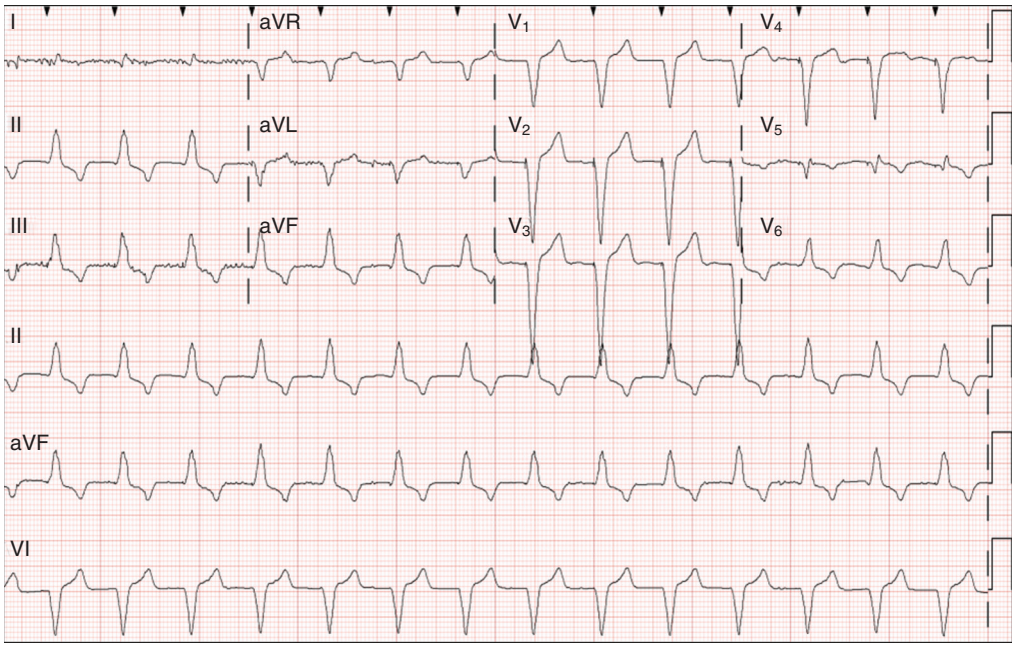
The internal jugular, subclavian, or femoral venous route can be used, but the internal jugular vein is generally the preferred approach. One subclavian vein should be reserved as a potential site for permanent pacemaker insertion, and the femoral vein carries a higher risk of infection, impedes patient movement, and requires fluoroscopic guidance. A variety of catheters are commercially available, the selection of which depends on operator preference, patient characteristics, and the availability of fluoroscopy (Fig. 5.5). Fluoroscopic imaging should be used routinely in patients with significant tricuspid regurgitation owing to the potential difficulty of catheter advancement across the tricuspid annulus. Fluoroscopic guidance should also be considered in patients with preexisting left bundle branch block owing to the potential for catheter-induced complete heart block as the result of mechanical trauma of the right bundle branch.[41]

Fluoroscopy simplifies catheter placement, but it may be unavailable, or a patient may simply be too unstable to transport to the catheterization laboratory. If portable fluoroscopy is unavailable, the procedure is best performed "blindly" at the bedside using a balloon-tipped catheter. Placement can be facilitated by electrocardiographic guidance, with or without pacing. If positioning is performed *with* pacing, the pacing catheter should be attached to an external pulse generator and set to pace at a rate slightly faster than the patient's intrinsic rate and at an intermediate pacing output (5–10 mA). After venous sheath placement, the catheter is then advanced slowly until ventricular capture is observed. Of

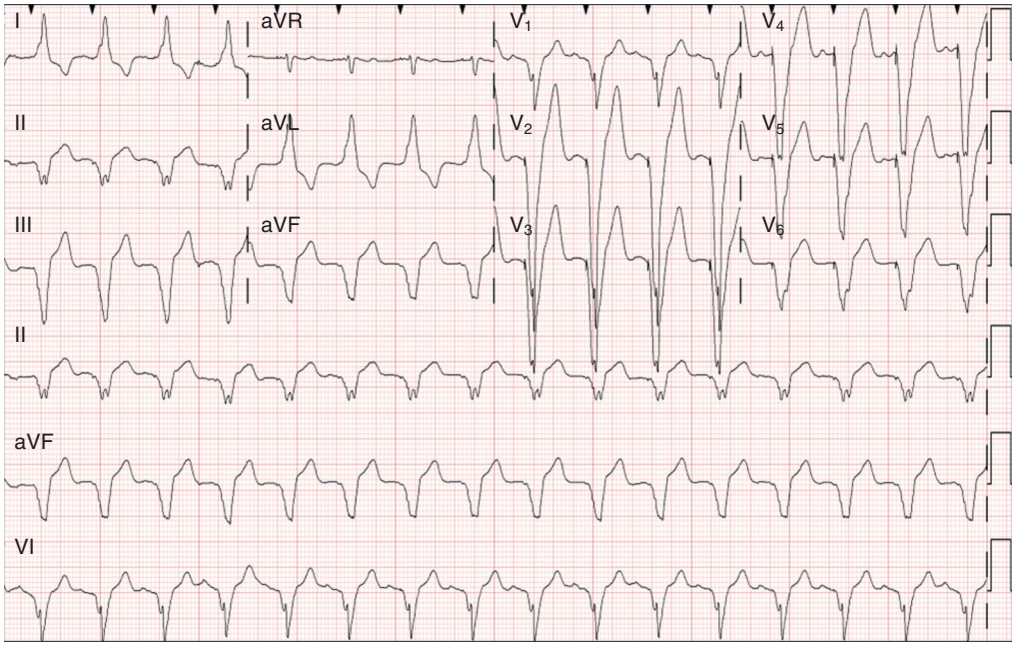


• **Fig. 5.5** Temporary bipolar pacing catheters. From *left to right,* atrial J, semifloating balloon-tipped, and two ventricular catheters with different curves. (Courtesy Daig Corporation/St. Jude Medical, Minneapolis, MN.)

note, right phrenic nerve capture and/or right atrial capture is sometimes incidentally observed as the catheter advances past these structures. Catheter contact and position can be assessed by examination of the paced QRS morphologic appearance: a left bundle branch block (LBBB) morphologic pattern with positive QRS complexes in leads II, III, and aVF (inferior frontal axis) suggests catheter position in the right ventricular outflow tract (Fig. 5.6), whereas an LBBB morphologic pattern with negative QRS complex in leads II, III, and aVF (superior frontal axis) suggests catheter position in the right ventricular apex (Fig. 5.7). If in the outflow tract, gentle withdrawal of the catheter will allow it to fall to a more inferior position and further advancement will guide it toward the apex. Deflating the balloon, then very gently advancing the catheter an additional 1 to 2 mm to wedge it in between the trabeculae of the right ventricle, can improve catheter stability.



• **Fig. 5.6** Paced morphologic pattern from right ventricular outflow tract. A paced QRS with a "left bundle branch block" morphologic pattern and "inferior" axis (positive QRS complexes in II, III, and aVF) suggests a pacing catheter position in the right ventricular outflow tract.

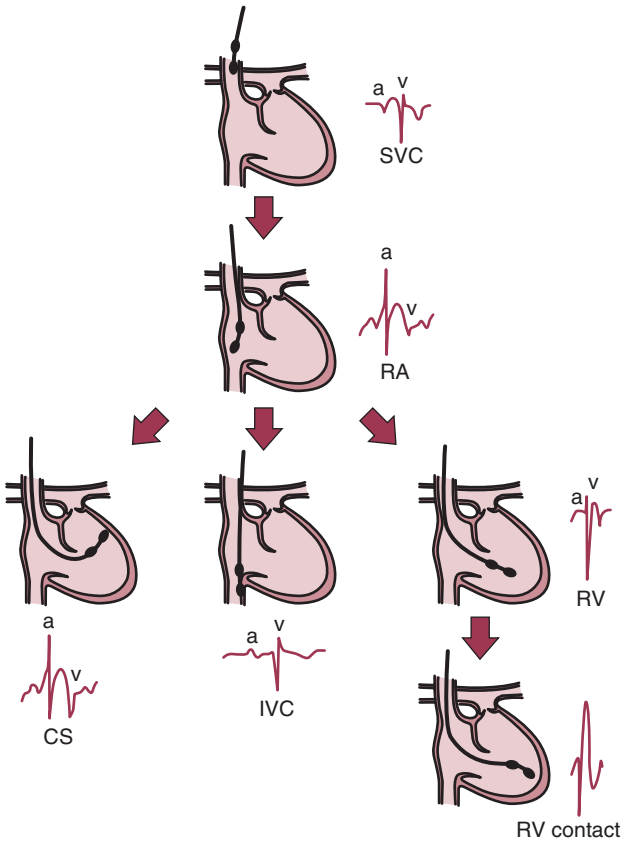


• **Fig. 5.7** Paced morphologic pattern from right ventricular apex. A paced QRS complex with a "left bundle branch block" morphologic pattern and "superior" axis (negative QRS complexes in II, III, and aVF) suggests a pacing catheter position at the right ventricular apex.

If positioning is performed *without* pacing, a pattern of ST-segment elevation on the local electrocardiogram indicates endocardial contact (Fig. 5.8).[42] The latter technique may be preferable in patients with complete heart block because even a brief period of overdrive pacing can extinguish a ventricular escape rhythm, resulting in immediate pacemaker dependency; therefore transcutaneous pacing patches should be in place and available for use. If the pacing catheter has been advanced more than 40 cm without evidence of capture, it may have looped within the right atrium or passed through the right atrium into the inferior vena cava. Either way, the catheter should be withdrawn with the balloon deflated and then advanced again after inflating the balloon. A sterile sleeve should always be placed over the catheter at the time of introduction so that subsequent repositioning can be performed aseptically.

Once good contact has been established, the pacing threshold can be tested by pacing at a rate above the underlying heart rate while reducing pacing output until loss of capture is noted on the monitor. R-wave sensing is assessed by setting the temporary pacemaker at a rate below the underlying heart rate and slowly *increasing* the sensitivity until undersensing is noted, in the form of inappropriate pacing spikes. Ideally, the pacing threshold should be below 2 mA and sensing should be greater than 5 mV. The system is set to a submaximal output several times the capture threshold, and a sensitivity of 20% to 30% of the measured R waves. If there is no underlying rhythm, the sensitivity can be set very high or to the asynchronous mode.

To prevent inadvertent dislodgment during manipulation of the external pulse generator, the pacemaker should be sutured to the patient's skin with a redundant loop in two locations. A new battery should be placed in the external pacemaker box. All connections between the catheter, cables, and pacemaker box should tightened and checked regularly for possible loosening. A chest radiograph should be performed immediately to rule out pneumothorax and to document catheter position.



• **Fig. 5.8** Electrogram guidance to place a temporary transvenous pacing lead. The end of the electrode is connected to an electrocardiogram to guide positioning. The electrogram appearances within the superior vena cava *(SVC)*, right atrium *(RA)*, inferior vena cava *(IVC),* and right ventricle *(RV)* are illustrated. When in contact with the RV, the electrogram demonstrates an injury current with ST-segment elevation. *CS,* Coronary sinus.

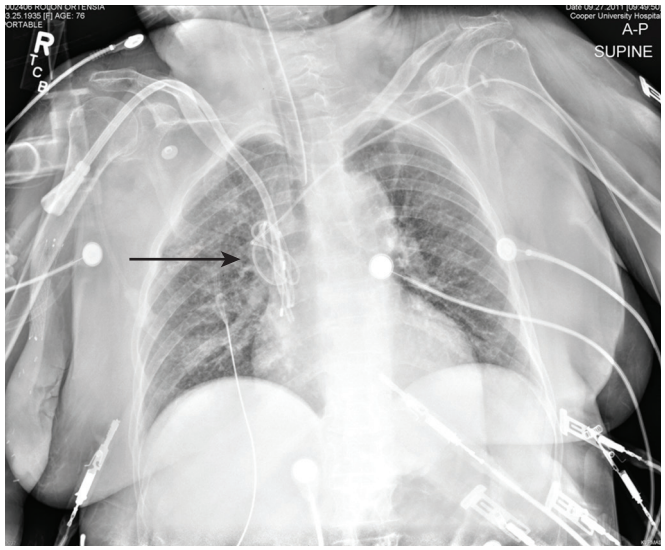
Special Considerations in Temporary Pacing

Contraindications

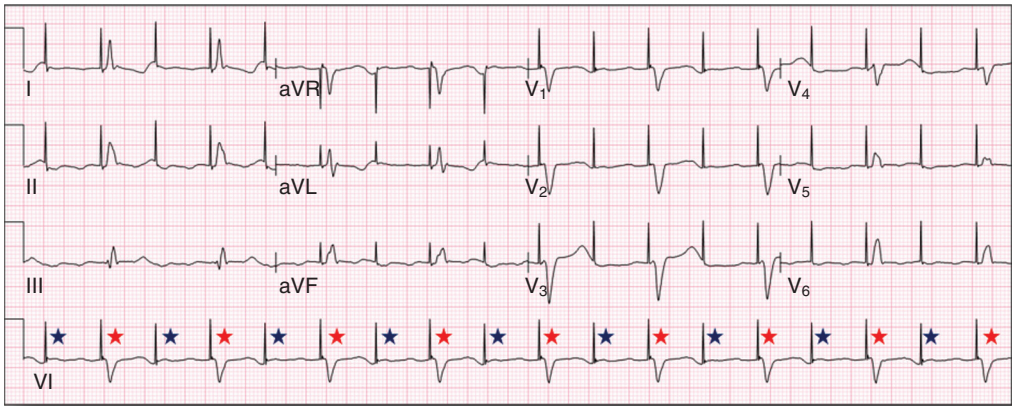
Transvenous pacing should not be attempted in patients with a known superior vena cava stenosis, and any resistance encountered during advancement of an intracardiac catheter should prompt the use of fluoroscopy (Fig. 5.9). Similarly, the presence of a mechanical tricuspid valve is an absolute contraindication owing to the potential for irreversible catheter entrapment.[43] Patients with a significant coagulopathy or an ongoing need for anticoagulation may be better served with transcutaneous pacing, if at all possible. If transvenous pacing is necessary, it should be performed under fluoroscopic guidance to minimize the risk of cardiac perforation. Femoral access may be preferable in these circumstances, particularly if the need for transvenous pacing is expected to be short-lived.

Sensitivity and Threshold Testing

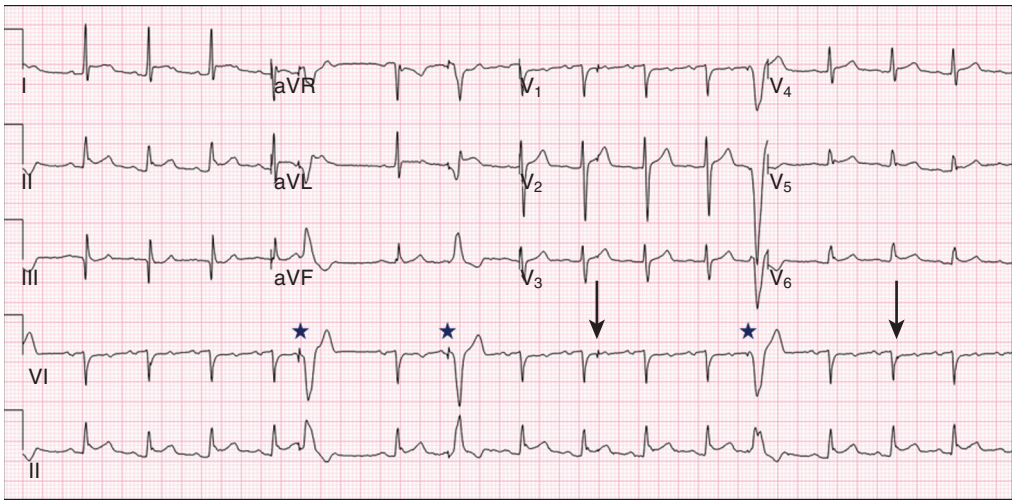
Owing to the inherent instability of a balloon-tipped catheter, sensing and pacing thresholds must be checked at least on a daily basis. Failure to sense can result in inappropriate pacing and precipitate polymorphic ventricular arrhythmias in rare circumstances.[44] Failure to capture in a pacemaker-dependent patient has obviously deleterious consequences, and it is imperative that the device be programmed with an adequate safety margin, typically at least two times the measured threshold. Failure to capture can be easily recognized on the 12-lead electrocardiogram



• **Fig. 5.9** Superior vena cava (SVC) stenosis. There is extensive entanglement of a temporary pacing catheter at the site of an SVC stenosis *(black arrow).* Any resistance encountered during catheter advancement should prompt the use of fluoroscopy.



• **Fig. 5.10** A 12-lead electrocardiogram demonstrating both capture *(red stars)* and failure to capture *(black stars)*. Failure to capture can be easily recognized by the presence of a pacing artifact without a subsequent QRS complex or T wave.



• **Fig. 5.11** A 12-lead electrocardiogram demonstrating failure to sense. There is indiscriminate delivery of a pacing artifact, independent of the underlying heart rate and rhythm *(black stars)*. Pacing intermittently fails to capture when falling within the refractory period of the ventricular myocardium *(black arrows)*.

or telemetry monitor by the presence of a pacing artifact without a subsequent QRS complex or T wave (Fig. 5.10). Failure to sense can be easily recognized by the inappropriate delivery of pacing spikes (Fig. 5.11).

Infection

Prevention of catheter-based infections is always important, but even more so in a patient who may ultimately require a permanent cardiac implantable electronic device. If a temporary pacemaker has been placed in emergent conditions, empiric coverage with a first- or second-generation cephalosporin is reasonable to minimize the likelihood of infection, particularly if femoral access has been chosen.

Timing of Reimplantation

The timing depends on a number of factors, including (1) the stability of the temporary pacing system; (2) the pacing indication; and (3) ongoing contraindications to permanent pacemaker implantation. In some circumstances—for example, in the setting of bloodstream infection—a prolonged period of transvenous pacing is required. Permanent, active fixation pacing leads with retractable screws can be inserted through a venous sheath and then attached to a permanent pulse generator on the patient's skin[45,46] (Fig. 5.12). This technique is highly favored for long-duration temporary pacing because it allows for ambulation and normal activity without concerns regarding lead dislodgement. In patients with recurrent ventricular tachyarrhythmias, a permanent defibrillator lead can be attached to an externalized defibrillator in the same fashion.[47] Permanent leads are more maneuverable than temporary leads, and the use of preformed stylets can facilitate delivery of leads to the right atrium, if atrial pacing is desired. If AV synchrony is desired and SN function is normal, a VDD lead with atrial sensing and ventricular pacing capability can be placed.[48]

Common Clinical Scenarios in Which Pacing Should Be Considered

SN Dysfunction and AV Block

As discussed earlier, the diagnosis of SN dysfunction is fairly straightforward, and electrocardiographic classification of AV

• **Fig. 5.12** Use of an active fixation permanent pacemaker lead for long-term temporary pacing. The lead was placed through a right axillary vein sheath and attached to an externalized permanent pacemaker generator. This allowed for normal patient activity and a low risk of lead dislodgment.

block is more challenging. Temporary pacing is indicated for hemodynamically significant or symptomatic bradycardia caused by SN dysfunction or AV block not known to be due to a promptly reversible cause. The relative risks and benefits of pacing and the overall clinical status of the patient should be taken into account. When there is clinical certainty that permanent pacing will be required and the patient is relatively stable, referral for expedited permanent pacemaker insertion should be considered instead.

Electrolyte and Metabolic Derangement

Hyperkalemia can precipitate complete AV block and can also elevate pacing thresholds in permanent pacemaker systems.[49–51] A progressive increase in extracellular potassium raises the resting membrane potential of cardiac myocytes, inactivating voltage-gated sodium channels that depend on a sufficiently negative resting membrane potential for normal function. The effect is more pronounced in the atrium and ventricle than within the specialized conduction system, explaining why the characteristic changes in the P wave, QRS complex, and T wave typically precede SN and AV nodal dysfunction: "peaked" T waves and QT shortening (potassium level 5.5 mEq/L); PR prolongation and QRS widening (potassium level 6.5 mEq/L); a "sinoventricular" rhythm caused by the apparent absence of atrial activity (potassium level 8–9 mEq/L); and lastly, a "sine wave" pattern owing to merging of the QRS and T wave that predicts impending cardiac arrest (potassium level 10 mEq/L).[52] Nevertheless, the 12-lead electrocardiogram may be entirely normal in cases of pronounced hyperkalemia, and AV block may occur in the absence of other electrocardiographic findings.[53–56] Therefore a routine metabolic evaluation is indicated in all patients with new conduction abnormalities.

The initial management of hyperkalemia-induced heart block is medical. If 12-lead electrocardiographic findings are pathognomonic for hyperkalemia, empiric treatment is appropriate while laboratory studies are pending. The administration of calcium chloride or calcium gluconate acutely antagonizes the electrical effects of potassium, partially restoring normal SN automaticity and conduction velocity. The effect is short-lived, however, and does nothing to correct extracellular potassium levels. Insulin, albuterol, and catecholamines reduce extracellular potassium through activation of the Na^+/K^+-ATPase pump, and sodium polystyrene sulfonate (Kayexalate) facilitates its gastrointestinal excretion. Dialysis is the most definitive treatment but requires peritoneal or vascular access. Temporary pacing may be helpful, but prohibitively high capture thresholds may be problematic. In patients with preexisting cardiac rhythm devices, pacing outputs can be increased if there is intermittent failure to capture.

Case reports and animal studies suggest a link between metabolic acidosis and heart block, and metabolic acidosis frequently accompanies hyperkalemia in the setting of chronic kidney disease.[57] The administration of sodium bicarbonate indirectly lowers extracellular potassium because of its effect on extracellular pH; this may improve responsiveness to vasopressors in emergent situations.[58]

Hyponatremia, hypokalemia, hypomagnesemia, and hypocalcemia have not been implicated as precipitants of bradycardia.

Medication Side Effects

A number of medications can cause severe sinus bradycardia, AV block, or both. β-Adrenergic blockers and nondihydropyridine calcium channel blockers are both negatively chronotropic, dromotropic, and inotropic, and their administration can result in significant bradycardia and hypotension, particularly in overdose. The hallmark of digitalis toxicity is the appearance of concomitant AV block and enhanced atrial or ventricular automaticity; it may present with high-degree or complete AV block. Amiodarone, dronedarone, and sotalol—class III antiarrhythmic drugs with mixed antiarrhythmic effects—frequently cause bradycardia owing to negative SN or AV conduction effects. Some studies suggest that drug-induced AV block—particularly at therapeutic levels—is a predictor of future conduction disorders.[59]

Clearly, the initial treatment is discontinuation of the offending medication(s). Directed therapy may occasionally be useful as well, but the evidence is largely anecdotal. β-Adrenergic blocker toxicity may respond to glucagon, and calcium channel blocker toxicity may respond to calcium or glucagon in refractory cases.[60–64] Vasopressors are occasionally necessary because of the vasodilatory and negative inotropic effects of these drugs. Digoxin toxicity can be treated with digoxin antibody fragments (Digibind).[65] If hemodynamic instability persists in the setting of severe bradycardia, temporary pacing is indicated. β-Adrenergic blockers and calcium channel blockers can increase pacing thresholds in permanent devices; if failure to capture is noted in a patient with suspected overdose of these agents, a temporary increase in pacing output may solve the problem.[66]

Infectious Disease

Lyme disease is the most common tick-borne illness in North America.[67] Erythema migrans is sufficient for diagnosis, but most patients cannot recall a tick exposure or rash.[68] The diagnosis of Lyme carditis requires serologic testing for confirmation, and *Borrelia burgdorferi* immunoglobulin M and G antibodies are positive in the vast majority of patients with the disease.[69] Regardless of patient history, the diagnosis of Lyme carditis should always be considered in a patient presenting with heart block in an endemic area, particularly during warmer months. Typically, Lyme carditis affects the AV node; progression from first- to third-degree AV block and back to normal conduction may be noted; resolution of complete heart block can take from several days to several weeks.[70] Temporary pacing is occasionally necessary because of hemodynamic instability. Third-degree AV block in Lyme carditis is associated with a stable junctional escape rhythm, but more diffuse involvement of the His-Purkinje system with a slower, more unstable escape is rarely noted.[71] It is essential for the clinician to always consider Lyme disease as a cause for AV block for two reasons. First, because this etiology is reversible, proper diagnosis prevents inappropriate permanent pacemaker insertion. Second, failure to treat Lyme disease at this otherwise asymptomatic stage allows for further unrecognized progression to fully disseminated Lyme disease and systemic organ involvement.[72]

Infective endocarditis can be complicated by a broad spectrum of conduction disturbances, including first-degree AV block, bundle branch block, and complete heart block. Any new conduction deficit suggests perivalvular abscess because of the proximity of the compact AV node and bundle branches to the membranous septum.[73,74] Conduction disturbances most commonly complicate aortic valve endocarditis, but the tricuspid valve and mitral valve are also susceptible.[75–77] Perivalvular abscess and heart block are indications for surgical repair.[78] Serial 12-lead electrocardiography should be performed in all patients with endocarditis, and temporary pacing should be strongly considered for any progressive conduction disturbance, including a significant increase in the PR interval.

Lymphocytic and giant cell myocarditis are typically associated with acute systolic dysfunction, but they can also be complicated by severe electrical abnormalities, including complete heart block. Lymphocytic myocarditis carries a more favorable prognosis than giant cell myocarditis, but permanent pacemaker dependency is possible with either condition.[79]

After Myocardial Infarction

Official guidelines for temporary and permanent pacing after ST-elevation and non-ST-elevation myocardial infarction (NSTEMI) were last updated in 2013 and 2014, respectively,[80,81] and permanent pacemaker indications after myocardial infarction were last updated in 2012.[82] The most recent guideline updates include a stronger focus on infarct location as a diagnostic consideration. Recommendations for temporary pacing are largely based on expert opinion, in addition to case reports, case series, and published summaries from before the reperfusion era.

The interventional cardiologist frequently assesses the need for temporary pacing at the time of percutaneous intervention, but familiarity with official guidelines and an understanding of the risk of progression are critical in the appropriate management of the patient after myocardial infarction. It is important to remember that bradycardia-induced hypotension and decreased cardiac output may exacerbate myocardial ischemia and limit reperfusion, and therefore heart rate support in the periinfarct setting should always be considered.

The culprit artery has prognostic implications. Complete heart block complicating anterior wall myocardial infarction—usually involving the proximal left anterior descending artery—is due to necrosis of the interventricular septum and irreversible damage to the His-Purkinje conduction system. In contrast, complete heart block in inferior wall infarction—usually involving the proximal right coronary artery (RCA)—is usually vagally mediated and atropine sensitive in the first hours of infarction.[83] Local accumulation of adenosine in the days after infarction may lead to longer-duration, atropine-insensitive AV block, but permanent pacing is rarely indicated.[84] Because the RCA supplies the sinoatrial nodal artery in 90% of cases, a proximal RCA infarction may also be complicated by sinus bradycardia, sinoatrial exit block, and sinus arrest; these, too, are typically transient in nature and atropine responsive.

In the case of both NSTEMI and ST-elevation myocardial infarction (STEMI), temporary pacing is indicated for asystole or for symptomatic or hemodynamically significant bradycardia unresponsive to medical therapy, which is usually limited to atropine because of concerns regarding pressor-induced myocardial ischemia. Overdrive pacing is also always indicated to prevent recurrence of bradycardia-induced ventricular tachycardia. Inferior NSTEMI is often associated with sinus bradycardia, which is usually treated medically, and with first-degree AV block, which does not require therapy. Transient high-degree AV block with a narrow QRS is also often seen after inferior NSTEMI, but this does not generally require pacing. However, new second- or third-degree AV block or bundle branch block after *anterior* NSTEMI is more ominous because of correlation with a larger amount of conduction system involvement, which portends a risk of progression to asystole. Prophylactic temporary pacing is therefore indicated for anterior NSTEMI associated with high-degree AV block, new bundle branch block, or bifascicular block. Of course, when the location of NSTEMI is unclear, the clinician should err on the side of caution and treat as if the infarct is anterior.

The most recent guideline update for STEMI has reduced the number of recommendations for transvenous pacing. Whereas temporary transvenous pacing was previously recommended for STEMI complicated by new bifascicular block or bundle branch block *and* concomitant Mobitz type II second-degree AV block, regardless of the culprit artery, and for alternating bundle branch block, regardless of the status of AV conduction,[85] the more recent guidelines stress STEMI location as an important diagnostic consideration. In the case of inferior/posterior STEMI, conservative management is recommended for transient second- or third-degree AV block, with application of prophylactic trancutaneous pacing pads. For anterior or lateral myocardial infarction, temporary pacing is recommended for even transient second- or third-degree AV block, new bundle branch block, or bifascicular block. The updated guidelines also indicate that either transcutaneous pacing or transvenous pacing can be chosen in these situations, which is less stringent than the prior edition.

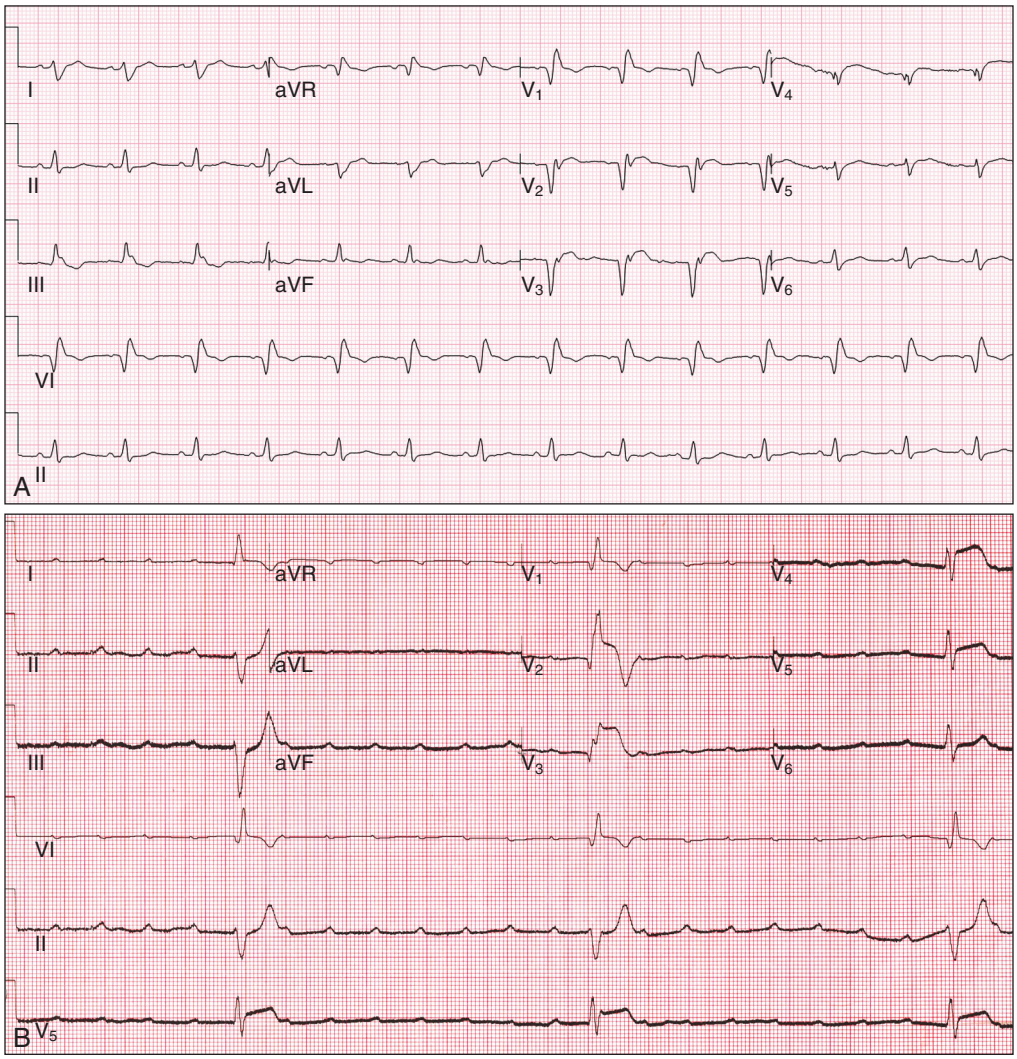
However, the critical care physician should be well versed in the significance of His-Purkinje abnormalities during the periinfarct setting, and it is good clinical practice to place prophylactic transcutaneous pacing pads in high-risk settings. In particular, alternating bundle branch block—right bundle branch block alternating with left bundle branch block, or right bundle branch block with alternating left anterior and posterior fascicular block—is a marker of severe His-Purkinje disease. Bifascicular block with

right bundle branch block and left posterior fascicular block carries a very poor prognosis with a high risk of progression to complete heart block (Fig. 5.13).[86,87] Any of these findings—or new or not previously known bundle branch block or intraventricular conduction delay—should be noted, and transcutaneous pacing should be readily available because of the risk of progression to clinically significant second- or third-degree AV block.

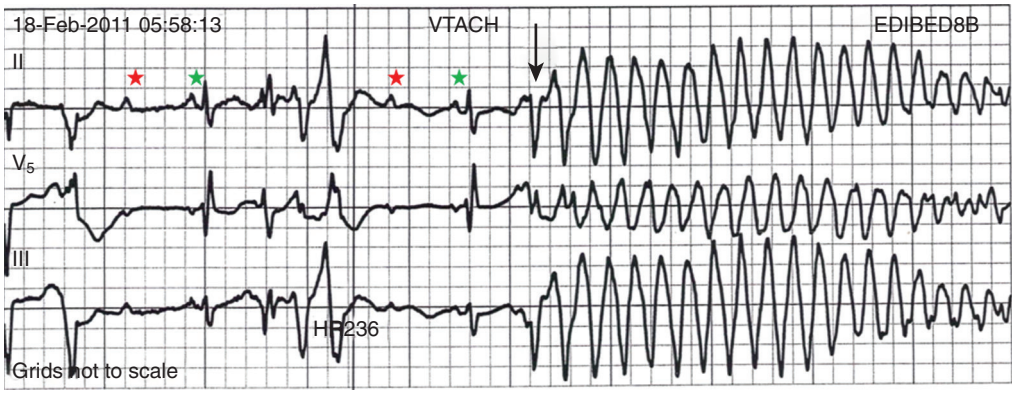
Torsades de Pointes

Torsades de pointes is a syndrome of *bradycardia-induced ventricular tachycardia* whose diagnosis requires the three elements of polymorphic ventricular tachycardia (typically with the appearance of "twisting" around the electrocardiographic baseline), a prolonged QT interval, and pause-dependent initiation of tachycardia, usually during the compensatory pause following a premature ventricular depolarization.[88–90] Not all cases of bradycardia-induced, or pause-dependent, ventricular tachycardia meet all three criteria, but pacing still plays a prominent role in management. Although ventricular tachycardia in torsades de pointes is usually nonsustained, it can rarely degenerate into ventricular fibrillation. The underlying QT prolongation can be either congenital or acquired, the latter of which is by far more common in the critical care setting and most often is due to either administration of a culprit drug or severe electrolyte disturbance.

The most important considerations in the management of torsades de pointes are appropriate recognition of the problem, correction of the underlying cause(s), and avoidance of QT-prolonging drugs that can further exacerbate the problem. Although this arrhythmia is polymorphic by definition, not all polymorphic ventricular arrhythmias are due to torsades de pointes. Polymorphic ventricular tachycardia may complicate acute coronary syndrome, but it is typically associated with a suggestive clinical history and ST-segment deviation. Temporary or permanent pacemaker



• **Fig. 5.13** Bifascicular block after acute, left anterior descending coronary artery infarction. A, A 12-lead electrocardiogram demonstrating sinus rhythm with normal atrioventricular (AV) nodal conduction, but right bundle branch block and left posterior fascicular block. There are also pathologic Q waves in leads V_1 to V_4, consistent with an anterior wall infarction caused by occlusion of a proximal left anterior descending artery. B, A 12-lead electrocardiogram of the same patient, 1 week later. There is now high-grade AV block with a right bundle branch block and left anterior fascicular block, owing to necrosis of the His-Purkinje system that has left only the left posterior fascicle capable of conduction.



• **Fig. 5.14** Telemetry strip demonstrating torsades de pointes. The rhythm is sinus with both conducted *(green stars)* and nonconducted *(red stars)* P waves. Premature ventricular complexes emerge from a dramatically prolonged QT-U complex *(black arrow),* eventually initiating polymorphic ventricular tachycardia.

malfunction with ventricular undersensing can lead to "R on T" pacing, and certain pacemaker settings that minimize ventricular pacing can predispose to "long-short" sequences and polymorphic ventricular arrhythmias as well.[91–94] If ventricular tachycardia is reliably initiated with pacing, pacemaker reprogramming may resolve the problem; electrophysiology consultation should be sought immediately.

The administration of intravenous magnesium sulfate (1–2 g over 5–10 minutes) and correction of hypokalemia is acutely effective in many patients.[95] If ineffective, isoproterenol (1–4 μg/min) can accelerate the heart rate and shorten the QT, but this should be avoided in long QT syndrome—particularly long QT type 1—because of the potential for proarrhythmia owing to the underlying ionic channel defect, in which catecholamines paradoxically prolong repolarization. Similarly, amiodarone should not be given for torsades; this is a common error, which can exacerbate QT prolongation. If an antiarrhythmic medication is essential, lidocaine is a reasonable alternative.

Temporary pacing is indicated for patients in whom electrolyte supplementation and pharmacologic augmentation of the heart rate fail, or for patients with severe AV conduction disturbances that predispose to long-short initiation sequences. Temporary pacing at an increased rate shortens the action potential and QT interval but also truncates the post–premature ventricular contraction pauses that typically trigger an episode (Fig. 5.14).[96] Typically, pacing at a rate of 90 to 100 beats/min is sufficient to suppress ventricular ectopy and/or avoid post–premature ventricular contraction pauses, but rates as fast as 140 beats/min may be necessary.[97] Patients with previously implanted cardiac rhythm devices should undergo bedside device reprogramming to achieve the same effect. In patients with normal AV nodal conduction, atrial pacing is preferred.

Conditions That Do Not Normally Require Pacing

Hypothermia

Hypothermia can produce dramatic electrocardiographic abnormalities—PR prolongation, QRS widening, and QT prolongation, in addition to both atrial and ventricular arrhythmias—and familiarity with this condition is increasingly important in the critical care setting owing to the widespread adoption of therapeutic hypothermia in survivors of cardiac arrest.[98–100] Moderate (32°C–33.9°C) hypothermia causes a reduction in cardiac output that is mediated by sinus bradycardia, but this is accompanied by an increase in myocardial contractility and proportional decrease in basal metabolism. No specific treatment is needed, and attempts to increase the heart rate with drug or temporary pacing are counterproductive.[101] Deep hypothermia (<30°C) is associated with an increased risk of atrial and ventricular arrhythmias, reduced responsiveness to electrical and pharmacologic cardioversion, and increased sensitivity to mechanical manipulation.[102] Resuscitation of severely hypothermic patients with transcutaneous pacing has been reported,[103] but the near-immediate initiation of ventricular fibrillation by transvenous pacing has also been described.[104] The role of temporary pacing—whether transcutaneous or transvenous—is limited and should be reserved for extreme situations of hemodynamic and electrical instability. The primary treatment is rewarming.

Hypothyroidism

Severe hypothyroidism is most commonly seen in the elderly and is often precipitated by infections. Case reports have established that severe hypothyroidism and myxedema coma can cause not only SN dysfunction but also a range of AV conduction abnormalities, including complete heart block. The symptoms of hypothyroidism can be vague, and the electrocardiographic manifestations—P-wave flattening, low QRS voltage and intraventricular conduction delays, QT prolongation, and T-wave flattening or inversion—are nonspecific. Thyroid hormone replacement, which is occasionally administered intravenously in severe cases of myxedema, can quickly normalize conduction but may take up to several weeks in some patients.[105–107] Patients who present with new conduction abnormalities—particularly the elderly and infirm—should be routinely screened for hypothyroidism. Temporary pacing is rarely needed in cases of advanced AV block. Thyroid hormone supplementation is usually curative.

Obstructive Sleep Apnea

Obstructive sleep apnea has been associated with cyclic patterns of SN and AV nodal conduction disturbances, occasionally resulting in prolonged periods of asystole during sleep.[108] In general, nocturnal arrhythmias are less clinically relevant than those during the day,

and the need for intervention should be taken in the context of the clinical situation. The finding on telemetry of profound sinus pauses or long-duration AV block during sleep should always generate a suspicion for sleep apnea, and patients should be evaluated accordingly.

Atropine has been shown to abolish cyclic variation and nocturnal bradycardia, suggesting that autonomic influences play a role.[109] One study suggested that atrial overdrive pacing reduces the number of central and obstructive apneic episodes,[110] but subsequent studies have shown no benefit, and pacing does *not* currently play a role in the chronic management of this disorder.[111–113] Continuous positive airway pressure, which is the therapy of choice for sleep apnea and associated bradycardia, abolishes conduction disturbances in the majority of patients, suggesting that hypoxia plays a role in the pathophysiology of the condition.[114]

Preoperative Considerations

Preexisting His-Purkinje disease—complete right or left bundle branch block, or bifascicular block, for example—does *not* routinely require temporary pacing before surgery. Patients with complete heart block, regardless of whether junctional or ventricular escape complexes are present, should be considered for temporary pacing during surgery owing to the potentially suppressive effects of general anesthesia on sympathetic tone and on a reliable escape mechanism. Patients with preexisting left bundle branch block who require Swan-Ganz catheterization have a small risk of procedurally related complete heart block caused by catheter-induced right bundle branch block.[41] In these situations, right-sided heart catheterization should be performed under fluoroscopy, and transcutaneous pacing should be immediately available. The presence of an "rS" complex in lead V_1 may reflect left-to-right septal activation and left bundle branch *delay*, rather than complete left bundle branch block; the risk of catheter-induced heart block may be lower in these circumstances.[115]

Seizure

Severe sinus bradycardia and prolonged periods of asystole complicate less than 0.4% of seizures.[116] "Ictal bradycardia" is likely vagally mediated, but there is disagreement within the epilepsy community about its potential contribution to sudden death.[117,118] Although the majority of episodes terminate spontaneously, some patients are ultimately referred for pacemaker implantation. In the critical care setting, simultaneous electrocardiographic and encephalographic monitoring can be quite helpful to rule out a primary bradycardic etiology when clinical features suggest prodromal seizure activity. Recently simultaneous video-electroencephalographic monitoring and tilt table testing has been introduced to distinguish between primary epilepsy and secondary seizures caused by bradycardia.[119] The most appropriate management of ictal bradycardia—including the potential need for temporary pacing—is unclear.

Spinal Cord Injury and Tracheal Suctioning

Severe cervical injury is nearly universally associated with sinus bradycardia, sinus pauses, and hypotension in the days after injury, but these changes typically resolve within 2 to 6 weeks.[120] Temporary or permanent pacing is almost never required in this situation and should be reserved for intractable cases where long pauses are clearly clinically significant. Endotracheal intubation, tracheal suctioning, and repositioning can precipitate prolonged, vagally mediated pauses, presumably caused by impairment of the sympathetic nervous system input during periods of increased parasympathetic tone. There have been case reports of asystolic cardiac arrest during tracheal suctioning; supplemental oxygen therapy was at least partially effective in preventing further episodes, suggesting that hypoxia played a role.[121] The administration of atropine, theophylline, aminophylline, and isoproterenol—individually or in combination—may attenuate these pauses, but their administration may be ineffective in the short term and cumbersome in the long term. There is no consensus on the issue, but some authors advocate placement of a permanent pacemaker in patients with medically refractory, profound pauses who require prolonged mechanical ventilation owing to the unpredictable nature of these events.[122] Temporary pacing can be considered on a case-by-case basis, but it is important to recognize that the primary underlying problem is autonomic in nature.

Permanent Pacing

As discussed previously, decisions made in the critical care setting regarding pacing primarily involve a decision whether or not urgent temporary pacing is indicated, and decisions regarding permanent pacemaker implantation are generally made in collaboration with cardiology and/or cardiac electrophysiology consultants. However, familiarity with indications for permanent pacemaker insertion is useful in cases where it may be appropriate and feasible to forgo temporary pacing in favor of expeditious permanent pacemaker insertion. This is certainly worth consideration when bradycardia is not due to a reversible or transient cause, as avoidance of temporary pacing minimizes overall procedural risk and length of stay. More importantly, expertise in the management of patients with previously implanted pacemakers, including management of pacemaker insertion complications, is essential.

Indications for Permanent Pacemaker Implantation

Indications for permanent pacemaker insertion are reviewed briefly. The American College of Cardiology Foundation, the American Heart Association, and the Heart Rhythm Society have jointly engaged in the production of guidelines for cardiac implantable electronic device implantation, with publication of updated guidelines in 2012.[82] These recommendations are primarily evidence-based, and this publication includes an extensive review of the literature on the topic. As with other guideline documents, recommendations are classified as class I, II, or III as follows:

- Class I: Benefit $\ggg$ Risk; the procedure/treatment *should* be performed/administered.
- Class II: Conditions for which there is conflicting evidence or divergence of opinion about the usefulness/efficacy of the procedure.
  - Class IIa: Benefit $\gg$ Risk; *it is reasonable* to perform the procedure/administer treatment, although additional studies with focused objectives are still needed.
  - Class IIb: Benefit $\geq$ Risk; the procedure/treatment *may be considered*, although additional studies with broad objectives are needed or additional registry data would be helpful.
- Class III: Risk $\geq$ Benefit; the procedure/treatment should *not* be performed/administered because it is not helpful and may be harmful.

The level of evidence or weight of evidence to support these recommendations is ranked as follows:

- Level of evidence A: Data are derived from multiple randomized clinical trials or meta-analyses.
- Level of evidence B: Data are derived from a single randomized trial or nonrandomized studies.
- Level of evidence C: Data represent the consensus opinion of experts, case studies, or standard of care.

Indications for permanent pacemaker implantation can be divided into the following categories: (1) pacing for bradycardia owing to SN and AV node dysfunction; (2) pacing for special conditions, such as carotid sinus hypersensitivity, neurocardiogenic syncope, and cardiac transplantation; (3) pacing for prevention and treatment of arrhythmias; and (4) pacing for hemodynamic indications, including cardiac resynchronization therapy (CRT) and hypertrophic cardiomyopathy. As SN and AV node dysfunction are the most common indications for permanent pacemaker implantation and are the most commonly encountered problems that require pacing in the intensive care setting, these indications are the main focus of this section.

Pacing Indications for Sinus Node Dysfunction

SND is the most common cause of bradyarrhythmias in clinical practice. The typical age at the time of diagnosis of SND appears to be in the seventh or eighth decade of life, with a mean or median age of 71 to 74 years in randomized clinical trials evaluating pacemaker therapy.[123–125] However, clinical manifestations of SND may occur at any age and may be secondary to several potential causes, including destruction of the SN, ischemia, infarction, infiltrative disease, surgical trauma, autonomic dysfunction, or endocrinologic abnormalities.[82,126]

Clinical manifestations of SND are diverse, and symptoms may include fatigue, reduced exercise tolerance, dyspnea on exertion, presyncope, lightheadedness, dizziness, or syncope. In the absence of any clearly reversible cause of bradycardia, the only effective long-term treatment for symptomatic bradycardia in patients with SND is permanent pacing. Of note, AV block may also occur in patients with SND, and 20% of patients with SND have some degree of AV block.[125] In addition, after permanent pacemaker implantation for SND, the risk of developing AV block within 5 years of follow-up is up to 35%.[127–130] Society guidelines stress the importance of *symptoms* in the decision-making process; a permanent pacemaker is rarely indicated in asymptomatic SND.

Pacing Indications for Acquired AV Block

Electrocardiographic classification of AV block, and considerations regarding level of AV block, have been discussed previously. Acquired AV block is most often due to aging or related to calcification of the conduction system. Ischemic heart disease, myocardial infarction, and traumatic surgical causes (such as cardiac valve surgery) are other common causes. Less common causes of AV block include infection (syphilis, Lyme disease, endocarditis), infiltrative disease (sarcoidosis, malignancy), neuromuscular disease, or medications (β-blockers, calcium channel blockers, digoxin, or membrane-active antiarrhythmic agents).

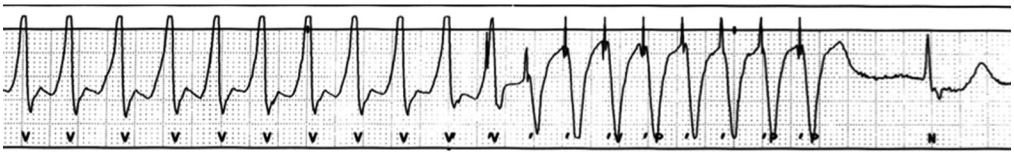
Patients with AV block may be asymptomatic, or they may have symptoms that vary from mild lightheadedness, dizziness, shortness of breath, or fatigue to presyncope and loss of consciousness. The decision regarding permanent pacemaker implantation should take into account whether or not symptoms are attributable to bradycardia, as well as the cause and "level" of AV block. Completely reversible causes of AV block, such as electrolyte disturbances or Lyme disease, should be excluded. Permanent pacing is usually indicated for acquired complete block without reversible causes. The reader is directed to the 2012 guidelines update for a more in-depth understanding of indications for permanent pacemaker insertion.[82]

Other Permanent Pacing Indications

In specific situations, permanent pacing may also be clinically indicated in some patients with carotid sinus hypersensitivity, neurocardiogenic syncope, or obstructive hypertrophic cardiomyopathy and after cardiac transplantation.[82] Historically, antitachycardia pacemakers were occasionally used to treat recurrent supraventricular arrhythmias, but they are rarely used in contemporary practice with the availability of catheter ablation therapy. Pace termination of ventricular tachycardia is frequently used for the treatment of monomorphic ventricular tachycardia as part of implantable cardioverter-defibrillator therapy; it can also be used to terminate frequent arrhythmia episodes using a temporary transvenous pacing system in the intensive care setting (Fig. 5.15).

Pacing may be useful in the prevention of pause-dependent, polymorphic ventricular tachycardia as well (see Fig. 5.14). Permanent pacing is indicated for pause-dependent ventricular tachycardia, with or without QT prolongation (class I indication, level of evidence C), and is reasonable for high-risk patients with congenital long QT syndrome (class IIb indication, level of evidence B). Atrial-based pacing (AAI or DDD mode) is considered the preferred pacing mode for prevention of polymorphic ventricular tachycardia associated with the congenital long QT syndrome.

Pacing the left ventricle can improve hemodynamics in patients with dilated cardiomyopathy and bundle branch block by altering the ventricular activation sequence, narrowing the QRS complex, and influencing regional contractility, and is particularly effective in patients with left bundle branch block. This therapy, for which congestive heart failure rather than bradycardia is an indication, is referred to as cardiac resynchronization therapy (CRT) or "biventricular pacing" and is beyond the scope of this chapter. The 2012 guidelines update addresses indications for CRT.[131]



• **Fig. 5.15** Telemetry strip demonstrating antitachycardia pacing. Pacing is delivered at a rate that is slightly faster than the underlying ventricular tachycardia, ultimately terminating the arrhythmia.

Complications of Permanent Pacemaker Implantation

Although pacemaker implantation is a well-established procedure with a low risk of major complications in experienced hands, physicians working in the critical care setting must be aware of complications that may require rapid recognition and therapy. Common complications include lead dislodgment, pneumothorax, hematoma, perforation with or without cardiac tamponade, and infection. Less frequent complications, including arrhythmias, thrombosis, inadvertent placement of a lead within the left ventricle, twiddler's syndrome, and pacemaker syndrome, are also discussed.

The most common complications after pacemaker implantation include bleeding, lead failure, and pneumothorax.[131] Higher complication rates are noted with less experienced operators.[131,132] Elderly patients (≥75 years) are also at increased risk of early postoperative complications.[133] Body mass index, congestive heart failure, use of anticoagulants, and passive atrial fixation leads are also independent predictors for development of short-term (within 2 months) pacemaker complications.[134]

Lead Dislodgment

The incidence of lead dislodgment noted in clinical trials is 1.8% to 2.6%.[125,135,136] Lead dislodgment rates depend on multiple factors including lead fixation mechanism issues and operator experience. Active fixation (or "screw-in") mechanisms have reduced the frequency of this complication. Typically, lead dislodgment rates should be below 3% with contemporary technology. Lead complications in general are more likely to occur with inexperienced operators.[132]

Lead dislodgment may lead to increased capture thresholds, loss of capture (see Fig. 5.10), or loss of sensing (see Fig. 5.11). When a change in lead position is detectable by chest radiograph, this is referred to as "macro-dislodgment." However, loss of capture or undersensing can also be seen with "micro-dislodgment" of leads, where there is no radiographically detectable change in lead position. In some cases of micro-dislodgment, intermittent undersensing of intrinsic complexes or a change in pacing threshold may be corrected by reprogramming the pacemaker sensitivity or output. However, large changes in lead position typically require lead revision. Intermittent motion of the cardiac lead may also result in increased ventricular ectopy, with a premature ventricular contraction morphologic pattern that is similar to the morphologic pattern of the paced complex.

Pneumothorax

Venous access may be obtained through subclavian or axillary puncture, as well as direct cephalic vein cut-down. Complications related to venous entry include bleeding, arterial injury caused by inadvertent arterial puncture, pneumothorax, hemothorax, thrombosis, air embolism, arteriovenous fistula, and brachial plexus injury. The risk of pneumothorax related to subclavian venous puncture is 1% to 2%[125,135]; this risk may be reduced by contrast venography before venipuncture.

Pneumothorax typically presents early after the procedure, usually within 24 hours. Symptoms include chest pain, shortness of breath, or respiratory distress, which may be associated with hypotension or hypoxemia. Patients may also be asymptomatic. Chest radiography is typically performed shortly after the implantation procedure to document baseline lead placement and exclude pneumothorax, even in asymptomatic patients. Small pneumothoraces can be managed conservatively with high-flow oxygen and serial chest radiography. Chest tube insertion should be considered in cases involving more than 10% of the pleural space and always in cases of hemodynamic compromise, hypoxia, or continued expansion of the pneumothorax.

Cardiac Perforation

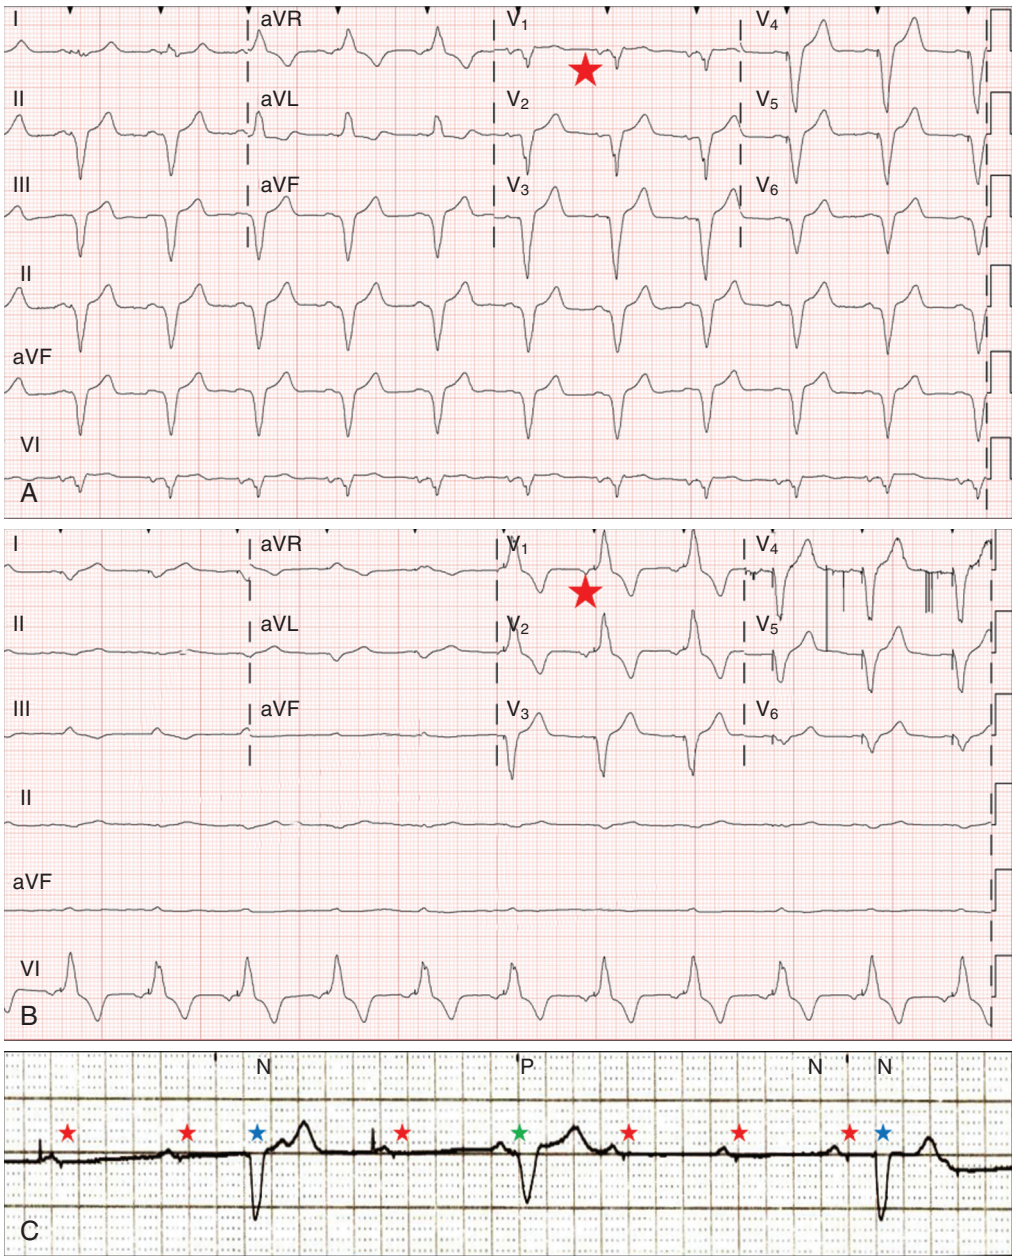
Cardiac perforation has been reported to occur in less than 1% of patients undergoing permanent pacemaker implantation.[135] The risk may be higher in elderly patients, particularly elderly women, or those requiring anticoagulation. Perforation may not be initially detected, as some patients are asymptomatic. Alternatively, patients may report chest pain or shortness of breath. Lightheadedness or syncope may also occur and can be associated with hemodynamic compromise in patients who develop cardiac tamponade owing to a large pericardial effusion.

Signs of perforation may include pacemaker undersensing, increased pacemaker lead impedance, increased pacing threshold, loss of capture, or any combination thereof. Depending on the location of the perforation, diaphragmatic pacing or pericardial rub may also be noted. A change in the paced morphologic features from left bundle branch block to right bundle branch block in a patient with a single, right ventricular lead (Fig. 5.16A and B) is highly suggestive of a lead perforation and should be investigated further. Chest radiography may reveal extension of the lead tip beyond the typical border of the right ventricle (Fig. 5.17). If loss of capture occurs in a pacemaker-dependent patient (see Fig. 5.16C), higher pacing outputs may temporarily stabilize the situation, as long as the lead maintains some degree of contact with the ventricular myocardium. This is not a long-term solution but may obviate the need for transcutaneous or temporary transvenous pacing. Urgent pericardiocentesis may be required if cardiac tamponade is present. Lead repositioning requires consideration of whether a lead tip is beyond the myocardial wall, as removal may leave a defect, causing renewed pericardial bleeding; in such cases, cardiac surgical consultation is essential.

Bleeding and Hematoma

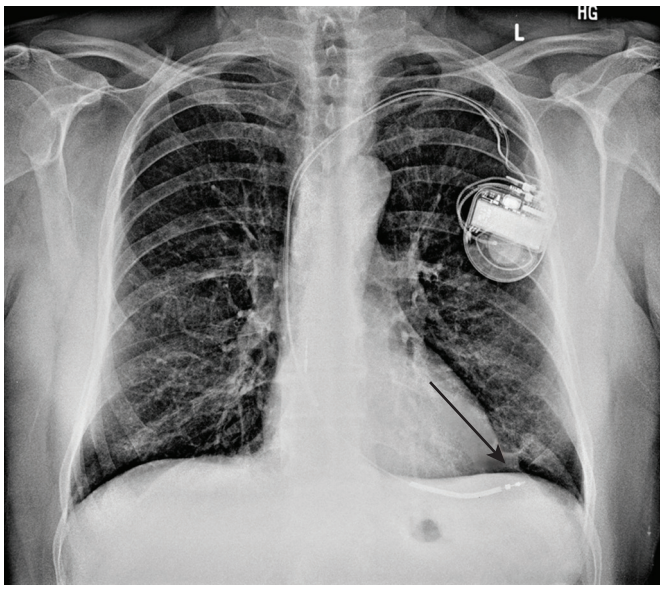
Hematoma is a common complication of pacemaker implantation, with an increased risk among patients receiving anticoagulation. Although not life-threatening, a large hematoma can be quite painful, result in significant blood loss, and increase the risk of infection.[137,138] In most cases, hematomata can be managed conservatively with observation and analgesia alone. Placement of a tight pressure dressing over the site, immobilization of the ipsilateral arm with a sling, and temporary discontinuation of anticoagulation are often effective. However, in some cases, hematomata may become large and very painful, with oozing or drainage from the site (Fig. 5.18). When concomitant infection cannot be excluded, open wound exploration in a sterile operative setting should be considered. Needle aspiration of a hematoma should *never* be attempted at the bedside because this increases the risk of infection.

Precautions should be taken to reduce the risk of bleeding preoperatively and postoperatively. As with any surgical procedure, the risk of bleeding associated with device implantation must be weighed against the risk of interruption of anticoagulation. In recent years, there has been a dramatic shift from official guidelines



• **Fig. 5.16** Lead perforation. A, A 12-lead electrocardiogram demonstrating sinus rhythm with synchronous ventricular pacing in a patient who had just undergone dual-chamber pacemaker placement. The paced morphologic pattern demonstrates a "left bundle branch block" appearance in lead V_1 *(red star)* with a leftward axis, consistent with normal lead position. B, A 12-lead electrocardiogram in the same patient demonstrating a "right bundle branch block" morphologic pattern in lead V_1 *(red star)* with a rightward axis, suggestive of lead perforation through the interventricular septum. C, Telemetry strip showing intermittent loss of ventricular capture shortly thereafter, caused by progressive migration of the lead tip. There are sinus P waves with ventricular capture *(green stars)* and failure to capture *(red stars)* with pauses truncated by ventricular escape complexes *(blue stars).* The patient required emergent lead revision.

recommending "bridging" anticoagulation with heparin products in patients with mechanical valves, atrial fibrillation, and venous thromboembolic disease deemed to be at high risk for thromboembolism[139] to evidence-based recognition that continuation of oral anticoagulation may be safer than "bridging" with unfractionated and low–molecular-weight heparin in most patients.[140–145] Most electrophysiologists now implant pacemakers and defibrillators in fully anticoagulated patients.[146] A patient with a compelling indication for anticoagulation may be better served by early initiation of warfarin, rather than a prolonged interruption of anticoagulation in the perioperative period. However, most operators perform pacemaker implantation if the international normalized ratio is in excess of 3.0. A growing body of literature suggests device insertions can also be performed safely in patients taking novel oral anticoagulants,[147] but randomized data are not yet available. Because there is significant variability in practice patterns, communication



• **Fig. 5.17** Lead perforation. The lead tip extends to the lateral border of the cardiac silhouette, well beyond the typical border of the right ventricle *(black arrow).*

• **Fig. 5.18** Hematoma. The edges of the hematoma at the site of pacemaker implantation are marked to follow the size and exclude continued expansion. A more erythematous area is noted on the medial lower edge of the hematoma. This may require drainage when large, tense, and painful, particularly if there is a need for early anticoagulation or if infection cannot be excluded.

with the physician implanting the device with regard to anticoagulation management is strongly recommended rather than routine discontinuation of anticoagulation in patients awaiting pacemaker or defibrillator insertion.

Patients who have undergone device insertion or revision should not receive unfractionated or low–molecular-weight heparin for *at least* 6 hours after completion of the procedure, and low–molecular-weight heparin should be avoided in patients with significant renal insufficiency.[148] Dual antiplatelet therapy also increases the risk of pocket hematoma,[149,150] but these agents are not commonly held. Thrombocytopenia and anemia are relative contraindications to device implantation, but a platelet count less than 50,000/μL and hemoglobin less than 7.0 g/dL are usually considered to be absolute contraindications for many implanters. Hematologic evaluation is recommended and transfusions may be necessary when pacemaker therapy is urgently required.

Inadvertent Lead Placement in the Left Ventricle

Very rarely, a ventricular lead may be errantly placed within the left ventricle. This may occur if the physician implanting the device inadvertently uses the subclavian artery for access, or if the pacing lead passes through a patent foramen ovale or atrial septal defect into the left atrium (Fig. 5.19). Twelve-lead electrocardiography typically shows a right bundle branch block morphologic pattern in lead V_1 during ventricular pacing, and lateral chest radiography demonstrates an abnormally posterior lead position. Left ventricular access introduces significant risk of arterial thromboembolism and should be corrected immediately. If identified early after implantation, the lead should be easy to reposition. A decision between lifelong anticoagulation versus advanced extraction techniques is required for chronically implanted left ventricular leads.

Arrhythmias

The most common arrhythmias occurring after pacemaker implantation are ventricular ectopic beats, particularly in the very early postoperative period. These ventricular premature beats typically have a QRS morphologic appearance similar to the paced complexes. Ectopy often subsides within the first 24 hours, rarely requiring intervention. However, a change in lead position should be excluded by chest radiograph and bedside pacemaker analysis.

Thrombosis

Subclavian or axillary venous thrombosis may be detected early or late after implantation and can be either asymptomatic or associated with upper extremity swelling and pain. This is typically managed with elevation and anticoagulation with heparin and then warfarin. More severe presentations of thrombosis, including superior vena cava syndrome or venous thromboembolic complications, are very rare.

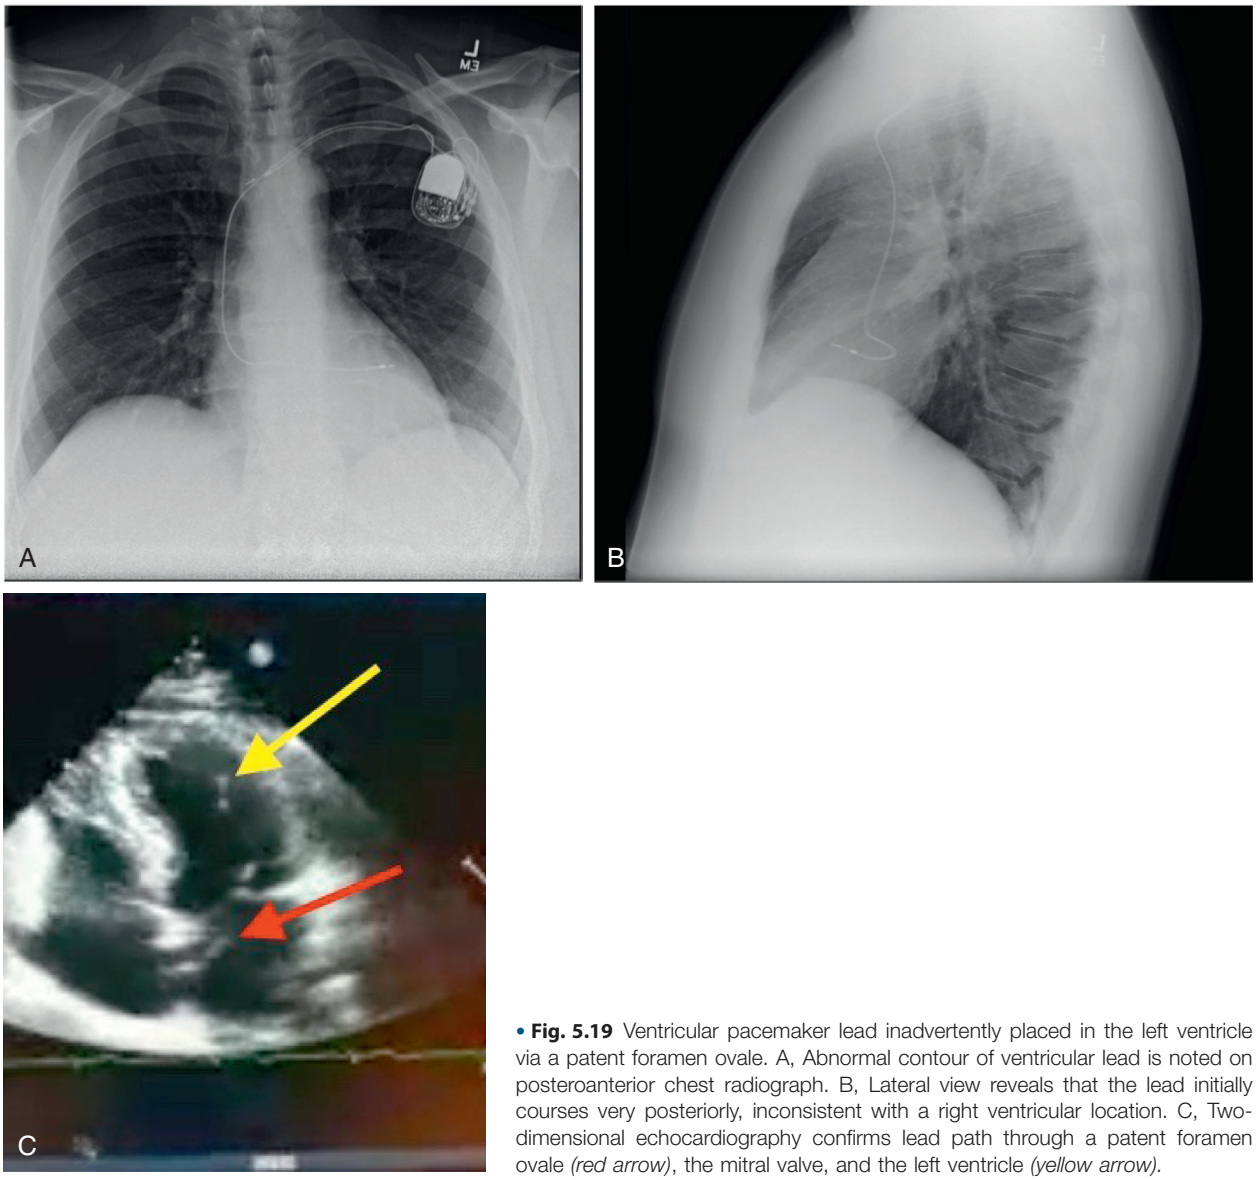
Lead Failure

Lead failure is typically due to fracture or insulation break, usually occurring long after initial implantation. Lead damage most often occurs close to the puncture site in the infraclavicular region (Fig. 5.20). Damage to the insulation may also occur at a site beneath the pulse generator owing to abrasion, or the damage may be the result of a suture being placed directly on the lead itself, in lieu of a suture sleeve. External trauma may also lead to lead damage and fracture.

Signs of insulation breaks include undersensing and reduced pacing lead impedance. Lead fractures may lead to high pacing lead impedance and loss of capture. Lead revision is indicated for lead fractures or insulation failure. Lead fracture typically requires replacement, but a localized insulation breach can often be repaired operatively using a silicone repair kit.

Twiddler's Syndrome

Some patients may manipulate the pacemaker pulse generator, leading to dislodgment or fracture leads. This is called "twiddler's syndrome." Telemetry or electrocardiographic findings may include



• **Fig. 5.19** Ventricular pacemaker lead inadvertently placed in the left ventricle via a patent foramen ovale. A, Abnormal contour of ventricular lead is noted on posteroanterior chest radiograph. B, Lateral view reveals that the lead initially courses very posteriorly, inconsistent with a right ventricular location. C, Two-dimensional echocardiography confirms lead path through a patent foramen ovale *(red arrow)*, the mitral valve, and the left ventricle *(yellow arrow).*

loss of capture and/or sensing. In addition to demonstrating lead dislodgment, the twisted leads within the pacemaker pocket may also be visualized on chest radiograph (Fig. 5.21A). Suturing the pulse generator to the chest wall, using a submuscular pocket, and use of a mesh pouch to stabilize the generator may all help reduce motion of the pulse generator, although patients should always be instructed to avoid manipulation of the pocket. The operative appearance of the leads at the time of pacemaker lead revision is illustrated in Fig. 5.21B.

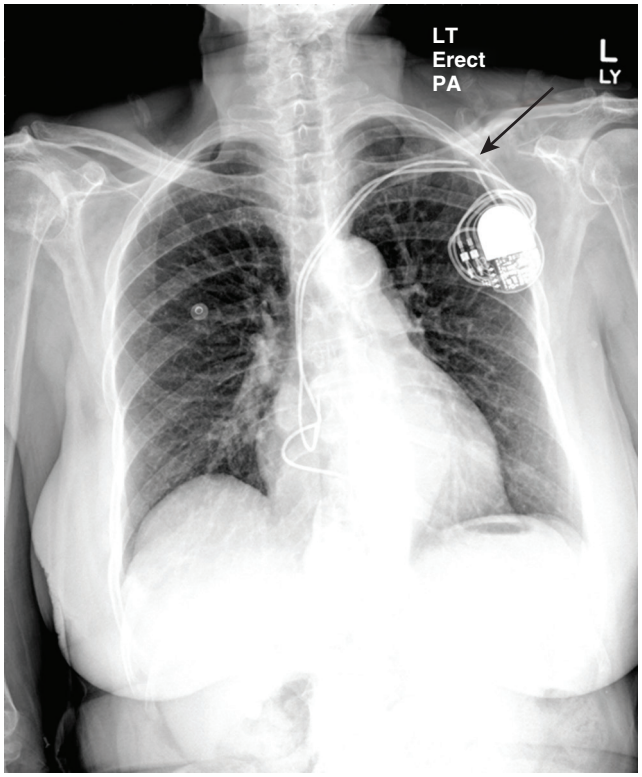
Pacemaker Syndrome

"Pacemaker syndrome" refers to a constellation of symptoms, such as fatigue, chest discomfort, dyspnea, cough, confusion, presyncope, or syncope, which are related to adverse hemodynamic effects resulting from loss of AV synchrony in patients who receive ventricular pacing. A significant drop in blood pressure may occur, and the diagnosis may be elusive in some cases unless specifically considered and confirmed by bedside evaluation. This can be corrected by reprogramming from the VVI mode to the DDD mode or AAI mode (in patients with intact AV conduction) or upgrading to a dual-chamber pacemaker, if a single-chamber ventricular device was implanted in a patient with sinus rhythm.

Infection

Care should be taken to avoid implantation of a permanent pacemaker in a patient with active infection, as this will increase the risk for device infection. Any active infection is a relative contraindication to permanent pacemaker implantation, although active bacteremia or fungemia are absolute contraindications. A fever or rising leukocytosis within the prior 24 hours should delay device implantation until a thorough investigation can be performed. Temporary pacing is appropriate in this setting, although that, too, has been associated with an increased risk of infection.[151] Patient characteristics also contribute to the risk of infection, and all modifiable risks should be optimized before device implantation. There are limited data on the efficacy of postoperative antibiotic administration, but most physicians who implant devices empirically continue antibiotics for 24 hours after the procedure.

Preoperative antibiotic administration has been shown to reduce the risk of device-related infection.[137] There is no standard regimen, but most practitioners administer a penicillin or first- or second-generation cephalosporin for coverage of staphylococcus.[152] Patients with a history of methicillin-resistant *Staphylococcus aureus* colonization or infection, recurrent or prolonged hospitalizations, or either a penicillin or cephalosporin allergy should be administered vancomycin. Patients with a history of vancomycin-resistant enterococcus require infectious disease consultation.



• **Fig. 5.20** Lead fracture. Chest radiograph demonstrating unequivocal fracture of an atrial pacing lead *(black arrow)*.

Pacemaker infection may be superficial or deep, with an incidence of less than 2% after initial implantation procedures, although it is be higher after generator replacement or lead revisions.[125,153–155] Infections vary in severity from superficial infection at the incision with a local stitch abscess to a pocket infection or systemic infection with bacteremia. Erosion of the pacemaker pulse generator or leads may result from infection.

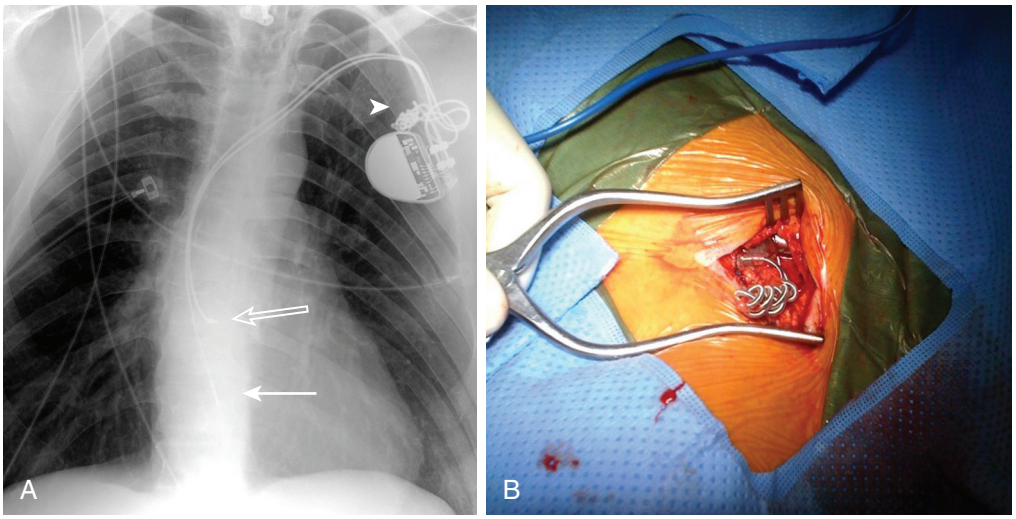
Superficial skin infections or stitch abscesses may be treated and cured with antibiotic therapy. However, lead-associated endocarditis is a more serious complication and is associated with a high mortality rate. Systemic infections with bacteremia and endocarditis require device and lead extraction. Vegetations may develop on the pacemaker lead itself and become large, requiring extraction and removal of the pacing system for cure (Fig. 5.22). Infections may occur many months after device implantation, and hematogenous spread of organisms from a distant site may be a contributing factor. The most common organisms responsible for cardiac implantable electronic device infections are *S. aureus* (often methicillin-resistant) and coagulase-negative staphylococci followed by streptococci, enterococci, and gram-negative rods.[156,157]

Special Considerations in Permanent Pacing

Intravenous Access

The vast majority of permanent device implants use the cephalic, axillary, or subclavian vein. Implants using the internal jugular and femoral vein are exceedingly rare. Devices are generally implanted on the nondominant side for reasons of patient convenience, but implants are usually less technically challenging on the left side. Devices should not be placed ipsilateral to the site of an arteriovenous fistula or graft because of the short-term risk of vein thrombosis and long-term risk of venous stenosis, both of which can compromise hemodialysis access flow.

If at all possible, the nondominant subclavian access should be preserved in the critical care patient who may require permanent device implantation. If temporary central venous access is required, the internal jugular vein should be used whenever possible; if subclavian access is necessary, the critical care physician should



• **Fig. 5.21** Pacemaker lead dislodgment caused by twiddler's syndrome. A, Chest radiograph illustrating dislodgment of the atrial *(outlined arrow)* and ventricular leads *(arrowhead)* as well as significant lead entanglement in the vicinity of the pulse generator *(solid arrow)* in a patient with twiddler's syndrome. B, Photograph taken at the time of lead revision, demonstrating significant entanglement of the leads.

first establish that the contralateral infraclavicular site is available and feasible for use during subsequent device implantation, and it should be "reserved" for that use.

Peripherally inserted central catheter lines (i.e., peripherally inserted central catheters) should be avoided ipsilateral to the side of the future permanent implant because of risk for venous thrombosis. Intraprocedural peripheral venography is not mandatory but can be helpful in very thin patients with a higher risk of pneumothorax and patients with signs of venous occlusion. It is therefore preferable to have an 18- or 20-gauge peripheral intravenous catheter in the upper extremity ipsilateral to the planned implantation site. Telemetry electrode placement over the planned surgical site should be avoided to preserve skin integrity. Finally, repeated preoperative skin cleansing with chlorhexidine-gluconate alcohol wipes the night before and the morning of implant procedures, a technique widely used in cardiac and noncardiac surgery, is a reasonable intevention to lower the risk of device infections.[158,159]

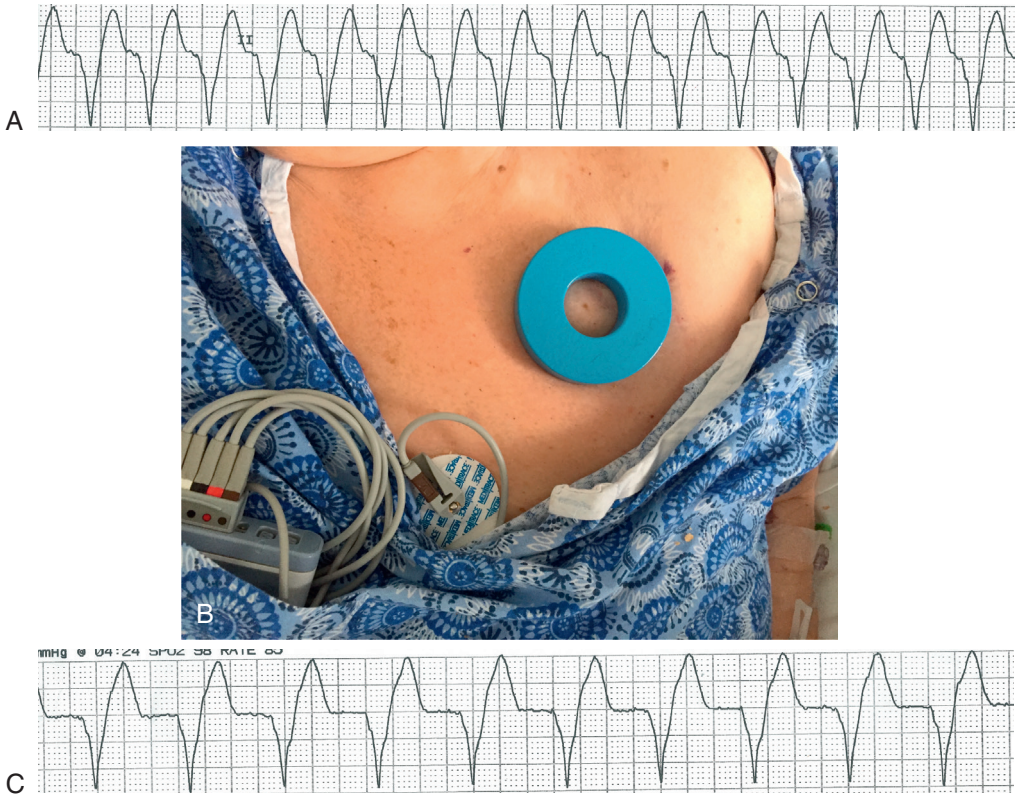
Magnet Application

Magnet application over a permanent pacemaker results in asynchronous pacing, such that regularized pacing stimuli are delivered *regardless* of the underlying rhythm.[160] Various magnet rates, generally between 60 and 100 beats/min, are characteristic of each pacemaker manufacturer. In contrast, a magnet placed over an implantable cardioverter-defibrillator suspends detection of ventricular arrhythmias, *but it does not change pacemaker function*. In the critical care setting, magnet application over a permanent pacemaker can be used to confirm capture, evaluate the morphologic appearance of the paced complex, increase the pacing rate, stop inappropriate rapid tracking of atrial arrhythmias, and terminate pacemaker-mediated tachycardia (Fig. 5.23). Prolonged periods of magnet-induced asynchronous pacing should be avoided in the critical care setting, when concomitant metabolic and electrolyte derangement may increase the risk of proarrhythmia from R on T pacing; reprogramming of the pacemaker should be performed as soon as possible so that the magnet can be removed. Among defibrillator patients who experience inappropriate shocks, magnet application may be lifesaving.



• **Fig. 5.23** Use of an external magnet for asynchronous pacing. A, Telemetry reveals upper rate behavior of a dual-chamber pacemaker owing to tracking of atrial arrhythmia. B, "Doughnut" magnet placed on skin overlying pacemaker generator. C, Resultant asynchronous pacing at 85 ppm.

Magnetic Resonance Imaging

Critically ill patients with previously implanted permanent pacemakers and defibrillators sometimes require magnetic resonance imaging (MRI) scanning. The vast majority of implanted devices are not approved for MRI scanning because of the potential for lead heating, changes in device and/or lead function, and myocardial stimulation with proarrhythmia.[161,162] Pacemaker-dependent patients with implantable defibrillators pose a particularly high set of risks. Since 2011, the U.S. Food and Drug Administration has approved several MRI-conditional permanent pacemakers and defibrillators, and many radiology departments have developed protocols for MRI scanning of patients with these devices. Interestingly, recent data suggest that the overall risk of MRI scanning may be overstated, even for patients with non–MRI-conditional devices, particularly at 1.5 T or below.[163,164] This is a rapidly changing field in which significant controversy exists.

Based on expert opinion, patients with new device implants (<6 weeks old), abandoned leads, passive fixation leads, or epicardial leads are ineligible for MRI outside highly specialized centers, regardless of the clinical indication.[165] Patients with temporary pacemakers are also ineligible because of similar concerns for lead heating, dislodgment, and external interference. If a patient with a non–MRI-conditional cardiac implantable electric device absolutely requires MRI scanning, close coordination with electrophysiology and radiology consultants is mandatory to minimize risk via assessment of system components and abandoned leads, appropriate monitoring during the scan, and device reprogramming before and after the MRI procedure.[166,167] In selected patients with no other alternatives, lead and pulse generator extraction may be an option.[167]

Conclusions

Many critically ill patients develop bradyarrhythmias or have previously implanted permanent pacemakers already in place. Pacing may relieve symptoms, improve quality of life, or provide lifesaving therapy. Therefore it is essential that critical care physicians are adept at arrhythmia recognition, at urgent delivery of temporary pacing, and at basic device troubleshooting. Temporary pacing is particularly useful in the critical care setting and can be performed using a variety of techniques, including transcutaneous, transvenous, and epicardial approaches.

Key Points

- Bradyarrhythmias may be caused by either intrinsic dysfunction of the SN or AV conduction system, or they may be due to a response of normal tissues to extrinsic factors.
- Transcutaneous pacing is most appropriate in situations in which pacing is required only briefly or intermittently, or as a bridging measure for placement of a transvenous system.
- Complete heart block with a narrow-complex escape rhythm does not typically require temporary pacing, unless it is accompanied by hypotension.
- Complete heart block with a wide-complex escape rhythm usually requires temporary pacing, even if the patient is hemodynamically stable.
- Temporary pacing should be avoided in severely hypothermic patients because of the potential risk of catheter-induced ventricular fibrillation.
- If there is an anticipated need for permanent pacing, the nondominant infraclavicular area and subclavian vein should be preserved for device placement.
- Permanent pacemakers are frequently implanted without interruption of therapeutic anticoagulation because the outcomes are better than "bridging" with parenteral agents.
- It is imperative that the critical care physician recognize the electrocardiographic and radiographic signs of lead dislodgment and perforation.

Review Questions

1. A 40-year-old man with no significant medical history presents to the emergency department with a 3-day history of mild fatigue. He denies recreational drug use and states that he is "in great shape" because he is an avid rock climber and backpacker. He reveals that his air conditioner broke during the current heat wave, and he has not been consuming adequate fluids. He is found to be volume depleted. His blood pressure is 100/60 mm Hg. His electrocardiogram reveals complete heart block with a ventricular rate of 40 beats/min and a narrow QRS complex. He is admitted for observation. Which of the following statements is correct?

a. Intravenous fluids are likely to reverse his dehydration-induced electrocardiographic abnormality.

b. A transvenous pacer should be placed and positioned in the right ventricular apex.

c. Serologic tests should be performed.

d. Electrophysiology consultation should be obtained for scheduling of permanent pacemaker insertion.

Answer: c. This clinical presentation—a young patient, active in the outdoors, during the summer months—is highly suggestive of Lyme disease complicated by carditis and complete heart block. This is a reversible condition, generally with a stable and narrow-complex escape, which generally does not require permanent pacing. The presence of volume depletion is incidental. Temporary pacing is indicated only for significant symptoms or hemodynamic instability. Blood samples for Lyme titers should be drawn, and infectious disease consultation should be obtained. The treatment is observation and antibiotics.

2. A 67-year-old woman has a permanent pacemaker implanted for high-degree AV block secondary to sarcoidosis. Several years after implantation, she has a syncopal event and telemetry while in hospital shows intermittent high-degree AV block with a ventricular rate of 30 beats/min. On telemetry, there are pacing spikes with no evidence for ventricular capture. Which of the following statements is correct?

a. Lead failure caused by insulation break is a possible explanation for pacing failure.

b. Sensitivity should be lowered and the pacemaker should be left in place.

c. This is a typical presentation of pacemaker-associated endocarditis.

d. Magnet application to the pacemaker will fix this problem.

Answer: a. Lead failure typically occurs years after initial implantation and most often occurs close to the puncture site of initial insertion. Lead failure is typically due to fracture or insulation break. Signs of insulation break include sensing abnormalities, failure to capture, and reduced pacing lead impedance. Lead failure is an indication for a lead revision procedure, as opposed to changing the programmed sensitivity. Endocarditis is one of the worst complications (albeit very rare) associated with permanent pacemakers. It presents in typical fashion, with signs and symptoms of bacteremia. The application of a magnet over a permanent pacemaker results in asynchronous pacing, such that pacing stimuli are delivered regardless of the underlying rhythm; because there is already failure to capture, asynchronous pacing will not be of benefit.

3. A 32-year-old man is brought to the emergency department after being found unconscious in the park during a cold winter night. His vital signs are significant for a heart rate of 30 beats/min, blood pressure of 85/30 mm Hg, and a rectal temperature of 30.2°C. Which of the following is correct?

a. A transvenous pacer should be placed immediately with the threshold turned up as high as possible.

b. Transcutaneous pacing should be undertaken immediately, with the pacing rate set as high as possible until blood pressure stabilizes.

c. The role for electrical pacing in this situation is limited, and the primary treatment should focus on rewarming.

d. There is no danger to attempting electrical pacing.

Answer: c. This patient is suffering from life-threatening hypothermia caused by environmental exposure. Hypothermia is known to produce dramatic electrocardiographic conduction abnormalities, eventually leading to mechanical abnormalities as well. Hypothermia can cause bradycardia, PR interval and QT interval prolongation, widening of the QRS complex, and ventricular arrhythmias. Treatment should be focused on rewarming as severe/deep hypothermia is associated with decreased responsiveness to electrical stimuli, and the potential to cause ventricular arrhythmias exists with attempting temporary pacing.

4. Immediately after successful placement of a transvenous temporary pacemaker in a patient, failure to pace occurs, resulting in asystole. All of the following are emergently indicated *except*

a. Cardiopulmonary resuscitation.

b. Placing the patient in the right lateral decubitus position.

c. Increasing current output to the highest possible setting.

d. Beginning transcutaneous pacing.

Answer: b. Emergency measures in the asystolic patient with pacing failure include (1) performing cardiopulmonary resuscitation; (2) increasing current output to highest setting possible; (3) checking and tightening all connections; (4) placing the patient in the left (not right) lateral decubitus position; (5) reversing polarity (if epicardial wires); and (5) establishing other means of heart rate support (i.e., transcutaneous pacing) or giving pharmacologic agents (i.e., atropine, isoproterenol).

Pericardial Tamponade: Clinical Presentation, Diagnosis, and Catheter-Based Therapies

TILAK K.R. PASALA, VLADIMIR JELNIN, AND CARLOS E. RUIZ

CHAPTER OUTLINE

Clinical Presentation
Diagnosis
- History
- Physical Examination
- Electrocardiography
- Echocardiography
- Other Imaging Studies
- Catheter-Based Diagnosis

Catheter-Based Therapies
Pericardiocentesis
Post-Pericardial Drain
Percutaneous Balloon Pericardiotomy
Surgical Drainage of Pericardium

Pericardial tamponade (PT) is a life-threatening condition caused by accumulation of fluid in the pericardial sac that causes critical cardiac compression. There is an impaired filling of the cardiac chambers, leading to a drop in the cardiac output. The spectrum of hemodynamic compromise in PT varies from mild to critical with varying prognosis. Without immediate intervention, critical PT can lead to cardiac arrest and death. For a timely recognition and intervention in PT, critical care physicians should have a thorough understanding of the pericardial anatomy, pathophysiology of PT, clinical presentation and differential diagnosis, understanding of imaging modalities, and knowledge of catheter-based interventions.

Clinical Presentation

The pericardium is a sac that contains the heart and includes the outer fibrous sac and the serosal component. The outer fibrous layer continues as the adventitia of the great vessels superiorly and is attached to the central tendon of the diaphragm inferiorly.[1] The pericardial cavity is enclosed by the serosal component, which forms the outer parietal (along with fibrous component) and inner visceral pericardium. The visceral pericardium reflects and becomes continuous with the parietal pericardium ensheathing the arteries and veins at the base of the heart. The reflections form the transverse sinus behind the great vessels and the oblique sinus behind the left atrium separated by the pulmonary veins and inferior vena cava. Pericardial fluid (normally 15–50 mL) is contained between the visceral and parietal pericardium that helps in lubrication and equalizes pressures between pericardial chamber and heart chambers. The accumulation of pericardial fluid beyond the pericardial reserve volume (dependent on the compliance of pericardium) causes elevation of the intrapericardial pressure, leading to PT. Equalization of the diastolic cardiac chamber pressures is seen. The cardiac chambers collapse, which restricts diastolic filling and results in low cardiac output.

PT varies in presentation. The presentation is dependent on the rate of accumulation of pericardial effusion and underlying cause (Box 6.1). Some patients are asymptomatic when accumulation of pericardial effusion is slow and chronic. With the chronic accumulation of fluid, pericardium stretches and becomes more compliant. A compliant pericardium can accommodate as much as 1 L of fluid without hemodynamic compromise. Clinical manifestations occur when a critical threshold of intrapericardial pressure is reached. In the cases of acute pericardial effusion where normal pericardium with lower distensibility is present, this threshold is reached at a lower volume (as low as 100 mL) of pericardial effusion (see Fig. 24.1). PT clinically manifests as dyspnea, tachycardia (acute bradycardia owing to vagal response), tachypnea, hypotension, elevated systemic venous pressure, pulsus paradoxus (PP) (exaggerated inspiratory decrease in arterial blood pressure >10 mm Hg). Clinical PT represents a later stage in the spectrum of hemodynamic compromise. Most patients show abnormalities on echocardiography and catheter laboratory hemodynamic measurements before overt clinical PT is seen.[2] Hypotension may be a late manifestation as the blood pressure is maintained by adrenergic response and vasoconstriction balancing the decreased stroke volume. After a critical threshold is reached, hypotension can be sudden and potentially fatal without intervention. Hence, it is important to have a high clinical suspicion for early recognition and prompt intervention of PT.

• BOX 6.1 Etiology of Pericardial Tamponade

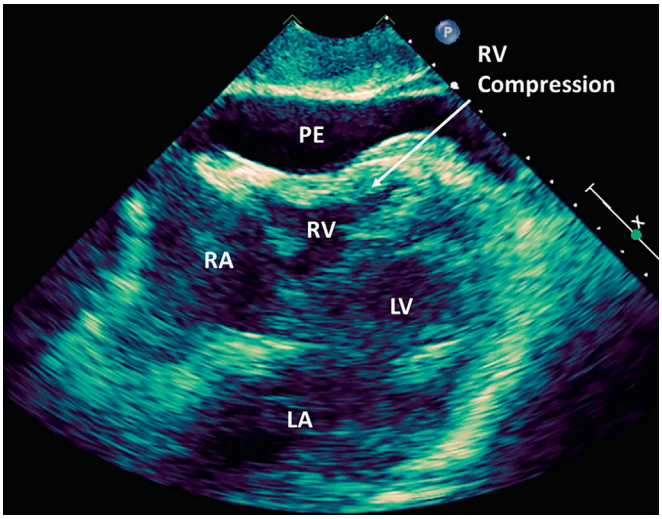
Neoplasm/Malignancy

Pericarditis (any process that causes pericarditis and pericardial effusion)

- Infectious: viral (enteroviruses, herpesviruses, and so on), bacterial (*Mycobacterium tuberculosis, Coxiella burnetii,* and so on); fungal (*Histoplasma* spp.)
- Neoplastic: secondary tumors common (lung and breast cancer)
- Autoimmune: systemic lupus erythematosus, Behçet syndrome, sarcoidosis, inflammatory bowel disease
- Metabolic: uremia
- Drugs: phenytoin, doxorubicin, cyclophosphamide, and so on

Iatrogenic (After Invasive Cardiac Procedures or Surgery)

Infectious diseases
Anticoagulation
Connective tissue disorders (systemic lupus erythematosus, rheumatoid arthritis, scleroderma)
After acute myocardial infarction
Idiopathic



• Fig. 6.1 Cardiac tamponade on echocardiography**.** Echo shows large pericardial effusion which is compressing the right ventricle. *LA,* Left atrium; *LV,* left ventricle; *PE,* pericardial effusion; *RA,* right atrium; *RV,* right ventricle.

Diagnosis

An early and prompt diagnosis is crucial. The combination of clinical signs and imaging modalities can usually clinch the diagnosis.

History

Patients can express various symptoms depending on the etiology of PT, chronicity, comorbidities, and stability of the patient's condition. The symptoms can range from chest pain, dyspnea, cough or dysphagia (with mass effect on the esophagus), fatigue, presyncope or syncope (reduced cardiac output), and even oliguria and edema if chronically present. Patients with iatrogenic catheter- or wire-related injury may report chest pain or shoulder pain as the result of pericardial irritation. Other atypical symptoms can include nausea, sweating, anxiety, and so on. Additionally, a good review of systems can point toward the etiology of the pericardial effusion. For example, patients with malignant or systemic disease may have weight loss and anorexia.

Physical Examination

Patients may be in distress and have tachycardia. The classic Beck's triad of jugular venous distention, decreased arterial pressure, and small quiet heart (owing to fluid accumulation around the heart) may be present. Jugular venous distention may be an early finding that increases as the tamponade worsens. However, this may be absent in patients with localized effusions or hypovolemia. There is blunting of the y descent (produced by early ventricular filling and lowering of atrial pressure) owing to compression on the right side of the heart throughout the cardiac cycle. Although a prominent x descent (produced by atrial relaxation and systolic descent of tricuspid valve during ventricular systole) is seen in tamponade, it can also be seen in constrictive pericarditis and restrictive cardiomyopathy. A drop in pulse pressure owing to a decrease in stroke volume during inspiration can be felt on palpation and arterial monitoring. PP, which is a fall in arterial systolic pressure by 10 mm Hg during normal inspiration, can be seen in PT. The mechanism of PP is ventricular interdependence where the left ventricular filling is impaired by the increase in right ventricular filling during inspiration. PP is not specific to tamponade and can be present in conditions that cause respiratory variation in ventricular filling, such as hypovolemic shock, acute massive pulmonary embolism, constrictive pericarditis, and so on. Heart sounds are muffled with large pericardial effusion. Pericardial rub may be present.

Electrocardiography

Although electrocardiography is not specific, low voltages can be seen. Another finding is an electrical alternans, which is a beat-to-beat alternation in voltage caused by a wide swinging of the heart in large effusions changing the direction of the electrical vectors.

Echocardiography

Echocardiography is the first-line imaging modality for diagnosing PT and follow-up (Fig. 6.1). Two-dimensional echocardiography allows quick assessment of the size of effusion; delineation of the size and distribution of the effusion, including loculated effusions; and helps assess the success of pericardiocentesis. The echocardiogram also can provide a reasonable estimate of the total volume of the effusion. A circumferential effusion greater than 1 cm in width is considered large[1] (>500 mL). Moderate effusions (100–500 mL) are usually circumferential but less than 1 cm, whereas small effusions (<100 mL) are usually localized posterior to the left ventricle and measure less than 1 cm. Classification criteria differ significantly among various echocardiographers and institutions. The typical echocardiographic signs of PT are listed in Box 6.2.

Other Imaging Studies

The chest x-ray film may show enlarged cardiac silhouette with large pericardial effusions that have accumulated chronically. It

• BOX 6.2 Two-Dimensional and Doppler Echocardiographic Features of Pericardial Tamponade

Key features
- Presence of pericardial effusion
- Dilated inferior vena cava
- Abnormal hepatic veins flow (blunting or reversal of diastolic flows in expiration)
- Reduced left ventricular end-diastolic and end-systolic dimensions
- Doppler evidence of reduced stroke volume and cardiac output

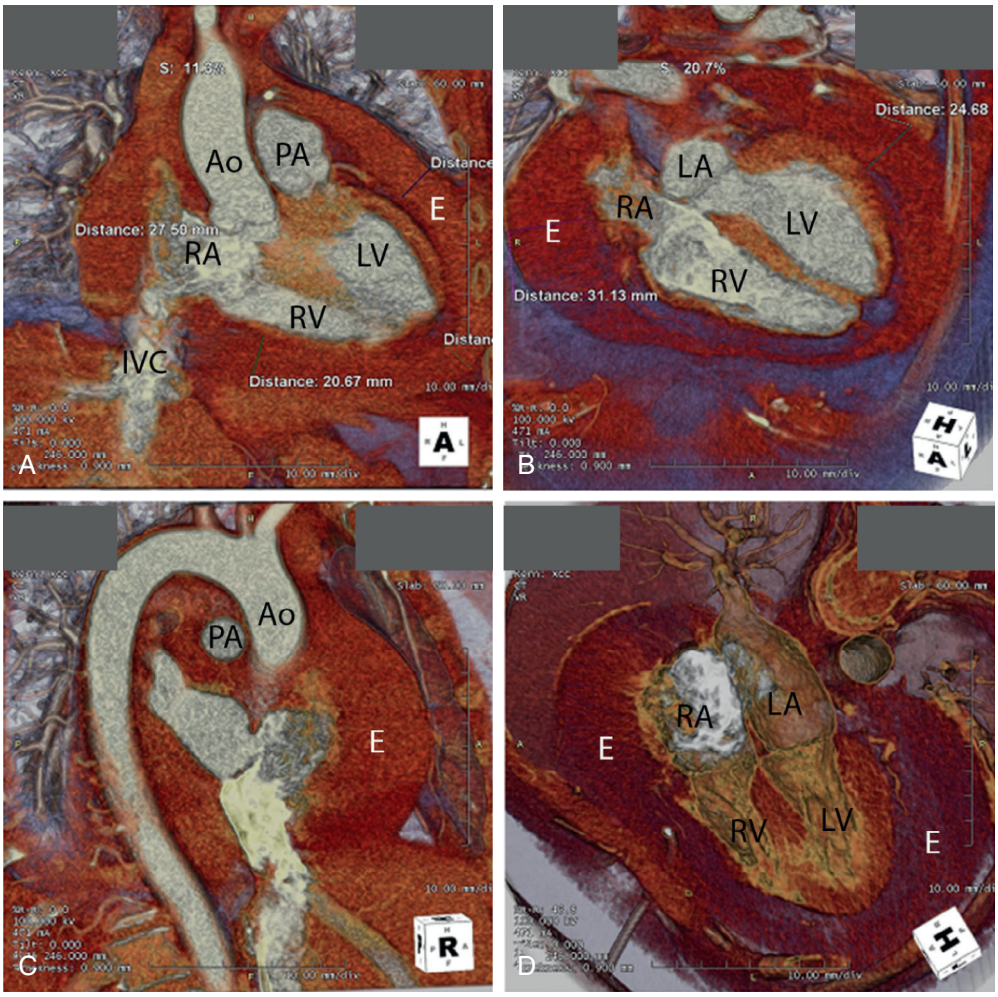
Additional features
- Right heart chamber collapse
- Inspiratory bounce of interventricular septum toward left ventricle
- Variation in mitral inflow (The maximal peak mitral E-wave inflow drop occurs with the first beat of inspiration and the first beat of expiration, usually exceeding more than 30% respiratory variation.)
- Variation in tricuspid flow (The maximal tricuspid E-wave inflow drop occurs on the first beat of expiration at the same time as the hepatic vein atrial reversal and usually exceeds more than 60% respiratory variation.)

may not be possible to distinguish tamponade from pericardial effusion without tamponade.

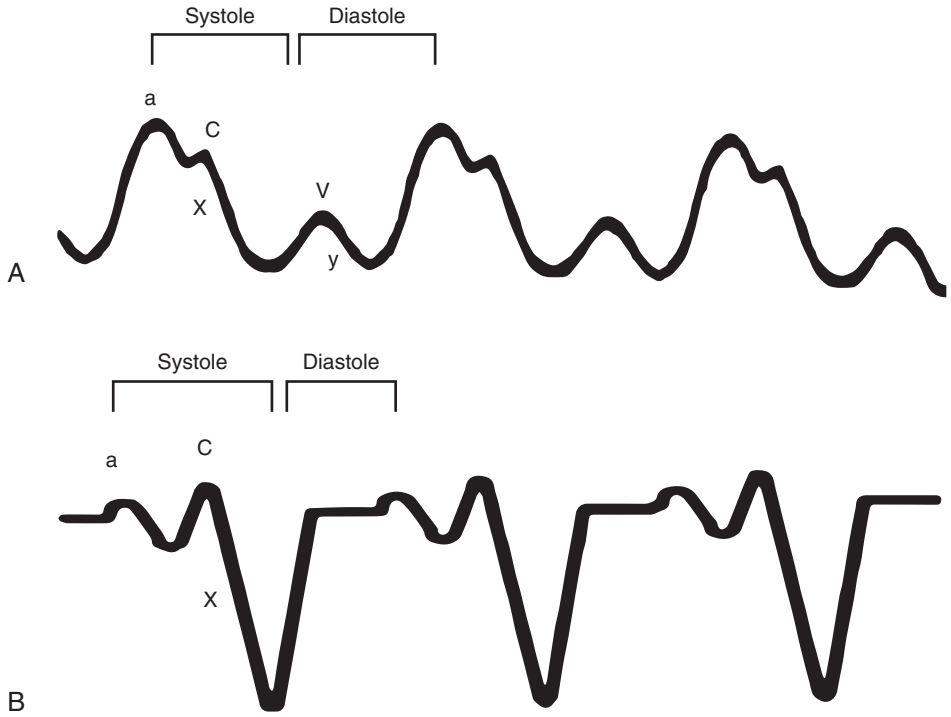
Computed tomography (CT) scanning can be used in instances in which loculated or complex effusions are suspected (Fig. 6.2). It may help in determining if percutaneous versus surgical drainage is feasible. Some of the signs seen on CT may include flattened heart, compressed coronary sinus, septal bowing, and increase in the size of superior vena cava/inferior vena cava. Cardiovascular magnetic resonance imaging can characterize tissues based on signal intensity.

Catheter-Based Diagnosis

Catheter-based hemodynamic assessment is rarely used when echocardiography is readily available (Box 6.3). There is an absence of the y descent on the central venous pressure waveform that can occur relatively early (Fig. 6.3). As tamponade progresses, there is equalization of pressures on the left and right sides of the heart with the pericardial pressure.



• Fig. 6.2 Cardiac computed tomography three-dimensional reconstruction: volume-rendering technique showing large pericardial effusion from different views. A, Straight anteroposterior view with cut plain through the aortic root; C, modified sagittal view; B and D, windows simulating echocardiographic modifications of four chambers view. *Ao,* Ascending aorta; *E,* pericardial effusion; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle.



• **Fig. 6.3** Central venous pressure (CVP) waveform in cardiac tamponade. A, Normal CVP waveform during systole and diastole is shown. B, There is absence of y descent because of restricted right ventricular filling. (From Carmona P, Mateo E, Casanovas I, et al. Management of cardiac tamponade after cardiac surgery. *J Cardiothoracic Vasc Anesth.* 2012;26:302–311.)

• BOX 6.3 Hemodynamic Features Seen on Heart Catheterization During Pericardial Tamponade

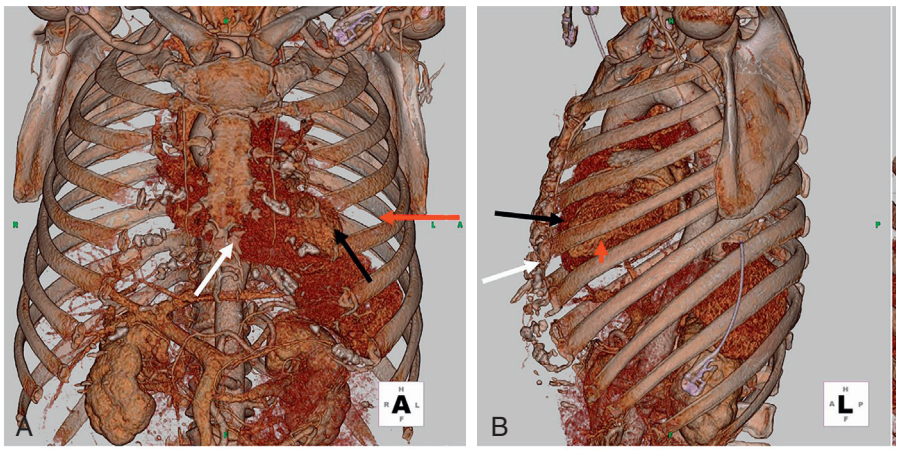
Key features
- Elevated atrial pressures
- Blunted or absent y descent and preservation of x descent
- Equalization of diastolic pressures
- Reduced cardiac output and stroke volume
- Alterations in systolic ejection period or pulse pressure (pulsus paradoxus)

Catheter-Based Therapies

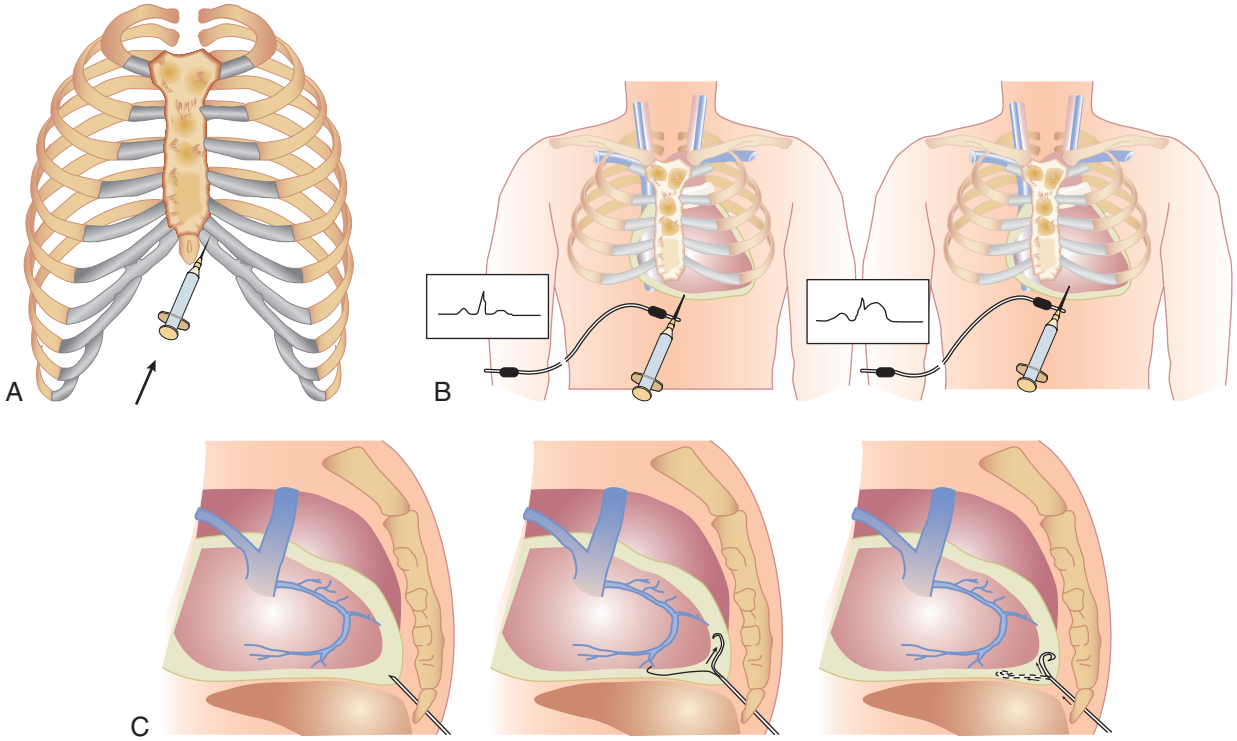
Prompt treatment of PT is crucial for survival and therapy should not be delayed once PT is diagnosed. Decompression of the pericardium can be achieved with pericardiocentesis (removal of pericardial fluid usually with a needle), and usually a catheter drain is placed for continuous and complete drainage of fluid. Surgical approaches to PT include (1) chest tube placement via a subxiphoid approach, thoracotomy, or sternotomy, and (2) a pericardial window where a small portion of pericardium is excised, allowing fluid to drain freely. The pericardial window provides a long-term solution for recurrent pericardial effusion but is invasive. Additionally, recurrence of pericardial effusion/tamponade can occur as the result of reorganization of pericardial space caused by adhesions. Catheter-based pericardiotomy, which is the percutaneous balloon dilation of the pericardium, is underused but can achieve results similar to pericardial window in expert hands.[3]

Pericardiocentesis

The site of pericardiocentesis should be guided by ultrasound to determine the optimal window. Most commonly a subcostal or subxiphoid approach is used (Fig. 6.4). However, an apical approach may provide the nearest distance. Other approaches include right-sided and lower parasternal approaches. With a subxiphoid approach the left lobe of the liver is situated near the needle track and care should be taken to avoid injury. Similarly, when an intercostal approach puncture is used, the site should be above the ribs to avoid blood vessels that travel inferior to the ribs. Care should be taken to avoid lingual and left pleural injury during an apical approach. Another structure to keep in mind is the left anterior descending artery. Echocardiography-guided pericardiocentesis has shown high procedural success with low risk of complications in a large series of patients from the Mayo Clinic.[4] It can be helpful in identifying even difficult loculated effusions. A long micropuncture needle is preferred (Fig. 6.5). A 10- to 20-mL syringe is attached to the needle and advanced with suction. Once the pericardial fluid is withdrawn through the needle, a stiff shaft microwire is passed through the needle. A microcatheter is advanced over the wire. Confirmation of pericardial space can be made by injecting agitated saline solution mixed with blood or Definity (Lantheus Medical Imaging, North Billerica, MA) contrast through the needle or microcatheter. Subsequently a guidewire is inserted through the microcatheter and positioned under fluoroscopy while confirming the guidewire is in the extracardiac space (Fig. 6.6). Then usually a pigtail catheter is advanced over the guidewire (Figs. 6.7 and 6.8). Pericardial fluid is drained with 60-cc syringes until it is dry, subsequently drained by either gravity or hooked to negative pressure.



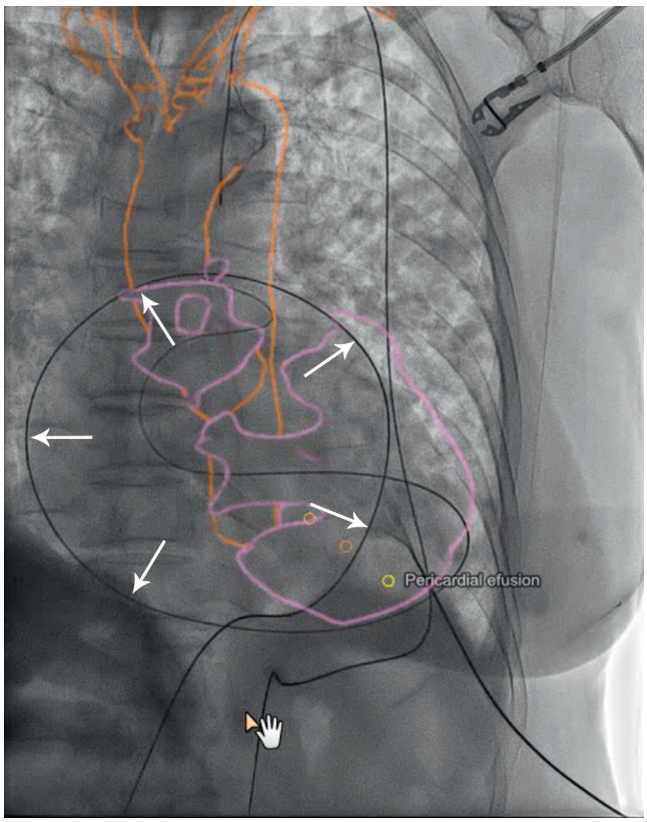
• **Fig. 6.4** Common access sites for pericardial drainage. Cardiac computed tomography angiography volume rendering of the chest used to plan access site for pericardial drainage. The subxiphoid approach *(white arrows)* is the most commonly used access site. Other options include midclavicular apical access *(black arrows)* and axillary access *(red arrows)*.



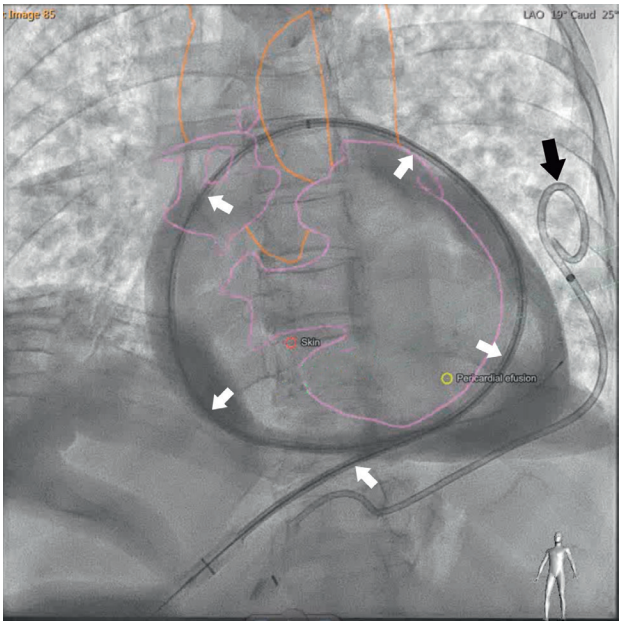
• **Fig. 6.5** Diagrammatic representation of a pericardiocentesis procedure via subxiphoid approach. A, A subxiphoid approach is used. B, A pericardial needle is connected to an electrocardiogram (ECG) lead and is advanced left lateral to the subxiphoid area aiming toward the left shoulder. ST-segment elevation is seen on the ECG lead tracing when the needle touches the epicardium. The needle should be retracted slightly until the ST-segment elevation disappears. C, After the pericardial space is entered with the pericardial needle, a guidewire is introduced in the pericardial space through the needle. The needle is removed, and a catheter is inserted in the pericardial sac over the guidewire (either anteriorly or inferiorly in the pericardial sac).

Post-Pericardial Drain

Depending on the etiology of pericardial effusion, there may be continuous extravasation of fluid into the pericardial space. The drain usually is left in place for 48 to 72 hours until no significant drainage of pericardial fluid is seen (50–100 cc/24 hr). Antibiotics are usually administered. Because the pericardium can cause pain, adequate analgesia should be given in anticipation of pain caused by pericardial irritation. Patients should be watched for recurrent PT; possible causes could be an inability to drain acute accumulation of pericardial fluid or blood, clogging of the pericardial drain that may need heparin flushes, or a repositioned drain. Patients should



• **Fig. 6.6** Guidewire in the pericardial space. A subcostal approach is being used. A long guidewire *(white arrows)* is seen encircling the extracardiac space, confirming that the wire is in the pericardial space.



• **Fig. 6.7** A pericardial drain *(white arrows)* is placed over the guidewire. A pigtail catheter can be placed as well. Additionally, a pleural drain *(black arrow)* is seen in the figure. The outlines of the aorta *(orange color)* and extent of effusion *(purple)* is seen from the overlaid computed tomography (CT) angiography (computed tomography angiography/fluoroscopy fusion was used for this procedure).

be watched for signs suggesting recurrent PT, and an echocardiogram should be obtained as a follow-up to rule out recurrence. Patients whose effusion continues to drain or have signs of recurrence could be considered for open surgical pericardial window or percutaneous balloon pericardiotomy.

Percutaneous Balloon Pericardiotomy

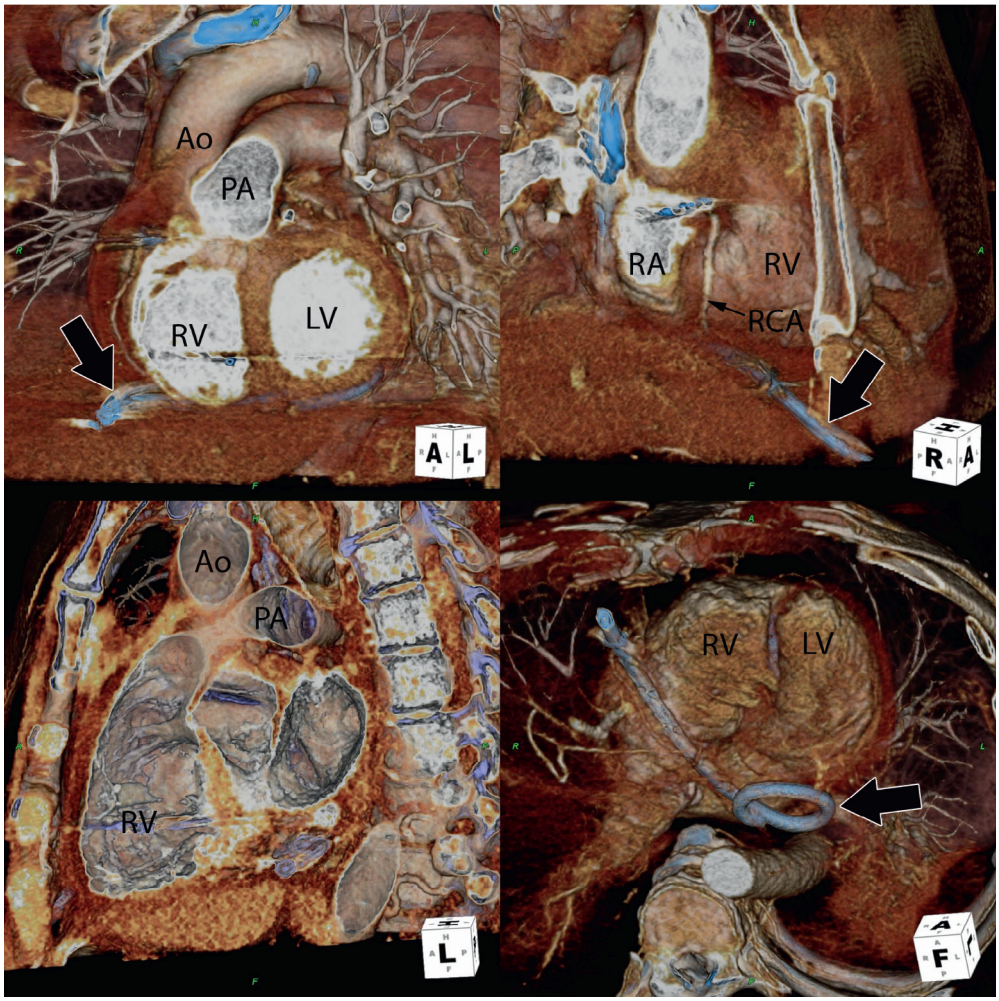
Percutaneous balloon pericardiotomy (PBP) is a procedure in which a pericardial window is created percutaneously using balloon inflation of the pericardium. This can be performed with the patient under conscious sedation and is relatively safe. In patients with persistent drainage or malignant pleural effusion, PBP can be particularly useful. The first human experience with the technique was done by Palacios et al., who performed PBP in eight patients with malignant pericardial effusion and tamponade.[5] They reported 100% success with no immediate complications. No recurrence was noted up to 6 months. In other literature, ~85% success is reported.[6]

The most common route is the subxiphoid approach. After accessing the pericardial space via the technique previously described, contrast dye is injected into the pericardial space (Fig. 6.9).

We used CT angiography fluoroscopy fusion imaging (superimposing relevant cardiac structures processed from cardiac CT angiography over fluoroscopy) in this example. The cardiac structures are segmented and color coded to identify each structure. Subsequently, this information is translated over the fluoroscopy, which helps in the orientation of the three-dimensional anatomy on fluoroscopy. A preshaped stiff guidewire is advanced through the needle or preferably a pigtail catheter. If pigtail catheter is used, it is removed and over-the-wire predilation of the skin is performed to accommodate the balloon. The skin, tract, and the pericardium are predilated to allow for the passage of the balloon. A 20-mm balloon is chosen to dilate the pericardium. The balloon is advanced beyond the skin and using contrast as a guide the balloon is positioned at the site of pericardium (Fig. 6.9C). Usually two to four inflations, until the waist of the balloon disappears, are performed to achieve adequate result. A major complication after the procedure is large pleural effusion that occurs frequently in large effusions. Here in our example, a pleural drain is placed at the time of procedure (see Fig. 6.9D). After the PBP, frequently a pericardial drain is left in place. Closure and recurrence can occur and one should monitor after the procedure with echocardiography.

Surgical Drainage of Pericardium

Surgical drainage of the pericardium is highly effective in the removal of pericardial fluid, for uncluttering of loculations, and improving hemodynamic compromise. Surgical pericardiotomy and pericardiectomy (pericardial window) can be achieved by subxiphoid incision or video-assisted thoracoscopic pericardiectomy.[7] Catheter pericardiocentesis remains the treatment of choice in most patients and should be the preferred surgical approach.[8] Surgical drainage has the advantage when pericardial biopsies are needed or pericardiectomy needs to be performed. In addition, surgery may have additional advantages in the case of extensive loculated effusion and reaccumulation of pericardial fluid after catheter drainage. The drawbacks of surgery are that it is more invasive, often requires general anesthesia, and is not emergently available. Surgical drainage should be reserved for PT related to trauma, recurrent malignant effusion, and loculated purulent pericardial effusion.



• **Fig. 6.8** Cardiac computed tomography three-dimensional reconstruction (volume rendering technique) after pericardial drain shows a pigtail catheter *(black arrow)* placed via subcostal, subxiphoid approach in the inferior border of the heart. *Ao,* Ascending aorta; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RCA,* right coronary artery; *RV,* right ventricle.

Key Points

- Patients with PT vary in presentation. It can range from asymptomatic tamponade to tamponade associated with shock and death.
- PT is associated with pericardial effusion increasing intrapericardial pressure beyond a threshold, causing pressure on the heart chambers that leads to restricted ventricular filling that causes decreased cardiac output.
- Echocardiography remains the mainstay of imaging modality to identify pericardial effusion, signs of PT. Typical features may not always be present and precede clinical manifestation of tamponade.
- Pericardiocentesis can be lifesaving and can be performed via various anatomical approaches. If available, echocardiographic or fluoroscopic guidance should be used.
- Percutaneous balloon pericardiotomy is an alternative therapy to surgical pericardial window and can be performed safely with training and imaging guidance.
- Recurrence of tamponade can occur and patients undergoing catheter-based procedures should be closely monitored clinically and with echocardiography.

Review Questions

1. Confirmation of the needle in the pericardial space is usually done by
- **a.** Injecting conjecting contrast dye into the pericardial space under fluoroscopy.
- **b.** Drawing back bloody fluid into the syringe.
- **c.** Injecting agitated saline solution mixed with blood or Definity contrast under echocardiographic guidance.
- **d.** Passing the wire through the needle and checking the path of the wire on fluoroscopy.

Answer: c. Confirmation of microneedle placement in the pericardial space is usually done by injecting Definity (Lantheus Medical Imaging, North Billerica, MA) contrast, which is a perflutren lipid microsphere injectable suspension that is an ultrasound contrast agent. It should be noted that cardiopulmonary adverse events (1.1%) can occur with this agent and patients should be monitored for 30 minutes after administration.

2. Care should be taken to avoid which structure while performing pericardiocentesis via apical approach?
- **a.** Left circumflex artery
- **b.** Left lobe of liver
- **c.** Left anterior descending artery
- **d.** Left phrenic nerve

Answer: c. The left anterior descending artery travels anteriorly in the interventricular groove and supplies the anterior wall and apex of the left ventricle. It can be injured via the apical approach. When it is available, echocardiographic guidance should be used and the advance of the needle should be avoided once the fluid is withdrawn into the syringe.

3. What is the common major complication that occurs after percutaneous balloon pericardiotomy for large pericardial effusion?
- **a.** Pericarditis
- **b.** Left phrenic nerve injury
- **c.** Pleural effusion
- **d.** Right coronary artery injury

Answer: c. Pleural effusion is commonly seen after percutaneous balloon pericardiotomy. The pleural drain is routinely placed at the time of the procedure along with a pericardial drain.

Cardiac assist technology has matured over more than a half century. The first practical device to enter routine clinical use, the intraaortic balloon pump (IABP), revolutionized the management of acute heart failure, and saw an ever-expanding variety of uses, including as an adjunctive tool to protect the heart during heart surgery and percutaneous interventions. It was also a test platform for learning the limitations of cardiac assist, including complications related to vascular access, and forced physicians to deal with a variety of practical and ethical limitations. A host of mechanical pumps initially required surgical placement, but with increasing miniaturization and better understanding of means to deal with hemolysis, thrombosis, energy delivery, and infection control, percutaneous ventricular assist devices (VADs) are now becoming dominant. A burgeoning list of high-level clinical trials, most published since the last edition of this textbook, have contributed substantially to appreciation of the role of these technologies in heart failure and as adjunctive therapy in surgical and percutaneous interventions. IABP has continuing utility and cost-effectiveness, but in a number of settings it appears clearly inferior to VADs such as the Impella device (Abiomed, Danvers, MA), TandemHeart (TandemLife, Pittsburgh, PA), and extracorporeal membrane oxygenation (ECMO). This chapter focuses largely on these four temporary support technologies (Table 7.1).

Intraaortic Balloon Pump Counterpulsation

Introduction and History

The first percutaneously placed cardiac assist device was the IABP, which displaces blood from the descending aorta during diastole and results in altered myocardial mechanics during systole. By raising diastolic perfusion pressure, the IABP has the potential to augment coronary flow. Unlike the majority of more recently developed devices, it provides auxiliary rather than independent support of cardiac output (CO). Although it uses complex software algorithms, it is the simplest of the invasive devices mechanically, the lowest in profile, and is associated with relatively low failure rates. Its advantages include ease of insertion in the cardiac catheterization laboratory (CCL), operating room, or the bedside, and a relatively small footprint, allowing placement in the vasculature with less morbidity than other devices in its class. The CCL has become the primary location of placement while bedside placement in critical care units has declined to the low single-digit percentages.[1,2]

Initial investigations aimed at altering the timing of phases of the cardiac cycle originated with animal experiments conducted by Adrian Kantrowitz in the early 1950s.[3] The focus was initially oriented toward improving coronary blood flow rather than augmentation of CO. Appreciating that coronary flow (particularly in the left coronary circulation) occurs primarily in diastole, the concept was to delay the peak systolic pressure pulse to the diastolic phase of the cardiac cycle.[4] The IABP was introduced in humans in 1967 (Fig. 7.1). Modification over the next decades improved packaging, ease of placement, improvement in timing algorithms, and proliferation of placement in the CCL.

Physiology

The classic concept of intraaortic balloon counterpulsation involves inflation in synchrony with aortic valve closure, at the onset of isovolumic diastole and the appearance of the dicrotic notch, displacing blood comparable to the balloon's volume into the peripheral circulation during diastole. An example of the effects of balloon counterpulsation on systolic and diastolic pressure is seen in Fig. 7.2.

TABLE 7.1 A Comparison of Temporary Mechanical Support Technologies

	IABP	Impella 2.5	Impella CP	Impella 5.0/LD	Impella RP	TH	ECMO
Flow augmentation	0.5–1	1.5–2.5	4	5	4	4	4–7
Size (Fr)	7.5	12	14	21	22	15	17–25
Placement	Percutaneous	Percutaneous	Percutaneous	Open	Percutaneous	Percutaneous	Percutaneous or central
Support	LV	LV	LV	LV	RV	LV, RV, biventricular	RV, LV, biventricular
Type of flow	Pneumatic	Axial	Axial	Axial	Axial	Centrifugal	Centrifugal
Time to initiate	+	++	++	++++	++	++++	+++

Flow augmentations are expressed in liters per minute.
+Signs refer to relative time to initiate support from shortest (+) to longest (++++).
2.5, CP, 5.0/LD, and RP refer to various Impella model brand names.

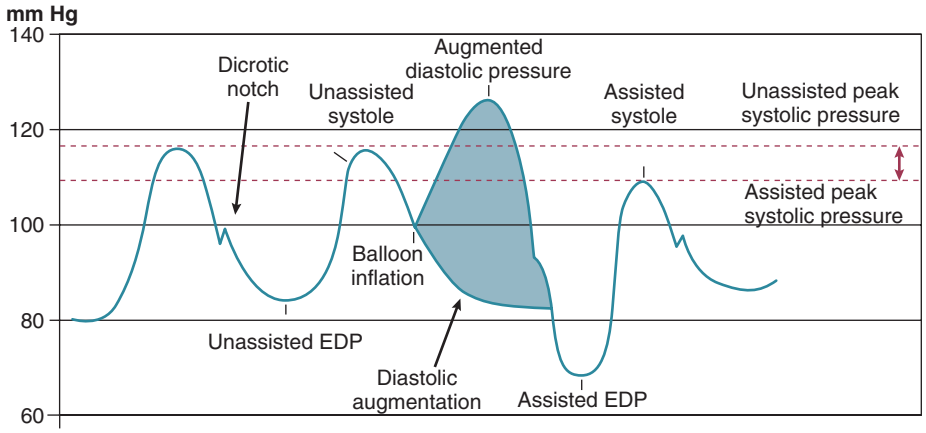
The "classic" response to IABP lowers systolic blood pressure and augments diastolic pressure. Initial studies showed a 20% decrease in systolic pressure and a 30% increase in diastolic pressure.[5] An important characteristic of IABP, in contrast to most mechanical assist devices, is that it contributes to pulsatile flow, with theoretical benefits to end-organ perfusion beyond any actual change in mean flow or pressures. Because the majority of coronary flow occurs in diastole, an increase in diastolic pressure has the potential to augment coronary flow as well as flow to other end-organs. However, diastolic pressure augmentation can be affected by compliance characteristics of the aorta and vascular bed[6] and increases in diastolic pressure; hence coronary perfusion pressure may not result in an increase in coronary flow because autoregulation modulates this potential. In patients with normal physiology, end-organs capable of autoregulation maintain flow without significant change. Thus experimental and clinical data fail to show change in flow in native coronary arteries[7,8] or in bypass grafts[9] regardless of the severity of coronary stenosis.[10] Although total coronary blood flow may not increase, coronary blood flow velocity has consistently been demonstrated to rise.[11–13] That pulsatile flow may have additional benefit was suggested in a randomized study comparing cardiopulmonary bypass with or without concomitant IABP; multiple parameters of whole-body perfusion were superior in the pulsatile flow setting.[14] In general, augmentation of blood flow appears most likely to occur in patients in profound shock.[11,13,14] Most of the benefits of IABP are related to improvement in hemodynamics with secondary relief of ischemia. Amelioration of ischemia may in turn result in improved left ventricular (LV) function and additional improvement in hemodynamics.

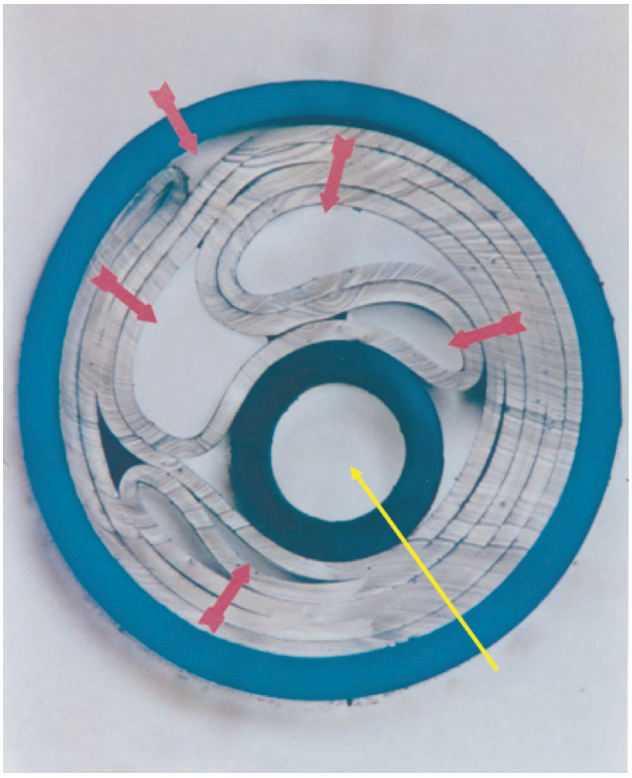
Although the IABP is generally described as both improving myocardial oxygen supply and lowering myocardial oxygen demand, the predominant effect is the latter. This is based on decreased afterload and decreased wall stress with increased stroke volume and CO, particularly in patients with low-output states. In general, the magnitude of hemodynamic response is proportional to the extent of depression of cardiac function.[6] When IABP results in improved end-organ perfusion, as evidenced by signs such as improved urine output, the overall prognosis is generally improved.[5]

Placement Removal and Troubleshooting

With the introduction of a separate guidewire lumen in the early 1980s,[15] the safety of IABP placement improved significantly. Improvements in technology allowed for the introduction of tightly folded balloons prewrapped around the central lumen (Fig. 7.3); previously a cumbersome process that sometimes led to device failure required the operator to wrap the balloon just before insertion. The available IABP catheters range in gas volume from 25



• **Fig. 7.2** Systemic pressure response to an intraaortic balloon pump. The console is set to trigger at 1:2, hence both unassisted and assisted systole and diastole are seen. Note the decrease in systolic pressure with balloon counterpulsation *(double arrow)* and augmentation of diastolic pressure (area under curve in *blue*), thus decreasing afterload and increasing inflow pressure to the coronary and other vascular beds during diastole. *EDP,* End-diastolic pressure. (Courtesy Zoltan G. Turi, MD.)



• **Fig. 7.3** Magnified cross-sectional view of a prefolded intraaortic balloon. This was a significant advance in technology in the early 1980s because it eliminated folding at the bedside, a process that occasionally led to tearing of the balloon membrane and substantially reduced the overall profile of the device at insertion. *Red arrows* point to membrane folds, *yellow* to the central pressure and guidewire lumen. (Courtesy Getinge, Wayne, NJ.)

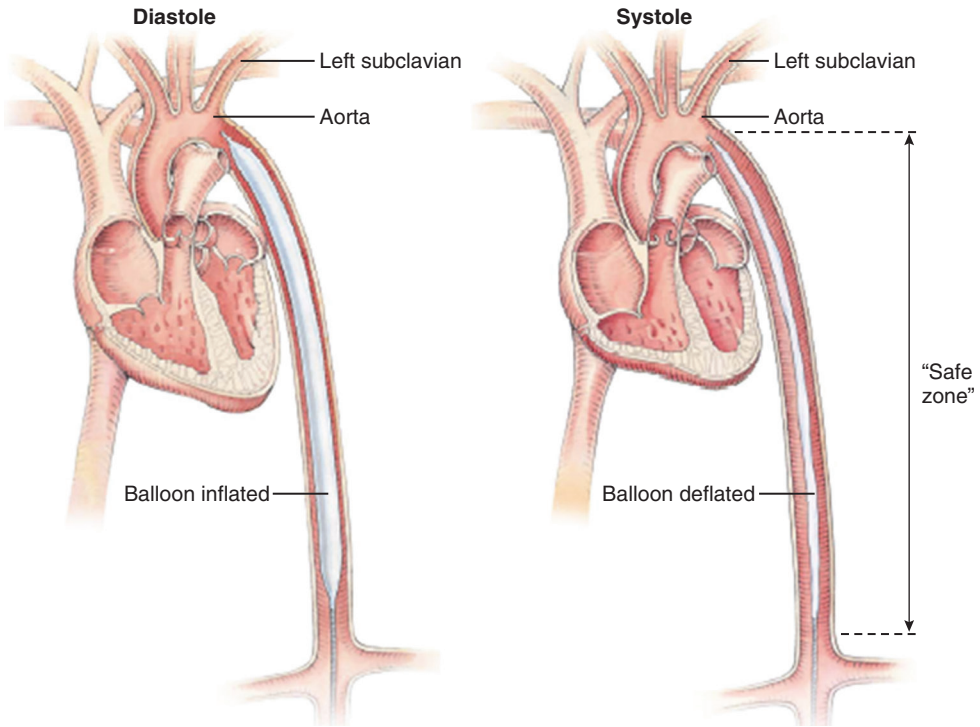
to 50 mL and in shaft lengths from approximately 60 to 72 cm, with the 40-mL balloon used in approximately three-fourths of patients.[16] It is essential to locate the balloon below the origin of the left subclavian artery at the upper margin and above the renal arteries at the lower (a "safe zone"; Fig. 7.4), the tolerances are relatively low.

IABP consoles trigger balloon inflation either from the electrocardiogram (including paced rhythms) or from pressure waveforms, although in some settings, such as during cardiopulmonary bypass, an automatic trigger at a preset rate can be used. Tachyarrhythmias and irregular rhythms have substantial influence on the effectiveness of IABP, the former in part because of the disproportionately shorter diastolic filling of the dicrotic notch.[17] A series of alarms identify leaks in the IABP circuit, high or low pressure, loss of trigger signals, blood in the gas line, low battery, and other anomalies that foreshadow or indicate impending or existing system failures. Fig. 7.5 demonstrates the control panel of a modern IABP console.

The IABP (Fig. 7.6) is designed to be introduced percutaneously through the common femoral artery, which is the method used in 95% to 98% of cases, two-thirds via the right common femoral.[16,18] Every effort should be made to ensure that the femoral puncture is above the femoral bifurcation and below the inguinal ligament. Puncture below the femoral head drastically increases the likelihood of puncture into the femoral bifurcation vessels (77% of femoral bifurcations are at or below the inferior margin of the femoral head[19]), which in turn is associated with acute leg ischemia as the result of vascular obstruction, and pseudoaneurysm formation on balloon removal.

IABP placement is ideally performed with fluoroscopy at the bedside. In the critical care setting, transesophageal echocardiography can be used as a suitable alternative to fluoroscopy for precise balloon placement.[20] Optimal placement of tip of the balloon is 1 to 2 cm inferior to the left subclavian artery origin (see Fig. 7.4), typically near the top of the descending aorta. The distal circulation should be assessed carefully after IABP placement. Distal ischemia is relatively common. Postprocedure and subsequent monitoring of left arm pressures can lead to early diagnosis of inadvertent balloon advancement obstructing left subclavian inflow, a phenomenon to which restless patients who flex their thigh are predisposed.

Alternatives to femoral placement include brachial, subclavian, axillary, iliac, transthoracic, and translumbar. In some cases, distal perfusion in the legs can be preserved by placing an external femorofemoral shunt.[21] Placement in subclavian[22] and axillary arteries[23,24] can be done to aid in allowing ambulation during prolonged use.



• **Fig. 7.4** Location of intraaortic balloon during systole and diastole. Ideally the tip should be a few centimeters distal to the origin of the left subclavian and the proximal portion above the origins of the renal arteries, the "*Safe Zone*." • **Fig. 7.6** A modern intraaortic balloon. A minimal sized central lumen allows advancement over a guidewire. Low-profile balloons such as this one use fiberoptic cable for pressure monitoring because the central lumen is of inadequate size for phasic pressure measurement. (Courtesy Getinge, Wayne, NJ.)

The timing of balloon inflation and deflation is designed to optimize afterload reduction and enhancement of diastolic pressure without interfering with ventricular ejection. Classically, it was considered optimal to inflate at the dicrotic notch, as soon as aortic valve closure occurred, and to deflate near the onset of ventricular depolarization, anticipating the beginning of mechanical systole (Fig. 7.7). Early deflation can result in reversal of both coronary and other end-organ (e.g., cerebral) flow back into the aorta, shunting blood from vital end-organs.[25] Early inflation results in increased afterload late in LV ejection with consequent impairment of LV systolic function.

A common problem has been proper timing in patients with underlying arrhythmias. Particularly vexing has been atrial

E

• **Fig. 7.7** Examples of timing of intraaortic balloon pump inflation and deflation with 1:2 balloon pumping, from top to bottom. Panel A demonstrates optimal timing, resulting in mild lowering of systolic pressure with diastolic augmentation. Examples are shown of early inflation before the dicrotic notch (B), late inflation (C), early deflation (D), and late deflation (E). (Figure courtesy Zoltan G. Turi, MD.)

fibrillation, with unpredictable beat-to-beat intervals. Rapid ventricular rates result in disproportionate decrease in the diastolic interval and limit the effectiveness of IABP because of the inherently short period of counterpulsation.[26] Operating at 1:2 rates may be required in this setting.

Adjunctive pharmacotherapy includes rhythm control, anticoagulation, and sedation. Antiarrhythmic agents to slow and regularize the heart rate can have important benefits for lengthening diastole and optimizing balloon timing, both of which in turn enhance IABP augmentation. The general consensus has been that anticoagulation should be administered if not contraindicated. Thrombus formation has been reported to be one of the most common complications, nearly 3% in one series of 911 patients undergoing coronary artery bypass grafting (CABG).[27]

Removing the balloon should be done with great care. Counterpulsation should not be turned off completely until the activated clotting time confirms that anticoagulation has been effectively discontinued and the patient is ready to have the balloon pulled, because thrombosis on the balloon surface occurs rapidly.[28] Most operators run the IABP at a low cycle rate, 1:3, until anticoagulation has worn off sufficiently and the balloon can be pulled. Nonfunctioning or stopped IABPs need to be removed promptly, preferably within 20 minutes. Because the balloon is delivered prefolded by the manufacturer (see Fig. 7.3), it passes readily through its delivery sheath during insertion. Once inflated, it will not refold when vacuum is applied, and the profile is too large for retrieval without bringing both the sheath and balloon out of the body together. The balloon gas line should be aspirated to reduce the balloon profile. It is essential to allow some bleeding after catheter removal and before compression to avoid stripping any clot off the balloon inside the common femoral artery. It is important to continue to monitor patients for adverse events because nearly 25% of complications have been reported to occur *after* IABP removal.[29]

Indications/Contraindications

Acute MI and Cardiogenic Shock

Historically cardiogenic shock (CGS) remained the most common indication for several decades[16]; however, recent studies have shown no clear mortality benefit from IABP in this setting.[30] Other common indications have included perioperative support for patients undergoing cardiac surgery, weaning from cardiopulmonary bypass, management of unstable angina, severe congestive heart failure, acute mitral regurgitation, and, with less evidence base, refractory ventricular arrhythmias or angina after myocardial infarction (MI), as well as a host of miscellaneous settings largely defined by case reports.

The classic understanding of CGS has been stunning or irreversible loss of a large amount of myocardium (≥40%) with resultant low output and compensatory elevated systemic vascular resistance to maintain central organ perfusion pressure. The most common current definition is hypotension (blood pressure <90 mm Hg systolic) for more than 30 minutes, with low cardiac index (<1.8 l/min per m^2 without support or <2.2 L/min per m^2 with support), and finally elevated filling pressure (pulmonary artery wedge pressure >15 mm Hg or LV end-diastolic pressure >18 mm Hg or right ventricular [RV] end-diastolic pressure >10–15 mm Hg).[31] Data from the SHOCK (SHould we emergently revascularize Occluded Coronaries in cardiogenic shocK) trial have called several classic assumptions into question,[32] in part because some of the patients with CGS in the trial had relatively preserved ejection fractions, whereas some patients with an apparently much greater amount of dysfunctional or nonfunctional heart muscle were hemodynamically compensated.

Although heart failure in ST-segment elevation MI (STEMI) has declined, the incidence of CGS has risen[33]; the most recent estimates are that is it seen in approximately 5.5% to 6% of AMIs. Mortality remains high however, with a nearly 40% in-hospital death rate reported in the Benchmark registry.[18] As discussed later in this chapter, some newer interventions are being investigated to determine if there is potential benefit to alternative types of cardiac support for this still very high mortality. In addition, more modern parameters for assessing shock, including cardiac power output and pulmonary artery pulsatility index, are being incorporated. In the interim, the existing data on IABP have continued to show relative futility: the IABP SHOCK-II trial randomized IABP use in patients with CGS undergoing percutaneous coronary intervention (PCI)[34] and showed no benefit on 30-day mortality. A number of study design concerns exist (particularly between group cross-overs and selection of a relatively low-risk CGS population) as well as the possibility that IABP placement before rather than after PCI (most patients had IABP placement after revascularization) would have shown additional benefit.[35] A smaller study, IABP SHOCK, demonstrated no significant improvement in serial APACHE (Acute Physiology and Chronic Health Evaluation) II scores[36] with IABP use. Several meta-analyses have come to similar conclusions.[37,38] Use of IABP in CGS in American Heart Association (AHA) and American College of Cardiology guidelines now carries a class IIa recommendation with level B evidence.[30] More recently in 2017 the European Society of Cardiology downgraded their prior recommendation to class III for routine use of IABP in STEMI complicated by CGS.[39] In short, for treatment of CGS, IABP has largely been relegated to second-tier or even inappropriate therapy.

Myocardial Ischemia and Revascularization

IABP use in unstable angina dates from an era in which the available alternates were medical therapy and coronary bypass surgery, and IABP was used to stabilize patients before being taken to the operating room. In certain settings, such as severe left main disease or in unstable angina with attendant hemodynamic instability, this algorithm remains appropriate.[40] The most recent American College of Cardiology Foundation (ACCF)/AHA guidelines[41] list adjunctive use of hemodynamic support, including IABP, as a class IIb recommendation for hemodynamically unstable patients undergoing PCI. A randomized controlled trial (Balloon-Pump Assisted Coronary Intervention [BCIS]-1)[42] of a particularly high-risk group, published after the guidelines were written, studied patients with ejection fractions less than 30%; this study did demonstrate a 34% reduction in mortality in the group with IABP protection during PCI.

IABP has been used in approximately 10% to 15% of patients undergoing cardiac surgery.[43] About half of this use is for coronary bypass patients; two-thirds of the CGS patients in the Society of Thoracic Surgeons (STS) database had IABPs inserted.[44] A number of studies have demonstrated a favorable influence on outcomes including mortality,[45–47] but there is lack of consensus regarding indications for perioperative IABP.[48] The vast majority of IABP insertions occur preoperatively[43,44]; the effectiveness of this approach has been controversial.

IABP with pulsatile flow during cardiopulmonary bypass also appears to have favorable effects on end-organ perfusion[25,49–51] with protection of both coronary and cerebral blood flow.[52] IABP insertion can also be used to assess prognosis; the requirement for

catecholamine support and overall hemodynamics 1 hour after institution of perioperative balloon pump insertion is highly predictive of overall outcome.[53] In the STS database, operative mortality with CGS patients, the majority of whom received IABP, was high, ranging from 20% in isolated CABG to 33% for CABG and valve surgery and 58% for CABG and ventricular septal repair.[54] IABP use in conjunction with ECMO is covered later in the chapter.

Contraindications

The classic absolute contraindication to IABP use is aortic insufficiency. Because the acute hemodynamic effects are so deleterious, animal and clinical investigations were completed in the 1970s.[55] Increased volume displacement retrograde into the left ventricle during diastole greatly exacerbates wall stress, with increased potential for hemodynamic decompensation as well as LV pseudoaneurysm formation and left ventricle rupture in the post-MI setting. The amount of aortic insufficiency that constitutes an absolute contraindication has no objective basis, but most operators use a threshold of trivial to mild. Similarly, the presence of aortic dissection and aortic aneurysm are considered absolute contraindications because of the risk of extending dissection or causing aneurysmal rupture. Patent ductus arteriosus, like aortic insufficiency, has theoretical deleterious results from shunting blood flow from the aorta with IABP induction, in this case increasing left-to-right shunting into the pulmonary artery.

Relative contraindications include placement of an indwelling foreign body into a patient with active infection including sepsis (the existing evidence base does not suggest significant hemodynamic benefit for patients with septic shock), severe peripheral vascular disease likely to result in limb ischemia, bleeding diathesis (though in practice many patients with low fibrinogen levels or on aggressive anticoagulant or antiplatelet treatment receive IABPs), and contraindications to afterload reduction, such as dynamic LV outflow obstruction,[56] a condition that has on occasion been unmasked by institution of counterpulsation.[57]

Complications

As would be expected, duration of IABP use correlates with risk of complications overall[58,59] including sepsis.[60,61] The overall complication rates have declined to 15% in a large single-hospital review[62] and 6.5% in the Benchmark Registry, which incorporates the largest experience to date.[63] In general, diabetic patients and women have a higher complication rate.[64]

Vascular complications including limb ischemia are the most common serious adverse events.[65] Trauma to the aorta has been reported, with paraplegia caused by spinal necrosis owing to subadventitial hematoma,[66] cholesterol embolization to spinal and mesenteric arteries,[67] and aortic dissection,[68] as well as in patients with no obvious cause. A complication particular to IABP is thrombocytopenia, occurring presumably because of destruction of platelets that adhere to the IABP surface. Critical care patients with IABP and using heparin have a 7:1 odds ratio of a 50% drop in platelet count compared with patients without IABP but receiving similar doses of heparin,[69] minimizing the likelihood that heparin-induced thrombocytopenia is the etiologic factor. Finally, balloon rupture is made apparent by the appearance of blood in the gas lumen, with triggering of alarms. The usual site of rupture has been at a point when the aorta is at its nadir in diameter along the course of the IABP. Rupture of the balloon with a major gas leak, a rare event, has been reported to cause stroke secondary to gas embolization.[70] Fracturing of the IABP can occur with entrapment, including separation and migration of part of the device.[71]

Active Mechanical Circulatory Systems

Introduction

The use of surgically implanted LV assist devices (LVADs) as an approach to "bridge" patients to recovery or cardiac transplantation or as "destination therapy" has opened new opportunities for patients with advanced heart failure whose condition might otherwise have been rendered medically futile. Nearly 1500 LVADs are implanted annually in the United States alone.[72] These devices have evolved from large, bulky pulsatile systems to smaller, compact, fully implantable continuous-flow (CF) pumps that generate minimally pulsatile blood flow when functioning optimally. These CF-LVADs use rotodynamic pumps to transfer kinetic energy from a circulating impeller to the bloodstream, thereby generating forward flow. CF-LVADs can be divided into two categories: axial-flow and centrifugal-flow pumps. In both cases, blood is pulled into the impeller of the pump via an inlet cannula connected to the LV apex and delivered to the systemic circulation via an outflow cannula connected to either the ascending or descending aorta. In parallel to the evolution of surgically placed LVADs, percutaneously delivered mechanical circulatory support systems (MCS) have also grown from counterpulsation balloon systems to centrifugally driven circuits, or catheter-mounted axial-flow pumps.[72]

These devices are differentiated from IABP in that they actively support forward flow; in contrast IABP has been labeled as "passive" hemodynamic support.[73] As described in discussions of the individual MCS technologies, they have potential for subsequently improving outcomes in a variety of clinical settings, including CGS. Fig. 7.8 shows the physiologic effect as well as complications of these technologies in the CGS setting. In general the MCS devices result in superior hemodynamics, somewhat higher complication rates, and as yet no global improvement in overall survival, albeit the active devices have been subject to relatively small studies, typically underpowered for mortality, and with clinical algorithms that may not be optimal.[73]

Physiology

The overall goals of MCS are to (1) increase vital organ perfusion, (2) augment coronary perfusion, and (3) reduce ventricular volume and filling pressures, thereby reducing wall stress, stroke work, and myocardial oxygen consumption. Clinical scenarios in which these devices are commonly used include CGS, mechanical complications after AMI, high-risk coronary and noncoronary intervention, and high-risk electrophysiologic ablations. Percutaneous circulatory support devices can be categorized by the type of pump used to generate either pulsatile or continuous blood flow. Each device affects native ventricular function in a unique way and requires adequate preload for optimal use.[74]

Careful hemodynamic interrogation before, during, and after initiation of percutaneous MCS is essential for optimal device function because MCS systems are affected by changes in preload and afterload. Inadequate LV preload owing to volume depletion, poor RV function, hypotension, pulmonary obstruction, or valvular disease will reduce flow generation. Similarly, increased afterload owing to hypertension, elevated systemic vascular resistance, or valvular disease will reduce device flow.

Percutaneous short-term active mechanical support devices in cardiogenic shock: a systematic review and collaborative meta-analysis of randomized trials. *Eur Heart J.* 2017;38:3523–3531. Used with permission.)

Three primary CF percutaneous MCS device platforms are currently used in clinical practice for LV hemodynamic support. These devices include (1) centrifugally driven left atrial–to–femoral artery bypass (TandemHeart), (2) centrifugally driven venoarterial ECMO (VA-ECMO), and (3) microaxial flow catheters (Impella and HeartMate Percutaneous Heart Pump [PHP]; Abbott Inc, St. Paul, MN). At present, the Impella devices are the only percutaneous MCS platform approved by the U.S. Food and Drug Administration (FDA) for high-risk PCI and CGS. The Impella RP device is approved for acute right heart failure.

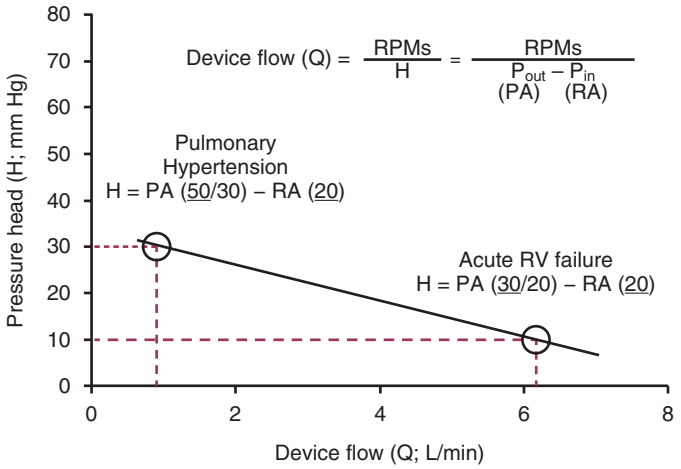
Flow through all CF (nonpulsatile) MCS devices is directly related to rotations per minute of the impeller and indirectly related to pressure at the inlet and outlet of the impeller. This pressure gradient (P_{in}-P_{out}) varies during systole and diastole. The relationship between pressure and flow is best described using an H-Q curve, where H is defined as the pressure head (P_{in}-P_{out}) and Q is defined as device flow. Each device has a specific H-Q curve signature (see Fig. 7.9). Axial-flow pumps tend to have a steeper H-Q slope, whereas centrifugal flow pumps have a flatter H-Q slope.

For the TandemHeart, Impella, and PHP devices, the pressure head (H) includes LV end-systolic pressure (LVESP) and aortic (Ao) pressure. For patients without decompensated heart failure or aortic valve disease (e.g., those undergoing high-risk PCI), peak aortic and LV systolic pressures (SPs) are matched and at peak systole (e.g., Ao SP-LVESP = 120 mm Hg − 120 mm Hg) the estimated systolic H is zero. Throughout diastole, typical aortic diastolic pressure ranges (DP) between 60 and 80 mm Hg (AoDP) and LVEDP is often below 20 mm Hg. Therefore the estimated H ranges between 40 and 60 mm Hg (AoDP − LVEDP) and 0 (AoSP − LVESP). Based on this principle, for a given rotations per minute, CF devices will provide higher flow at peak systole (H = 0) and lower flow in diastole (H = 40–60). In contrast, the patient with CGS may have a substantially lower H during diastole with high LVEDP and low AoDP. For this reason, for a given rotation per minute rate, CF devices provide higher flow at both peak systole and end-diastole compared with a patient without decompensated heart failure or shock.[72] This phenomenon is true for RV support devices like the Impella RP as well. The pressure head increases with pulmonary artery hypertension (when pulmonary vascular resistance increases), and consequently device flow decreases. With acute RV failure the pressure head decreases and at the same rotations per minute flow through the device increases. Fig. 7.9 shows an H-Q curve for RV failure.

Impella Devices

The Impella devices are a series of catheter-based, axial-flow, peripherally inserted heart pumps: the Impella 2.5, CP, 5.0, LD, and RP models. (The Impella LD model is designed for open, direct aortic surgical implantation.) They are useful in ventricular failure causing CGS, and as support used prophylactically before or during high-risk procedures, particularly complex PCI (but also

other procedures including high-risk ablation and some structural heart interventions). The left-sided Impella devices are placed retrograde across the aortic valve into the left ventricle and generate antegrade blood flow in the ascending aorta while simultaneously directly unloading the left ventricle.[75] In contrast, the RP model is positioned antegrade across the tricuspid and pulmonic valves, with the inlet in the right atrium and the outlet in the main pulmonary artery. The left-sided and right-sided devices have been used in tandem to support patients with biventricular failure, known as the BiPella approach.[76] As CF devices, none of the Impella pumps require being timed to the cardiac cycle. The 2.5, CP, and 5.0 devices provide 2.5, 3.5, and 5 L/min of flow, respectively, whereas the RP device can provide support in excess of 4 L. The devices require some preservation of contralateral ventricular function for maximal flows (left-sided devices require some RV function as described subsequently, and the RP requires some preservation of LV function; these are typical of VADs in general).



• **Fig. 7.9** Pressure *(H)* - flow *(Q)* curve for continuous flow device demonstrating H-Q curve for the Impella RP device. When pulmonary vascular resistance is elevated (pulmonary artery hypertension), device flow is limited. When acute right ventricular *(RV)* failure occurs, flow through device increases significantly because the pressure head *(H)* lessens. *PA,* Pulmonary artery; *RA,* right atrium; *RPMs,* rotations per minute. Underscore identifies pressure used for calculating the pressure head. (From Kapur NK, Esposito ML, Bader Y, et al. Mechanical circulatory support devices for acute right ventricular failure. *Circulation.* 2017;136:315–326.)

The Impella 2.5, CP, and RP devices are implanted using a percutaneous technique, most commonly via the femoral artery or vein (the only option for the RP model). It is imperative that these devices be placed with fluoroscopic guidance to ensure safety and aid in proper positioning. Each device has a pigtail that helps provide positioning stability. The 5.0 device, which is most commonly inserted surgically, can be placed via the femoral artery; however, current practice uses the axillary artery in most cases. The axillary approach allows for a stable and durable device position as well the possibility of patient ambulation. All devices are inserted over a guidewire using a monorail technique. Novel approaches, such as transcaval, have been used for patients with prohibitive peripheral vascular disease,[77] and the percutaneous approach to axillary artery implantation has also been described.[78] All Impella pumps require systemic anticoagulation, as well as a purge system that prevents blood from entering the motor. The Impella device is monitored and controlled by an automated console with the motor speed adjusted by P (performance) levels that correspond to rotations per minute (Fig. 7.10). This allows for the optimization of flows for any given patient as well as the ability to wean the patient from the device. The length of approved use for high-risk PCI is less than 6 hours and for treatment of CGS is less than 4 days.[79] In practice, dwell times have been longer when awaiting definitive therapy (e.g., bridge to durable VAD) or when there is evidence that myocardial recovery is continuing to improve and eventual weaning may be successful.

The devices include a controller that is powered by an alternating current plug and has an internal battery that can last up to 1 hour, which is helpful during transport. The setup of controller, infusion system, and catheter are shown in Fig. 7.11 and the effect on physiology in Fig. 7.12. Specific contraindications to the use of the LV Impellas include the presence of a mechanical aortic valve or LV thrombus. An aortic valve area less than 0.6 cm^2 makes passage of the cannula difficult, although Impellas have been used in patients with critical aortic stenosis who require PCI, with facilitation of Impella passage by placing a balloon simultaneously across the aortic valve. The latter, even without balloon aortic valvuloplasty, can facilitate device passage.[80] As is obvious, the device should not cross a mechanic valve. RV failure is a relative contraindication to percutaneous LVAD placement because unloading of the left side can

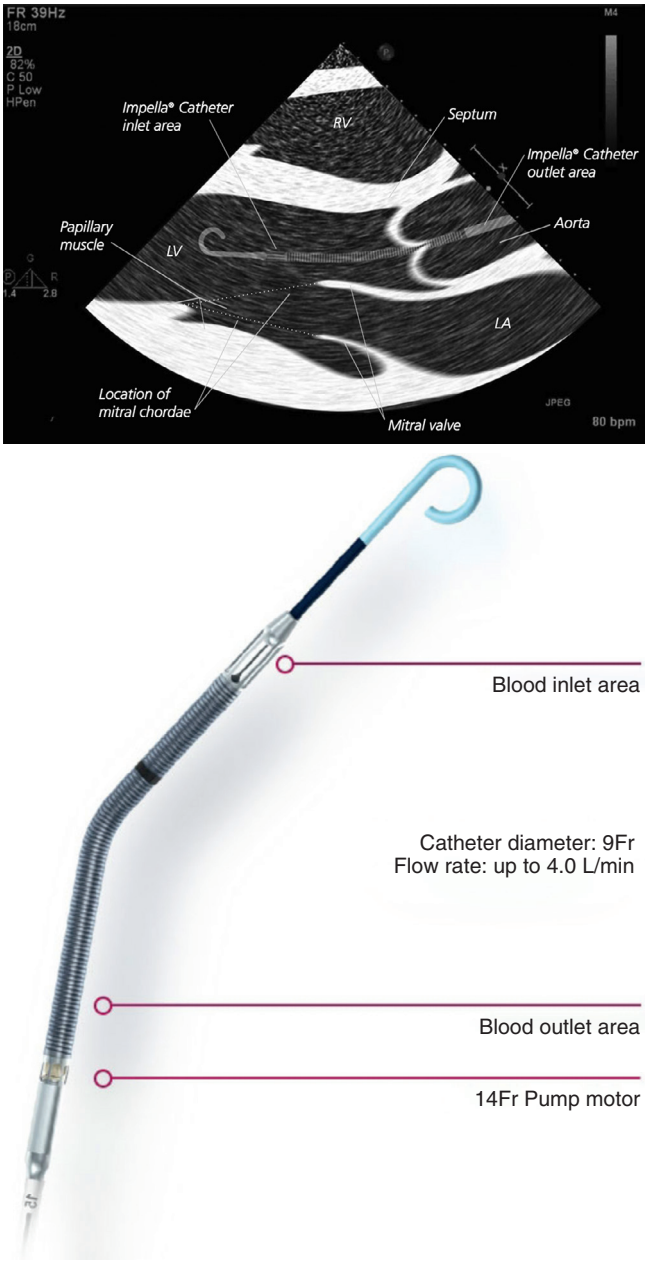
change septal and RV geometry, unmasking RV failure. In addition, a failing right ventricle is unable to deliver adequate LV preload, and the device may then be prone to suction events and associated hemolysis. Aortic regurgitation, aortic dissection, bleeding diathesis, and uncontrolled sepsis are typically contraindications. The Impella RP device is contraindicated in the presence of caval or right atrial thrombus; relative contraindications include the presence of an inferior venacaval filter or significant right-sided valvular heart disease as well as atrial and ventricular septal defects. Severe peripheral vascular disease may make placement of left-sided Impella devices difficult to impossible, in particular via the femoral artery, and may compromise remaining peripheral circulation, although as with IABP, an external femorofemoral shunt can address potential lower extremity ischemia distal to device insertion.[21]

Left-Sided Impellas

A standard placement signal for Impella 2.5 or CP devices can be seen in Fig. 7.10, with a pulsatile tracing that appears somewhat like an arterial line. Of note, this cannot be used as absolute blood pressure; true arterial monitoring from another line should be used for this purpose. Proper placement needs to be confirmed daily with x-ray imaging, and upon demand with transthoracic echocardiography if there is any change in placement signal, flows, or there is unexplained deterioration in the patient's condition. The most useful bedside confirmation of device location is via echocardiography; an idealized transthoracic echocardiography view is shown in Fig. 7.13. The end of the visualized catheter should be 3.5 cm past the aortic valve.[79] The catheter should be directed toward the apex and stay clear of the mitral apparatus and papillary muscles. After placement, the Impella device can be placed in auto mode where the flow is maximized by internal algorithm for 3 hours. Alternatively, the flow can be changed by increasing the power settings, P0 through P8, at the bedside. The bottom left of the controller screen shows the calculated flow in liters per minute (see Fig. 7.10); this is in addition to any native flow that is progressing through the heart. The higher the P level, the higher the flow and less stroke work attributable to the native heart.

The hemodynamics provided by the Impella devices are favorable for patients in CGS. The active forward flow and systemic aortic pressure contribution increase mean arterial pressure (MAP); the forward flow augments end-organ perfusion, which requires both pressure and flow. The objective measure of these parameters is their product (MAP × CO/451) and is referred to as the cardiac power output. This value has been identified as an important



• **Fig. 7.13** Simulator image showing TTE View of proper Impella placement *(top)* and for reference, the catheter is shown below. (Images courtesy Abiomed Inc.)

predictor of mortality in CGS.[81] Cardiac power output can be used to determine whether mechanical support is necessary, gauge the impact of a chosen support type and level after initiation, and whether support needs to be escalated or can be weaned. In addition to these two mechanisms, the left-sided Impella devices directly unload the left ventricle. The active removal of blood from the LV cavity reduces end-diastolic volume and pressure (LVEDV, LVEDP) and augments peak coronary flow. For patients in CGS, coronary flow increases through a dual mechanism. First, increased aortic pressure (the pressure head for coronary flow during diastole) increases the upstream pressure for myocardial perfusion, and second, through the Impella's unloading mechanism, with continuous removal of ventricular volume, LV wall tension falls. As LV wall tension (characterized by Laplace as Pressure × Diameter/Wall thickness) falls, so does the microvascular resistance within the myocardium. The end result of a rise in MAP and a drop in LVEDP is that the myocardial perfusion gradient improves along with coronary perfusion. This is relevant for patients in CGS when a low perfusion gradient can aggravate coronary ischemia and precipitate cardiovascular collapse. Impella support allows for maintenance of this gradient and augmentation of coronary perfusion. The coronary perfusion effects of Impella have also been assessed using the coronary flow velocity reserve technique with significant increased hyperemic flow velocity and coronary flow velocity reserve correlating with increasing levels of Impella support.[82] The myocardial perfusion effects of Impella devices can also be visualized on myocardial scintigraphy.[83] In addition, improvements in end-organ perfusion with an Impella device have been demonstrated through advanced imaging of the sublingual mucosal vasculature in the setting of STEMI with shock.[84]

Another beneficial effect of ventricular unloading and the reduction of LVEDV and LVEDP is the potential for the reduction of infarct size, as demonstrated in the animal model.[85] Of particular note, the most significant reduction in infarct size resulted from unloading the left ventricle before revascularization. Extrapolating on this observation, again in an animal model,[86] two different management algorithms were compared. Both had 90 minutes of ischemia, but in one group animals had immediate reperfusion, whereas in the second LV unloading was performed first, thereby subjecting the heart to 60 minutes of additional ischemia followed by reperfusion. Despite the additional ischemic time, infarct size was significantly reduced in the LV-unloaded group. These animal laboratory results have led to the FDA approval of a clinical trial investigating the safety and feasibility of ventricular unloading in the setting of acute MI (AMI). The primary endpoint will be the reduction of infarct size at 30 days by magnetic resonance imaging.[87]

There are now numerous clinical society guidelines for Impella therapy (Table 7.2).[88] Currently the FDA has approved left-sided Impella devices for treatment of CGS occurring less than 48 hours after AMI or open heart surgery. Two registries are of note: the original USpella Registry[89] and the more recent Catheter based Ventricular Assist Device Registry (cVAD),[90] the latter an observational, multicenter, retrospective global registry designed to capture data reflecting "real-world" use of Impella devices. Data extracted from the latter[88] included 324 patients who underwent a PCI and were supported with a left-sided Impella in the setting of CGS and AMI. Before Impella support initiation, while receiving catecholamines and/or IABP support, these patients exhibited signs of tissue hypoperfusion and end-organ failure and required substantial pump flow. In keeping with extensive morbidity, the median duration of hospitalization was up to 23 days. To compare the outcomes in these patients to data from randomized CGS trials, the patients in this registry were divided into two groups: one that would have potentially been enrolled in prior studies (e.g., a group who may have qualified for the SHOCK trial) and a second "salvage" group of patients who would have been excluded from the randomized studies. The salvage population included those with anoxic brain injury before implanting of the device, out-of-hospital cardiac arrest, and those who were transferred from another hospital. The overall 30-day survival results (Kaplan-Meier curve estimates) for the two subgroups are shown in Fig. 7.14. As expected, the salvage group of patients had poorer outcomes than those who would likely have been enrolled in CGS trials. Although the analysis is based in part on historical controls, these results suggest improved outcomes for treated patients in CGS compared with the abysmal results noted in historical benchmarks.[88]

TABLE 7.2 Use of Impella in Guidelines for Management of Cardiogenic Shock, Acute Myocardial Infarction, and Coronary Revascularization

Clinical Society Guideline Populations (SCAI, ACCF, HFSA, STS, ISHLT, HRS)	Class	Latest Update	Impella FDA Approval
PCI in cardiogenic shock	I	2013	2016

There are only a few small randomized controlled trials evaluating the Impella device for patients with CGS. The bottom line on these small studies is that the Impella device resulted in superior hemodynamics without mortality benefits at short-term follow-up. The ISAR-SHOCK trial (Efficacy Study of LV Assist Device to Treat Patients with Cardiogenic Shock) is an example; it enrolled only 26 patients.[91] Secondary endpoints included lactic acidosis, hemolysis, and mortality after 30 days. After 30 minutes of support, CI increased more with the Impella 2.5 device (0.49 ± 0.46 L/min per m^2) than with IABP (0.11 ± 0.31 L/min per m^2; $P = 0.02$); 30-day mortality was unaffected, although the extent of lactic acidosis trended lower. In a more recent study,[92] the Impella CP model was compared to an IABP in 48 patients with shock after AMI; again 30-day mortality was identical. These trial data were combined with data from a study of the Impella 2.5 device versus IABP in 26 subjects with CGS.[93] The resultant meta-analysis[94] reported no difference in mortality or LV ejection fraction at 30 days. None of these studies were powered to detect differences in mortality. There are few studies, mostly nonrandomized trials, assessing the utility of Impella 5.0; all have significant limitations. In a retrospective, nonblinded, single-center 34-patient review that included patients who crossed over,[95] the Impella 5.0 group had 33% 30-day survival compared with 24% for patients who received the Impella 2.5 device. Several similar studies have shown more favorable outcomes for CGS when treated with the Impella 5.0 device.[96] In a multicenter, prospective, feasibility study without a control group, the Impella 5.0 device was used in 16 patients with postcardiotomy CGS with 94% survival at 30 days.[97]

Similar to the findings in the animal laboratory already discussed,[86] in 154 consecutive real-world patients from the USpella Registry with CGS undergoing PCI, those who received the Impella 2.5 device before PCI had reduced mortality compared with those

receiving the device after PCI (40.7% vs. 65.1%; $P = 0.003$).[89] Almost 90% of these patients had not responded to inotrope therapy and/or IABP, and 38% of them would have been considered too ill to be included in the IABP-SHOCK II trial.[34] A small recently reported study of even more critically ill patients (40% had cardiac arrest before Impella placement and 9% had active cardiopulmonary resuscitation at the time of implantation) demonstrated 48.1% 30-day survival when the Impella device was placed before PCI and only 12.5% when it was placed afterward.[98] These findings might be expected based on the physiology already described; in the ischemic myocardium setting, the Impella device not only augments CO and increases MAP, but it also minimizes stoke work of the native heart, minimizes LV end-diastolic pressure, reduces oxygen consumption of the myocardium, and brings the supply/demand mismatch into balance. This outcome is supported in animal models of coronary ischemia where placement of Impella devices in swine limited infarct size—a phenomenon termed mechanical preconditioning.[99] Following up on the study just described, Basir et al. recently reported a preliminary experience with systematic multi-center early institution of Impella CP support in AMI CGS prior to revascularization.[100] The outcomes included a dramatic improvement in survival compared to historical data, as well as ability to wean the device. In turn, these early results have fostered the National Cardiogenic Shock Initiative; the algorithm for management is included as Fig. 7.15. Despite considerable enthusiasm generated by pilot data, it is worth noting that routine unselected use of these devices in CGS is not yet supported by recent analysis of the admittedly limited available evidence base.[73] Regardless, in the future there will likely be more focus on "shock to unload time" rather than "door to balloon time" in patients already in CGS.[82]

High-Risk Percutaneous Coronary Intervention

A total of 10 studies have examined the use of Impella devices for myocardial protection during high-risk PCI, such as last remaining vessel and unprotected left main disease.[101] However, only one study, the PROTECT II trial, was a randomized controlled comparison to IABP. It enrolled 448 patients and demonstrated no difference in major adverse events but a superior hemodynamic profile for the Impella 2.5 device compared with IABP.[102] Smaller nonrandomized studies[103] have looked at prophylactic use of the Impella device in acute coronary syndromes excluding patients with STEMI and described low mortality rates with the ability to perform high-risk procedures while maintaining patient hemodynamic stability. Similarly, a recent examination of the USPella database[104] revealed a significant number of such patients (127) had left main PCI with prophylactic Impella use, low mortality, and relatively low complication rates. Thus despite a relative paucity of high-level evidence, and with the guidelines for elective coronary revascularization relatively out of date, the practice of routine use of the Impella device in high-risk PCI has become fairly widespread.

Impella RP

Data for the use of the Impella RP device are considerably more limited and consist primarily of findings in the Recover Right trial[105] and subsequent continued access and postapproval studies. In these, the use of the RP device in RV shock was evaluated in two groups: after durable LVAD implant or after AMI or cardiac surgery. The mean duration of support for all patients ($n = 60$) was 90 hours with RP flows in excess of 3 L/min. Similar to the left-sided Impella devices, hemodynamics were favorably impacted with reduction of central venous pressure and improvement of left-sided CO (Fig. 7.16). The overall survival at 30 days or to next therapy was 73%. In a review of the global usage of the Impella RP device, CGS after AMI is the leading indication for support. One-third of these patients were supported with a BiPella configuration. Lala et al. applied the inclusion criteria from the Recover Right trial to the hemodynamic data from the SHOCK trial and registry.[106] They found that RV failure was quite common, often underrecognized and undertreated. Finally, data on the use of BiPella support in a small group of CGS patients was recently reported.[107] Although the results were favorable, the overall experience is limited. This remains a challenging group of patients deserving of further study. An excellent review of the use of the Impella and other ventricular support devices can be found in a recent review by Kapur and colleagues.[108]

TandemHeart

The TandemHeart device (TandemLife, Pittsburgh, PA) is a left atrial to femoro-iliac bypass, powered by an external centrifugal pump that provides up to 5 L/min of forward flow (Fig. 7.17). It requires transseptal puncture and institution of cardiac bypass with relatively large arterial cannulas (21F in the left atrium, 15F–19F in the iliac artery). Left atrial–to–femoral artery cannulation reduces LV preload and thereby limits the propensity for LV overload associated with right atrial–to–femoral artery cannulation such as seen with VA-ECMO (described later). It unloads the ventricle by decreasing left atrial volume and thus lowers LVEDP; however, it returns blood into the arterial tree and thus can increase afterload, which limits its benefits for LV workload.[72] The TandemHeart configuration does not require an oxygenator in the circuit because oxygenated blood is displaced from the left atrium into the arterial circulation. The left atrial–to–femoral artery configuration is particularly well suited for chronic left heart failure and mitral valve pathology (i.e., stenosis, prosthetic valve thrombosis, or regurgitation), where left atrial volume is large.[109–116] Like the Impella device, it cannot be shut off temporarily and requires more aggressive monitoring than balloon counterpulsation.

Small randomized trials have been performed comparing the TandemHeart with IABP in patients with CGS, demonstrating superior hemodynamics[117,118] but higher complication rates with the TandemHeart.[118] There is a paucity of multicenter clinical trial data for the TandemHeart, with primarily single-center series reports.[113,119,120] Like the Impella, the TandemHeart device has been used to support patients undergoing high-risk PCI, albeit with significantly less evidence base.[121,122] The TandemHeart device receives a class IIb recommendation in the guidelines for use of LVADs in CGS in the 2017 European Society[39] and IIa in the 2013 AHA/American College of Cardiology guidelines.[30] The TandemHeart RVAD device has been used similar to the Impella RP device in patients with right heart failure.[108]

As with Impella devices, potential contraindications for the TandemHeart device include aortic insufficiency and peripheral vascular disease. Because there is no cannula placed across the aortic valve, it is not per se contraindicated in aortic stenosis, although dramatic decreases in preload could potentially have significant adverse hemodynamic effects. Monitoring for excessive left atrial volume depletion is generally important during TandemHeart use. Unlike the Impella device, it can potentially be used

• **Fig. 7.17** The TandemHeart device (A) draws oxygenated blood from a left atrial catheter placed across the interatrial septum and provides arterial return via a cannula placed into the femoral artery. The Impella catheter (B) draws blood from the left ventricle via a pigtail catheter placed retrograde across the aortic valve and pumps blood into the aorta. Both devices actively provide cardiac output independent of left ventricular ejection.

in patients with LV thrombus because no cannula is placed into the left ventricle. Although post-MI ventricular septal rupture is uncommon, caution should be applied in using TandemHeart or Impella in that setting, since they could theoretically trigger severe right-to-left shunting because of low LV pressure as a result of substantial volume extraction from the left heart circulation.

Complications

The Impella device requires 14F access and is therefore associated with potential limb ischemia or other vascular injury, hemolysis (isolated cases of severe hemolysis have been reported, a complication associated with axial flow devices), renal failure, and thrombocytopenia; valve injury has not been noted in analysis of randomized trial data.[102] The TandemHeart's complication profile adds those associated with transseptal puncture and the need to maintain a fully anticoagulated large-bore bypass circuit (with optimal de-airing) in addition to the vascular issues associated with large arterial and venous cannulae.[118]

Extracorporeal Membrane Oxygenation

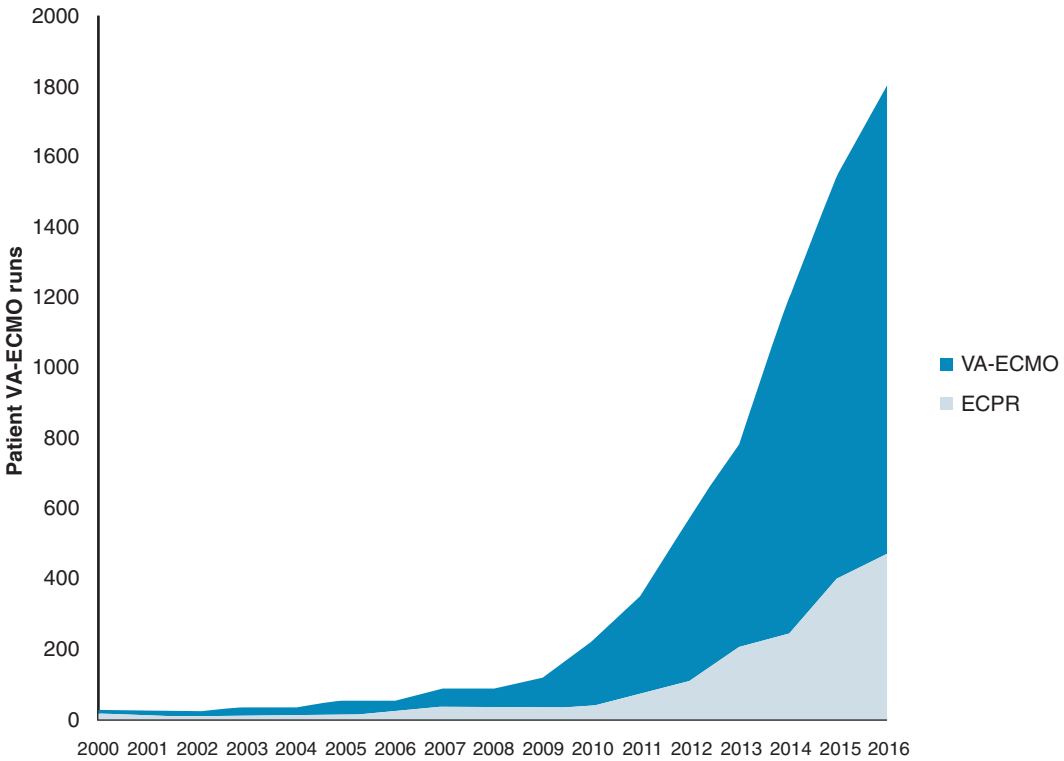
History

ECMO began with the advent of the "heart-lung machine" in the 1950s followed by the development of membrane oxygenators in the 1960s. Pioneering work by Hill and Bartlett in the 1970s introduced the use of ECMO as a method to support patients with respiratory failure followed by the establishment of the Extracorporeal Life Support Organization in the late 1980s to advance engineering, logistics, and clinical protocols associated with the use of ECMO and to develop a global registry to evaluate clinical outcomes.[123–125] With more than 50 years of experience, ECMO is now an integral part of any advanced critical care program. Its use has grown exponentially in the past decade. Several reasons for the expanding use of ECMO include (1) global familiarity with large bore femoral venous and arterial access; (2) no mandate for fluoroscopic guidance for cannula deployment, thereby allowing for bedside or out-of-hospital cannulation; (3) ability to provide rapid increases in systemic blood pressure and oxygenation; and (4) versatile use for cardiac arrest, CGS, biventricular failure, septic shock, and primary pulmonary failure. Furthermore, ECMO use outside the operating room for primarily medical indications has grown similarly.

ECMO implantation is being performed more commonly by nonsurgical personnel, including invasive cardiologists, pulmonologists, and critical care intensivists. A recent analysis from the Extracorporeal Life Support Organization reported more than 320 centers and more than 8000 ECMO implants in 2016 in the United States alone[126] (Fig. 7.18). Another analysis confirmed a 433% increase in ECMO utilization in the adult population between 2006 and 2011 in the United States.[127] In this section, we discuss the technical features of various percutaneously delivered ECMO configurations, the hemodynamic effects of VA-ECMO, and clinical outcomes associated with VA-ECMO.

ECMO Configurations (Table 7.3)

The basic components of any ECMO circuit include a rotary blood pump, an oxygenator, a heat exchanger, inflow and outflow



• **Fig. 7.18** Adult cardiac venoarterial ECMO *(VA-ECMO)* and extracorporeal cardiopulmonary resuscitation *(ECPR)* runs in the United States. (Recreated from ELSO Registry of Adult ECMO for Cardiogenic Shock and ExtraCorporeal CPR, 2000–2017 International Extracorporeal Life Support Organization Report 2016. www.elso.org.)

TABLE 7.3 Extracorporeal Membrane Oxygenation Configurations

Inflow	Outflow	Configuration and Indications
Femoral, subclavian, or internal jugular vein	Femoral, subclavian, or internal jugular vein	Peripheral cannulation VV-ECMO
Dual lumen (inflow and outflow)		
Right atrium, IVC, SVC	Right atrium, IVC, SVC	Central cannulation VV-ECMO
Femoral artery	Right atrium	Peripheral cannulation VA-ECMO
Right atrium, SVC or IVC	Femoral/subclavian artery	Central cannulation VA-ECMO
Right internal jugular	Subclavian artery	Ambulatory VA-ECMO
Right atrium	PA or left atrium	Right ventricular support
Left atrium	Aorta or femoral artery	Left ventricular support
Left and right atrium	Femoral/subclavian artery	Peripheral cannulation biatrial ECMO

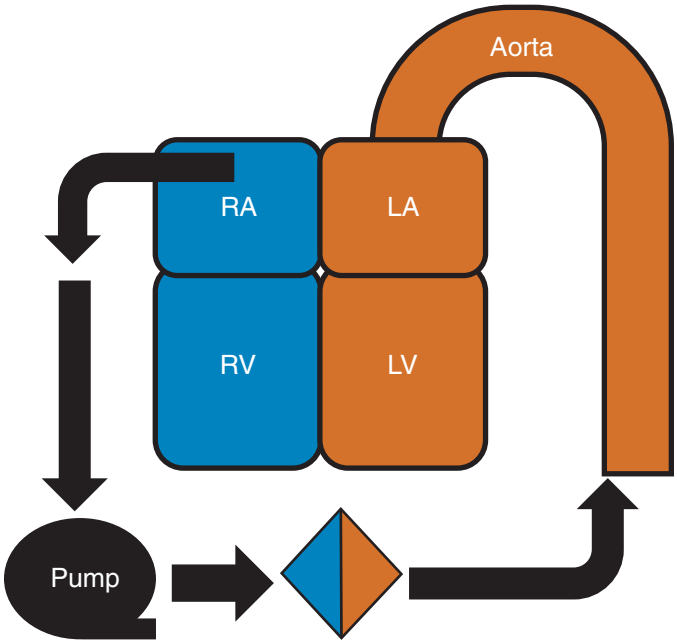
cannulas, connecting tubing, systemic anticoagulation, and specialized personnel to manage the ECMO circuit.[128,129] The most common blood pump used is a rotodynamic, centrifugal pump that transfers kinetic energy from a circulating impeller to the bloodstream, thereby generating forward flow. Depending on the clinical scenario, ECMO can be applied as a venovenous (VV) or venoarterial (VA) circuit. A major indication for VV-ECMO is primary pulmonary failure without cardiovascular collapse. VV-ECMO drains deoxygenated venous blood from the body and returns oxygenated blood into the venous circulation. Inflow and outflow cannulas can be positioned in the right atrium, inferior or superior vena cava, or other central veins such as the subclavian, internal jugular, or femoral veins. Two separate cannulas or a single, dual-lumen venous cannula can be used to support VV-ECMO. In rare instances, if arterial blood pressure is sufficiently high, systemic oxygenation can be augmented without use of a pump or oxygenator by cannulating and connecting the femoral artery and vena cava or right atrium, also known as reverse arteriovenous cannulation.[130,131]

Primary objectives for VA-ECMO are to increase systemic blood pressure and oxygenation during cardiovascular or cardiorespiratory collapse. VA-ECMO (Fig. 7.19) withdraws deoxygenated venous blood and pumps oxygenated blood to the arterial circulation. Inflow cannulas are often positioned in the right atrium or across the superior and inferior vena cava using a large multistaged venous cannula. Outflow cannulas can be positioned in the femoral or subclavian arteries. Of note, a vascular graft surgically attached to the subclavian or femoral arteries can also be used in lieu of outflow cannulas to return oxygenated blood back to the arterial system. Because no venous reservoir is used, VA-ECMO cannot be described as cardiopulmonary bypass.

Several unique ECMO configurations can also be used. For profound biventricular failure, inflow cannulas can be positioned in both the left atrium (via transseptal puncture) and right atrium to reduce both right and LV preload (biatrial ECMO).[132–134] Another approach for biventricular failure is to place a second venous inflow cannula into the pulmonary artery in addition to the standard VA-ECMO configuration to reduce left atrial preload (PA-ECMO).[135] Venovenoarterial (VVA)-ECMO refers to two venous inflow cannulas spliced together to enhance venous drainage into the centrifugal pump, thereby leading to a greater reduction in cardiac and pulmonary preload. Venoarterial-veno (VAV)-ECMO refers to a single venous inflow cannula that drains deoxygenated blood into the pump and oxygenator, which then returns oxygenated blood via an arterial cannula and back into the venous system using a venous cannula. VVA-ECMO and VAV-ECMO are more commonly used when a patient has severe cardiopulmonary failure.[128,129] "Ambulatory" VA-ECMO can also be achieved by using a right internal jugular inflow venous cannula and an outflow cannula or graft in the subclavian artery.[136]

Central or surgical cannulation with ECMO can be performed to replicate the hemodynamic effects of a VAD. Direct right atrial–to–pulmonary artery cannulation or pulmonary artery–to–left



• **Fig. 7.19** Configuration of venoarterial extracorporeal membrane oxygenation. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

atrial (PA-LA)-ECMO can be used to provide RV support, whereas direct left atrial–to–aortic cannulation (LA-Ao) can provide LV support.

Hemodynamics and Left Ventricular Venting Strategies (Table 7.4)

VA-ECMO displaces blood volume from a large venous reservoir into the arterial circulation. Depending on the capacity of the venous reservoir and degree of venous congestion, VA-ECMO may reduce RV filling pressures. By pressurizing the arterial system, systemic blood pressure increases rapidly. If native LV function is preserved, LV systolic pressure will increase with a minor increase in LV diastolic pressure.[128,129,137,138] However, if native LV function is compromised, LV systolic and diastolic pressures will increase as the native left ventricle is unable to pump effectively against the increased afterload imposed by the centrifugal flow pump and pressurized arterial tree. This increase in LV afterload increases LV wall stress and myocardial oxygen consumption, and may lead to worsening pulmonary congestion, acute lung injury, and in rare instances, pulmonary hemorrhage.[139]

To mitigate the potential for LV loading during VA-ECMO support, close hemodynamic monitoring with a pulmonary artery catheter is required. If elevated LV filling pressures are identified, operators often combine VA-ECMO with LV venting strategies. Inotropes are commonly used to enhance LV contractility to achieve LV decompression. However, inotropes may be of limited value if a patient has minimal contractile reserve or is prone to atrial or ventricular tachyarrhythmias. IABP counterpulsation (Fig. 7.20) can also be used as an adjunct to VA-ECMO in patients with CGS as a successful venting strategy.[140–142] Theoretically, by augmenting central aortic diastolic pressure, the addition of an IABP to VA-ECMO may improve coronary flow in critically ill patients with ischemic heart failure. An alternative to IABP-mediated venting, insertion of an Impella axial-flow catheter, can also reduce LV pressure and volume in the setting of increased afterload owing to VA-ECMO.[143–147] The Impella 2.5 LP, CP, and Impella 5.0 devices have all been used as venting strategies. Percutaneous implantation of an Impella 2.5 or CP device can be performed rapidly without the need for surgical vascular access. Importantly, when using an Impella device or any transvalvular axial flow pump as an LV vent, the flow setting on the Impella should be reduced during VA-ECMO support to avoid LV suction and hemolysis. A recent analysis among six patients with VA-ECMO plus Impella LV support reported reduced pulmonary capillary wedge pressure, pulmonary vascular resistance, and increased RV stroke volume.[148] Alternative invasive approaches to LV venting with VA-ECMO include advancing a second venous cannula into the left atrium or pulmonary artery to indirectly reduce LV preload (as described

earlier), balloon atrial septostomy, or blade and balloon atrial septostomy.[149–153]

The use of a concomitant LV decompression strategy can improve clinical outcomes for patients with CGS requiring VA-ECMO. One series[154] compared outcomes among 42 patients receiving VA-ECMO alone to 21 patients receiving VA-ECMO plus Impella LV (ECPella) support. Compared with VA-ECMO alone, the ECPella group had significant lower in-hospital mortality and a higher success rate bridging to recovery, durable mechanical support, or orthotopic heart transplantation.

Inadequate preload as the result of volume depletion or venous obstruction will reduce VA-ECMO flow. Similarly, increased afterload from hypertension, elevated systemic vascular resistance, or arterial obstruction can also reduce VA-ECMO flow. For these reasons, careful hemodynamic interrogation before, during, and after initiation of VA-ECMO is required for optimal device function.

Pulmonary Indications and Clinical Outcomes

VV-ECMO is commonly used to support patients with acute respiratory distress syndrome, refractory hypoxemia, or hypercapnic respiratory failure.[155–163] Patients with refractory hypoxia as the result of acute respiratory distress syndrome continue to have a high mortality, in the 70% to 90% range based on different reports. Whether this strategy improves outcomes compared to conventional treatment remains poorly understood.[155–161] A potentially catastrophic presentation of respiratory collapse often occurs secondary to acute pulmonary embolism (PE). VV-ECMO will improve systemic oxygenation and should be considered in acute PE with refractory hypoxemia and without cardiovascular collapse. For patients with right heart failure refractory to inotropes in the setting of a PE, right atrial–to–pulmonary artery cannulation can be performed to provide RV support with or without an oxygenator. If a patient has profound CGS in the setting of a PE, then VA-ECMO with consideration of a concomitant LV vent strategy may be more effective. Because all ECMO circuits require systemic anticoagulation, the combination of antithrombotic therapy with hemodynamic and respiratory support can effectively stabilize patients with acute PE. Several reports identified that ECMO for acute PE is associated with up to 70% survival to discharge when combined with other strategies, including anticoagulation, surgical embolectomy, or thrombolysis.[162,163] ECMO should be used with caution in the setting of thrombolytic use owing to the large-bore cannulation and risk of bleeding.

Cardiac Indications and Clinical Outcomes

Ventricular Arrhythmias and Cardiac Arrest

Use of VA-ECMO during cardiopulmonary resuscitation is known as extracorporeal cardiopulmonary resuscitation (ECPR). Two observational, single-center studies report that ECPR may improve survival for *in-hospital* cardiac arrest.[164,165] Factors associated with improved survival after ECPR for in-hospital cardiac arrest include a shockable initial rhythm, a shorter duration of cardiopulmonary resuscitation, lower lactate levels before ECPR, and lower Sequential Organ Failure Assessment scores within 24 hours of admission to an intensive care unit.[166]

ECPR for out-of-hospital cardiac arrest is currently under study with mixed results from recent reports indicating a trend toward improved survival but no definitive evidence of improved outcomes.[167,168] Other single-center series have reported 30% survival rates to hospital discharge combining ECPR with traditional resuscitation efforts in experienced centers where extracorporeal life support can be rapidly implemented.[169–172] A prospective study was done of patients with refractory in-hospital and out-of-hospital cardiac arrest. Return of spontaneous circulation was achieved successfully in 96% of patients. Median duration of ECMO support was 2 days, with 54% of patients successfully weaned from ECMO. Survival to hospital discharge with full neurologic recovery occurred in 54% of patients.[172] Future studies are required to understand the potential clinical utility of EPCR for in-hospital and out-of-hospital cardiac arrest.

Use of VA-ECMO has also been reported in patients with refractory ventricular arrhythmias[173–178] and acute heart failure owing to myocarditis.[179–182] A recent preclinical study reported that VA-ECMO provided superior systemic hemodynamic support compared with the Impella 2.5 and TandemHeart devices in a swine model of ventricular fibrillation.[183] In addition to being used as a bailout strategy, VA-ECMO is now more commonly being used to support high-risk electrophysiologic ablation procedures. An advantage of this approach for electrophysiologists is the lack of cannula penetration into the heart, thereby allowing for free movement of ablation catheters and minimal interference with electric fields for detection and treatment.[184,185]

Advanced Heart Failure and Cardiogenic Shock

The role of peripherally cannulated, VA-ECMO in advanced, chronic heart failure remains poorly understood. Owing in part to the loading effect on the LV, patients with isolated LV failure are more commonly supported with a dedicated LV support device (i.e., Impella, TandemHeart, IABP). At present, no specific algorithms exist to identify which patients will develop LV pressure overload as the result of VA-ECMO. However, experience with VA-ECMO in left heart failure is growing rapidly. Common applications for VA-ECMO in CGS with LV-dominant failure include (1) failure to wean from cardiopulmonary bypass,[186] (2) AMI,[187–189] and (3) mechanical complications after AMI.[190]

VA-ECMO is also more commonly being used to temporarily support patients with refractory CGS or multiorgan failure being evaluated for LVAD implantation or orthotopic heart transplantation. Small case series suggest that hepatic and renal function may improve with use of VA-ECMO in patients with CGS awaiting LVAD implantation.[191–193] In some reports, VA-ECMO can be converted to VV-ECMO after LVAD implantation in case of respiratory failure.[194] Other retrospective studies have reported a 73% survival-to-hospital discharge rate in patients supported with VA-ECMO as a bridge to heart transplantation strategy.[195–197] One of the major challenges with VA-ECMO in the pre-VAD population is limited ability to assess RV function during support. This can be problematic if a patient supported by VA-ECMO is being considered for destination therapy LVAD implantation (DT-LVAD) because the development of RV failure after destination therapy LVAD implantation would represent a major clinical challenge for this population. Future studies are required to confirm the potential utility of VA-ECMO in advanced left heart failure and as a support mechanism before LVAD or orthotopic heart transplantation.

Primary graft failure (PGF) after orthotopic heart transplantation is one of the strongest risk factors for mortality after heart transplant. The incidence of PGF has increased over the past few years, likely the result of increasing use of marginal donors in high-risk patients. The incidence has been described as between

3% and 26% with mortality as high as 50%. The use of VA-ECMO in severe PGF after heart transplantation has been reported.[198–200] One study of PGF with ECMO support demonstrated that 72% of patients were able to be weaned from support with 44% of them eventually discharged.[201]

Right Heart Failure

VA-ECMO can be considered for patients with RV failure caused by decompensated pulmonary hypertension,[202] RV MI,[203] pulmonary embolism,[162,163] after LVAD implantation,[204,205] or after orthotopic heart transplantation.[206,207] As already described, dedicated acute MCS devices for RV support include the Impella RP or TandemHeart RVAD.[105,108,208–210] No data exist comparing the use of VA-ECMO to a dedicated RV support device. More recently, the Protek Duo (TandemLife) dual-lumen cannula for right atrial–to–pulmonary artery bypass has been introduced into practice.[211]

Complications

Major complications associated with VA-ECMO include (1) vascular injury, (2) limb ischemia, (3) bleeding, (4) infection, (5) deep venous thrombosis, (6) stroke, and (7) insufficient upper body oxygenation (North-South syndrome). Other potential complications include hemolysis, thrombocytopenia, acquired von Willebrand syndrome, disseminated intravascular coagulopathy, and air embolism. Bleeding events are exacerbated by the mandate for systemic anticoagulation during ECMO support. However, anticoagulation is required to limit thrombosis and limb ischemia. Among these complications, proper cannulation technique and critical care management can reduce the likelihood of limb ischemia and North-South syndrome. Limb ischemia is best prevented by inserting an antegrade perfusion sheath into the arterial vessel distal to the insertion site of the arterial cannula.[21,212–216] North-South syndrome occurs in the setting of severe lung injury, which causes deoxygenated blood to enter the left ventricle where it is pumped into the systemic circulation.[128,129,217] If VA-ECMO is initiated in this setting via femoral cannulation, retrograde flow from the femoral arterial cannula may provide oxygenated blood up to the aortic arch. However, deoxygenated blood pumped from the native left ventricle will compete with ECMO flow in the aortic arch and the great vessels may distribute deoxygenated blood to the brain and upper extremities. Monitoring arterial saturations from the right radial or axillary artery will help identify North-South syndrome, which can often be resolved by changing the cannula configuration to either VAV or VVA-ECMO. In rare instances, adding a negative inotrope can be used to reduce native LV ejection, thereby allowing for less competition for retrograde VA-ECMO flow in the aortic arch.

Key Points

- IABP improves hemodynamic parameters but has no mortality benefit in cardiogenic shock.
- Microaxial flow percutaneous ventricular assist devices provide superior increase in cardiac output compared with IABP. They increase mean arterial pressure, coronary perfusion, increase cardiac output, decrease myocardial stroke work, and decompress the ventricle setting the stage for myocardial recovery.
- Patients in severe hemometabolic shock require the highest flow and oxygen delivery to reverse shock. VA-ECMO offers the highest flow rate and less deployment time in comparison with the Impella 5.0 device.
- Peripheral VA-ECMO does not reduce left ventricular end-diastolic pressure, which is important for both left ventricular functional recovery and recovery of lungs. Venting of the left ventricle with another procedure or device is often required.
- ECPR is extremely resource intensive, but can improve mortality in out-of-hospital and in-hospital arrest if specific inclusion criteria are followed.

Review Questions

1. A 75-year-old man with known coronary artery disease status post–coronary artery bypass grafting has ischemic cardiomyopathy and a baseline left ventricular ejection fraction of 20%. He comes to the catheterization laboratory with acute onset of chest pain and ST-segment elevation myocardial infarction (STEMI). He had chest pain for 5 hours at home before calling emergency medical services. Two stents were placed to a culprit lesion in a bypass graft to the left anterior descending (LAD) artery. He had nonobstructive lesions not amenable to stenting. In the cardiac care unit afterward he develops a cool and clammy appearance, low blood pressure (90s/50s), and lactate level of 3.5 mEq/L (normal 0.5–2.2 mEq/L). He has a right heart catheter placed that shows a central venous pressure (CVP) of 15 mm Hg, pulmonary artery pressure (PAP) 40/20 mm Hg, wedge 18 mm Hg, and cardiac index of 1.8 L/min per m^2. He is returned to the catheterization laboratory and an intraaortic balloon pump IABP is placed. His cardiac index in the intensive care unit increases to 2.2, urine output increases to 100 mL/h, the lactate level normalizes, and he no longer appears to be in shock. The next morning his cardiac index improves to 2.3, his lactate level is normal, the creatinine level on morning laboratory tests is normal, but urine output drops from 100 mL/h to 5 mL/h at 5 a.m. after receiving a sponge bath and changing his bed sheets. What is the most likely diagnosis?

a. IABP balloon rupture
b. Timing error of IABP
c. Malpositioning of IABP
d. Return of cardiogenic shock

Answer: c. The patient's laboratory values indicate that his shock indices have improved from the prior day with higher cardiac index, normalization of lactate level, and on morning laboratory tests even his creatinine is improving. An acute decrease in urine output in a patient with IABP should prompt investigation. A chest x-ray (CXR) should be ordered to verify that the tip of the IABP is just distal to the subclavian artery. The CXR in this patient would have revealed a change in position coinciding with the IABP now positioned across the renal arteries and impairing their perfusion, essentially causing a prerenal state in a patient with improving hemodynamic profile. The IABP should be readjusted. Rupture of balloon pump (choice a) would result in blood inside the sheath and loss of inflation pressures. Timing error (choice b) could cause decrease in cardiac index. Return of cardiogenic shock (choice d) is incorrect because the cardiac index is improving. Acute kidney injury is a possibility and may not have been evident on morning laboratory tests; renal function should continue to be monitored going forward.

2. A 52-year-old male presents with anterior STEMI and has ventricular tachycardia (VT), arrests twice on the catheterization laboratory table during revascularization with percutaneous coronary intervention and two drug-eluting stents placed in the LAD. After return of spontaneous circulation the patient is requiring drips of epinephrine 30 μg/min, norepinephrine 50 μg/min, and vasopressin 0.04 units/min. Doses of drug continue to quickly escalate. Pink frothy secretions are noted from the endotracheal tube, and the point-of-care lactate level is 18 mEq/L (normal 0.5–2.2 mEq/L). Which of the following is the next appropriate step?

a. Trial of a second inotrope to see if this improves shock.
b. Perform echocardiography and place a pulmonary artery catheter to further classify the type of cardiogenic shock.
c. Place a left-sided Impella CP device and right-sided Impella RP device to provide biventricular support.
d. Book the patient in the operating room for a placement of an Impella 5.0 device.
e. Proceed directly to venoarterial extracorporeal membrane oxygenation (VA-ECMO).

Answer: e. This patient has advanced hemometabolic shock and has limited time before sustaining irreversible end-organ damage or having an arrest. The most important thing at this time is to restore perfusion, correct metabolic derangements, restore normal acid-base balance, and spare the stunned myocardium the toxic milieu of high-dose vasopressors and inotropes. Pink frothy exudate shows that there is high left atrial pressure and LV failure. The best and simplest way to restore perfusion quickly is VA-ECMO (choice e), which offers the highest flows of all acute mechanical circulatory assist devices. Placement and classification of shock, left ventricular/right ventricular (LV/RV) function in this patient can be done after perfusion is restored and during weaning. He is already on the catheterization laboratory table with fluoroscopy available, so deployment should be rapid. This advanced degree of shock is too profound to be medically managed (choice a). Performing echocardiography and pulmonary catheter placement, although desirable for future management (choice b), may delay treatment and should not be the next step, which is the question asked. However, a right heart catheter should be placed once ECMO is deployed. It should be noted that right heart catheterizations are more difficult while the patient is supported by ECMO, but it will be facilitated by the availability of fluoroscopy while the patient is still on the catheterization table. The Impella CP device may not provide sufficiently high lows to reverse this state of shock and does not address hypoxemia (choice c). Impella 5 device placement (choice d) takes too long to deploy and will not immediately address hypoxemia either.

3. A 35-year-old previously healthy woman presents to the emergency room with shortness of breath for 3 weeks after an upper respiratory viral illness a month ago. CXR shows hilar fullness and bilateral pulmonary edema. Echocardiography shows global hypokinesis with left ventricular ejection fraction of 10%, dilated left ventricle and left atrium, and only mild RV dysfunction. Dobutamine and milrinone are started empirically. Laboratory testing results show a lactate level of 5 mEq/L (normal 0.5–2.2 mEq/L) and elevated creatinine level of 3.1 mg/dL (normal 0.57–1.3 mg/dL). Her arterial blood gas testing shows partial pressure of arterial oxygen (PaO_2) 80 mm Hg on 4 L via nasal cannula. A right heart catheterization reveals central venous pressure (CVP) 22 mm Hg, pulmonary artery pressure (PAP) 48/29, with wedge pressure of 28 mm Hg, systemic vascular resistance (SVR) 1280 dynes/s per cm^{-5} and cardiac output 3.0 (L/min), and cardiac index of 1.7 L/min per m^2. Coronary angiography reveals no coronary artery disease. Which of the following is the next therapeutic intervention?

a. Start third inotrope epinephrine and consult nephrology for acute kidney injury.
b. Start sildenafil to reduce pulmonary hypertension.
c. Place left-sided Impella CP device and start furosemide bolus with infusion.
d. Place right- and left-sided Impella microaxial percutaneous ventricular assist devices (VADs; BiPella).
e. Proceed directly to VA ECMO because she has end-organ failure

Answer: c. The patient has a clinical picture of viral myocarditis with resultant nonischemic cardiomyopathy. She has end-organ impairment and pulmonary congestion. Right heart catheterization and echocardiographic findings classify this as left heart–dominant shock with relatively preserved oxygenation (although certainly not normal). The patient needs support of the cardiac index and is not responding to medical management. The best chance of recovery is workup and treatment of the underlying myocarditis in conjunction with support of the cardiac index to limit end-organ impairment and addressing the pulmonary congestion with diuretics. Choice a would expose the patient to potential additional toxicity of epinephrine without substantially improving her overall picture and choice b would not help greatly given relatively unimpressive PAP and pulmonary vascular resistance. This patient does not appear to need a BiPella strategy (choice d) at this time given mild RV dysfunction by echocardiography and preserved pulmonary artery pulse pressure. VA-ECMO (choice e) subjects the patient to the risks of ECMO, would still require an LV venting strategy to encourage LV recovery, and it could potentially increase left atrial pressures and worsen pulmonary edema.

4. A 45-year-old male weighing 70 kg collapses at the 22nd mile while running a marathon. He receives immediate bystander cardiopulmonary resuscitation (CPR) and has ventricular tachycardia (VT) rhythms that are shocked twice and the rhythm then converts to pulseless electrical activity en route to a hospital that is 5 minutes away. The hospital has a cardiac catheterization laboratory with advanced heart failure therapies, including ECMO capabilities in both the catheterization laboratory and the emergency department. CPR continues in the emergency department with a total CPR time of 20 minutes after cardiac arrest. Point-of-care laboratory test results reveal normal sodium, elevated creatinine 2.0 mg/dL (normal 0.57–1.3 mg/dL), and elevated lactate 13 mEq/dL levels and PaO_2 35 mm Hg while intubated with fraction of inspired oxygen (FIO_2) of 100%. Which of the following is the next best therapy?

a. Proceed to the catheterization laboratory while maintaining CPR for planned left heart catheterization.
b. Continue CPR and if the patient has return of spontaneous circulation, then proceed immediately to the catheterization laboratory for therapeutic left heart catheterization.
c. Proceed to the catheterization laboratory while maintaining CPR for planned BiPella placement.
d. Try to reach a family member by phone to discuss therapies for acute mechanical circulatory support before proceeding.
e. Initiate ECMO in the emergency department and then proceed directly to the catheterization laboratory for planned left heart catheterization and potential percutaneous coronary intervention.

Answer: e. Door-to-balloon time has been a standard quality process metric. However, this has been shifting with respect to patients in cardiogenic shock. Now the focus is shifting to door-to-unloading (of ventricle), or door-to-mechanical support times. Quick action is indicated. The 2015 American Heart Association guidelines for resuscitation state that ECMO can be deployed when readily available and the suspected etiology can be treated with a short course of mechanical support. Although the etiology of this patient's collapse is unknown, it is rational to believe that it is potentially reversible. Studies have shown that ECMO increases neurologically intact survival compared with conventional CPR, even in out-of-hospital arrest when it is of cardiac origin. Instituting full mechanical support with ECMO will allow for preservation of end-organs, reverse shock, and allow time to safely diagnose and treat the underlying condition. In addition, the patient is hypoxemic and even if CPR is effective at promoting blood flow, it is lacking sufficient oxygen content (PaO_2 = 35) to preserve end-organ function. Choice a would be reasonable if no ECMO program were available. Choice b does not address the underlying cause of arrest, and if resources are available to support the patient they should be instituted. Choice c is inappropriate: BiPella placement is time intensive and not easily deployed while also maintaining high-quality CPR. In addition, BiPella therapy does not adequately address the hypoxemic component of the shock. Choice d is inappropriate owing to the acuity of the situation. Time should not be wasted trying to discuss therapies or obtain consent as organ systems begin to fail. After stabilization and rescue of the patient, a thorough briefing with the family and medical decision maker can take place.

Hemodynamic Assessment

Stroke and Other Systemic Emboli

Summary

Echocardiography has evolved into a crucial noninvasive imaging modality in the critically ill patient. Its portability, safety, and widespread availability allow for the rapid diagnosis of life-threatening cardiac problems and rapid exclusion of cardiac disease in critically ill patients who present in an undifferentiated fashion. This chapter uses a systematic approach to the use of echocardiography in the critically ill, from the assessment of left ventricular (LV) and right ventricular (RV) function to valve disease, as well as pericardial disease, aortic disease, stroke, and rapid hemodynamic assessment.

Approach to Echocardiography

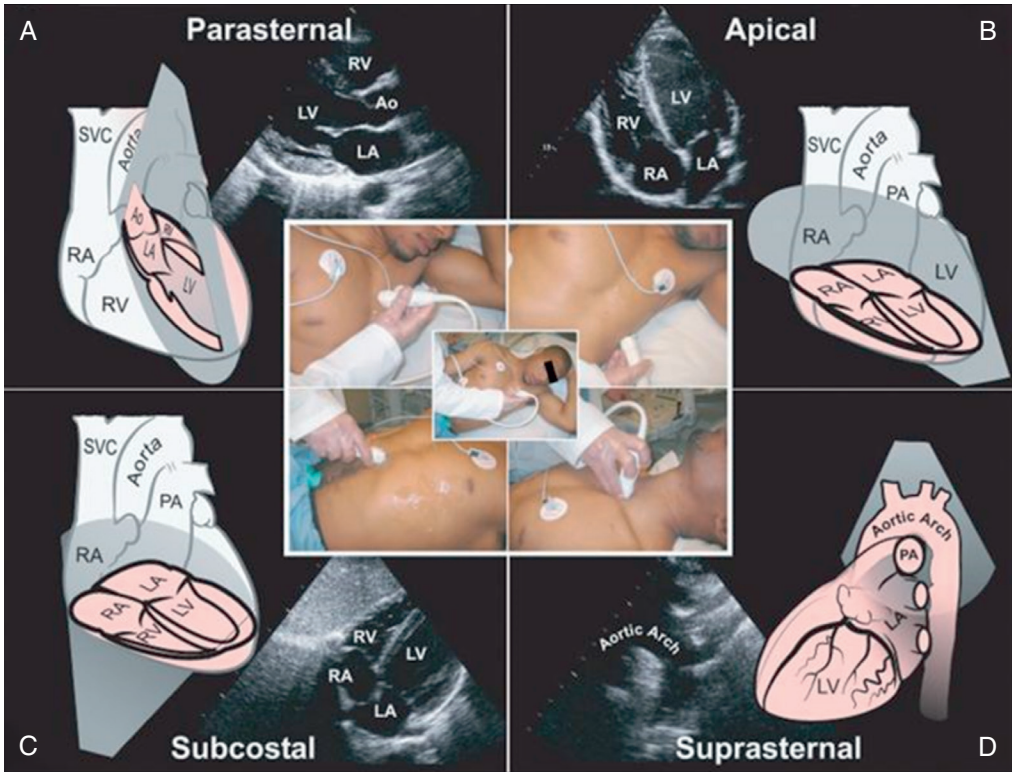
Cardiac Anatomy

Transthoracic echocardiography provides an excellent noninvasive means of assessing cardiac anatomy. The standard examination consists of parasternal views, taken from approximately 2 cm leftward from the sternum and the fourth to fifth rib interspace; apical views, taken from the LV apex; subcostal views, taken from the xiphoid process; and suprasternal views, taken from the sternal notch. Multiple images from different projections are needed to provide a complete view of the heart, manipulating the probe to provide long- and short-axis images of each structure interrogated.[1–3] The position of the echocardiographic transducer and the subsequent views produced are summarized in Fig. 8.1 (Videos 8.1 to 8.8).

Basic Echocardiographic Principles

Echocardiography uses ultrasound (i.e., sound above the audible range) to evaluate the heart and proximal great vessels and typically combines two modalities: tissue imaging (two-dimensional [2D]) and blood flow detection with velocity determination (Doppler). Cardiac tissue imaging is based on the transmission of ultrasound into the chest and its reflection by intrathoracic structures, which is determined by their acoustic properties. Imaging modalities in general use are 2D (transthoracic and transesophageal), Doppler, and, with increasing frequency, three-dimensional (3D) imaging. M-mode imaging, no longer applied as an isolated technique, can still provide useful information for timing of events, such as valve opening and closing.

Two-dimensional images are obtained from multiple sequential scan lines generated electronically (phased array) and processed to create a tomographic imaging plane with an expanded field of view. The time required to obtain all necessary scan lines reduces the frame rate to the range of 30 to 80 frames per second. Current ultrasound systems use both fundamental and harmonic imaging. Harmonic imaging transmits sound at a particular frequency (the *fundamental frequency*) but creates the image from sound reflected at twice the fundamental frequency, called the *second harmonic*, which improves image quality because the stronger harmonic signal undergoes considerably less distortion. This is particularly useful for endocardial border definition.



• **Fig. 8.1** Line graphic demonstrating the four basic probe positions for transthoracic echocardiography. A, Parasternal long-axis imaging plane. B, Apical four-chamber view. C, Subcostal view. (With permission of Solomon S. *Essential Echocardiography: A Practical Handbook* (with DVD). New York: Springer Science+Business Media (Humana Press); 2007.)

Doppler echocardiography uses ultrasound to determine blood flow velocity and direction within the heart. Two principal types of *spectral* Doppler techniques are used, termed *continuous wave* (CW) and *pulsed wave* (PW). CW uses two separate transducer crystals, one continuously transmitting and one continuously receiving the ultrasound signal. The high sampling rate of CW allows it to measure high velocities, but the source of any specific velocity measurement along the interrogated path cannot be differentiated *(range ambiguity).* On the other hand, PW uses one crystal, which alternates between sending and receiving an ultrasound pulse. The principal advantage of PW is that signals arise only from the area of interrogation, called the *sample volume (range resolution)*; however, because the same crystal is used for sending and receiving the signal, a new pulse of ultrasound cannot be transmitted until the previous returning signal has been detected. This "pulsed" process results in a sampling rate too low to quantitate high velocities. PW and CW are thus complementary, with PW localizing the source of a signal and CW allowing for the unambiguous measurement of high velocities.[4] *Color flow imaging* is a form of PW in which information is coded with colors and superimposed on a 2D ultrasound image. The colors black and white identify anatomic structures and color identifies blood flow velocities. Color Doppler has great utility in the evaluation of valvular regurgitant lesions and intracardiac shunts. An example of color Doppler identification of an atrial septal defect (ASD) is shown in Fig. 8.2 (Videos 8.9 and 8.10). Pulsed Doppler can also evaluate the velocity of moving myocardium, producing a signal of low velocity but high amplitude, called tissue Doppler imaging (TDI). Systolic and diastolic velocities within the myocardium and at the corners of mitral annulus can be recorded. Mitral annular velocities as measured by TDI are commonly used to evaluate diastolic function.[5]

Echocardiographic Modalities

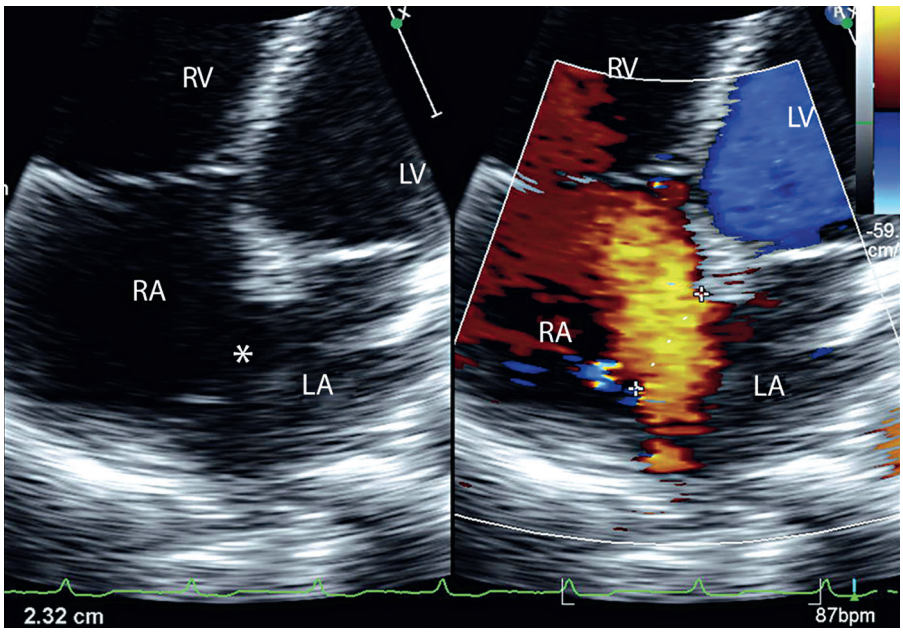
Transesophageal Echocardiography

Transthoracic echocardiographic (TTE) image quality may be suboptimal in patients who are obese, ventilated, or immobilized, and transesophageal echocardiography (TEE) can be of great use in this context.[6,7] TEE involves insertion into the esophagus of an endoscope-like probe with an ultrasound transducer on its tip. Image resolution is improved with TEE because the ultrasound beam is unimpeded by bone and air, and because proximity to the heart enables use of high-frequency (7 MHz) probes. TEE can easily be performed at the bedside. Active esophageal disease is the major contraindication. The TEE can be done with a nasogastric tube in place, but the nasogastric tube should be removed if there are any difficulties with passing the TEE probe or with acquiring the images. As some form of sedation is required, vital signs need to be monitored during the procedure. A comprehensive transesophageal examination typically takes about 20 minutes for imaging.

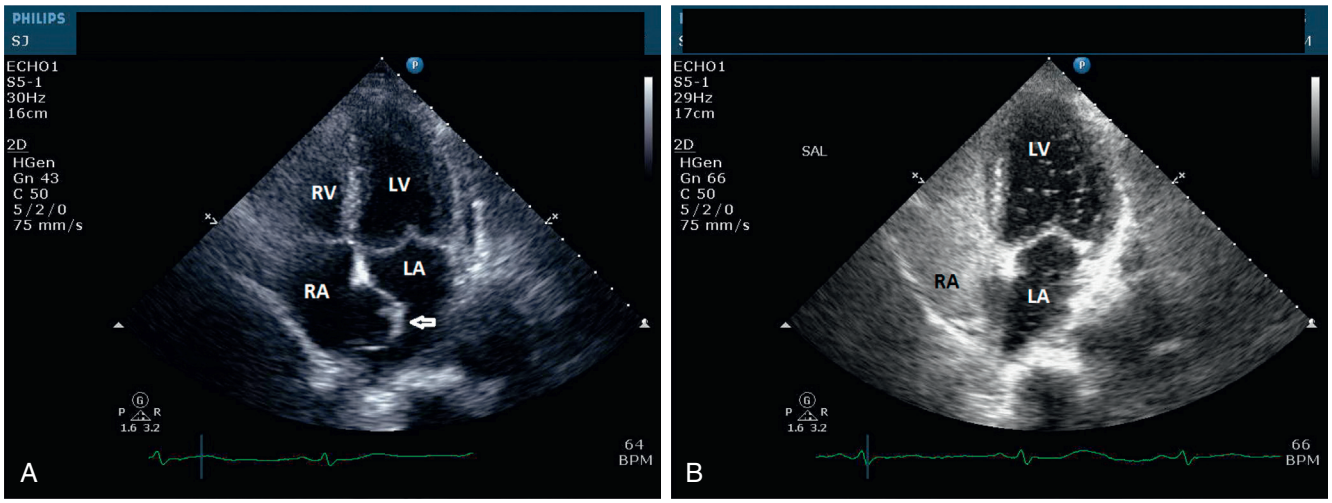
Contrast Enhancement

Saline Solution Contrast

Echocardiographic contrast agents are substances that enhance the reflected ultrasound signal. Simple agitated saline solution contrast can be used to detect intracardiac shunts, commonly at the atrial

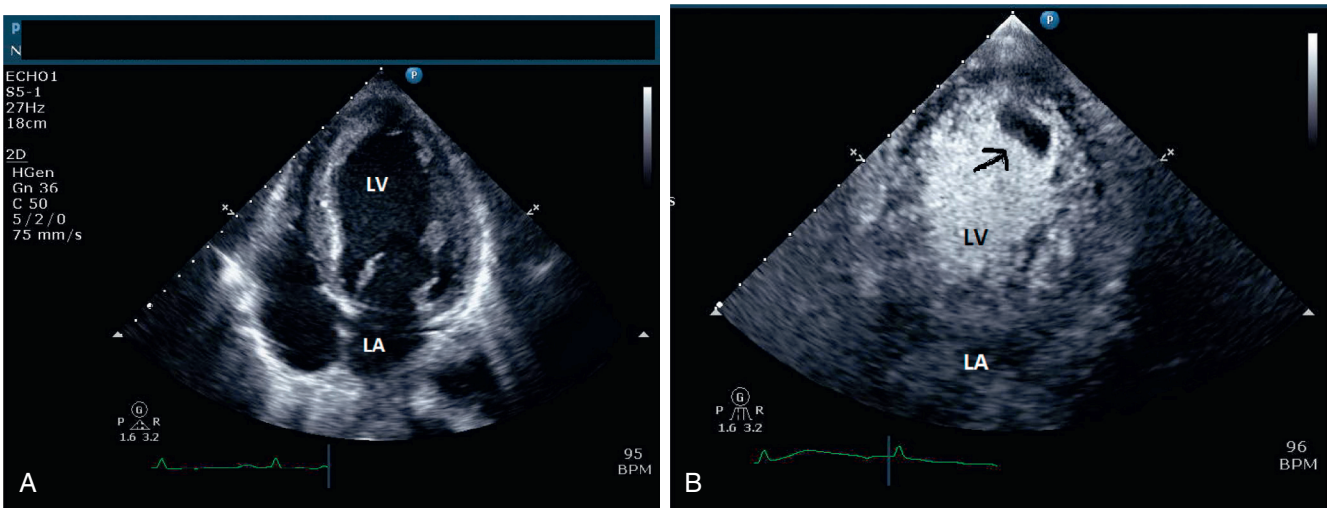


• **Fig. 8.2** Color flow of secundum atrial septal defect. A, Apical image of dilated right-sided structures. The asterisk indicates ASD. B, Color flow *(orange)* from left atrium through defect. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.



• **Fig. 8.3** Apical four-chamber view demonstrating atrial septal aneurysm *(arrow)* bulging into the left atrium (A) and (B) saline solution opacifying the right heart and bubbles crossing over into the left heart. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

level. In this technique, a prefilled 10-mL syringe of normal saline solution is connected to a second 10-mL syringe via a three-way stopcock. Brisk exchange of the saline solution between the syringes creates microbubbles, which are then rapidly injected as an intravenous bolus, resulting in opacification of the right chambers of the heart. Saline solution contrast bubbles are too large to pass through the pulmonary capillaries but may appear in the left atrium and left ventricle as a result of passage across an intracardiac (ASD or patent foramen ovale [PFO]) or intrapulmonary communication; occasionally, a cough or Valsalva maneuver may transiently increase right-sided heart pressures and facilitate right-to-left crossover of bubbles.[8] Although controversial, PFO may be implicated in embolic strokes, and these patients represent the most common group of patients who benefit from saline solution injection. Patients with persistent hypoxia without obvious cause may also benefit from saline contrast injection with echocardiographic imaging. Pulmonary arteriovenous malformations will demonstrate appearance of saline contrast in the left atrium; however, these bubbles are typically smaller than those that transit across an intracardiac shunt and usually appear late after injection (after >7–10 beats) and *persist* in the left heart after the right side of the heart empties of contrast saline, representing the typical transit time of the contrast saline through the pulmonary bed and the arteriovenous malformation into the pulmonary veins. An example of saline contrast echocardiography in a patient with an atrial septal aneurysm (ASA) and right-to-left interatrial shunt is shown in Fig. 8.3 (Videos 8.11 through 8.15).



• **Fig. 8.4** Apical four-chamber view with and without contrast enhancement, demonstrating dilated left ventricle *(LV)* without contrast (A) and (B) dilated LV with contrast demonstrating apical thrombus *(arrow). LA,* Left atrium.

Contrast for LV Opacification

Commercially available contrast agents are specifically formulated to pass through the pulmonary capillary bed, and they can be used to opacify intracardiac chambers to enhance endocardial border definition. When activated, contrast agents yield perfluorocarbon microbubbles encapsulated in either a lipid or albumin shell, which exhibit lower acoustic impedance than blood and enhance the intrinsic backscatter of blood.[9] The most important clinical use of contrast agents in critical care is for left ventricular opacification (LVO), to be used when standard TTE images of all LV wall segments are suboptimal.[10] These agents can provide substantial additional diagnostic information and are especially useful in identifying LV thrombus (Fig. 8.4). In patients in whom contrast for LVO is used, spectral Doppler signals can also be enhanced, enabling the detection of faint tricuspid regurgitant signals to enable measurement of pulmonary artery (PA) pressure, or for enhancing signals across the aortic valve (Videos 8.16 and 8.17).[11,12]

Goal-Directed Echocardiography

Laptop and handheld ultrasound devices are small, highly portable devices that can easily go to the bedside without requiring an external power source. Although these devices have limited analysis capabilities, they can provide reasonable 2D and color Doppler images, have been shown to correlate reasonably well with full echocardiographic platforms, and can detect clinically relevant findings.[13] "Goal-directed" 2D imaging (focused ultrasound exam [FOCUS]) is typically limited to the assessment of biventricular size and function, the presence or absence of pericardial effusion, and the evaluation of volume status—that is, a *study done to provide assessment relevant to the immediate clinical situation.* A focused 2D study done by a trained individual with a handheld device has great potential for rapid triage of select patients in the emergency room or the intensive care area.[14–17] It is important to emphasize that unclear or ambiguous findings on a focused examination should be followed by a complete study on a full echocardiographic platform to obtain an accurate and comprehensive diagnosis.

Three-Dimensional Echocardiography

Matrix-array transducers have allowed acquisition and display of real-time 3D imaging. Three-dimensional echocardiography has been shown to be more accurate in the assessment of LV volumes and ejection fraction (EF) because it avoids geometric assumptions about cardiac chambers.[18,19] In addition, it offers more accurate "surgical" views of cardiac valves, provides better assessment of regional wall motion abnormalities,[20] and can quantify LV dyssynchrony in patients with heart failure to guide cardiac resynchronization therapy.[21] In addition, 3D imaging affords reliable volumetric quantification of shunts, cardiac output, and valve regurgitation.[22] Importantly, 3D imaging can provide guidance for the rapidly expanding interventional procedures that are currently available for structural heart disease.[22]

Indications for Echocardiography

Although a broad range of critically ill patients are candidates for TTE to assess cardiac pathology and function, specific indications are summarized in Box 8.1. In general, any critical care patient with unexplained hypotension, pulmonary congestion, hemodynamic instability, known cardiac disease, a significant unexplained cardiac murmur, thoracic trauma, or suspected endocarditis are candidates for echocardiography. Common indications for TEE in critical care include suspected infective endocarditis (IE), aortic dissection, cardiac source of embolus, and as a supplement to inadequate TTE images (Box 8.2).

Assessment of LV Function

Systolic Function

Although there are a variety of methods to assess LV systolic function by echocardiography (Doppler calculation of stroke volume, the first derivative of pressure measured over time using mitral regurgitation [MR] signal, tissue Doppler systolic velocity, and systolic strain and strain rate), the most commonly used and clinically relevant is the calculation or estimation of LV ejection fraction (EF).[18,23,24] As defined in current guidelines, calculation of left

• BOX 8.1 Indications for Transthoracic Echocardiography in Critical Care

Hemodynamics
Left ventricular function
- Regional wall motion abnormalities
- Global dysfunction
- Transient dysfunction (sepsis, ischemic/catecholamine stunning)

Right ventricular function
Hypotension
Pericardial effusion/tamponade
Assess volume status
Outflow tract obstruction
Valvular stenosis/insufficiency

Hypoxia
Right ventricular function
Right ventricular pressure
Intracardiac/extracardiac shunting
Pulmonary embolus

Infections
Bacterial endocarditis

Trauma
Blunt thoracic trauma
Penetrating thoracic trauma

General
Assess proximal ascending aorta—dissection, hematoma
Source of murmur
Source of embolus
Procedural guidance (especially pericardiocentesis)

• BOX 8.2 Indications for Transesophageal Echocardiography in Critical Care

Inadequate or nondiagnostic transthoracic echocardiographic images
Evaluate suspected aortic dissection or trauma
Evaluate prosthetic valves, especially mitral
Investigate persistent hypoxemia
Detect presence of valvular vegetations
Identify complications of infective endocarditis:
- Abscesses
- Leaflet perforation
- Pseudoaneurysm formation
- Fistulas

Identify cardiac source of systemic embolus:
- Thrombus in left atrium and left atrial appendage
- Patent foramen ovale/atrial septal aneurysm
- Atheromatous debris of the aorta

Identify pulmonary embolus in transit
Characterize intracardiac shunts:
- Atrial septal defect (ASD)
- Ventricular septal defect (VSD)
- Anomalous pulmonary venous connections

Guide invasive procedures:
- Shunt closure
- Percutaneous balloon valvuloplasty
- TAVR, MitraClip
- LAA Closure Devices

LAA, Left atrial appendage; *TAVR,* transcatheter aortic valve replacement.

ventricular ejection fraction (LVEF) by Simpson's method of discs (Fig. 8.5) is recommended.[18] EF (end-diastolic volume – end-systolic volume/end-diastolic volume) is dependent not only on intrinsic contractility but also on LV preload and afterload. Therefore both factors should be considered when assessing LV systolic function. Normal values are shown in Table 8.1. In the presence of regional dysfunction, EF from multiple views should be integrated to accurately assess LV systolic function. To improve the accuracy of EF calculation by echocardiography, it is essential to avoid foreshortened apical views and to use intravenous contrast material when needed to enhance endocardial border definition. Aside from measurements of systolic function, 2D echocardiography is of great use in reliably assessing LV dimensions, wall thickness, volumes, and mass.[18] In experienced hands, 3D echocardiography–derived LVEF measurements are more accurate and reproducible.[18,19] Reliable assessments of LV dimensions and EF, particularly when combined with knowledge of filling pressures, can be used to guide and assess the response to therapeutic measures of volume infusion or

Severely depressed	<30

intravenous administration of inotropic/vasodilator or vasopressor drugs.

TDI-derived myocardial velocities (Fig. 8.6) have been used to assess global LV systolic properties.[25,26] This approach is dependent on tissue Doppler technology to record mitral annulus and myocardial signals, which can be acquired from any area of the heart. However, because of their dependence on Doppler principles, they are of limited value when proper alignment cannot be achieved between the ultrasound beam and the plane of cardiac motion. TDI measurements of systolic annular velocity have been shown to reflect systolic dysfunction, even in the presence of normal LVEF (such as in hypertrophic cardiomyopathy [HCM] or infiltrative cardiomyopathy [ICM]).[25,26] Using speckle tracking imaging, a 2D echocardiographic technique that measures myocardial motion over time, myocardial deformation (strain) and rate of deformation (strain rate) can also be used to assess LV systolic function.[27,28] As in TDI, strain and strain rate can detect significant myocardial systolic abnormalities, even in the presence of preserved LVEF.[29,30] As with TDI, this is of particular importance in patients with diastolic heart failure, hypertensive heart disease, HCM, and infiltrative disease, when normal EF can coexist with significant and clinically important abnormalities of systolic function.

Diastolic Dysfunction

LV diastolic function refers to the filling phase of the cardiac cycle. Filling is dictated by LV relaxation (measured as the rate of decay of LV systolic pressure during the isovolumic relaxation period) as well as atrial systole and atrial and ventricular compliance. LV relaxation is an adenosine triphosphate–expending process. This active process is responsible only for early diastolic filling, whereas compliance is important throughout filling and particularly during atrial systole. The LV compliance is calculated using measurements of LV volume and pressure during the diastolic filling period. However, prediction of LV filling pressures integrates the effects of the preceding hemodynamic variables as well as other factors such as RV filling, pericardial constraint, and left atrial (LA) function on LV diastolic function. Increased LV filling pressure is often used as a clinical surrogate for diastolic dysfunction. LV filling pressure can be measured as a mean pulmonary capillary wedge pressure, mean LA pressure, mean LV diastolic pressure, or LV end-diastolic pressure. A direct measurement of LV filling pressure requires an invasive intervention, which has significant risk and costs. Echocardiography offers a noninvasive evaluation of diastolic function and estimation of LV filling pressures.

LV diastolic dysfunction in the intensive care unit (ICU) may be present as a result of cardiac as well as systemic disorders that

can affect cardiac function: coronary and hypertensive heart disease, diabetes mellitus, amyloidosis, and HCM. A careful assessment of LV diastolic function by echocardiography can contribute essential information for the management of these patients,[31–33] whereas the serial estimation of filling pressures can serve as an important guide for titration of diuretic therapy.

The recommended clinical approach for the assessment of LV diastolic function begins with the 2D examination to determine LV dimensions and volumes and to define the presence and extent of LV hypertrophy (Figs. 8.7 and 8.8). Patients with a depressed EF or LV hypertrophy have impaired LV relaxation. Therefore, even in the absence of any corroborating Doppler information, one can still conclude that LV relaxation is impaired in these patients. Furthermore, this information can be combined with the mitral inflow pattern to predict filling pressures. It is also important to measure LA volume using apical four- and two-chamber views because LA volume is related to the extent of diastolic dysfunction when an increase in LA volume parallels deterioration of LV diastolic function.[34] Mitral inflow is obtained using pulse Doppler, with a 1- to 2-mm sample volume placed at the level of mitral valve tips.[35,36] Early diastolic flow and velocity (the E wave) occur in response to a positive pressure gradient between the LA and the LV, resulting from a rapidly decreasing LV pressure owing to LV relaxation and early diastolic suction. In late diastole, LA contraction leads to another positive-pressure gradient and late diastolic flow, or the A velocity. With normal LV relaxation, early diastolic flow predominates and the E/A ratio is greater than 1. However, when LV relaxation is impaired, LV diastolic pressure is elevated and a reduced E velocity is observed. This leads to a higher LA preload and contraction velocity. Therefore the E/A ratio decreases in the presence of impaired LV relaxation. Because LA pressure usually increases to maintain forward stroke volume, the early diastolic transmitral pressure gradient increases, leading to a higher E velocity and E/A ratio. Because of the simulation to normal mitral inflow, this pattern is referred to as a pseudonormal mitral inflow pattern. In more advanced disease with markedly elevated LA pressure, the E velocity increases even

further, resulting in a "restrictive" inflow pattern, in which the E/A ratio is 2 or greater. It is possible to unmask the presence of impaired LV relaxation in these cases by performing a Valsalva maneuver. The decrease in venous return during the strain phase of Valsalva results in a decrease in LA pressure and E/A ratio.[37,38] Tissue Doppler–derived early diastolic mitral annular velocity (e′) can be recorded by pulsed Doppler at mitral annulus. When combined with E, the E/e′ ratio is obtained, which has been shown to be a reasonable correlate of LV filling pressure,[39] although multiple diastolic echo-Doppler variables need to be synthesized to result in an accurate assessment of LV diastolic function.[40–42]

Pulmonary venous flow can also be analyzed to predict LV filling pressures. Pulmonary venous flow signals are readily recorded in the majority of patients seen in the outpatient laboratory but can be challenging in the critical care setting. Antegrade forward flow from the pulmonary vein into the left atrium occurs during systole (S) and early and mid-diastole (D). After atrial contraction, retrograde flow (atrial reversal) from the left atrium into the pulmonary vein occurs. At the earlier stages of diastolic dysfunction where LV end-diastolic pressure is increased, the peak velocity and duration of atrial reversal become more prominent.[41] Subsequently, with the rise in mean LA pressure, antegrade systolic flow decreases, whereas the D velocity increases with a shortening of its deceleration time. Assessment of PA systolic and diastolic pressures (see later text) can provide helpful corroborating evidence of the status of LV filling pressures. In the absence of pulmonary parenchymal and vascular disease, and in the presence of significant cardiac valvular disease or cardiomyopathy, one can reasonably infer that PA pressures are increased due to an elevated LA pressure. Fig. 8.9 shows an example of the assessment of diastolic function integrating multiple echo-Doppler variables.

Ischemia/Infarction Including Complications

Echocardiography is essential for the assessment of LV regional function in the critical care setting when the diagnosis of ischemia/infarction is entertained. Adequate images, particularly when combined with harmonics and intravenous contrast, can provide reliable information regarding the presence and extent of segmental wall motion abnormalities.[43] Furthermore, serial assessment of regional function is possible after the administration of any therapeutic intervention. In addition to technically good images, interpretation by an experienced echocardiographer is essential for achieving high accuracy. Regional function is determined by examining endocardial motion as well as local thickening. Abnormal LV regional function is usually determined when the dysfunction is observed in more than one plane, with particular LV segments corresponding to specific coronary artery distributions. An echocardiographic regional map for the identification of wall motion abnormalities and their correlation to coronary anatomy is shown in Fig. 8.10. In general, thinned (<5 mm in diameter) bright segments with abnormal or absent motion are indicative of scars (Videos 8.18 through 8.20). When there is a thinned segment that moves in a direction opposite to adjacent, normal walls ("bulging"), aneurysm is often the cause. Regional wall motion abnormalities can occur in the absence of epicardial coronary artery disease; thus final conclusions regarding the cause of wall motion abnormalities should be made only after integration of all clinical findings. In the setting of acute myocardial infarction, a number of studies have substantiated the prognostic power of echocardiography, particularly determination of LVEF, LV diastolic function, RV function, and significant valve dysfunction.[43] Regional function is most reflective of long-term outcome when imaging is performed after recovery of myocardial stunning (usually a week to 10 days after presentation). However, in the acute setting, echocardiography may be obtained to help establish the diagnosis of an acute ischemic syndrome, determine the extent of myocardium at risk, identify apical thrombus (Fig. 8.11), and detect the presence of mechanical complications such as a ruptured papillary muscle (Fig. 8.12), contained cardiac ruptures called pseudoaneurysms (Fig. 8.13), MR, pericardial effusion, and RV infarction, all of which may require urgent intervention (Videos 8.21 through 8.31).[44]

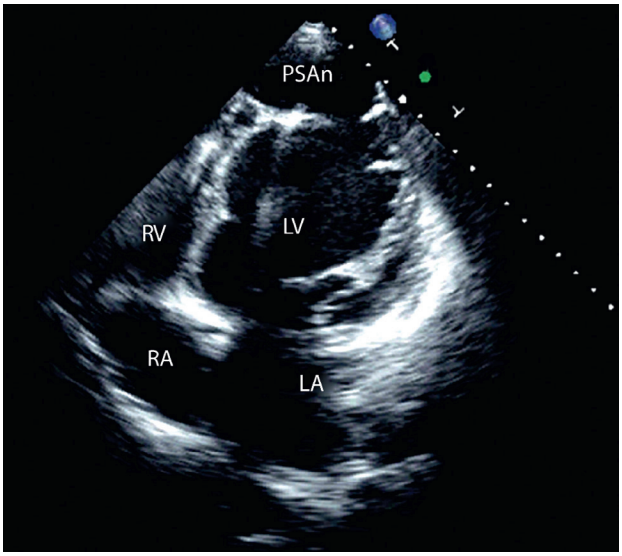
Cardiomyopathies

Hypertrophic Cardiomyopathy

HCM is an inherited disorder characterized by marked, commonly asymmetric hypertrophy without an identifiable cause.[45] At the pathologic level, there is myocyte disarray, wherein healthy myocytes are replaced by fibrosis. Thick walls are the hallmark of the echocardiographic findings (Fig. 8.14). Hyperdynamic LV systolic function is typical early in the disease and can progress to depressed systolic function, occasionally with aneurysm formation at the apex. There are various morphologic types of HCM, including asymmetric septal hypertrophy with systolic anterior motion of the mitral valve (Figs. 8.15 and 8.16, Video 8.32), concentric (uniform) hypertrophy, apical hypertrophy, and hypertrophy located in myocardial segments other than the septum. Apical hypertrophy, originally described in Japan in 1976, can be associated with giant negative T waves on the electrocardiogram (ECG). Although the overall mortality of apical HCM is low (0.1% annually), a continuum of apical abnormalities may exist wherein apical ischemia leads to apical outpouching or aneurysmal remodeling. There is a high incidence of ventricular dysrhythmias and atrial fibrillation and stroke in this cohort.[45] Echocardiography is uniquely positioned to differentiate the various morphologic types of HCM, to determine LV systolic function, to assess left ventricular outflow tract (LVOT)



• **Fig. 8.13** Pseudoaneurysm *(PSAn)* of the left ventricular apex. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

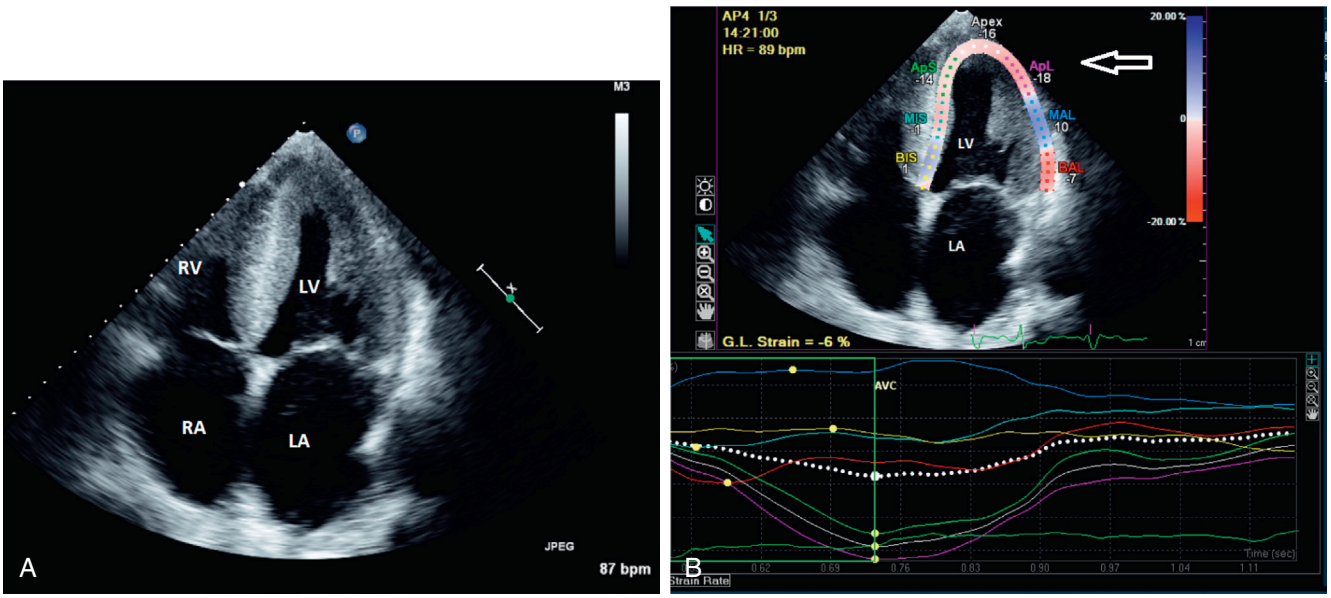
or intracavitary obstruction, to identify associated MR, and to determine LV filling pressures and PA pressure.[46] Reduced LV compliance eventuates elevation of left atrial and pulmonary venous pressures, and abnormal myocardium, with or without obstruction, results in rhythm disturbances. Clinically, HCM patients can present to critical care with hypotension, congestive heart failure, arrhythmias, stroke, and cardiac arrest; echocardiography is crucial in differentiating the underlying disease state and the functional and morphologic associations with these presentations.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is global LV dilatation and systolic dysfunction often associated with RV dysfunction. Although viral myocarditis can cause this same picture, in general, DCM refers to familial inherited cardiomyopathy but can also be caused by a variety of conditions, including alcohol abuse, chemotherapeutic agents, and endocrine disorders. As genetic methods for diagnosing inherited DCM become more refined, an increasing proportion of idiopathic nonischemic cardiomyopathy is found to be inherited.[47] Echocardiography demonstrates a dilated LV and depressed EF, usually with associated RV dysfunction and biatrial enlargement (see Fig. 8.16); for final diagnosis, exclusion of a sufficient degree of coronary artery disease to explain the degree of LV dysfunction is necessary.[48] Secondary MR and tricuspid regurgitation (TR) can be seen by color Doppler. LV filling and PA pressure assessments are important in clinical management (Videos 8.33 through 8.36).

Infiltrative/Restrictive Cardiomyopathy

ICMs are characterized by the deposition of abnormal substances within the myocardium that cause the ventricular walls to become progressively rigid, thereby impeding ventricular filling.[49] This impedance to normal LV filling is termed "restrictive filling"; hence the other name, "restrictive cardiomyopathy." However, because any cardiomyopathic process can have restrictive filling (ischemic, dilated, hypertrophic), the preferred term is ICM. Some ICMs can cause LV and RV thickening, such as the archetypal ICM cardiac amyloidosis, although others can cause ventricular thinning, such as sarcoidosis. From the echocardiographic point of view, thickened ventricular walls, occasionally "smudgy" in appearance, in association with restrictive LV filling and at times depressed LVEF, are seen in amyloidosis, as well as "sparing" of the apical



• **Fig. 8.17** Apical four-chamber view (A) of cardiac amyloidosis. Note bright thick walls. B. Strain imaging demonstrating typical apical sparing *(arrow). LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

segments by strain imaging (Fig. 8.17).[50,51] The low voltage on the ECG as typically seen in patients with amyloid can help make the distinction between HCM and hypertensive disease. For sarcoidosis, many LV patterns can be seen, but focal LV aneurysms are typical; heart block on the ECG is also often seen.

Takotsubo Syndrome

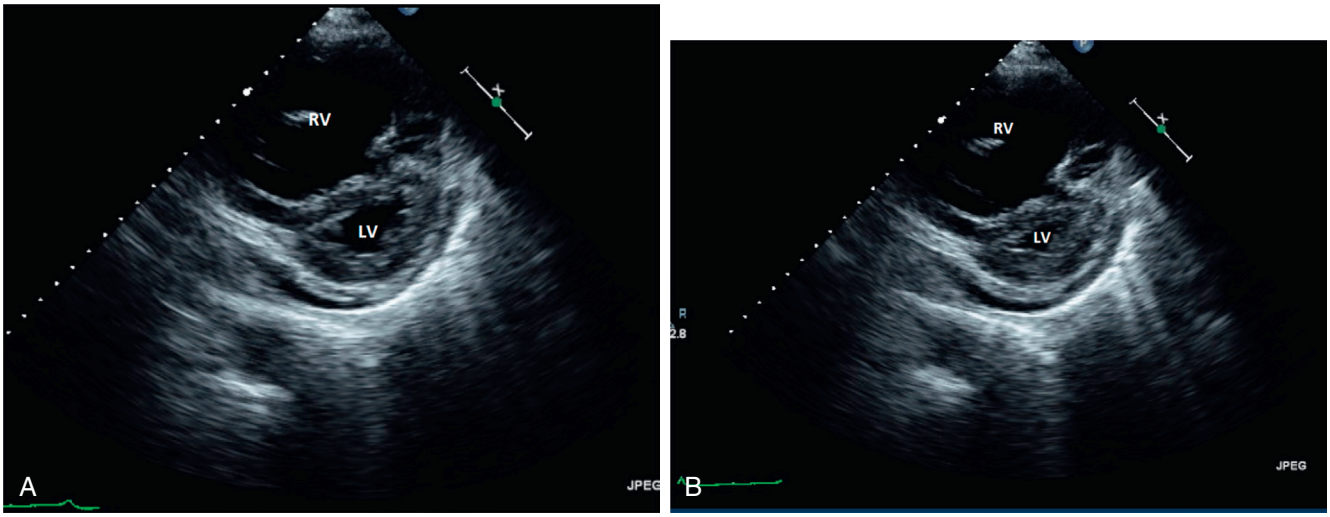
The Takotsubo (*Japanese octopus pot*) syndrome, originally described in Japan in 1990, is characterized by regional LV wall motion abnormalities, commonly completely reversible, that occur in the absence of significant coronary artery disease.[52] In the early experience, it was most commonly found in women older than 50 years of age, occurred after an emotional or physical stressor, and presented with ST-segment elevation and an apical "ballooning" LV contraction abnormality. It is now recognized to be more clinically varied, has been identified in men and younger individuals and, importantly, diverse LV contraction patterns beyond the classic apical ballooning pattern (75%–80%) are now recognized, including midventricular ballooning (10%–20%) and basal segment ballooning ("inverted ballooning"; uncommon and occurring in only 1%–2%).[52,53] It can present during diagnostic procedures or during hospitalization for acute illness, and recent evidence suggests an association with sepsis.[54,55] Although no single feature distinguishes Takotsubo from other conditions with a similar acute presentation, characteristic symptoms include chest pain, ischemic ECG changes with a troponin elevation, and an LV wall motion abnormality in a segment being supplied by a normal coronary artery. *Reversibility* of LV wall motion abnormalities is expected within 3 months. Hemodynamic instability requiring intervention with vasopressor agents or intraaortic balloon pumping occurs in up to 15% of patients, and in-hospital mortality is as high as 5%. The recurrence rate may be as high as 20%. Elevated catecholamine levels may be involved in Takotsubo pathophysiology. Current evidence does not suggest survival benefit with the use of β-blockers in the hospital, although 1-year survival showed marginal improvement with the use of angiotensin-converting enzyme inhibitors.[54,55] A registry has been established (the International Takotsubo Registry) to improve diagnosis, treatment, and outcomes (Videos 8.37 and 8.38).[56]

Assessment of RV Function

Echocardiographic assessment of the right ventricle is challenging because of its complex shape. However, it is possible to integrate information from multiple views to reach reasonably accurate conclusions on RV size and function. Visually, assessment of RV size is usually done by comparing RV and LV transverse dimensions in the parasternal short-axis (Fig. 8.18) and apical views (Fig. 8.19). In general, the RV dimensions are one-third of the LV dimensions. Severe RV enlargement is operant when the RV is bigger than the left and the RV forms the cardiac apex. It is possible to measure RV end-diastolic and end-systolic dimensions and area in the apical four-chamber view; however, caution should be exercised to avoid tangential and foreshortened views. Normal RV dimension at the tricuspid annular level in the apical four-chamber view is less than 4.1 cm.[57] RV wall thickness is normally less than 0.5 cm and is most reliably measured by 2D echocardiography in subcostal views at the level of the tricuspid valve chordae tendinae.[57]

RV systolic function is estimated qualitatively in clinical practice as normal or mildly, moderately, or severely depressed function. It is also possible to obtain a quantitative measurement of RV systolic function by measuring RV fractional area change (FAC = end-diastolic area − end-systolic area/end-diastolic area) in the apical four-chamber view. This is a simple method with reasonable reproducibility and accuracy, and normal value is greater than 35%. The tricuspid annulus motion can provide useful information in patients with suboptimal visualization of RV free wall; normal tricuspid annular plane systolic excursion (TAPSE) is greater than 1.6 cm.[57,58] Additional information may be obtained by the tissue Doppler–derived tricuspid annulus systolic velocity.[59,60]

Conditions of RV volume overload (e.g., ASD, severe TR or pulmonary regurgitation) result in diastolic flattening of the



• **Fig. 8.18** Short-axis view of "D-shaped" left ventricle in systole (A) and diastole (B) with marked right ventricular enlargement. *LV,* Left ventricle; *RV,* right ventricle.

interventricular septum, but RV pressure overload (primary pulmonary hypertension, acute or chronic thromboembolic disease, cor pulmonale) results in systolic and diastolic flattening of the interventricular septum ("D-shaped ventricle" in systole and diastole; see Fig. 8.18).[61] Acute RV dilatation can reduce LV filling through an increase in intrapericardial pressure, which in turn reduces LV transmural filling pressure.[62,64] An acute decline in RV function is usually accompanied by RV dilatation and a decrease in RV systolic function in the presence of normal wall thickness. In the setting of an acute coronary syndrome, this may happen as a result of RV ischemia or infarction. The presence of normal/reduced PA pressures along with regional dysfunction can help identify these patients. Patients with chronic RV pressure overload (for example, idiopathic pulmonary hypertension) often exhibit a dilated right ventricle with reduced contractility and increased wall thickness (see Fig. 8.19) in the presence of increased PA pressures and vascular resistance. A simple echocardiographic prediction rule using LA size measurement, the lateral E/e′ ratio, and the pulsed wave Doppler of the right ventricular outflow tract has been proposed by Opotowsky et al. to predict the likelihood that a given patient has pulmonary hypertension attributable to either pulmonary vascular disease or to left heart disease.[63] In this population, all subjects with a positive score had pulmonary vascular disease; all subjects with negative scores had elevated wedge pressure.

Although it is true that as many as 70% of patients with proved pulmonary embolus (PE) have no significant echocardiographic abnormalities, recent data suggest that several parameters of RV function are associated with mortality in patients presenting with acute PE.[65] These parameters include (1) the ratio of RV to LV end-diastolic diameter (≥0.9); (2) RV systolic pressure derived from the tricuspid regurgitant jet velocity (≥50 mm Hg); (3) TAPSE (<15 mm); and (4) inferior vena cava (IVC) collapsibility.[64] Another study suggested that the (1) McConnell sign (hypokinesis of the RV free wall with normal contraction of the RV apex); the (2) "60/60" sign, which is the coexistence of a shortened pulmonary ejection acceleration time (AcT) (<60 msec) with mid-systolic velocity deceleration ("notch") and a tricuspid regurgitation peak gradient <60 mm Hg; and (3) right heart thrombus were all strongly suggestive of pulmonary embolus.[65] Work by Dahhan et al. found an association of free wall global RV strain and RV Tei index with mortality.[66,67] They did not find such a relationship between other measures, including TAPSE, RV size, and the RV/LV ratio; in fact, TAPSE, subjective RV dilation, and subjective RV dysfunction were not statistically different between survivors and nonsurvivors.[67] *All* studies agree, however, that there is a paucity of data from large clinical trials defining which echocardiographic parameters are actually useful in risk assessment in acute PE, and whether such parameters are of utility in identifying patients who might benefit from an intervention (Videos 8.39 through 8.43).

Determining Valvular Function and Dysfunction

Echocardiography provides important anatomic and physiologic information on cardiac valves. Features of valve morphology and motion, such as a flail leaflet, can be reliably assessed using 2D imaging. Importantly, secondary changes such as chamber

TABLE 8.2 Echocardiographic Assessment of Aortic Regurgitation Severity

Finding	Mild	Moderate	Severe
Central jets: color jet width/LVOT diameter	<25%	25%–64%	≥65%

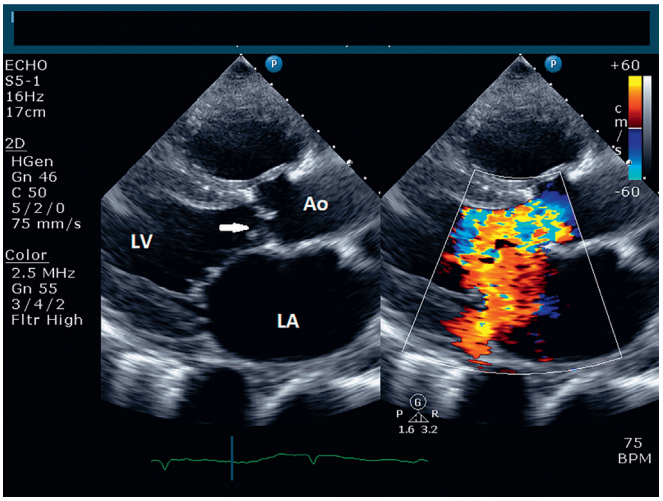
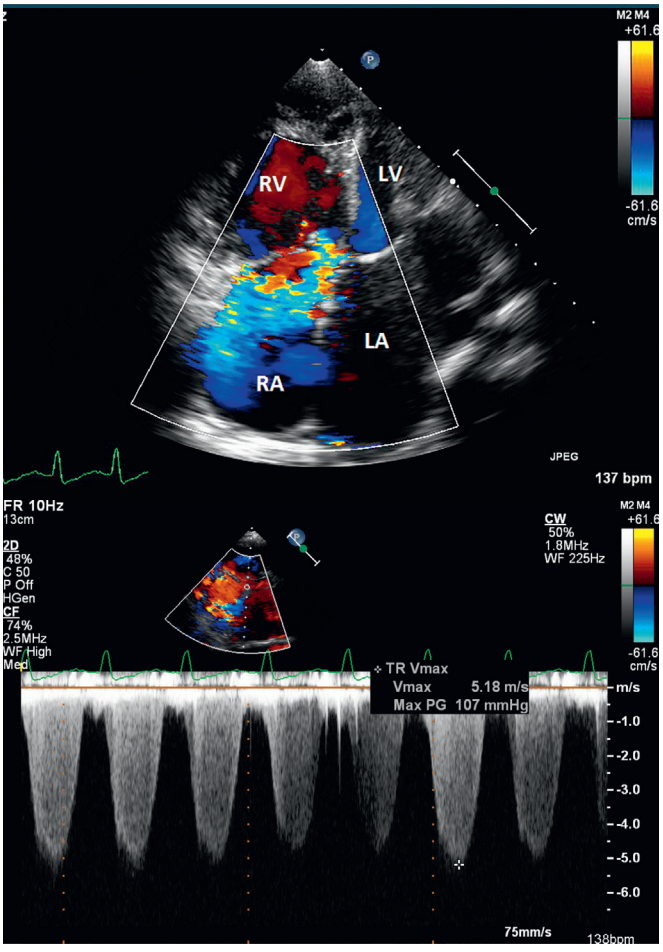
enlargement and LV/RV function can be followed serially, thus enabling timely decisions with respect to surgery or percutaneous interventions. Using 2D images and Doppler, it is possible to assess the severity of valvular stenosis or regurgitation and to calculate PA pressures.

Evaluation of Mitral, Tricuspid, and Aortic Regurgitation

Similar principles apply to the assessment of mitral (MR), tricuspid (TR), and aortic (AR) regurgitation. Pulsed, CW, and color Doppler are useful, when combined, in identifying and accurately grading AR (Table 8.2), MR (Table 8.3), and TR (Table 8.4).[68] Echocardiographic assessment of regurgitant valves includes the 2D and comprehensive Doppler imaging in multiple views to identify the direction and size of regurgitant jets. Color Doppler has reasonable accuracy in assessing the severity of MR, TR, or AR when jets are central, although the severity of eccentric jets can be underestimated. In addition, several technical and physiologic factors can affect the size of the jet, irrespective of regurgitant volume, including color gain, pulse repetition frequency, filter settings, and atrial (or aortic)/ventricular pressures. Therefore it is important to record blood pressures at the time of echocardiography. For MR and TR, the ratio of the jet area to the LA or RA area has been used in clinical and research studies to assess these lesions; it is important that the Nyquist limit for color Doppler be greater than 55 cm/sec for accurate assessment. For AR, the width of the jet at its origin is related to that of the LVOT to arrive at the ratio that expresses the severity of AR. It is also possible to measure the cross-sectional area of the regurgitant jet by planimetry and relate that to the corresponding area of the LVOT in the short-axis views. Fig. 8.20 shows an image of severe MR, Fig. 8.21 demonstrates significant AR, and Fig. 8.22 shows severe TR.



• **Fig. 8.21** Long-axis view demonstrating severe aortic regurgitation *(arrow). Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.



• **Fig. 8.22** Severe tricuspid regurgitation *(TR)* by color Doppler *(upper panel).* Continuous wave Doppler demonstrating very high gradient consistent with severely elevated pulmonary pressures *(lower panel). RA,* Right atrium; *RV,* right ventricle; *LA,* left atrium; *LV,* left ventricle.

The "vena contracta" of the regurgitant jet, defined as the narrowest area of the jet that occurs at the orifice,[69] can be readily imaged and measured. As the regurgitant volume increases, vena contracta width increases (Fig. 8.23). The flow convergence method (proximal isovelocity surface area, or PISA, method) is a quantitative approach that can measure the regurgitant volume and the effective regurgitant orifice (ERO) area. Color flow mapping enables the visualization of the concentric hemispheres of flow as they approach the ERO. The ERO area is calculated as:

$$6.28 \times r^2 \times V_a / V_{peak},$$

where V_a is the aliasing velocity, r is the maximal radius of the PISA, and V_{peak} is the peak velocity of the regurgitant signal by CW Doppler[70] (Fig. 8.24). This method is most reliable when jets are centrally located and the regurgitant orifice is adequately visualized. The CW signal can provide useful information, as the density of these signals relative to antegrade flow increases with increasing severity of regurgitation. For patients with MR or TR who have severe lesions and a rapid rise in LA or RA pressure resulting in a large regurgitant V wave, low-velocity, early systolic peaking Doppler regurgitant signals are seen. For AR, the deceleration time (DT) (pressure half-time = 0.29 × DT) of the AR spectral Doppler signal is related to the rate at which aortic and LV pressures equilibrate in diastole, such that patients with hemodynamically significant lesions exhibit a rapid rise in LV diastolic pressure, leading to steep deceleration of the AR velocity signal. In general, severe AR correlates with pressure half-time less than 250 msec, and mild AR with pressure half-time greater than 500 msec.[68] The pressure half-time is most reliable in cases with acute AR and may be prolonged in patients with chronic severe AR owing to a concomitant increase in LV compliance. For MR and TR, peak early diastolic filling velocity by PW (peak E velocity) is increased in the setting of significant regurgitation because of the increased transvalvular flow generated by the regurgitant volume; in severe MR, a peak E velocity greater than 1.2 m/sec is usually present. In addition, pulmonary and hepatic venous flow will show systolic reversal of flow in severe MR or TR, respectively, corresponding to the large regurgitant V wave in atrial pressure. In hemodynamically significant AR, diastolic flow reversal is noted in the descending aorta. Normally, no (or minimal) flow reversal is seen in the descending aorta in early diastole. In patients with severe AR, holodiastolic flow reversal is observed.[68]

In arriving at final conclusions, it is important to integrate all the findings obtained by 2D and Doppler imaging.[68] For example, patients with chronic severe regurgitant lesions usually have dilatation of cardiac chambers (for MR, LA and LV; for TR, RA and RV; for AR, LV) along with a large regurgitant volume. If the quality of the transthoracic images precludes the assessment of valvular disease, or the severity of MR or AR, it is reasonable to proceed to TEE. All of the preceding methods can be applied for the quantification of regurgitant lesions imaged by TEE. However, with respect to MR assessment by TEE, given the proximity of the TEE probe to the left atrium, the MR jet area can be larger than that acquired by transthoracic imaging. In addition, TEE can provide unique information that is essential for successful mitral valve repair. Particularly, 3D TEE provides excellent anatomic information on specific mitral anatomy and function[22] (Fig. 8.25).

Evaluation of Aortic Stenosis

Patients with aortic stenosis (AS) have abnormally thickened or calcified valve leaflets along with reduced leaflet excursion, as seen by 2D echocardiography (Fig. 8.26, Video 8.44).[71] In patients older than 70 years of age, the most common cause is degeneration of a trileaflet valve; in patients younger than 70 years, the most common cause is a bicuspid aortic valve. In addition to morphologic changes of the aortic valve, 2D imaging is needed to determine LV size, wall

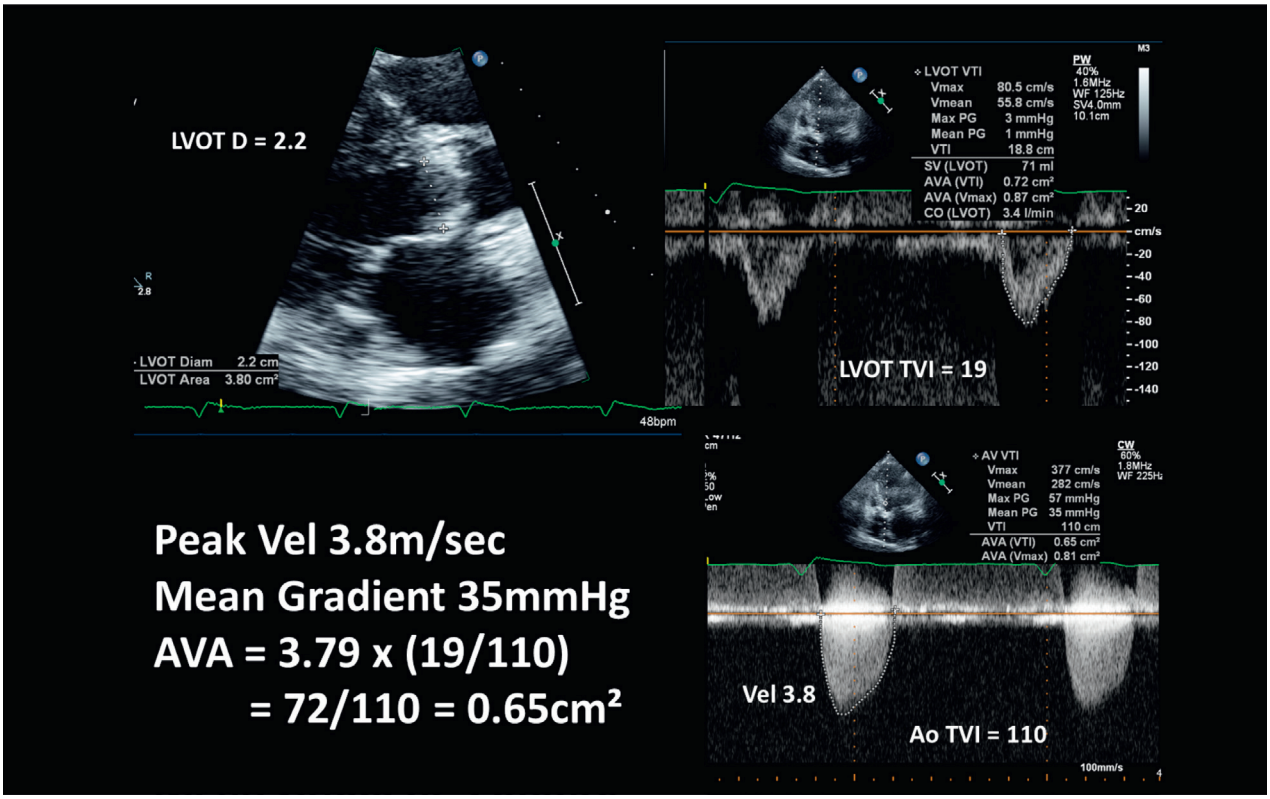
thickness, and EF. Such data are essential to assess the impact of AS on LV function, which is needed as part of the routine evaluation of patients with this disease. AS severity is assessed most reliably by the mean transvalvular systolic pressure gradient across the aortic valve and by the valve area, both of which are measured by Doppler echocardiography. Using the modified Bernoulli equation ($\Delta P = 4v^2$), the peak and mean gradients across the aortic valve can be calculated from the velocity (v) CW Doppler signal. An excellent correlation was observed between invasive and Doppler measurements of mean gradient when both measurements were obtained simultaneously.[72] However, several technical requirements are needed, including parallel alignment of the ultrasound beam with aortic flow and the use of multiple imaging windows (apical, right parasternal, subcostal, and suprasternal). Patients with a mild degree of AS may develop increased velocity and gradient when the transvalvular flow rate is increased, whether because of AR or the development of a hyperdynamic state; however, in this case the valve area will reflect the mild severity. Likewise, patients with severe AS may have lower than expected gradients with significantly depressed EF, severe MR, severe RV dysfunction, severe TR, or intravascular volume depletion; again, in such cases, AV area is very useful to put the gradients in context of the stroke volume.[75]

Aortic valve area is calculated using the continuity equation. The underlying principle is that the amount of blood flow through the LVOT and aortic valve will be the same because they are in continuity.[71] Aortic valve area (in centimeters squared) is given by systolic flow through LVOT/time velocity integral (TVI) of AS signal by CW (LVOT diameter^2 × 0.785 × LVOT TVI/aortic TVI) (Fig. 8.27). The main source of error in this calculation is in the measurement of the LVOT diameter. However, when there is doubt, and in the absence of other significant valvular lesions, it is possible to use systolic flow through the RV outflow tract or diastolic mitral inflow in the numerator. Alternatively, LV stroke volume measured by 2D echocardiography (difference between end-diastolic and end-systolic volumes) may be used, provided adequate 2D images are present.

Some patients with severely depressed EF have only mildly or modestly elevated transvalvular gradients across the aortic valve, yet significant AS when the valve area is calculated (typically <1 cm^2). It is reasonable to proceed to low-dose (up to 20 μg/kg per minute) dobutamine echocardiography in these patients to assess not only LV contractile reserve but also the effect of increased transvalvular flow on the calculated aortic valve area.[73] Patients with a dobutamine-induced increase in aortic valve area (>1 cm^2) are unlikely to have real AS, but their reduced valve area is largely the result of reduced flow rate. On the other hand, when there is an increase in gradient but still a severely reduced aortic valve area, valvular surgery should be considered because LV function and clinical status are likely to improve after valve replacement.[74,75]

Evaluation of Mitral Stenosis

In patients with rheumatic mitral stenosis, 2D imaging shows the presence of valvular thickening and calcification along with abnormal leaflet mobility, such that there is doming of the anterior mitral leaflet along with reduced mobility of the posterior leaflet. Doming



• **Fig. 8.27** Assessment of aortic stenosis using the continuity equation. *Ao,* Aorta; *AVA,* aortic valve area; *LVOT,* left ventricular outflow tract diameter; *TVI,* time velocity integral; *Vel,* velocity.

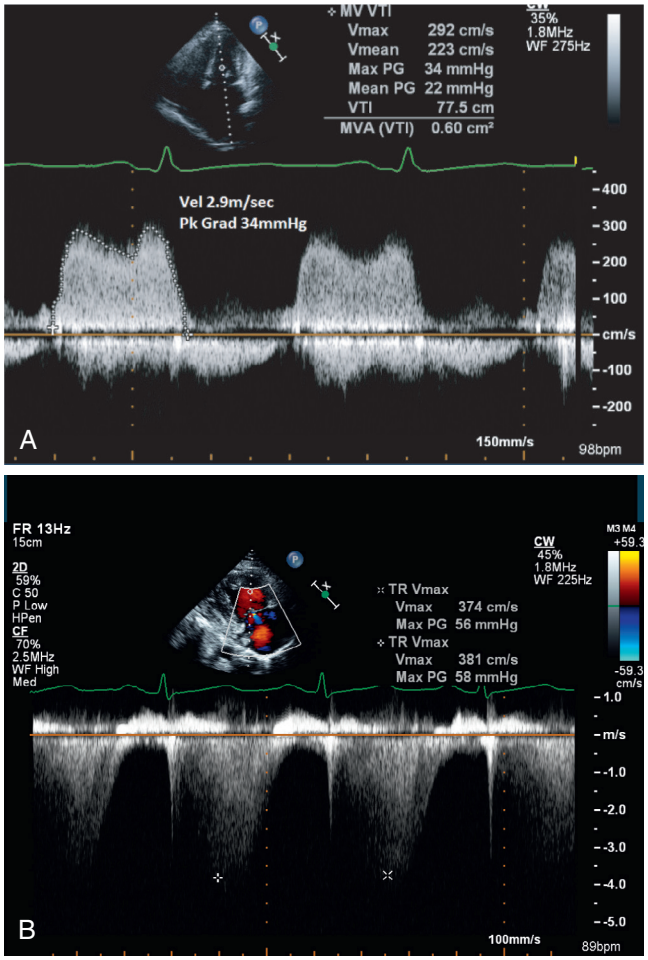
of leaflets occurs as a result of commissural fusion and produces the typical "hockey-stick" appearance of the valve when viewed in the parasternal long-axis and apical views (Fig. 8.28). Variable degrees of calcification, thickening, and subvalvular disease may be present. Direct planimetry of the mitral valve area is feasible in cases in which the mitral valve orifice is well visualized in the parasternal short-axis view. However, this measurement can be inaccurate when there is extensive calcification of valve leaflets, and when the short-axis plane is not positioned correctly at the level of valve tips. Spectral Doppler can provide reliable peak and mean transmitral pressure gradients and mitral valve area in most patients with mitral stenosis, as well as determining the hemodynamic impact on the right side of the heart with the development of pulmonary hypertension (Fig. 8.29). Doppler-derived gradients have been shown to have excellent reproducibility and accuracy when compared to the simultaneously obtained LA-LV pressure gradient by cardiac catheterization. However, the transmitral pressure gradient is dependent on many variables other than the valve area. Therefore the mean gradient can be increased with high transvalvular flow (whether because of a hyperdynamic flow state or MR), or short RR interval, even though mitral stenosis is only of a mild degree.

Mitral valve area is most easily calculated by Doppler, using the pressure half-time method. This method was originally conceived in the cardiac catheterization laboratory.[76] The severity of the stenosis is judged based on the time needed for the transmitral pressure gradient to decrease by 50% from its initial value in early diastole. This time increases with the severity of the stenosis, and mitral



• **Fig. 8.29** A, Continuous wave Doppler across stenotic mitral valve, demonstrating peak/mean gradients of 34/22 and a valve area of 0.6 cm^2. B, Continuous wave Doppler of tricuspid regurgitation in same patient demonstrating gradient of 56 mm Hg, c/w elevation of pulmonary pressures.

valve area (in centimeters squared) can be derived as 220/pressure half-time (in milliseconds). Although simple and highly reproducible, its accuracy is limited in patients with abnormal LA or LV compliance and in those with significant AR.[77] The continuity equation is an additional method that is applicable in cases without significant AR and MR. In this method, the mitral valve area is calculated by systolic flow through the LVOT/TVI of the mitral stenosis jet by CW.

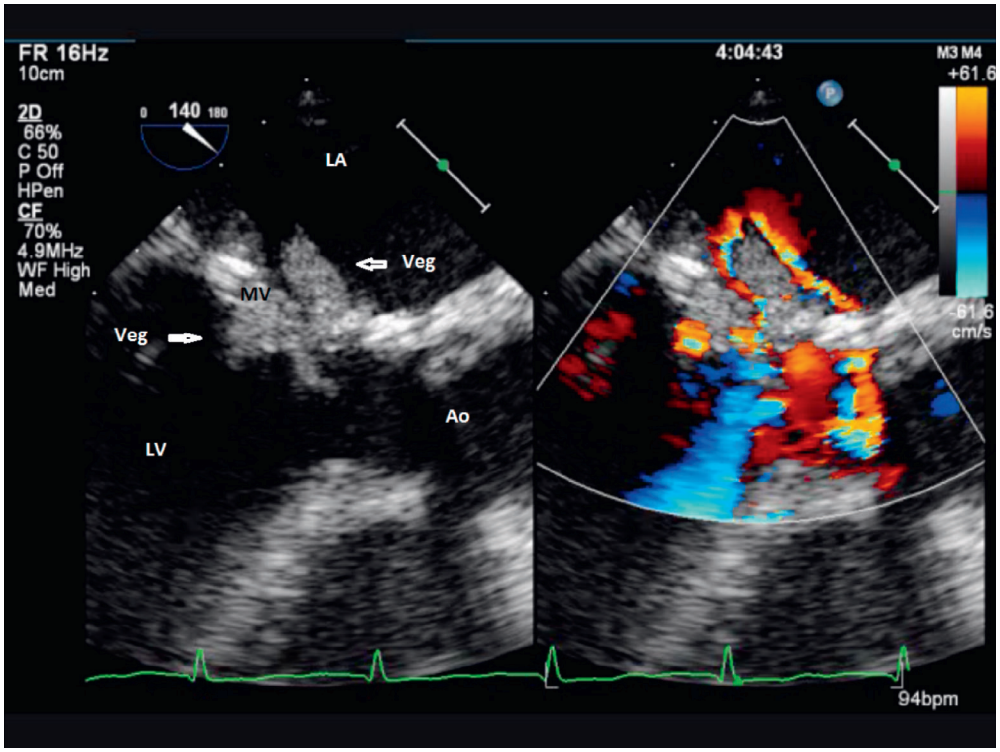
Evaluation of Prosthetic Valves

Echocardiography is the test of choice to assess prosthetic valve function.[78–80] From transthoracic windows, it is possible to identify the type of prosthetic valve, whether tissue or mechanical, the latter producing significant prosthetic echo artifact (Figs. 8.30 and 8.31). In some cases, large vegetations (Fig. 8.32) or thrombi may be visualized. However, in many situations of suspected prosthetic valve disease, TEE is needed because TTE images, especially with mechanical valves, can be obscured by echo artifact. Reliable recording of transvalvular gradients is possible by Doppler in almost all cases, provided the ultrasound beam is parallel to the direction of flow. Prosthetic valve gradients should be interpreted with the knowledge of the valve type, size, and position, as values vary depending on these variables (Table 8.5). Furthermore, consideration should be given to stroke volume/ventricular function/heart rate when conclusions are drawn about prosthetic valve function. It is very useful to compare Doppler-derived gradients to previous results (taking into consideration both flow and heart rates) in detecting

TABLE 8.5 Normal Doppler Values in Patients With Prosthetic Valves

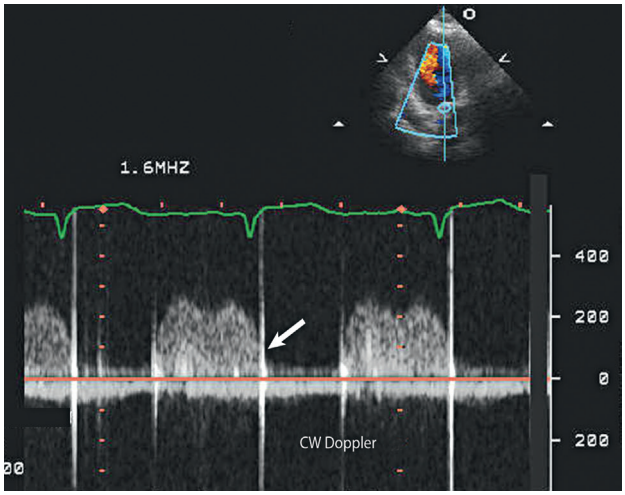
Valve Type	Peak Velocity	Mean Gradient	Doppler Velocity Index
Aortic	≤3 m/s[a]	≤25 mm Hg[a]	≥0.30
Mitral	<1.9 m/s[b]	≤5 mm Hg[b]	
Tricuspid	<1.5 m/s[b]	≤3 mm Hg[b]	
Pulmonary	≤3 m/s[a]	≤25 mm Hg[a]	≥0.30

[a]Assuming normal stroke volume/ventricular function.
[b]Assuming normal heart rate (50–70 beats/min).



• **Fig. 8.32** Transesophageal echocardiography image of a bioprosthetic mitral valve with multiple large vegetations (*arrows* in left panel). *Right,* significant incompetence by color Doppler through and around the valve apparatus. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *MV,* mitral valve; *Veg,* vegetations.

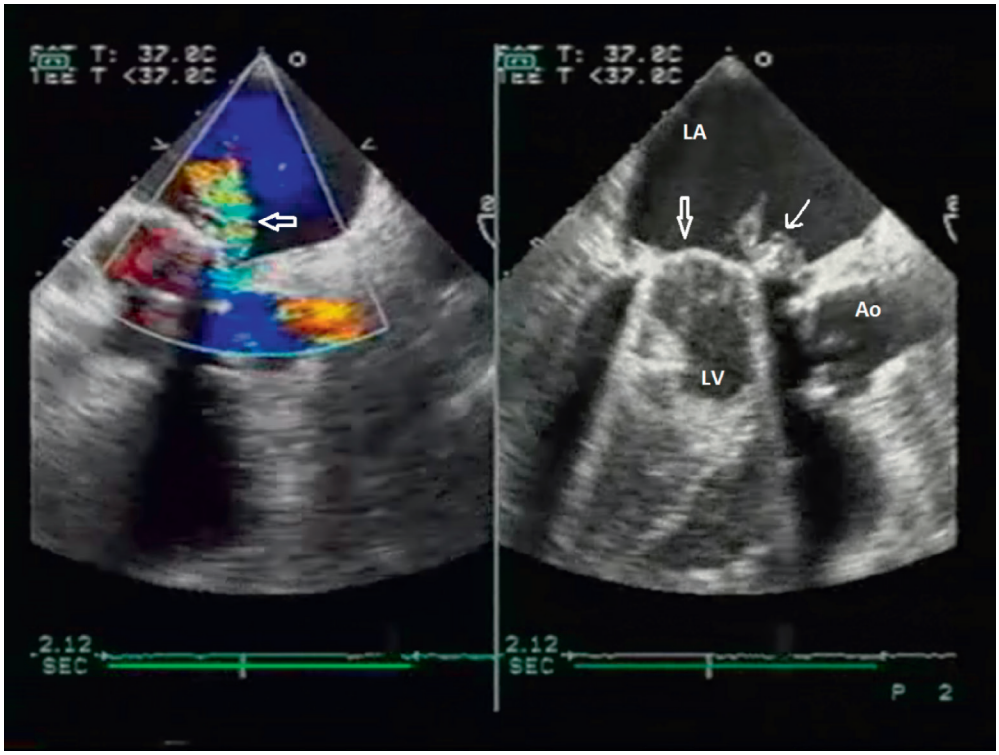
possible changes in prosthetic valve function over time. For prosthetic aortic valves, the Doppler velocity index is calculated as peak velocity in LVOT/peak velocity across the valve by CW Doppler. Patients with normal function have a ratio that is 0.25 or greater. This ratio is particularly helpful in patients with increased transvalvular flow rate leading to increased mean gradient, as they will also have an increased flow velocity in the LVOT and therefore a normal Doppler velocity index.[81] Prosthetic mitral valves are best assessed by mean gradient, taking into account heart rate, as the faster the heart rate, the higher the gradient. In general, a mean prosthetic mitral gradient at a heart rate of 60 to 70 beats/min should be less than 5 mm Hg in a normally functioning mitral prosthesis (Fig. 8.33). When there is doubt about structural or functional abnormalities of prosthetic valves, TEE should be considered. Complications of prosthetic valve endocarditis such as abscess are readily assessed by TEE (Fig. 8.34). A pannus or thrombus may result in reduced or absent leaflet motion and prosthetic valve stenosis. Depending on the thrombus burden and the clinical status of a given patient, TTE and TEE may be used to guide and follow the response to intravenous thrombolytic therapy. Although the severity and cause of prosthetic valve regurgitation may not be easily determined by TTE because of acoustic shadowing, TEE is extremely useful in evaluating the degree of regurgitation and in identifying the site of origin and direction of perivalvular leaks. Unlike prosthetic mitral valves, adequate visualization and Doppler interrogation of mechanical prosthetic aortic valves can be challenging by TEE. Therefore if doubt remains, one should consider biplane fluoroscopy to assess the mobility of aortic valve discs. Normal Doppler values for prosthetic valves in the aortic, mitral, tricuspid, and pulmonary positions are shown in Table 8.5.



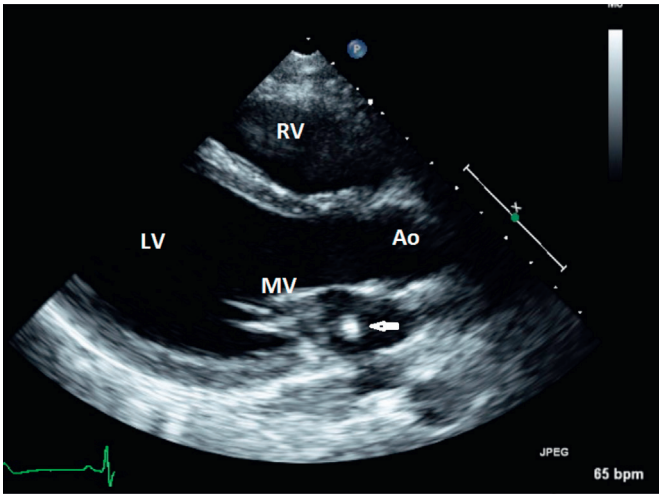
• **Fig. 8.33** Continuous wave Doppler image of an obstructed mechanical mitral valve prosthesis. Peak velocity 2.5 m/sec; time velocity integral, 80 cm; mean gradient, 18 mm Hg; heart rate, 93 beats/min. The *arrow* indicates mitral closing click.

Infective Endocarditis

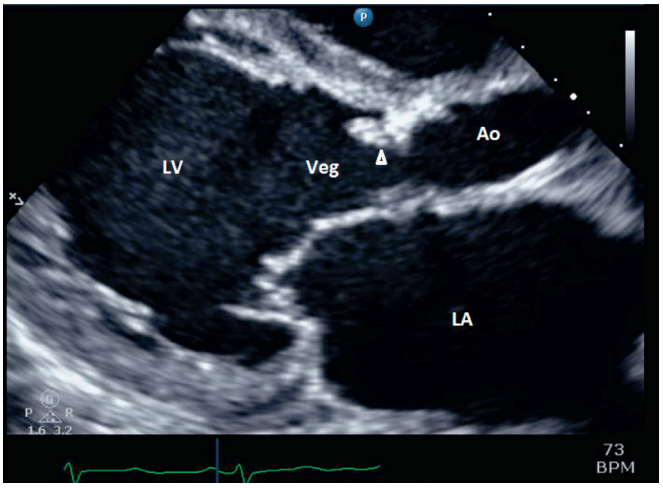
Echocardiography is particularly well suited to the evaluation of IE and is the technique of choice for the diagnosis and subsequent monitoring and management of patients with IE. Echocardiography should be used to (1) visualize the location, size, and morphology and motion of vegetations (Figs. 8.35 through 8.37); (2) define the structural integrity of the infected valve and identify any coincidental valve disease; (3) define ventricular size and function;



• **Fig. 8.34** Mechanical mitral prosthesis (*solid arrow* on right) with large prolapsing vegetation *(arrows)*. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle.



• **Fig. 8.35** Long-axis view of large prolapsing mitral valve vegetation *(arrow). Ao,* Aorta; *LV,* left ventricle; *MV,* mitral valve; *RV,* right ventricle.



• **Fig. 8.36** Long-axis view of aortic valve vegetation *(arrowhead). Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *Veg,* vegetation.

(4) determine any extension of the infectious process, including abscesses, pseudoaneurysms, leaflet perforation, and pericardial effusion; and (5) offer prognostic information. TEE may be performed when the index for IE is high but TTE is negative and should be performed in the setting of known aortic endocarditis to assess for root abscess and extension of the infectious process to surrounding tissue. Persisting or worsening heart failure, persistent uncontrolled infection despite appropriate antibiotics, and multiple embolizations despite antibiotic therapy are indications for surgery in the active phase of the disease (Videos 8.45 through 8.48).[82]

Pericardial Disease

The detection of pericardial effusion generated much of the early interest in ultrasound as a useful cardiac diagnostic tool.[83] Today, echocardiography is routinely used to diagnose and manage pericardial disease. Pericardial effusion, tamponade, and, to a lesser extent, pericardial constriction, can be readily and reliably assessed with echocardiography.

Echocardiographic findings of pericardial effusion include an echo-free space adjacent to the heart in the absence of pericardial

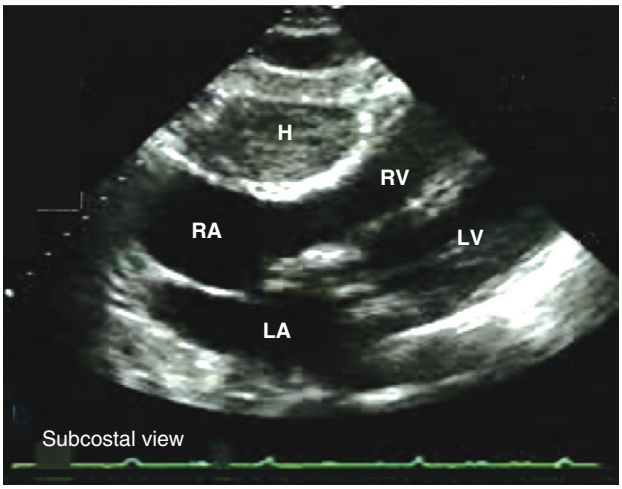
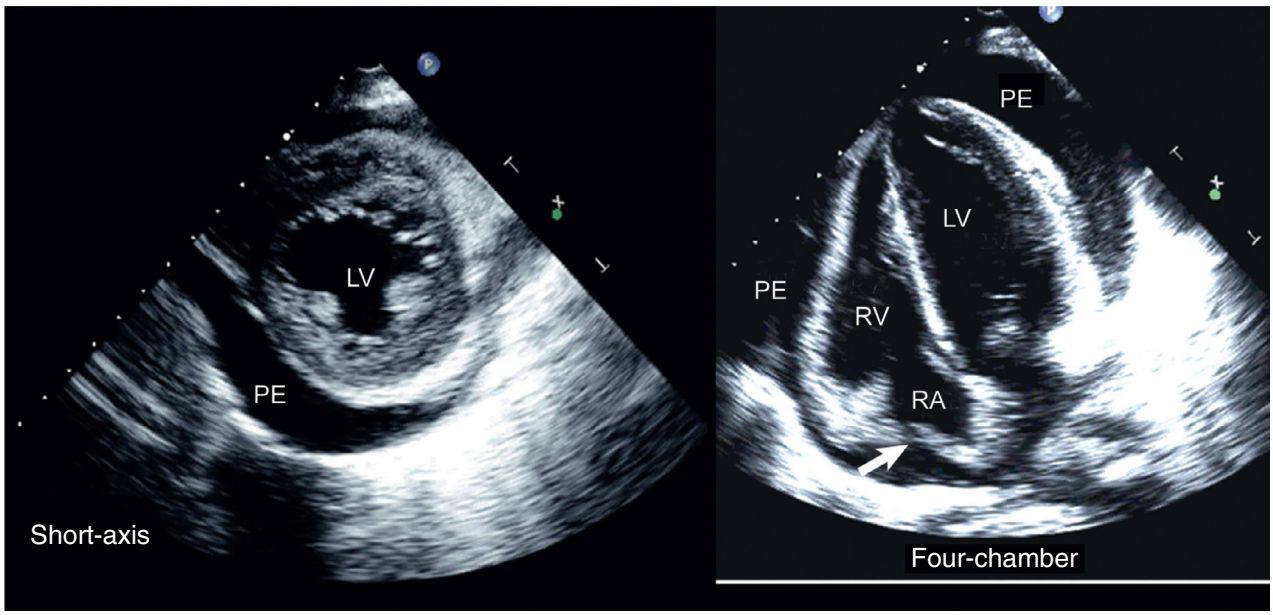
motion (Fig. 8.38). Effusions are termed small, moderate, and large (Fig. 8.39) based on the visually estimated volume of fluid and its location (posterior only or circumferential). The subcostal view is particularly useful for identifying pericardial effusions (Fig. 8.40). Large effusions may occasionally result in "swinging" of the heart within the pericardial space, a phenomenon that correlates with the electrical alternans noted on the ECG.[84] Loculated pericardial effusions are seen in patients after cardiac surgery and in patients who sustain chest trauma. In these circumstances, the effusion is localized to a single area of the pericardial space. It is important to note that rapid development of a small volume of fluid in a critical location may quickly result in hemodynamic compromise. Localized hematoma in patients after cardiac surgery, percutaneous intervention, electrophysiology study, or trauma can create a compressive effect that compromises cardiac hemodynamics (Fig. 8.41).

Pericardial tamponade occurs when, in the presence of fluid accumulating in the pericardial space, the pressure in the pericardium exceeds the pressure in the cardiac chambers, resulting in impaired

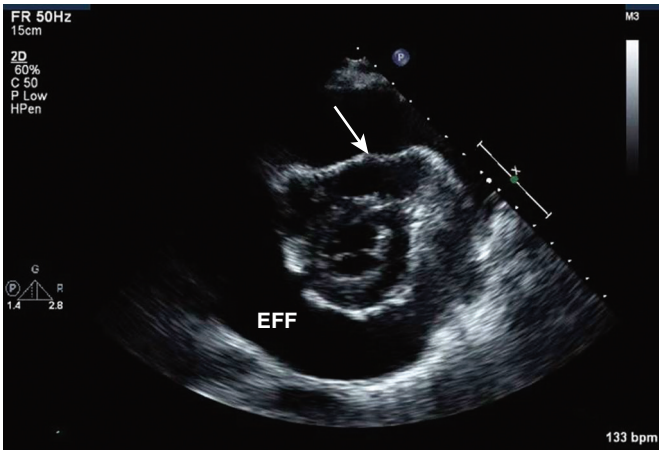


• **Fig. 8.41** Subcostal view of intrapericardial hematoma *(H). LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.



• **Fig. 8.42** Left ventricle short-axis view (A) of large circumferential pericardial effusion *(PE).* Apical four-chamber view (B) demonstrating right atrial collapse *(arrow)* and circumferential effusion. *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

filling and reduction of stroke volume and cardiac output, eventuating tachycardia, hypotension, and jugular venous distention.[85] The physiologic consequences depend on the amount of fluid, the rate of accumulation, the distensibility of the pericardium, and the compliance of cardiac chambers.[85] Tamponade may result from accumulation of fluid, pus, blood, clots, or gas within the pericardium. There are several echocardiographic features of pericardial tamponade. Pericardial effusion, usually at least moderate in volume, must be present (unless acute as described earlier). As the pressure within the pericardium increases, cardiac chamber collapse will ensue.[86] Impairment of filling is sequential: the atria will collapse before the higher-pressure ventricles.[86] The compressive effect of fluid is seen when the pressure is lowest in the chamber; RA collapse begins in late ventricular diastole (before or at the P wave) and should persist through at least one-third of ventricular systole (Fig. 8.42). RA collapse occurs early in the course of tamponade but is a less specific marker than collapse of the right ventricle because the thin-walled right atrium can invert in the absence of tamponade when there is intravascular volume depletion. RV collapse occurs in early diastole.[86] This finding will manifest later in the continuum but is more specific for significant hemodynamic compromise.[86] RV collapse is best appreciated when the ultrasound beam is perpendicular to the RV outflow tract from subcostal or parasternal views (Fig. 8.43). Timing of the onset and duration of RV collapse can be appreciated with M-mode (Fig. 8.44). Right-sided chamber collapse may be absent when tamponade occurs in the setting of severely elevated right-sided filling pressures (pulmonary hypertension).[85] When the effusion is loculated behind the left ventricle in the setting of reduced LV volumes, as might be seen in postoperative patients, diastolic collapse of the LV may be the only indicator of hemodynamic compromise. A dilated IVC that does not change dimension with respiration is also consistent with elevated intrapericardial pressures (Fig. 8.45), although this finding is nonspecific in intubated patients owing to positive intrathoracic pressures.



• **Fig. 8.43** Short-axis view of the left ventricle demonstrating large circumferential effusion with right ventricular collapse *(arrow). EFF,* Effusion.

Reciprocal respiratory changes in RV and LV volumes become evident in tamponade, and increased right heart filling occurs at the expense of left heart filling in a process mediated by the pericardium. RV volume increases with inspiration, shifting the septum toward the left ventricle in diastole and toward the right ventricle in systole. RV volume decreases with expiration, normalizing septal motion as LV filling increases (Figs. 8.46 to 8.48). These findings correspond to the clinical finding of pulsus paradoxus. Transvalvular Doppler flow velocities demonstrate respirophasic changes in tamponade as well.[87] Initial transmitral velocities are enhanced with expiration and diminished (>25%) with inspiration in tamponade; transtricuspid flow augments with inspiration and diminishes with expiration (Figs. 8.49 and 8.50). Correspondingly, the RV outflow TVI increases with inspiration while the LV outflow TVI decreases. These are useful findings but can be difficult to demonstrate with precision in the acutely ill patient.

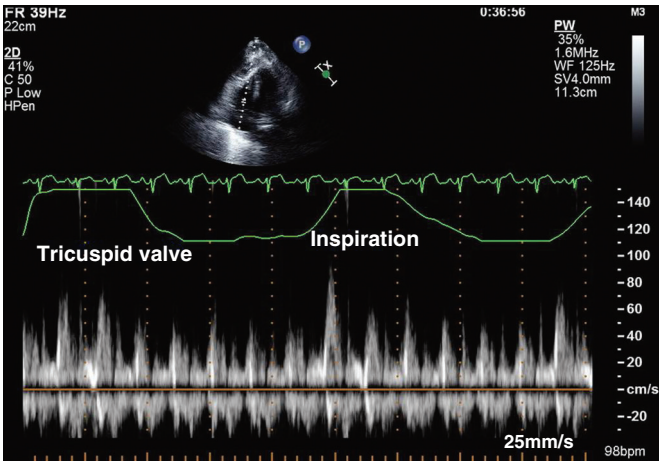
Echocardiography has been used to guide the percutaneous drainage of pericardial fluid.[88] Subcostal imaging is valuable in demonstrating the amount of inferior fluid in the typical location accessed by the subxiphoid needle approach, as well as determining the optimal site of puncture. Imaging from the cardiac apex in patients with large circumferential effusions can aid in determining needle position and guide advancement, although identifying the needle tip can occasionally be problematic. Once needle position is deemed appropriate and initial aspirate is obtained, an injection of a small amount of agitated saline solution confirms correct needle position within the pericardium[88] (Fig. 8.51).

Constrictive physiology is present when the visceral and parietal layers of the pericardium become adherent and fibrotic, resulting in marked impairment of LV filling. Chronic constrictive pericarditis is usually not associated with free pericardial fluid. The echocardiographic findings in constriction include a thickened pericardium (pericardial thickening may not be uniform); normal LV size with LA dilatation; abrupt termination of ventricular filling in early diastole (best seen on M-mode); respiratory-related interventricular septal motion demonstrating a diastolic inward "bounce" in early diastole; and dilatation of the IVC. In addition, there is Doppler flow evidence of ventricular interaction with exaggerated respirophasic changes in transvalvular velocities (Figs. 8.46 to 8.48, 8.52, and 8.53). TDI is of significant value in the assessment of pericardial constriction. Typically lateral tissue Doppler velocities are higher than medial velocities. In constrictive physiology, the medial mitral annular velocities are greater than the lateral velocities because lateral expansion in CP is limited; this is a phenomenon known as "annulus reversus."[89] These observations are also valuable in distinguishing pericardial constraint from myocardial restraint; in restrictive physiology, both medial and lateral tissue Doppler velocities are less than or equal to 8 cm/sec (Videos 8.49 through 8.71).[89,90]

Aortic Disease

Although TEE is the preferred echocardiographic method for evaluating the aorta, transthoracic imaging can define aneurysmal



• **Fig. 8.50** Doppler inflow of tricuspid valve in tamponade. Note respirometer.

changes of the proximal ascending aorta and can occasionally identify an intimal flap from aortic dissection (Fig. 8.54) (Videos 8.72 through 8.74), either from the parasternal views or from the suprasternal notch. In addition, in the setting of proximal dissection, TTE can evaluate the integrity of the aortic valve and quantify the degree of AR, recognize any LV wall motion abnormalities, and identify any associated pericardial effusion. It is important to note that, as seen in aortic aneurysms, patients with dissection very often have significant aortic dilation; thus lack of aortic dilation may argue against dissection. However, overall, the sensitivity of TTE for the diagnosis of dissection in the aortic arch and descending aorta is low, and TEE (and/or computed tomography) is often indicated. The close proximity of the esophagus to the aorta makes TEE a preferred modality for the evaluation of aortic dissection, with both sensitivity and specificity of 98%.[91–94] The ascending aorta, aortic arch, and descending thoracic aorta can be visualized with excellent resolution. TEE can be performed rapidly and safely at the bedside. Common features of dissection on TEE imaging include the following:

- An intimal flap that moves toward the false lumen in systole (Fig. 8.55)
- Color Doppler flow in both the true and the false lumens
- Color flow identification of entry/exit sites
- Stasis or thrombosis within the false lumen
- Intramural hematoma (IMH)

IMH, originally described as bleeding into the outer layers of the aortic media owing to rupture of the vaso vasorum without a primary tear, appears as crescentic thickening of the aortic wall greater than 0.7 cm in the absence of a frank dissection flap

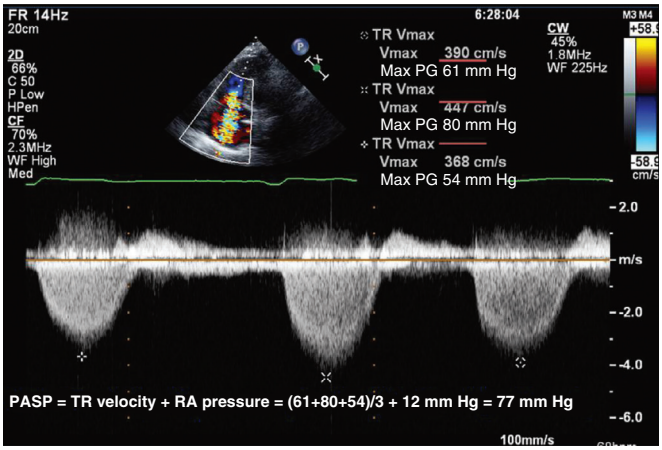
(Fig. 8.56).[95] Considered a variant of overt aortic dissection, IMH is an important diagnosis to make, as data suggest IMH is a lethal condition when it involves the ascending aorta, and 16% of patients with IMH have evidence of evolution to classic aortic dissection on serial imaging.[95]

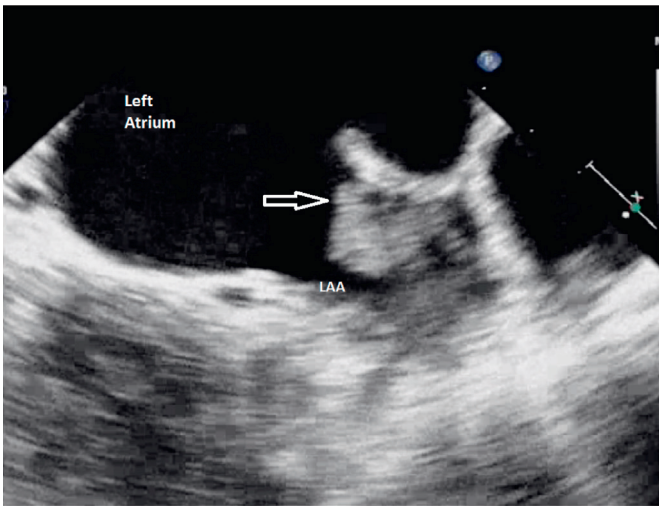
Hemodynamic Assessment

It is possible to calculate blood flow at several levels in the heart and aorta using Doppler echocardiography.[96] Such measurements of flow can be very useful in the ICU setting to derive LV stroke volume, cardiac output, regurgitant volumes, and the response to therapeutic measures such as intravenous administration of inotropic drugs or the effect of an intraaortic balloon pump on systemic output. Stroke volume in milliliters (or cubic centimeters) is calculated as the product of the cross-sectional area (in centimeters squared) of the LVOT and the TVI (in centimeters) by PW Doppler (Fig. 8.57) at this site.[96,96a] Cardiac output can then be calculated as the product of stroke volume and heart rate. A number of studies have shown good accuracy of Doppler echocardiography when compared with measurements derived by thermodilution, including data obtained from patients in the ICU. Doppler-derived stroke volume can provide important clues in situations of reduced output (whether caused by volume depletion or LV systolic dysfunction) as well as cases of high-output states such as sepsis and liver failure.

Peak PA systolic pressure is calculated from the peak Doppler velocity (v) of TR by CW (Fig. 8.58). Using the modified Bernoulli equation, the peak systolic gradient (ΔP) in millimeters of mercury between the right ventricle and the right atrium is given by $4v^2$ (where v is in meters per second). An estimate of RA pressure is then added to ΔP to estimate peak RV systolic pressure, and in the absence of pulmonary stenosis, peak PA systolic pressure.[97] RA pressure can be estimated from the change in IVC diameter with spontaneous breathing, as recorded from subcostal views. Normal collapse of the IVC with breathing (>50%) implies normal RA pressure (0–5 mm Hg); partial collapse (<50%) is generally estimated at 5 to 10 mm Hg, whereas no (or only minimal) change



• **Fig. 8.58** Method for calculation of right ventricular systolic pressure (see text). *PASP,* Pulmonary artery systolic pressure; *RA,* right atrial; *TR,* tricuspid regurgitant velocity.

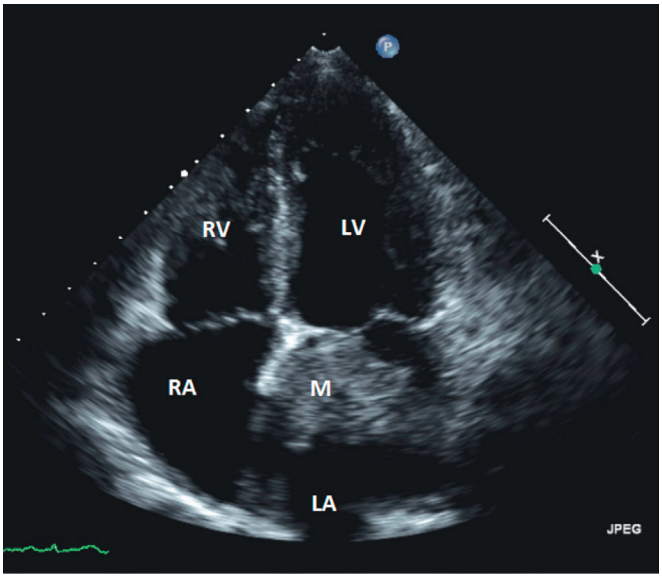


• **Fig. 8.59** Transesophageal image of a thrombus *(arrow)* in the left atrial appendage *(LAA).*

in IVC diameter implies an RA pressure of 15 mm Hg or more. When available, RA pressure should be obtained directly from a central venous pressure tracing.

Stroke and Other Systemic Emboli

Between 17% and 25% of all strokes are cardioembolic in origin.[98] Echocardiography is commonly used to search for potential cardiac sources of arterial emboli, the most common of which are LA appendage thrombus (Fig. 8.59), LA masses (Fig. 8.60, Video 8.75), valvular vegetations, atheromatous disease of the aorta (see Fig. 8.61, Videos 8.76 and 8.77), LV thrombus (see Fig. 8.11), and PFO with/without atrial septal aneurysm (see Fig. 8.3).[98,99] Atrial fibrillation predisposes to thrombus formation in the body of the left atrium and in the LA appendage, and TEE is necessary to assess the entire left atrium and the LA appendage, which is the most common site of thrombus formation in atrial fibrillation.[100,101] A significant association exists between aortic atheroma and stroke.[102] TEE reliably identifies aortic debris and can determine location, morphologic characteristics, and mobility of identified lesions (see Fig. 8.61).[98,102] The most common disorders associated with stroke identified by echocardiography are listed in Box 8.3.



• **Fig. 8.60** Apical four-chamber view of left atrial myxoma *(M). LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle;

• BOX 8.3 Echocardiographic Evaluation of Cardiac Source of Embolus

Intracardiac thrombus
- Ventricular (apex)
- Atrial (body of left atrium, left atrial appendage)
- Prosthetic material (valves, monitoring lines, pacer wires)
- Spontaneous contrast

Valvular vegetations
Patent foramen ovale/atrial septal defect
Atrial septal aneurysm
Intracardiac tumors
- Primary (myxoma, fibroelastoma)
- Metastatic (lung, breast)

Mitral valve prolapse
Mitral annular calcification
Aortic annular calcium
Atheromatous debris of the aorta

Summary

Echocardiography with Doppler is a vital tool in the assessment of patients in critical care. Ventricular function and complications of myocardial infarction can be determined; the presence and significance of pericardial effusion can be assessed; hemodynamically significant valve disease can be quantified; the presence and extent of infective endocarditis can be assessed; fundamental intracardiac hemodynamics can be calculated; cardiac complications of trauma can be noted; potential cardiac causes of stroke can be determined; and the assessment of aortic disease can reliably be accomplished. When TTE does not produce diagnostic images or when pertinent clinical questions remain unanswered, TEE can readily provide additional morphologic and hemodynamic information that can affect patient management and outcome in the critical care setting.

Key Points

- Echocardiography is an invaluable noninvasive tool for the detection of cardiovascular abnormalities in the critical care setting.
- TEE should be used to provide more detailed or more comprehensive information when transthoracic images are inadequate. TEE may be considered for the evaluation of the aorta, for the assessment of native and prosthetic valves, and for the evaluation of intracardiac shunting. Three-dimensional imaging may provide additional structural information.
- Commercially available contrast agents for LVO can now salvage many otherwise uninterpretable transthoracic studies.
- Echocardiography offers a number of reasonably accurate methods to assess global LV systolic properties, including EF using 2D imaging and tissue Doppler imaging. Stroke volume and cardiac output can also be reliably determined in most patients by echo-Doppler.
- Echocardiography now offers numerous methods to determine LV filling pressures with reasonable accuracy. A reliable assessment of LV dimensions and EF, when combined with knowledge of filling pressures, can be used to guide and assess the response to therapeutic measures.
- PA systolic and diastolic pressures can be calculated with confidence in many patients in the critical care setting.
- Mechanical complications of myocardial infarction, including acute MR, ventricular septal defect, pseudoaneurysm formation, and LV thrombus, are readily evaluated with echocardiography.
- Although the echocardiographic assessment of the right ventricle is still challenging because of its complex shape, it is possible to integrate information from multiple views to reach reasonably accurate conclusions regarding RV size and function, particularly in the setting of RV pressure or volume overload, and acute pulmonary embolus.
- Echocardiography is particularly well suited to the evaluation of cardiac valve anatomy, morphology, and motion. The integration of 2D anatomy with spectral and color Doppler methods of quantifying obstructive and regurgitant lesions provides a comprehensive assessment of valvular disease. TEE may be needed to evaluate prosthetic valves and approaches to surgical repair. Three-dimensional imaging offers great insight into the mechanism of valve dysfunction.
- Pericardial effusion can be localized and quantified, and its hemodynamic impact can be assessed, with thoughtful application of imaging and Doppler techniques. In the setting of trauma and the cardiac surgical postoperative state, opportunistic loculated effusions must be identified.

Review Questions

1. Goal-directed (focused) echocardiography
- **a.** Should provide a comprehensive assessment of both left- and right-sided intracardiac hemodynamics
- **b.** Should determine the morphology and motion of cardiac valves
- **c.** Should provide assessment relevant to the immediate clinical situation
- **d.** Can with confidence determine patients who will benefit from intervention after an acute pulmonary embolus

Answer: c. Goal-directed two-dimensional (2D) imaging (FOCUS) is typically limited to the assessment of biventricular size and function, the presence or absence of pericardial effusion, and to the evaluation of volume status—that is, a study done to provide assessment relevant to the immediate clinical situation. A focused 2D study done by a trained individual with a handheld device has great potential for rapid triage of select patients in the emergency room or the intensive care area.[14–17] It is important to emphasize that unclear or ambiguous findings on handheld examination should be followed by a complete study on a full echocardiographic platform to obtain an accurate and comprehensive diagnosis

2. Takotsubo syndrome (or cardiomyopathy)
- **a.** Only occurs in women older than 50 years of age
- **b.** Will only manifest as an apical "ballooning" appearance on echocardiography and angiography
- **c.** Will demonstrate reversal of wall motion abnormalities, typically within 3 months
- **d.** Will demonstrate increased survival with beta blockade use while in the hospital

Answer: c. In the early experience, it was most commonly found in women older than 50 years of age, occurred after an emotional or physical stressor, and presented with ST-segment elevation and an apical ballooning left ventricular (LV) contraction abnormality. It is now recognized to be more clinically varied, identified in men and younger individuals, and importantly, diverse LV contraction patterns beyond the classic apical ballooning pattern (75%–80%) are now recognized, including midventricular ballooning (10%–20%) and basal segment ballooning (inverted ballooning; uncommon and occurring in only 1%–2%).[52,53] It can present during diagnostic procedures or during hospitalization for acute illness, and recent evidence suggests an association with sepsis. Although no single feature distinguishes Takotsubo syndrome from other conditions with a similar acute presentation, characteristic symptoms include chest pain, ischemic ECG changes with a troponin elevation, and an LV wall motion abnormality in a segment being supplied by a normal coronary artery. *Reversibility* of LV wall motion abnormalities is expected within 3 months. Hemodynamic instability requiring intervention with vasopressor agents or intraaortic balloon pumping occurs in up to 15% of patients, and in-hospital mortality is as high as 5%. The recurrence rate may be as high as 20%. Elevated catecholamine levels may be involved in Takotsubo pathophysiology. Current evidence does not suggest survival benefit with the use of β blockers in the hospital, although 1-year survival showed marginal improvement with the use of angiotensin-converting enzyme inhibitors.[54,55] A registry has been established (the International Takotsubo Registry) to improve diagnosis, treatment, and outcomes.[56]

3. Parameters of right ventricular function that *may* be associated with mortality in patients presenting with acute pulmonary embolus include all but which of the following?
- **a.** Right ventricular/left ventricular end-diastolic diameter ratio
- **b.** The "60/60" sign
- **c.** Normal pulmonary ejection acceleration time
- **d.** Right heart thrombus

Answer: c. Although it is true that as many as 70% of patients with proved pulmonary embolus (PE) have no significant echocardiographic abnormalities, recent data suggest that several parameters of right ventricular (RV) function are associated with mortality in patients presenting with acute PE.[65] These parameters include (1) the ratio of RV to left ventricular (LV) end-diastolic diameter (≥0.9); (2) RV systolic pressure derived from the tricuspid regurgitant jet velocity (≥50 mm Hg); (3) tricuspid annular plane systolic excursion (TAPSE) (<15 mm); and (4) inferior vena cava collapsibility.[64] Another study suggested that (1) the McConnell sign (hypokinesis of the RV free wall with normal contraction of the RV apex); (2) the 60/60 sign, which is the coexistence of a shortened pulmonary ejection acceleration time (AcT) (<60 msec) with midsystolic velocity deceleration ("notch") and a tricuspid regurgitation peak gradient <60 mm Hg; and (3) right heart thrombus were all strongly suggestive of pulmonary embolus.[65] Work by Dahhan et al. found an association of free wall global RV strain and the RV Tei index with mortality.[66,67] They did not find such a relationship between other measures, including TAPSE, RV size, and the RV/LV ratio; in fact, TAPSE, subjective RV dilation, and subjective RV dysfunction were not statistically different between survivors and nonsurvivors.[67] *All* studies agree, however, that there is a paucity of data from large clinical trials defining which echocardiographic parameters are actually useful in risk assessment in acute PE, and whether such parameters are of utility in identifying patients who might benefit from an intervention.

- Ventilator-Associated Events
- Gastrointestinal Bleeding
- Venous Thromboembolism

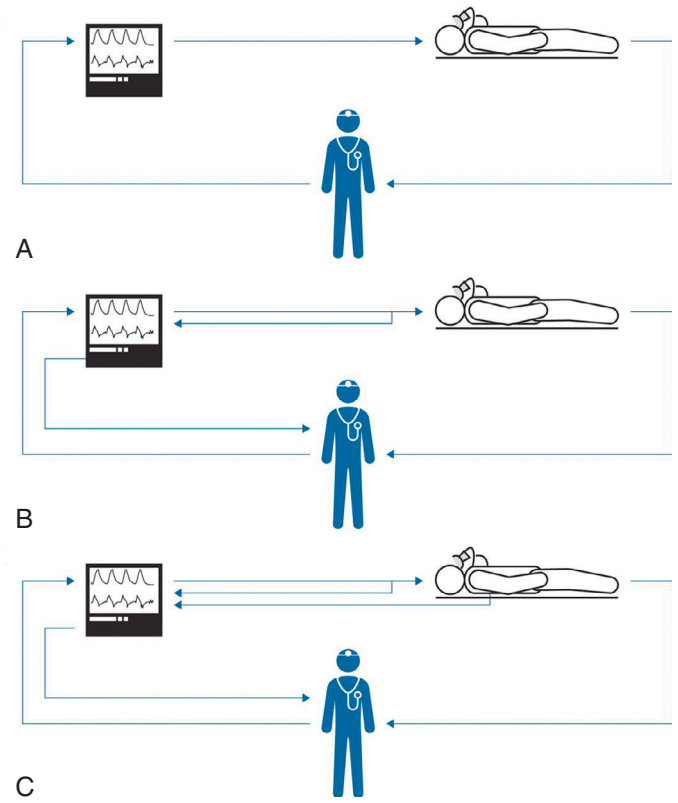
Noninvasive Positive-Pressure Ventilation
- High-Flow Nasal Cannula: A Potential Alternative to Mechanical Ventilation

The institution of mechanical ventilation can be a lifesaving measure. However, the mechanical ventilator also has potential for great harm and, in and of itself, does not reverse underlying disease. Limiting iatrogenic injury from ventilator-induced lung injury (VILI) should take high priority, along with acceptable levels of oxygenation and ventilation. The clinician should be aware of basic and advanced principles involving mechanical ventilation, allowing flexibility when applying evidence-based practices to the individual patient. Knowledge of guidelines and large clinical trials is vitally important, and the consideration of patient trajectory, individual physiology, timing of therapy, and severity of illness will make tailoring the ventilator prescription most effective.[1] The evolution of mechanical ventilation is fascinating (Fig. 9.1) with current newer modes often with complex computer interaction and automatic adjustments of ventilation parameters.[2] This chapter, which briefly discusses those modes, focuses on the traditional and still most frequently used modes of mechanical ventilation.

History

In 1530, Paracelsus (1493–1541) used a fire bellows connected to a tube inserted into a patient's mouth as a ventilator device.[3] The first known mechanical device designed specifically to provide ventilation for the patient was the foot pump developed by Fell and O'Dwyer in the 1880s.[4]

The first generation of mechanical ventilators focused primarily on the intermittent delivery of a bulk volume of gas to the patient with limited monitoring.[5] Negative-pressure ventilators were invented and applied a negative pressure around the body or chest



• **Fig. 9.1** Evolution of the concept of mechanical ventilation. A, The first mechanical ventilators were not equipped with sensors. B, Mechanical ventilators monitor all the ventilation parameters, allowing both closed-loop control of the generated waveform and providing information to the clinicians. C, Mechanical ventilators monitor the condition of the patients and automatically adjust the ventilatory parameters on the basis of patients' needs. (From Dellaca' RL, Veneroni C, Farre R. Trends in mechanical ventilation: are we ventilating our patients in the best possible way? *Breathe (Sheff).* 2017;13:85–98.)

cavity. Two classic devices that provided negative-pressure ventilation were the iron lung and the chest cuirass or chest shell.[6] Iron lungs were widely used during the poliomyelitis epidemics of the 1930s and 1940s. These devices encased the patient from the neck down and applied negative pressure around the patient to expand the lungs. The chest cuirass was intended to alleviate the problems of patient access and "tank shock" that occurred secondary to venous pooling during the application of negative pressure associated with iron lungs.[7] Although the chest cuirass improved patient access and decreased the potential for tank shock, ventilation with this device was limited by the difficulties in maintaining an airtight seal between the shell and the patient's chest wall.

After the polio epidemic of the 1960s, the era of respiratory intensive care emerged, as positive-pressure ventilation via an artificial airway became commonplace.[6] Controlled mechanical ventilation eventually led to assisted modes of support, and positive end-expiratory pressure (PEEP) was introduced in the late 1960s. The improvements in mechanical ventilators came about as understanding was gained in manipulating variables of flow and pressure for patient benefit. Further technical evolution of ventilators included advances such as intermittent mandatory ventilation and synchronous intermittent mandatory ventilation. Modern ventilators now boast microprocessors that serve both in the operating mechanism of the device and in the monitoring systems, enabling automatic adjustment of most aspects of the mechanical breath being delivered.

Mechanical Ventilation

Basic Concepts

For a breath to be generated, flow must exist. During normal spontaneous breathing, the diaphragm and other respiratory muscles create gas flow by lowering pleural, alveolar, and airway pressures relative to atmospheric pressure. Alveolar pressure is normally atmospheric at end-inspiration and end-expiration. Diaphragmatic and intercostal muscle activation during normal inspiration expands the chest and decreases intrapleural pressure from −5 cm H_2O to −8 cm H_2O. Alveolar pressure fluctuates from +1 cm H_2O during exhalation to −1 cm H_2O during inspiration.

A ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch occurs when areas of the lung are perfused but either poorly ventilated (low $\dot{V}/\dot{Q}$) or not ventilated at all (shunt). The latter is an intrapulmonary (IP) (capillary) shunt. Shunt may also be intracardiac (anatomic). Venous admixture, as a measure of less than fully oxygenated blood after passing through the lung, includes both low $\dot{V}/\dot{Q}$ areas of lung and IP shunt. Normal venous admixture is about 2% to 5%. Mechanical ventilation may increase the venous admixture to approximately 10% in the normal individual. Mechanical ventilation usually decreases venous admixture in alveolar lung disease, such as acute respiratory distress syndrome (ARDS), improving the distribution of ventilation, especially in previously underventilated lung areas. Pressures greater than alveolar opening and closing pressures expand the collapsed alveolus and prevent its collapse, respectively. However, if positive-pressure ventilation produces overdistention, redistribution of pulmonary blood flow to unventilated regions may occur, resulting in hypoxemia. *Dead space* refers to areas of the lung with a higher $\dot{V}/\dot{Q}$ ratio. *Anatomic dead space* is the volume of the conducting airways of the lungs, about 150 mL. *Alveolar dead space* refers to alveoli that are overventilated relative to perfusion; it is increased by any condition that reduces pulmonary blood flow, such as pulmonary embolism (PE) or with overdistention of the lung. *Mechanical dead space* refers to the rebreathed volume of the ventilator circuit; this volume behaves like an extension of the anatomic dead space. Mechanical ventilation can also increase dead space if it leads to overdistention.

An increased dead space fraction requires a greater minute ventilation to maintain alveolar ventilation and $PaCO_2$ (partial pressure of carbon dioxide in arterial blood). Hyperventilation lowers $PaCO_2$. Hypoventilation raises $PaCO_2$; a modest elevation (50–70 mm Hg) reduces pH and is usually not by itself injurious in the mechanically ventilated patient. It has become increasingly recognized that hypercapnia during mechanical ventilation is well tolerated and may not be harmful. An exception occurs in the presence of increased intracranial pressure.

Although modern ventilators have evolved into complex machines, the basic premise remains: a ventilator is designed to replace or augment a patient's muscles in performing the work of breathing.[8] Ventilators use input power (electricity or compressed gas) to ventilate the lungs. To generate a breath (whether it be spontaneous or positive pressure), a pressure gradient must be generated from the airway opening to the alveoli. The volumes delivered and pressures generated largely depend on the mechanical properties of the respiratory system: the lungs and chest wall as well as the abdomen.[8] Each of these components has mechanical properties that determine

the overall behavior of the respiratory system. Although the respiratory system can be quite complex, the main *variables* of interest are pressure, flow, and volume. The ventilator must generate a *pressure* to cause *flow* through an open circuit and therefore increase lung *volume*.[9] The pressure required to do this reflects a combination of the pressures to inflate the lung and chest wall. This can be illustrated by the equation of motion[9,10]:

$$\text{Musclepressure} + \text{Ventilatorpressure} = (\text{Elastance} \times \text{Volume}) + (\text{Resistance} \times \text{Flow})$$

Compliance describes the ease or difficulty of the respiratory system to expand in response to a delivered pressure and volume. Simplistically, compliance is defined by the change in volume (ΔV) divided by the change in pressure (ΔP), and the compliance of the respiratory system (C_{RS}) is $\Delta V/\Delta P_{alveolar}$. *Elastance* is the inverse of compliance, or the ratio of pressure change to volume change, and describes the tendency to recoil. *Resistance* describes the impedance to airflow through the respiratory system, or the ratio of pressure change to flow change. The *elastic load* is the pressure required to overcome the elastance of the respiratory system, and the *resistive load* is the pressure required to overcome flow resistance of the ventilator circuit, endotracheal tube (ET), and airways.[8]

The equation of motion illustrates several basic principles. To drive gas into the patient, a ventilator can directly control either the pressure or the flow and volume applied at the airway. Despite its complexity a ventilator is simply a machine controlling one of these two variables (*control* variables). For example, in pressure control and PSV, pressure is the control variable and is held constant, although flow and lung inflation vary based on the patient's respiratory mechanics and inspiratory time (I time) (the latter set directly in pressure control and patient influence with pressure support). In volume ventilation, flow is the control variable and pressure and lung inflation vary with the patient's respiratory mechanics. Flow and volume are intimately linked: volume (L) = flow (L/sec) × I time (sec).

The Ventilator Circuit

The ventilator circuit consists of plastic tubing connecting the artificial airway or mask with the mechanical ventilator. Within the circuit may reside humidifiers, devices for the delivery of aerosolized medications, filters, suction catheters for secretion clearance, and heated wires.[11] The length and compliance (2–3 cm^3/cm H_2O) of the ventilator circuit are responsible for a volume of gas contained within the circuit, termed the *compressible volume*. This is partly responsible for the discrepancy between the set tidal volume (VT) delivered and the expiratory volume measured and displayed by the ventilator. The ventilator circuit also adds resistance to the system, but it is minimal compared to either the patient's inherent mechanics or the ET. Although frequently colonized with bacterial pathogens, the routine change of the ventilator circuit for infection prevention (e.g., ventilator-associated pneumonia [VAP]) is not recommended.

In the body, inspired gases are conditioned in the airway just before the carina so that they are fully saturated with water at body temperature by the time they reach the alveoli (37°C, 100% relative humidity, 44 mg/L absolute humidity, 47 mm Hg water vapor pressure). This portion of the airway acts as a heat and moisture exchanger (HME). Under normal conditions, about 250 mL of water is lost from the lungs each day to humidify the inspired gases.

Gases delivered from mechanical ventilators are typically dry, and the upper airways of patients being ventilated are functionally bypassed by artificial airways, necessitating the use of an external humidifying apparatus in the breathing circuit. Because the upper airway is bypassed during mechanical ventilation, the inspired gas temperature should be kept close to the body temperature. Inspired gases that bypass the upper respiratory tract through ETs or tracheostomy tubes should be heated to at least 32°C to 34°C at 95% to 100% relative humidity. The temperature probe for the heated humidifier should be placed inside the inspiratory limb of the ventilator circuit as close to the patient as possible. Moisture loss and subsequent dehydration of the respiratory tract result in epithelial damage.

An HME, which is placed between the artificial airway and the ventilator circuit, may be used to replace the traditional heated humidifier. During exhalation, moisture and heat from the patient are absorbed into the honeycomb structure of the exchanger and are transferred back to the patient during the next inhalation. Ventilator circuits with bacterial-viral filtering HMEs cost less to maintain and are less likely to colonize bacteria than those with heated humidifiers.[12,13] Contraindications for use of an HME are thick or large amounts of secretions, minute volume exceeding 10 L/min, body temperature less than 32°C, and need for aerosolized medications.[14]

Alarms and Safety

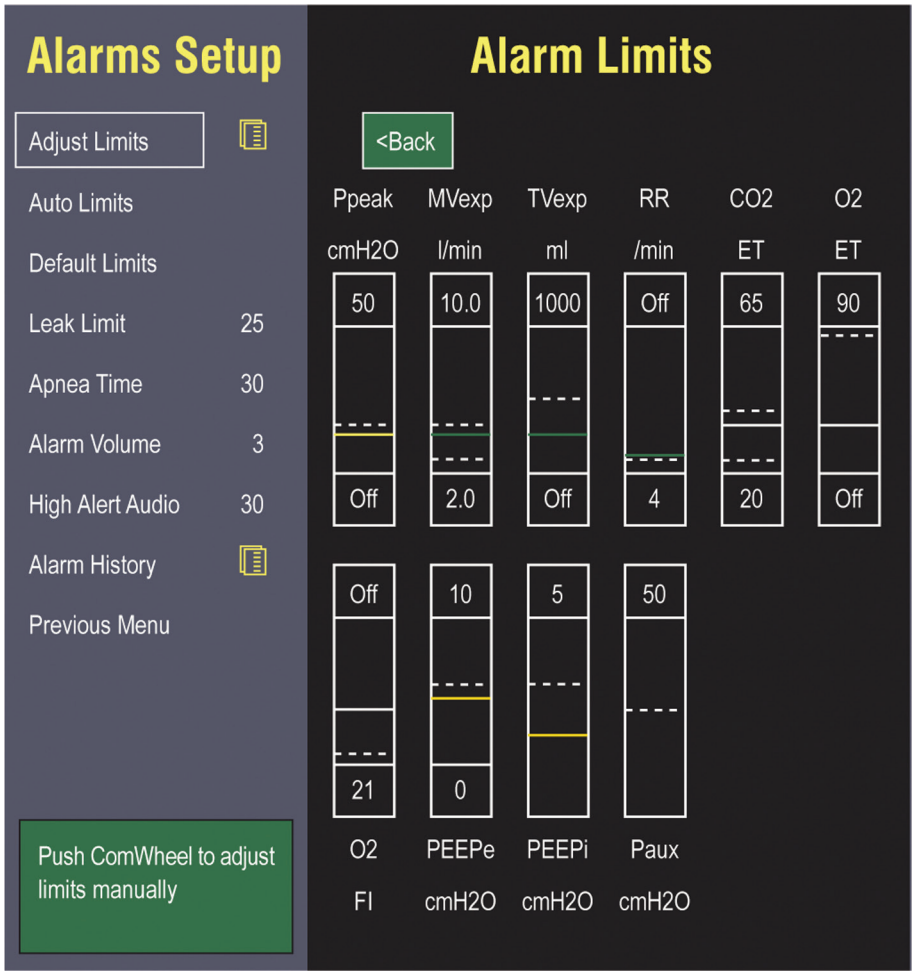
Current ventilators are equipped with monitors that constantly or periodically assess the ventilator's operation and the patient's status (Fig. 9.2). These monitors are usually associated with alarms that visually or audibly notify the operator of any variation from the preset norm. Ventilator alarms can warn of potentially life-threatening events, must have an appropriate level of sensitivity and specificity, and must be evaluated clinically and in a clinical context.[15] There are some alarms related to *power input* (e.g., low battery, loss of power, loss of air supply) and *control circuit* (e.g., nonfunctioning ventilator, incompatible settings), but most alarms are related to measured *output*, such as pressure, volume, and flow.[8]

High-pressure alarms are triggered by patient factors (such as decreased compliance and increased resistance of the respiratory system) or by ventilator circuit malfunction (obstruction or kinking of the ET). Low-pressure alarms are generally secondary to a leak in the system (ventilator circuit, ET or cuff) or patient (large pressure loss from a bronchopleural fistula). A high expired volume alarm could be seen with improved pulmonary mechanics during pressure-control ventilation. Low expired volume could be secondary to patient-ventilator disconnect or a leak in the system or patient. A high-frequency alarm is secondary to either autotriggering or hyperventilation, and a low-frequency alarm indicates bradypnea or apnea.[8,15]

Automatic Tube Compensation

Traditionally, most clinicians apply some amount of pressure support during inspiration to compensate for the increased work of breathing related to artificial airway resistance. The amount of pressure support needed to counterbalance this resistance is highly variable, depending not only on the internal diameter of the ET but also on flow, bend of the tube, and changing demands of the patient. This variability makes one level of pressure insufficient to meet these changing demands.[16]

Automatic tube compensation (ATC) compensates for ET resistance via closed-loop control of calculated tracheal pressure.



• **Fig. 9.2** The alarm panel of a Draeger Evita 4 ventilator showing the alarms typically used on current ventilators. (From Draeger Medical, Inc., Lübeck, Germany.)

A ventilator with ATC compensates for the pressure drop across the ET during inspiration by increasing the airway pressure and during expiration by decreasing airway pressure according to actual gas flow.[17–19] This technique uses a continuous calculation of the flow-dependent drop in pressure across the ET. ATC is similar to PSV, but the pressure applied by the ventilator varies as a function of ET resistance and flow demand. Most of the interest in ATC revolves around eliminating the imposed work of breathing during inspiration. During expiration, however, ATC may also compensate for that flow resistance by lowering the pressure in the expiratory limb transiently from its PEEP setting, helping reduce effective expiratory resistance and auto-PEEP.[17,20] In addition to overcoming the work of breathing imposed by the artificial airway, ATC may improve patient-ventilator synchrony by varying the flow commensurate with demand and may reduce air trapping by compensating for imposed expiratory resistance. During weaning trials, this technique may allow a more reliable prediction of patient performance when the tube is removed.

Indications for Mechanical Ventilation

Mechanical ventilation is instituted for a number of reasons (Table 9.1).[21] Most commonly, these indications are a combination of a failure to adequately oxygenate, ventilate, or meet the metabolic demands of a physiologically stressed patient. Clinical indicators, such as tachycardia, arrhythmias, hypertension, and tachypnea; use of accessory respiratory muscles; diaphoresis; and cyanosis, are used to diagnose respiratory distress. Type I respiratory failure is hypoxemic respiratory failure, defined as a partial pressure of oxygen in arterial blood (PaO_2) less than 60 mm Hg. Type II respiratory failure is hypercarbic respiratory failure, defined as $PaCO_2$ greater than 50 mm Hg, if elevated from patient baseline and associated with acidosis.[22] Blood pH is generally a better indicator than $PaCO_2$ for adjusting minute ventilation. Hypercapnia should not prompt aggressive intervention if pH remains acceptable and the patient remains alert. Hypercapnia is generally well tolerated, but this clearly depends on the underlying pathophysiology and comorbid conditions of the patient (e.g., right ventricular dysfunction). However, a sustained pH of 7.65 or greater or 7.10 or less is often considered sufficiently dangerous in itself to require control of minute ventilation by mechanical ventilation. Mechanical ventilation may also be instituted to maintain normal blood pH, decrease work of breathing, assist left ventricular function in the setting of acute decompensated heart failure, or for airway protection in the setting of toxic overdose, traumatic brain injury, or any other significant acute central nervous system illnesses. Box 9.1 suggests guidelines for setting basic operating parameters in a mechanical ventilator.

TABLE 9.1 Potential Indications for Mechanical Ventilation

Physiologic Mechanism	Clinical Assessment	Normal Range	Value(s)/Finding(s) Supporting Need for Mechanical Ventilation
Hypoxemia	$P(A\text{-}a)O_2$ gradient (mm Hg) PaO_2/FIO_2 ratio SaO_2	25–65 425–475 98%	>350 <300 <90% despite supplemental oxygen
Hypercarbia/inadequate alveolar ventilation	$PaCO_2$	35–45 mm Hg	Acute increase from patient's baseline pH <7.20 Mental status decline

• BOX 9.1 Guidelines for the Initiation of Mechanical Ventilation

1. Choose the ventilator mode with which you are most familiar. The primary goals of ventilatory support are adequate oxygenation/ventilation, reduced work of breathing, synchrony between the patient and ventilator, and avoidance of high end-inspiratory alveolar pressures.
2. The initial FIO_2 (fraction of inspired oxygen) value should be 1.0. The FIO_2 thereafter can be titrated downward to maintain the SpO_2 (oxyhemoglobin saturation) at 92% to 94%. In severe ARDS, >88% SpO_2 may be acceptable to minimize complications of mechanical ventilation.
3. Initial V_T should be 8–10 mL/kg. Patients with acute respiratory failure from neuromuscular disease often require V_T of 10–12 mL/kg to satisfy air hunger. In patients with ARDS, it is recommended to use a V_T of 6 mL/kg and to keep inspiratory plateau pressure 30 cm H_2O or less.
4. Choose a respiratory rate and minute ventilation appropriate for the particular clinical requirements. Target pH, not $PaCO_2$ (partial pressure of carbon dioxide). Initial respiratory rate is typically 10–12 breaths/min.
5. Use PEEP in diffuse lung injury to support oxygenation and reduce the FIO_2.
6. In patients with chronic obstructive pulmonary disease, avoid choosing settings that limit expiratory time and cause or worsen auto-PEEP.
7. When poor oxygenation, inadequate ventilation, or excessively high peak inspiration pressures are thought to be related to patient intolerance of ventilator settings and are not corrected by ventilator adjustment, consider initiating or increasing sedation or analgesia.

Mechanical Breath Generation

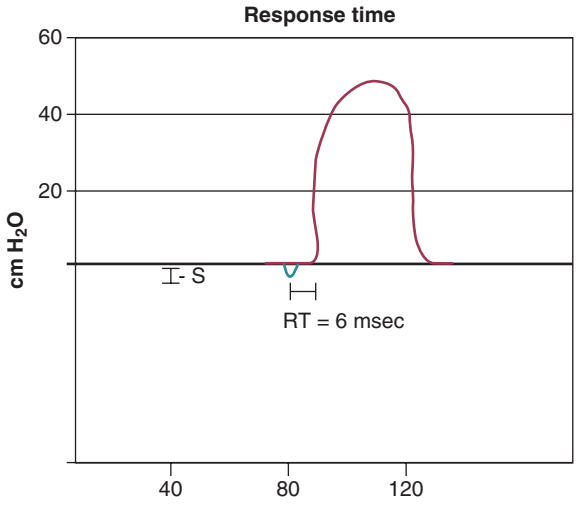
The breath generated by a mechanical ventilator can be separated into four *phases*: triggering, inspiration, cycling, and expiration.

Triggering represents the change from expiration to inspiration and occurs either because of a drop in circuit pressure or diversion of flow (when patient triggered) or because of elapsed time. Sensitivity refers to a preset threshold of pressure or flow. When this threshold is reached, a mechanical breath is delivered. This threshold can be adjusted, and is usually set at −1 to −2 cm H_2O. If sensitivity is set too low, the ventilator will be triggered by any process that causes the airway pressure to drop below the set threshold. Such processes include patient motion, external compression, gastric suctioning, and air leaks in the circuit. Conversely, if the threshold is set too high, the work of breathing increases, as the patient must make a significant effort to overcome the threshold limit for inspiratory flow to occur. In the setting of pressure triggering, airway pressure is reduced (by patient effort) in the proximal circuit, the expiratory valve closes, pressurization of the inspiratory limb of the circuit occurs, and the patient receives a breath. Flow sensing was developed as an alternative to pressure triggering to reduce the delay in response time between neural input from the patient and delivery of gas volume by the ventilator.[23,24] In the setting of flow triggering, the patient's inspiratory effort induces a disruption of the constant flow in the ventilator inspiratory circuit. This change in flow signals the expiratory valve to close and for the ventilator to deliver the next breath. Flow triggering was initially demonstrated to decrease the work of breathing compared with pressure triggering. However, with improvement in response time,

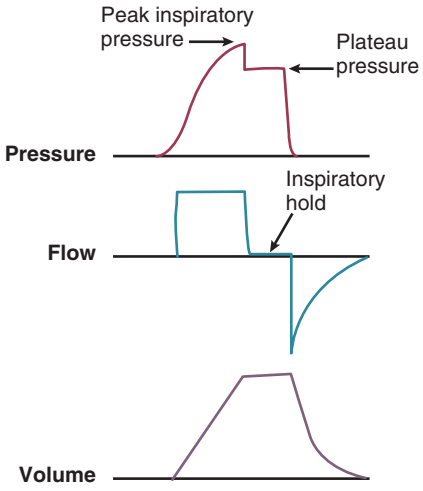
monitoring, and feedback, pressure and flow triggering are similar in this regard.[25,26] Fig. 9.3 is a representation of patient effort and ventilator response time.

During *inspiration*, flow is channeled through the open inspiratory valve of the ventilator to the patient with the exhalation valve closed. This phase can be controlled by how one sets flow or pressure in the ventilator proximal to the open inspiratory valve. For example, volume-assist control is flow controlled and pressure-assist control is pressure controlled. The choice of control variable is largely the discretion of the clinician, as either can be manipulated to achieve set goals. It should be noted, however, that in volume-targeted ventilation, excessive airway pressures can arise secondary to worsening pulmonary mechanics. In this situation, the pressure alarm will cause a pressure limit to cycle to expiration. At the end of inspiration in volume-targeted ventilation, an inspiratory hold maneuver can be performed (Fig. 9.4), which can distinguish the peak airway pressure from the plateau pressure (because flow is stopped, resistance is negligible). In pressure-targeted ventilation, minute ventilation is not guaranteed. It is a function of the compliance and resistance of the respiratory system. The clinician therefore should monitor these physiologic changes closely to avoid untoward changes in either airway pressure or $PaCO_2$ levels.

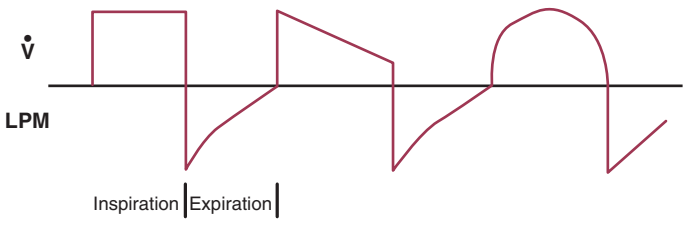
With pressure control and pressure support (PS) breaths, the pattern of inspiratory flow is a natural decelerating pattern as the pressure gradient for flow decreases as pressure rises in the patient's lungs. The pattern of inspiratory flow with a flow-controlled breath (volume cycled) is typically square with an almost instantaneous rise to a preset level (40 L/min, 60 L/min, and so on) followed by constant flow until cycling occurs. The flow pattern can be computer altered to be *decelerating* or *sinusoidal* (Fig. 9.5). Decelerating flow results in a rapid rise to a maximum level followed by a gradual decrease until cycling. Sinusoidal flow pattern most closely represents normal physiologic breathing. It results in flow that gradually increases and then decreases during inspiration. The choice of inspiratory flow pattern should be based on patient characteristics, and a few common clinical scenarios should be familiar to the clinician. Square flow over time results in a shorter inspiratory time (I time) for a given VT, and therefore longer expiratory time (E time). For this reason it may be preferred in patients with obstructive physiology (chronic obstructive pulmonary disease [COPD] or asthma).[27,28] It is also usually tolerated better in patients with demand for high minute ventilation, such as severe metabolic acidosis or elevated intracranial pressure. In this situation, there is a potential for dyssynchrony to occur during the progression of the inspiratory phase if decelerating flow is chosen. The trade-off is higher peak airway pressures with a square waveform, which may be ameliorated if it leads to a reduction in hyperinflation and iPEEP. Decelerating flow results in a longer I time and likely a better distribution of flow. With pulmonary pathophysiology involving heterogeneous distribution of injury (ARDS as the prototype example), decelerating flow is likely the best choice, as the longer I time can lead to more homogeneous distribution of ventilation. The distribution of ventilation can be quite different when the flow pattern changes. A decelerating flow pattern yields the most even distribution under most abnormal airway conditions.[29] Studies have also demonstrated that a decelerating flow pattern improves the geographic distribution of lung vibration as a presumed surrogate of airflow.[30] The length of inspiration depends on several factors. In the pressure control mode of ventilation, the clinician directly controls the I time and I:E ratio. With pressure support the patient primarily controls I time. In flow-controlled (volume-targeted) ventilation, the I time is a function of set VT and flow rate (VT/inspiratory flow rate) as well as flow wave characteristics (shape). The end-inspiratory alveolar pressure, as measured by an end-inspiratory hold, is the same for a given VT regardless of the type of ventilator breath.



• **Fig. 9.3** Pressure wave showing time relationship between patient inspiratory effort and ventilator response time *(RT)*.



• **Fig. 9.4** A plateau pressure measurement can be obtained in assist volume control mode by the performance of an inspiratory hold to better estimate the pressure in the lungs.



• **Fig. 9.5** Depicted left to right are square, decelerating, and sine inspiratory flow waveforms as options for delivery of volume ventilation. Note that the square waveform produces the shortest inspiratory time and that the decelerating waveform does not return to zero flow at end inspiration. *LPM,* Liters per minute; *V̇,* flow.

Cycling is the transition from inspiration to expiration (closing inspiratory valve and opening expiratory valve). It can occur due to a threshold of decrease in flow, elapsed time, or delivered volume. *Flow-cycled breaths* are PS breaths. With PS breaths flow rate decreases dramatically as (a) patient inspiratory effort decreases and then ceases and (b) the pressure rises in the patient's lungs as the breath is delivered. With a fixed pressure application the gradient for flow decreases. The patient often senses control not only of initiation of breath but also of its termination. When a predetermined decrement in flow occurs, inspiration is terminated and the patient cycles to expiration. This is typically set at 25% of initial flow, but can be manipulated based on different clinical conditions. For example, if a large leak occurs (bronchopleural fistula or ventilator circuit leak) it may be wise to set the cycle at a higher percentage of initial flow to terminate inspiration at the appropriate time. Strength and duration of patient inspiratory effort influence VT. For safety reasons, PS breaths can be cycled due to excessive pressures (e.g., coughing during inspiration) or elapsed time (e.g., secondary to a leak in the system which would prolong inspiration). In *time-cycled breaths* (pressure control), inspiration is terminated after a preset interval, regardless of whether preset pressure has been achieved or a desired VT has been delivered. Pressure is maintained at a preset level throughout inspiration, yielding a square pressure waveform. Pressure-targeted ventilation is time cycled, and the time can be adjusted to yield a precise inspiration/expiration (I:E) ratio. In *volume-cycled breaths* (flow controlled), the clinician has selected the targeted VT. Volume is delivered until that volume is reached. Airway pressure is directly dependent on the VT and the mechanical characteristics of the patient's respiratory system. For safety reasons, volume-cycled breaths will be pressure cycled if airway pressures exceed the pressure alarm limit. In this situation, the delivered VT will not reach the set volume target unless the pressure alarm limit is increased.

At the end of inspiration, flow from the ventilator ceases, the exhalation valve opens, and gas is allowed out from the lungs. This release occurs passively. Expiratory flow should cease prior to expiration. If this does not occur, the patient has auto-PEEP or intrinsic PEEP (iPEEP). This is most commonly seen in patients with expiratory flow limitation (COPD or asthma) or high inspiration/expiration (I:E) ratios (see later text).

Ventilator Modes

A ventilator mode describes ventilation over time and a set of specific combinations of breath characteristics delivered to a patient, including types of breaths, phase variables, and mandatory versus spontaneous breaths.[16] Clinician familiarity, unit, and institutional practice patterns determine to a large extent the mode that is used. Also, data showing definitive improvement in clinically relevant outcomes comparing one mode to another are lacking. Patient need and response to therapy should guide mode selection. Table 9.2 summarizes the features of some of the modes of mechanical ventilation, and Table 9.3 lists some of their advantages and disadvantages. Fig. 9.6 also shows some characteristic waveforms of various modes of mechanical ventilation.

Continuous Mandatory Ventilation

With continuous mandatory ventilation (CMV), the patient has no influence on mechanical ventilation, and all breaths are time (ventilation) triggered. Patient-ventilator interaction is solely from the ventilator to the patient; it is time triggered and cycled by the ventilator. Current ventilators do not have a CMV setting; this mode is essentially what is achieved when a patient using assist control (AC) ventilation has no interaction with the ventilator secondary to conditions such as heavy sedation, neuromuscular blockade, or central nervous system injury.

Assist Control Ventilation

In AC ventilation, a mandatory number of breaths are set and delivered with a set pressure or flow (assisted or unassisted), and if the patient's respiratory rate is higher than this backup setting (rate), additional assisted breaths to the preset pressure or flow are delivered. The target variable can be pressure (PC/AC) or volume (VC/AC).

Synchronized Intermittent Mandatory Ventilation

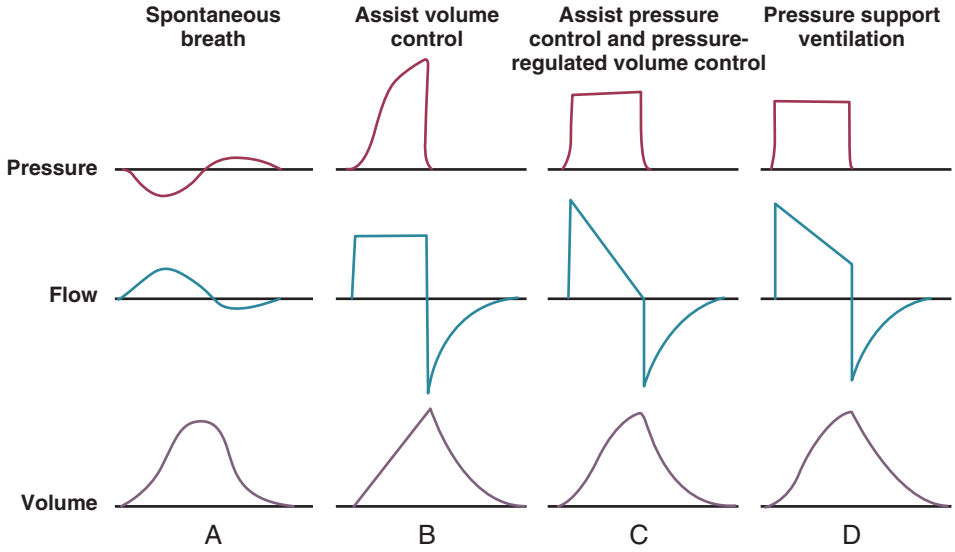
With synchronized intermittent mandatory ventilation (SIMV), the ventilator delivers a mandatory number of breaths with a set

TABLE 9.2 Overview of Features of Selected Modes of Mechanical Ventilation

Ventilator Mode	Trigger	Control	Cycling	Inspiratory Flow
Continuous mandatory ventilation	Time	Flow or pressure	Volume or time	Selected or decelerating
Volume control/assist control (VC/AC)	Patient or time	Flow	Volume	Square, decelerating, or sinusoidal
Pressure control/assist control (PC/AC)	Patient or time	Pressure	Time	Decelerating
Synchronized intermittent mandatory ventilation	Patient or time	Pressure for patient breaths Flow (VC) or pressure (PC) for ventilator breaths	Flow for spontaneous breaths Volume or time for ventilator breaths	Decelerating for spontaneous breath Square (VC), decelerating (VC or PC), sinusoidal for spontaneous breaths
Stand-alone pressure-support ventilation	Patient	None	Flow	Decelerating

TABLE 9.3 Potential Advantages and Disadvantages of Selected Modes of Mechanical Ventilation

Mode	Advantage(s)	Disadvantage(s)
Controlled mechanical ventilation	Rests muscles of respiration	Requires use of heavy sedation/neuromuscular blockade
Assist volume control	Reduced work of breathing Guarantees delivery of set tidal volume (unless peak pressure limit alarm is exceeded)	Potential adverse hemodynamic effects May lead to inappropriate hyperventilation and excessive inspiration pressures
Assist pressure control	Allows limitation of peak inspiratory pressures	Same as for assist volume control Potential hyperventilation or hypoventilation with lung resistance/compliance changes
Synchronized intermittent mandatory ventilation	Less interference with normal cardiovascular function	Increased work of breathing compared with assist control Patient may find it difficult to adjust to two different types of ventilator breaths
Stand-alone pressure-support ventilation	Patient comfort Improved patient-ventilator interaction Decreased work of breathing	Apnea alarm is only backup Variable patient tolerance



• **Fig. 9.6** Characteristic pressure-flow waveforms with breathing spontaneously and various types of ventilation. A, Spontaneous breath. Such breaths are spontaneous, and inspiratory flow is achieved by the negative pressure generated by the respiratory muscles. Expiration occurs as these muscles relax. The combination of mandatory ventilator breaths (B or C) with spontaneous breaths (with or without pressure support) is called synchronized intermittent mandatory ventilation. B, Assist volume control ventilation. The flow is constant and pressure increases throughout inspiration. C, Assist pressure control ventilation or pressure-regulated volume control (PRVC). The pressure is constant and flow decreases throughout inspiration. In PRVC, the level of applied pressure may vary from one breath to the next. D, Pressure support ventilation. The pressure is constant and flow decreases throughout inspiration. When the flow reaches one-fourth of its initial value, inspiration ends (flow-cycled). The flow and respiratory time are determined by patient effort and level of pressure support applied. The tidal volume varies from one breath to the next.

pressure or flow (assisted or unassisted), similar to AC. However, spontaneous breaths are delivered upon patient triggering during a timing window created around the delivery of mandatory breaths. These spontaneous breaths can be totally driven by patient effort or pressure-enhanced as pressure-controlled/flow-cycled (PS) breaths. The ventilator will attempt to synchronize the delivery of this mandatory breath with the spontaneous effort of the patient (if effort is present). If the patient does not trigger a breath, then the ventilator will deliver a regularly scheduled mandatory breath (time triggered).

Stand-Alone Pressure Support Ventilation

This mode of ventilation is patient triggered, pressure controlled, and flow cycled with a decelerating flow inspiratory waveform. Cycling to expiration typically occurs when the flow rate decreases

to a set percentage of inspiratory flow (typically 25% of initial inspiratory flow). However, if there is a leak in the system, inspiratory flow may never decrease to the cycle threshold. In this situation, for safety purposes, flow can be time cycled as well. During inspiration, the ventilator will adjust flow to maintain the preset pressure, and VT is dependent on patient effort and the mechanics of the respiratory system. The pressurization rate to the goal pressure is determined by the rise time, which can be adjusted on many ventilators. If the rise time is set too low, increased work of breathing can occur; if it is set too high, the preset pressure may be exceeded (overshoot), causing early cycling to expiration. PSV is effective at decreasing patient effort and work of breathing.[31–33] Data suggest that most clinicians view PSV as a weaning mode of mechanical ventilation, despite its being fully capable of appropriate full support in patients with respiratory failure and intact respiratory drive.[34]

Dual Control Modes

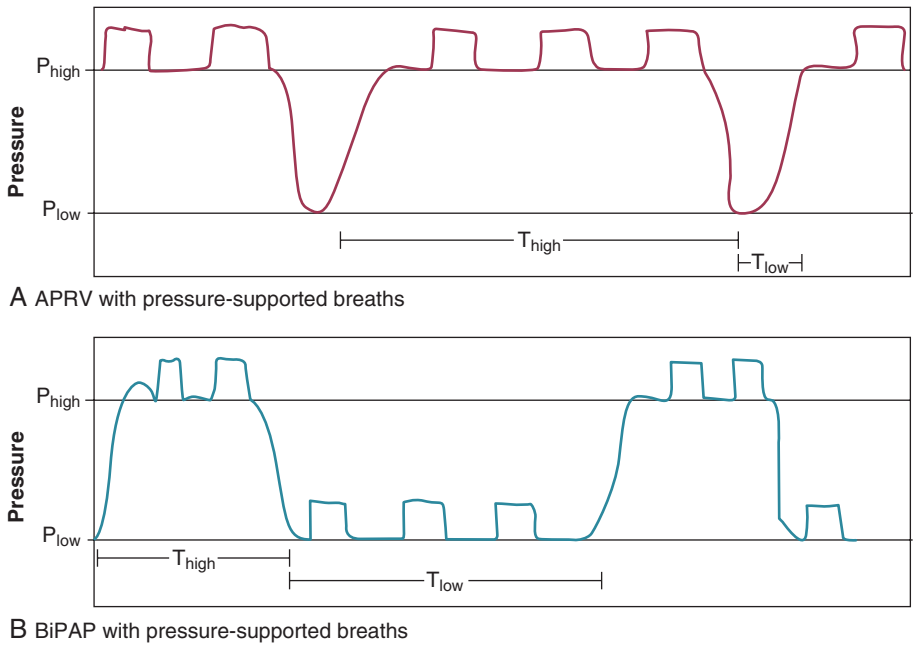
The preceding modes of mechanical ventilation are classically referred to as "conventional" ventilator modes, which is purely arbitrary. Dual control modes of ventilation manipulate pressure or volume on either a breath-to-breath basis or within the same breath. Breath-to-breath modes include volume support (VS) and pressure-regulated volume control (PRVC), also called "pressure control volume guarantee." VS is PSV (pressure limited, flow cycled) that uses VT as a feedback to adjust the pressure support level.[16] PRVC is pressure control ventilation (pressure limited, time cycled), but uses VT as a conditional variable to adjust pressure to achieve desired VT. Proportional assist ventilation (PAV) measures patient inspiratory demand while calculating compliance and resistance to offload inspiratory muscles in proportion and in synchrony with patient effort.[35] When compared to PSV it has been shown in one study to be associated with less dyschromy.[36]

Other Modes of Mechanical Ventilation

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) has been described in the literature since 1987.[37] It is a time-triggered, pressure-controlled, time-cycled mode of mechanical ventilation that exactly resembles AC/PC with very extended I:E ratios if the patient is not spontaneously breathing.[38,39] It has been described as continuous positive airway pressure (CPAP) with an intermittent time-cycled release phase to a set lower pressure. Whereas conventional modes of mechanical ventilation elevate airway pressure up from a set baseline to accomplish tidal ventilation, APRV uses very high I:E ratios to maintain mean airway pressure and brief deflations to accomplish ventilation. When APRV is used in ARDS (primary use) short time low (T_{low}) is used, whereas this mode can be used in patients without ARDS with longer T_{low} and is often called "bilevel positive airway pressure" in that circumstance (Fig. 9.7). The expiratory valve in APRV also facilitates spontaneous breathing throughout the ventilatory cycle, facilitating ventilation. Because this mode is primarily used with ARDS with long time high (T_{high}) and very short time low (T_{low}), breathing occurs primarily during T_{high}. Pressure high (P_{high}) is the baseline airway pressure that occupies most of the ventilatory cycle. Pressure low (P_{low}) is the release pressure and is set at 0 cm H_2O. T_{high} is the length of time for which P_{high} is maintained, and T_{low} is the length of time for which P_{low} is maintained. This is primarily semantics, but the term *APRV* implies longer I:E ratios than bilevel positive airway pressure, and a P_{low} setting of 0 at all times.

Although outcome data are lacking compared with conventional ventilation using protective lung strategies, the reported advantages of APRV include sustained alveolar recruitment with improved oxygenation, higher mean airway pressures accomplished with



• **Fig. 9.7** Pressure-time waveforms showing the use of airway pressure release ventilation (APRV). A, APRV as used in ARDS with pressure-supported breaths taken on T_{high} only and short T_{low} (dump time) to allow CO_2 removal and PEEP setting. B, A variant of APRV often called bilevel positive airway pressure with longer T_{low} and pressure-supported breaths allowed on both T_{high} and T_{low}. *P_{high}*, Pressure high; *P_{low}*, pressure low; *T_{high}*, time high; *T_{low}*, time low.

lower P_{peak} and P_{pl}, spontaneous breathing throughout the ventilatory cycle, and decreased use of sedation and neuromuscular blockade in severe ARDS.[39] The maintenance of spontaneous breathing may improve $\dot{V}/\dot{Q}$ matching by preferential ventilation of dependent lung regions, and the higher mean airway pressure, relative to P_{peak} and P_{pl}, may limit VILI.

Alveolar recruitment is a pan-inspiratory phenomenon and alveoli that are recruited are more compliant than recruiting or nonrecruited alveoli. With prolonged elevated pressures, APRV likely recruits alveoli, which require a longer inflation with higher threshold opening pressures.[38,39] Sustained inflation maintains recruitment, decreases shunt and dead space, and uses the more compliant expiratory limb of the pressure-volume (PV) curve. Ventilation is determined by the stored kinetic energy at the high pressure, the intermittent release phase, and is augmented by spontaneous breathing. Although minute ventilation is decreased with this mode of ventilation, ventilation is also improved by a decrease in dead space.

Clinical data are limited but have shown improved oxygenation, less shunt and dead space, as well as decreased need for sedation and neuromuscular blockade.[39–43] Data on clinically relevant outcomes, such as mortality rates, mechanical ventilation days, and intensive care unit (ICU) days, are limited. This mode remains physiologically attractive for its effects on oxygenation and potential to limit VILI, but no specific recommendations can be made given the lack of good outcome data.

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilation (HFOV) is very different from conventional bulk flow ventilation and uses respiratory frequencies much higher and VTs much lower than conventional modes. It is similar to APRV in that it aims to elevate mean airway pressure to maximize recruitment and oxygenation while limiting P_{peak}.[44] Oxygenated, humidified gas (bias flow) passes in front of an oscillating membrane and generates very small VTs at very high respiratory rates. This is actively driven by a piston pump that oscillates the diaphragm. This produces sinusoidal or somewhat erratic pressure waves that are actively driven in both inspiration and expiration (unique in that expiration is not passively driven by elastic recoil). This component is created by the backward movement of the diaphragm or piston of the oscillator. Resistance valves are used to apply a constant distending airway pressure, over which small VTs are superimposed at a high respiratory frequency; in this fashion, it uncouples, for the most part, oxygenation and ventilation.

Given the fact the VT is often less than anatomic dead space, HFOV relies on gas transport mechanisms much different from those used by bulk flow ventilation. These mechanisms include some convective gas transport, but also molecular diffusion, pendelluft, coaxial flow, and Taylor dispersion.[45]

When initiating HFOV, the patient's ET should be verified to be patent, as heavy secretions or kinks in the ET will significantly harm ventilation. The mean airway pressure should be set at about 5 cm H_2O higher than that achieved with conventional settings. The bias flow delivers fresh gas into the ventilator circuit at 40 to 60 L/min and helps maintain mean airway pressure.[45] The power control allows adjustment of amplitude (Δpressure), which is set high enough to elicit vibrations of the patient to the lower abdomen or midthigh. Frequency helps determine ventilation and is set typically at 3 to 5 Hz. It should be noted, however, that at low frequencies, higher VTs and bulk flow can be achieved, which assists in ventilation (and may contribute to VILI). The percentage of I time is set at 33% or 50%, depending on ventilation goals.

This effect would be predicted to be most beneficial when applied early in the course of severe ARDS.[44,46] Clinical trials of the comparison of HFOV with ARDS net setting standard ventilation in patients at the onset of moderate or severe ARDS showed no benefit of HFOV, and one of the two trials showed an increased mortality rate in the HFOV arm.[46,47] This would imply consideration of HFOV use only as salvage therapy in ARDS. The clinician should note that patients ventilated with HFOV require heavy sedation or neuromuscular blockade.

Effort-Adapted Modes of Mechanical Ventilation

Early mechanical ventilators, such as the CMV mode setting, performed work on the patient and adapted the patient to the ventilator, with complete ventilator and physician control over breath characteristics and delivery. Although this can achieve adequate oxygenation and ventilation, it can come at a great expense to the patient, with side effects including dyssynchrony, increased work of breathing, respiratory muscle weakness, and increased use of sedative infusions. Advances in ventilator technology and increased recognition of the side effects of mechanical ventilation have led to an increased awareness to adapt the ventilator to the patient, using the patient's physiology and demand to assist the respiratory muscles in proportion to effort and need. These effort-adapted modes of mechanical ventilation include PAV, neurally adjusted ventilatory assist (NAVA), and adaptive support ventilation (ASV).

PAV is a mode of partial support in which ventilator assist is delivered in proportion to patient effort. A defined level of assist, or unloading, relieves the resistive and elastic burden of the respiratory system.[48,49] The ventilator responds to the *mechanical output* of the patient and will amplify patient effort with a preset proportional amount of pressure support. The theory behind PAV is based on the equation of motion; based on changes in flow and volume, flow-proportional and volume-proportional pressure support is given. A percentage of effort is set by the clinician, and applied airway pressure develops as a function of volume to overcome elastance or a function of flow to overcome resistance.[48] Reported benefits of PAV include improved synchrony, better physiologic breathing pattern, and improved sleep quality.[50–56] A limitation of PAV is that it relies on the mechanical output from the patient; therefore continuous knowledge of the elastic and restrictive properties of the patient is a necessity. If PAV incorrectly estimates the mechanical properties, the ventilator may overassist, causing delayed inspiratory ending ("runaway phenomenon"). This problem has been improved by the development of PAV+ (PAV with load adjustable gain).

NAVA is similar to PAV in that it is also an effort-adapted mode of partial assist. Unlike PAV, which responds to the mechanical output from the patient, NAVA responds to the *neural input* from the electrical activity of the diaphragm (Edi). Pressure is applied in a linear proportion to Edi, and this requires the placement of an esophageal electrode (similar to nasogastric tube placement). The ventilator is triggered based on Edi or conventional signals (whichever comes first), therefore improving synchrony, as the time delay from patient effort to breathe is very brief. In addition, the amount of ventilator assistance varies based on Edi. As such, to achieve greater assistance, the patient must increase Edi. Reported

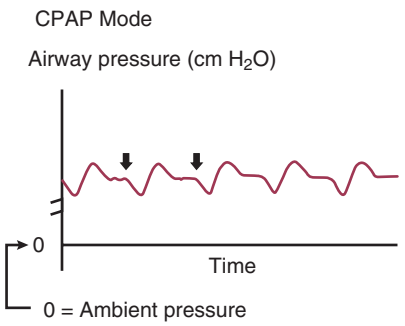
benefits include improved synchrony[57–61] and preserved variability in breathing pattern.[48,62,63] High NAVA levels and high Edi may result in high inspiratory pressures and VT delivery, especially in patients with unstable respiratory patterns or high respiratory drive.[64,65]

ASV ensures a set target minute ventilation based on measurements of the patient's E time constant and dynamic compliance, along with preset information of predicted body weight, minimum minute volume limit, and a pressure limit.[48] The ventilator attempts to minimize the work of breathing by combining the most effective combination of rate and VT, while limiting pressure support. ASV potential benefits include decreased work of breathing and improved patient-ventilator interaction.

Effort-adapted modes of ventilator assist are physiologically attractive, especially considering that most conventional modes of mechanical ventilation are decades old. The decision to use these modes should be tailored to the individual patient. Patients with a high amount of dyssynchronous breaths and iPEEP secondary to obstructive physiology may benefit from a switch to these modes. They do not, however, ameliorate iPEEP, and extrinsic PEEP should be delivered appropriately. In patients who are severely hypoxemic or hemodynamically unstable, these modes should likely be avoided. All require an intact ventilator drive, and ongoing assessments of pulmonary mechanics are a necessity. Finally, the clinician must give up a significant amount of control with these modes of ventilation (which may be unappealing to some practitioners), and outcome data are currently lacking.

Positive End-Expiratory Pressure

CPAP maintains airway pressure above atmospheric pressure throughout the respiratory cycle by pressurization of the ventilator circuit. In mechanically ventilated patients, the purpose of CPAP is to achieve therapeutic PEEP in the presence of ARDS or pulmonary edema (Fig. 9.8). In these patients PEEP restores functional residual capacity, reduces IP shunt, shifts ventilation to a more compliant portion of the PV curve, and prevents end-expiratory volume loss (derecruitment).[66] PEEP recruits previously nonaerated lung tissue and homogenizes regional distribution of tidal ventilation. The net effect on gas exchange reflects the balance between recruitment and overdistention. In the setting of obstructive physiology or expiratory flow limitation, PEEP serves less to improve oxygenation but more to improve patient-ventilator synchrony and triggering.[27,28,67]



• **Fig. 9.8** A pressure-time waveform in a patient with continuous positive airway pressure *(CPAP)* without application of pressure support ventilation is demonstrated. The patient is breathing spontaneously at an elevated baseline system pressure. With initiation of inspiration *(arrows),* pressure becomes more negative (but remains positive), and with expiration, pressure becomes more positive.

PEEP is not without side effects. Given the heterogeneous distribution of lung injury in ARDS, PEEP can overdistend more compliant lung units, contributing to VILI.[68] If PEEP leads to overdistention, it can augment dead space, increase pulmonary vascular resistance, and cause right-sided heart dysfunction. It can also decrease venous return and, in the setting of volume depletion, decrease cardiac output.

The optimal way to set PEEP is debated and controversial, as is the optimal level of PEEP to use.[69–84] See Chapter 11 for a detailed discussion of PEEP application in ARDS.

Monitoring the Ventilated Patient

Hemodynamics

Positive-pressure ventilation causes predictable physiologic changes and cardiopulmonary function is intimately linked—respiratory function alters cardiovascular function and vice versa.[85,86] The venous system is a low-pressure reservoir that contains about three-fourths of our total blood volume.[85,87] This can be divided into the stressed and unstressed volume. The stressed volume contributes to the return of blood to the heart. The right ventricle's main function is to accept venous return and eject the optimal amount of blood into a (usually) highly compliant pulmonary vascular system.[86–89] This maintains a low right atrial pressure, thereby maximizing venous return and overall myocardial performance. A positive-pressure breath increases lung volume and increases intrathoracic pressure, which increases juxtacardiac pressure and therefore right atrial pressure. This can decrease venous return and therefore left ventricular preload several cardiac cycles later. At the same time, positive-pressure ventilation decreases left ventricular afterload by increasing the juxtacardiac pressure, therefore assisting ventricular contraction.

With respect to the mechanical ventilator, arterial blood pressure monitoring is commonplace in all ICUs. Although noninvasive cuff measurements can be adequate, invasive, continuous monitoring is much more informative when ventilator settings are dynamically changing. A fall in blood pressure temporally related to a ventilator change is a fairly specific indicator of a drop in cardiac output.[87] A narrow pulse pressure may indicate relative hypovolemia, although a widened pulse pressure may point to vasodilation or regurgitant cardiac valve disease. Pulse pressure variation (secondary to previously described heart-lung interactions) in mechanically ventilated patients is also the most accurate predictor of determining preload responsiveness.[90] Central venous pressure (CVP) is a reflection of right atrial pressure and normally is low to maximize venous return. Despite the commonality of its use in determining volume status and preload responsiveness, data and physiology have shown that to be inaccurate.[91] This does not indicate that the measurement of CVP is not of value. The absolute value and morphologic appearance (e.g., large v wave) of the CVP tracing can serve as valuable surrogates for right ventricular function, and an inspiratory fall in CVP can indicate preload responsiveness.[92] There are multiple other hemodynamic variables that could be measured in the mechanically ventilated patient, such as pulmonary artery occlusion pressure and mixed venous oxygenation, and these should be based on individual patient characteristics.

Pulse Oximetry

Pulse oximeters determine oxygen saturation by determining arterial blood light absorption at 660-nm and 940-nm wavelengths. The

ratio of absorption of these two wavelengths is then calibrated against computer-stored algorithms to determine the oxygen saturation. Pulse oximeters are quite accurate at their upper range but lose accuracy at lower oxygen saturations, require a good pulsatile signal, and have other limitations. These limitations include hypoperfusion, motion artifact, dyshemoglobinemias, ambient light, certain intravenous dyes, and deeply pigmented skin. Pulse oximetry is virtually ubiquitous in the ICU. Its use includes detection of hypoxemia, monitoring response to ventilator changes (such as PEEP setting), weaning fraction of inspired oxygen (FIO_2), and as a surrogate for pulmonary gas exchange.[93]

End-Tidal Capnography

End-tidal capnography ($ETCO_2$) is a useful way to monitor the concentration of exhaled carbon dioxide (CO_2), plotting it against time. A normal capnogram consists of a low value at baseline during inspiration and while emptying CO_2-free dead space. This is followed by a steep increase as alveolar units empty CO_2, and this increases progressively until a plateau is reached. A normal value (e.g., when ventilation and perfusion are matched) is about 5 mm Hg less than the $PaCO_2$, and a normal shape consists of a low baseline, steep ascending portion, plateau, and steep decline. The $ETCO_2/PaCO_2$ gap can widen in patients with altered $\dot{V}/\dot{Q}$ relationships or changes in cardiac output; the morphologic pattern of the waveform can be altered in patients with endobronchial intubation, expiratory flow limitation, and ventilator dyssynchrony.

Transcutaneous Carbon Dioxide Monitoring

Transcutaneous carbon dioxide ($PtCO_2$) monitoring allows noninvasive and continuous approximation of $PaCO_2$. This technique was described by Severinghaus in 1960. $PtCO_2$ monitoring uses disposable skin electrodes.[94,95] Measurement of $PtCO_2$ has been examined in patients with acute and chronic respiratory failure and as a monitoring tool. In these studies, $PtCO_2$ monitoring shows a good correlation with $PaCO_2$.[96–99] Some studies support $PtCO_2$ as superior to $ETCO_2$ monitoring in terms of reflecting $PaCO_2$.[100,101]

Limitations of the measurement for approximating $PaCO_2$ include frequency of the need for recalibrations, time needed to achieve skin warming, accuracy of measurements with thick skin, and the need for adequate tissue perfusion.[102]

Ventilator Waveforms

Modern ventilators allow continuous monitoring of pressure, volume, and flow waveforms, all of which are plotted against time. They are useful in readily identifying the mode of mechanical ventilation being used, as well as identifying physiologic abnormalities. Examination of the flow waveform can allow detection of iPEEP. A ripple-like waveform can indicate water or secretion buildup in the ventilator circuit. A prolonged expiratory flow pattern can indicate expiratory flow limitation. The pressure waveform allows calculation of compliance of the respiratory system, and an estimation of transalveolar pressure with an end-inspiratory hold maneuver to calculate plateau pressure. An initial overshoot in the pressure waveform may signal high patient effort or an overshoot on ramp speed. An upward inflection at the end of the pressure waveform could signal overdistention, and a dip in an otherwise square pressure waveform can signal patient effort and dyssynchrony.

Maintaining Support of the Ventilated Patient

Sedation and Analgesia

Critically ill patients who are mechanically ventilated often require sedative and analgesic drugs, and pain is common among ICU patients.[103] The ideal sedative and analgesic regimen would provide adequate sedation and pain control, rapid onset of action, rapid recovery after discontinuation, minimal systemic accumulation, and minimal adverse effects—without raising health care costs.[104] The primary aim of these medications is to reduce the physiologic stress of respiratory failure and to improve the tolerance of mechanical ventilation. As more patients survive acute illness, the importance of goal-oriented sedation and analgesia has emerged, and the deleterious side effects of these medications are evident.[105]

Historically, mechanically ventilated patients have been treated with continuous infusions of benzodiazepines, opiates, and propofol.[106–108] Unfortunately, emerging data point to increased side effects associated with these medications, such as delirium, increased mechanical ventilation days, increased lengths of hospital stay, and higher mortality rate.[105,109,110] This has prompted interest in novel regimens with agents such as dexmedetomidine, an α_2-agonist with sedative and analgesic properties. Data have shown that dexmedetomidine use is associated with a reduction in delirium, improved cognitive function, and a decrease in mechanical ventilation days.[111–115]

Regardless of the sedation regimen chosen, the mechanically ventilated patient should have sedation and analgesia titrated to a validated scale, such as the Richmond Agitation-Sedation Scale, and delirium should be monitored at least daily, also with a validated scale (Confusion Assessment Method-Intensive Care Unit). All patients should be assessed daily for readiness to be liberated from the ventilator (spontaneous awakening trial [SAT]), and this should be paired with a spontaneous breathing trial (SBT).

Positioning

There is no optimal position for an individual patient and certainly no evidence-based gold standard. Predictable physiologic changes occur in patients when placed in the supine position, including reduced functional residual capacity, alteration in pleural pressure, reduced lung compliance, and change in $\dot{V}/\dot{Q}$ matching. The supine position should be avoided, as it is a risk factor for VAP.[116,117] In patients with unilateral lung injury, the "good side" should be placed in the dependent position to optimize $\dot{V}/\dot{Q}$ match. Patients with severe hypoxemia (PaO_2:FIO_2 ratio <100) should be considered for prone positioning early in the course of ARDS, as this will likely improve oxygenation and may offer survival benefit in this patient cohort.[118]

Secretion Clearance

Secretion clearance is impaired in the mechanically ventilated patient owing to decreased mucociliary activity and inability to cough effectively. Removal of oral and tracheobronchial secretions is commonplace and standard care of the mechanically ventilated patient. Because of insufficient data and complications, scheduled and routine suctioning should be avoided, but the decision is based on patient assessment. The use of closed-circuit catheters is now commonplace, but data are conflicting with regard to patient benefit

when compared to open-circuit catheters. Before the suctioning procedure, the caregiver should be aware of the potential for complications, such as hypoxia, airway trauma, and cardiac arrhythmias.

Early Physical Therapy in Acute Respiratory Failure

Although overall evidence is limited and controversial, a recent clinical practice guideline "suggests" protocolized rehabilitation directed toward early mobilization for patients with acute respiratory failure and mechanical ventilation for greater than 24 hours.[35,119] It notes early physical therapy beneficial effects on duration of mechanical ventilation and ability to walk at discharge. These are mixed findings with regard to improvement in functional performance in various studies, and studies have not been able to demonstrate shortened mechanical ventilation, ICU stay, or hospital stay.[36,120] Early physical therapy is likely beneficial for select patients. Studies that inform on patient selection and dose of therapy are needed.

Weaning From Mechanical Ventilation

The five essential steps that facilitate achieving ventilation independence are (1) preparation (such as cardiovascular status, fluid balance), (2) evaluation (such as spontaneous breathing trial), (3) withdrawal of ventilation support, (4) extraction of ET, and (5) peri-extubation care.[121] (A more extensive discussion of weaning is found in Chapter 14).

Shortly after a patient is endotracheally intubated to initiate mechanical ventilation, thoughts should turn toward liberation from the ventilator. The withdrawal of mechanical support is a continuum from intubation until hospital discharge.[122,123] Depending on severity of illness, patient comorbid conditions, and critical care treatments needed, the timing of this may range from hours to weeks or months. There are several evidence-based guiding principles that shorten mechanical ventilation days across a broad cohort of critically ill patients.

A key component in liberation from the ventilator is the targeted use of sedation, limitation of sedative and opioid infusions, and the monitoring for and aggressive treatment of delirium.[105] Patients should also undergo daily interruption of sedative medications (SAT), which has been shown to decrease ventilator days and ICU length of stay.[124] After awakening, the patient should be assessed for readiness to wean. The literature abounds with weaning predictors, all of which have modest sensitivity and specificity, including the frequency/VT ratio.[123] Given this, as opposed to weaning predictors, the patient should undergo an SBT based on common sense, overall clinical trajectory, lack of hypoxia, and hemodynamic stability. The SAT should be paired with an SBT, as the SAT-SBT pairing decreases ventilator days, shortens ICU and hospital length of stay, and improves mortality rate.[125] An SBT can be conducted unassisted through a T-piece, on low-level PSV or on CPAP, once or multiple times a day and from 30 to 120 minutes; SIMV weaning is not recommended.[126–131] If a patient has an unsuccessful SBT, a reason for that failure should be sought and corrected. This could include sedation, weakness, delirium, respiratory muscle fatigue, or left ventricular dysfunction. Also, afterward the ET should be placed immediately on comfortable full mechanical support, as delaying this and prolonging the SBT to the point of respiratory muscle exhaustion can delay extubation. After a successful SBT, the patient should be extubated unless a reason exists to leave the ET in place (e.g., no cough reflex and heavy pulmonary secretions). The ability to predict successful extubation is challenging, and if the clinician never experiences a reintubation, he or she is likely not extubating patients based on the best available evidence.

Complications of Mechanical Ventilation

Hemodynamics

Blood pressure (BP) is simply the product of cardiac output (CO) and systemic vascular resistance (SVR; BP = CO × SVR). Although the transition of positive-pressure ventilation is associated with a predictable set of physiologic responses, the overall hemodynamic response is largely a consequence of underlying patient comorbid conditions (such as left ventricular dysfunction) and preload status. Immediately after endotracheal intubation, worsening hemodynamics are usually secondary to a decrease in preload, as right atrial pressure will increase, or a drop in arteriolar tone from sedation and analgesia. Any change in hemodynamics in the mechanically ventilated patient should prompt a thorough and almost algorithmic evaluation for potential causes.

Ventilator-Induced Lung Injury

Mechanical ventilation can be a lifesaving intervention. However, it has great potential for harm, and the clinician's focus should extend beyond normalization of gas exchange to providing safe and physiologically sound mechanical ventilation. Perhaps nowhere is this demonstrated more significantly than with the concept of VILI. Most patients with ARDS do not die of hypoxia, but rather multiple organ dysfunction syndrome.[132–135] Applied airway pressures in patients with ARDS distribute in a heterogeneous fashion, leaving more compliant lung units overdistended and others collapsed and nonrecruited. Respiratory system compliance is related to the amount of normally aerated lung tissue that remains, the so-called baby lung.[136] This heterogeneity leads to a maldistribution of ventilation, with some alveoli overdistended, others collapsed throughout the respiratory cycle, and others cyclically opening and closing. VILI is a spectrum, classically defined as barotrauma, atelectrauma, and volutrauma (stretch injury).[137] All of these can lead to biotrauma, or the decompartmentalization of the inflammatory response secondary to increased alveolar epithelial-capillary endothelial permeability. This results in the release of biologic inflammatory mediators and the spread of injury to distant organs, causing multiple organ dysfunction syndrome and death. VILI is much more complex than the preceding definitions and involves tissue stress and strain modifiers, complex molecular mechanisms, as well as gene activation and upregulation.[138,139]

Human studies support the concept of VILI and the importance of a protective ventilation strategy with low VTs and the use of PEEP. Low VT ventilation is the only intervention shown to consistently improve outcome in ARDS, and support for protective lung ventilation to decrease VILI from several well-conducted clinical trials exists.[73,74,140] This includes data showing a decrease in inflammatory mediators in patients ventilated with a protective lung strategy. In the absence of a patient-specific factor to suggest otherwise, a protective ventilation strategy, consisting of low VT ventilation, PEEP setting, and limitation of plateau pressure, should be attempted at all times. Emerging data suggest that these strategies should be used not only in patients with ARDS, but in all patients receiving mechanical ventilation, especially those with known risk factors for the development of ARDS.[141]

Spontaneous breathing during mechanical ventilation may lead to improved oxygenation through better aeration and ventilation-perfusion matching, reduced need for sedation, and a smaller risk of diaphragm deconditioning.[35] However, it also potentially increases transpulmonary pressure and risk for ventilation-associated lung overinflation injury.[35] It may displace gas from nondependent more-recruited areas to dependent less-recruited areas, the so-called pendelluft effect. With strong diaphragm contractions during early inspiration spontaneous breathing may lead to regional overinflation and ventilation induced lung injury. Properly applied higher PEEP may decrease this pendelluft effect.[142]

Ventilator-Associated Events

Diagnosis of VAP has been a controversial issue in the critical care setting. Problematic is that clinical findings for VAP are subjective and nonspecific. In 2013, the Centers for Disease Control and Prevention published a new algorithm for surveillance of what are called ventilator-associated events (VAEs).[143–145]

The new three-tier algorithm defines associated events as a significant and sustained worsening in oxygenation variables after an initial period of stabilization or improvement. This deterioration in oxygenation can occur from infectious and noninfectious conditions.

This three-tier definition is as follows:

1. Tier 1: Ventilator-associated condition (VAC) defined as new respiratory deterioration.
2. Tier 2: Infection-related ventilator-associated complication (IVAC) defined as VAC − clinical signs of infection.
3. Tier 3: Possible or probable VAP defined as IVAC + evidence of pulmonary infection.

Patients with VAEs have a high morbidity and mortality rate compared with patients without VAEs.[146,147] Avoiding intubation, minimizing the duration of mechanical ventilation, and targeting the specific causes of VAEs are three important approaches to improve outcome in critically ill patients.[148]

One of the most frequent complications of mechanical ventilation is the development of VAP.[149–160] VAP is discussed in Chapter 40.

Gastrointestinal Bleeding

Mechanical ventilation is a risk factor for gastrointestinal bleeding secondary to stress ulceration, trauma (especially traumatic brain injury), and major burns. Mechanical ventilation for longer than 48 hours is regarded as the most frequent risk factor.[161] The most effective treatment of stress ulceration is prevention. H_2-receptor antagonists and proton pump inhibitors have been shown to reduce the incidence of clinically important bleeding compared with sucralfate and are considered the first-line therapy among many clinicians.[162–166]

Venous Thromboembolism

Venous thromboembolism (VTE) refers to the development of deep venous thrombosis or pulmonary embolism in the critically ill patient. Patients in whom deep venous thrombosis develops have worse clinical outcomes, including prolonged mechanical ventilation.[167] Furthermore, VTE is common and frequently asymptomatic in mechanically ventilated patients. Given the adverse clinical outcomes associated with VTE, thromboprophylaxis with low–molecular-weight heparin or unfractionated heparin, both administered subcutaneously, should be given unless contraindicated.[168–170]

Noninvasive Positive-Pressure Ventilation

Noninvasive positive-pressure ventilation (NIPPV) offers the potential to provide ventilatory assistance without an invasive artificial airway. NIPPV may be accomplished using a face mask or nasal mask fitted to the face and connected through standard ventilator tubing to either a standard mechanical ventilator or smaller ventilators made specifically to deliver noninvasive mechanical ventilation.

In patients with COPD and type II respiratory failure, NIPPV reduces dyspnea, decreases intubation rates, and improves mortality rates.[171–173] Similarly, in patients with cardiogenic pulmonary edema, NIPPV decreases intubation rates and improves survival.[173,174] NIPPV may also serve a critical role in decreasing mechanical ventilation days and improving weaning success, especially in patients with COPD recovering from type II respiratory failure.[175,176] Finally, immunocompromised patients, especially those with hematologic malignancies, should be considered for NIPPV.[177] Before initiation of NIPPV, the patient should be assessed for an adequate mental status for airway protection, hemodynamic stability, and lack of excessive secretions. (See a more detailed discussion of NIPPV in Chapters 36 and 38.)

High-Flow Nasal Cannula: A Potential Alternative to Mechanical Ventilation

High-flow nasal cannula (HFNC) oxygen therapy is a noninvasive respiratory support system that delivers heated and humidified high-flow oxygen via special nasal prongs at a rate of up to 60 L/min as the F_{IO_2} is set from 0.21 to 1.0.[178]

HFNC oxygen therapy is considered to have multiple physiologic effects other than providing a high F_{IO_2}, including (1) washout of nasopharyngeal space CO_2 to reduce the anatomic dead space, (2) a therapeutic PEEP effect, (3) constant F_{IO_2} without intubation or noninvasive ventilation by mask, and (4) humidification of inspired gas. Results of these physiologic effects of HFNC reduce the work of breathing.[179–183]

In patients with acute hypoxemic respiratory failure, HFNC offers patient tolerance and comfort and has been associated with improved oxygenation, reduced need for intubation, decreased respiratory rate, decreased work of breathing, and decreased mortality.[184–191] Also, in immunocompromised patients with acute respiratory failure one study showed that patients treated with HFNC had lower intubation and mortality rates than noninvasive mechanical ventilation.[192]

HFNC oxygen therapy has potential value in postextubation respiratory failure but remains controversial.[193,194]

Key Points

- Consideration of patient trajectory, individual physiology, timing of therapy, and severity of illness will make tailoring the ventilator prescription most effective.
- High-pressure alarms are triggered by patient factors (such as decreased compliance and increased resistance of the respiratory system) or by ventilator circuit malfunction (obstruction or kinking of the ET).
- Low-pressure alarms are generally secondary to a leak in the system (ventilator circuit, ET or cuff) or patient (large pressure loss from a bronchopleural fistula).
- Closed-loop control of calculated tracheal pressure, as seen with ATC, allows compensation for ET resistance.
- The breath generated by a mechanical ventilator can be separated into four phases: triggering, inspiration, cycling, and expiration.
- With pressure control and pressure support breaths the pattern of inspiratory flow is a natural decelerating pattern as the pressure gradient for flow decreases as pressure rises in the patient's lungs.
- In AC ventilation, a mandatory number of breaths are set and delivered with a set pressure or flow (assisted or unassisted), and if the patient's respiratory rate is higher than this backup setting (rate), additional assisted breaths to the preset pressure or flow are delivered. The target variable can be pressure (PC/AC) or volume (VC/AC).
- With SIMV, the ventilator delivers a mandatory number of breaths with a set pressure or flow (assisted or unassisted), similar to AC ventilation. However, spontaneous breaths are delivered upon patient triggering during a timing window created around the delivery of mandatory breaths. These spontaneous breaths can be totally driven by patient effort or pressure enhanced as pressure-controlled/flow-cycled (PS) breaths.
- Although outcome data are lacking compared with conventional ventilation using protective lung strategies, the reported advantages of APRV include sustained alveolar recruitment with improved oxygenation, higher mean airway pressures accomplished with lower Ppeak and Ppl, spontaneous breathing throughout the ventilatory cycle, and decreased use of sedation and neuromuscular blockade in severe ARDS.
- PAV is a mode of partial support in which ventilator assist is delivered in proportion to patient effort.
- NAVA is similar to PAV in that it is also an effort-adapted mode of partial assist. Unlike PAV, which responds to the mechanical output from the patient, NAVA responds to the neural input from the Edi. Pressure is applied in a linear proportion to Edi, and this requires the placement of an esophageal electrode (similar to nasogastric tube placement).

Review Questions

1. A patient is triggering the ventilator and is being ventilated with a pressure-controlled, time-cycled breath, using a decelerating inspiratory waveform pattern. Flash pulmonary edema develops. Which of the following statements are true?

a. Owing to a decrease in compliance, airway pressure will increase until the alarm limit is reached.

b. Owing to a decrease in compliance, flow and tidal volume will decrease, and airway pressure will stay the same.

c. Owing to a change in mechanics, intrinsic positive end-expiratory pressure (PEEP) will develop, as exhalation will be prolonged.

d. Tidal volume will stay the same, but flow will increase owing to increased work of breathing.

Answer: b. The patient is being ventilated with pressure-assist control ventilation (i.e., "pressure control"). This mode of ventilation is patient triggered, because the patient is actively triggering and can use pressure or flow triggering (like many modes). During inspiration, a clinician-set pressure is controlled, or targeted, and pressure control is always time-cycled with a decelerating inspiratory waveform pattern. In pressure-targeted breaths, if mechanics change, flow and volume will change. In the case of pulmonary edema, the problem lies in reduced compliance. As such, flow and tidal volume will decrease. Answer a would be correct if the patient was on volume-assist control, as tidal volume would stay the same, but pressure would increase. A decrease in compliance will not cause a reduction in expiratory flow; therefore answer c is incorrect. In reference to answer d, because this is a pressure-targeted breath, flow may indeed increase if the patient's work of breathing and inspiratory effort increases. However, tidal volume will decrease as a result of the decreased compliance.

2. Which one of the following is most correct concerning hemodynamic effects of positive-pressure ventilation?

a. A positive-pressure breath is always associated with a drop in arterial blood pressure.

b. During volume-assist controlled ventilation, intrinsic positive end-expiratory pressure (PEEP)-induced elevated intrathoracic pressure can be minimized by decreasing inspiratory flow.

c. The immediate effect of a positive-pressure breath is a decrease in venous return secondary to an elevation in right atrial pressure and an increase in left ventricular stroke volume secondary to increased venous return from the pulmonary veins.

d. By increasing pleural pressure, mechanical ventilation increases left ventricular afterload.

Answer: c. The physiology of a positive-pressure breath is predictable: an increase in intrathoracic pressure causes an increase in juxtacardiac and right atrial pressure. As right atrial pressure is the back pressure for venous return, right ventricular venous return decreases. At the same time, compression of the pulmonary veins causes an increase in left ventricular return and stroke volume on the left side of the heart increases. Several cardiac cycles later, the decreased venous return from the right side now presents itself to the left side (usually during expiration), and left-sided stroke volume decreases. This is one example of ventricular interdependence and is what generates pulse pressure variation. The overall hemodynamic effects, such as arterial hypotension, are typically dependent on volume status and baseline left ventricular function. Decreasing flow during volume-controlled ventilation will increase inspiratory time and worsen intrinsic PEEP. Positive-pressure ventilation always decreases left ventricular afterload.

3. All of the following statements about mechanical ventilation are correct *except*:

a. A decrease in the end-tidal carbon dioxide ($ETCO_2$)–partial pressure of carbon dioxide ($PaCO_2$) gap indicates an increase in dead space.

b. Pairing a spontaneous awakening trial (SAT) with a spontaneous breathing trial (SBT) effectively reduces ventilator time and days in the intensive care unit.

c. An SBT can be conducted through a T-piece or on low-level pressure support.

d. Mechanical ventilation in acute respiratory distress syndrome (ARDS) is approached with the knowledge that overdistention can result in alveolar injury.

Answer: a. A normal $ETCO_2$-$PaCO_2$ gap is about 5 mm Hg, with $ETCO_2$ being less than PaCO2. An increase in that gap is typically indicative of an increase in dead space, whether due to altered ventilation-perfusion relationships or an acute drop in cardiac output. Daily assessment of readiness to liberate from the ventilator, along with protocolized SATs and SBTs and targeted sedation practices, are the most effective means of safely discontinuing mechanical ventilation. The literature supports the fact that SBTs can be conducted via a T-piece, low levels of pressure support or continuous positive airway pressure (CPAP), once or twice daily, and for 30 minutes up to 120 minutes.

The literature support exists for a greater beneficial effect of PEEP when applied immediately after the onset of ARDS. Overinflation at end inspiration produces an upper deflection zone on the pressure-volume curve. Mechanical ventilation in ARDS is approached with the knowledge that overdistention can result in barotrauma, whereas allowing alveoli to collapse at the end of each expiration (below lower inflation point) may result in shearing-type airway and alveolar injury. Overdistention is a prime driver of ventilator-associated lung injury.

PEEP and CPAP in Severe Airflow Obstruction
- Newer Modes of Ventilatory Support in Airflow Obstruction
- Weaning ("Liberation") Phase
- Predicting Readiness for Spontaneous Breathing
- Weaning Approaches
- Periextubation Phase

Positive pressure ventilators have been in widespread clinical use for more than five decades. Our understanding of respiratory muscle function and ventilatory failure has undergone major revision over that period, helping to gear equipment and treatment strategies more effectively to patient requirements. Some of the more important advances in this area concern the interactions of patients with obstructive pulmonary disease (airflow obstruction [AO]) with the mechanical ventilator. Improved noninvasive ventilation (NIV) has transformed both the initial rescue and weaning phases of acute episodes requiring critical care. Other advances stem from better developed understanding of physiologic principles important in safe management and withdrawal of machine support from ventilator-dependent patients, many of whom have chronic obstructive pulmonary disease (COPD) or asthma. With these advances in mind, this chapter provides an updated physiologic background for understanding mechanical ventilation in patients with AO, in addition to reviewing selected aspects of this problem that are frequently overlooked and, though noteworthy, may be unfamiliar to many practitioners. NIV and high-flow nasal cannula (HFNC), modalities of immense value in the treatment of alert patients with moderately severe obstructive illnesses, are not extensively addressed here, as they are covered in other chapters of this text.

Special Challenges of Patients With Severe Airflow Obstruction

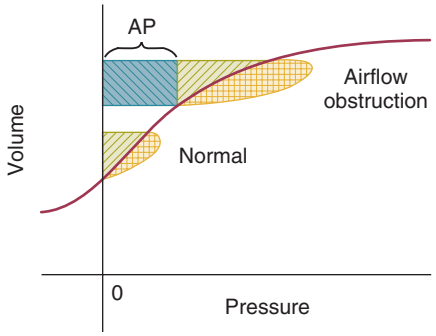
By assuming a major portion of the ventilatory workload, mechanical ventilation affords the opportunity to rest the respiratory muscles while maintaining pH homeostasis and oxygenation, thereby averting progressive ventilatory failure, respiratory arrest, or both. Unfortunately, these benefits are not cost-free—mechanical ventilation is expensive, often uncomfortable, and inherently hazardous; few would dispute the desirability of avoiding the need for airway intubation, implementation machine support, or of accelerating the process of withdrawing such interventions. Although deceptively simple in concept, the management of patients with AO who require mechanical support often proves to be a rather complex clinical undertaking. To manage respiratory failure effectively in patients with severe AO, it is important to understand their distinctive pathophysiology. Paramount among these characteristics is the dynamic hyperinflation that increases work of breathing and compromises the muscular pump that must contend with it. During acute exacerbations, such patients are also distinguished by their susceptibility to the hazards of machine support.

Increased Work of Breathing

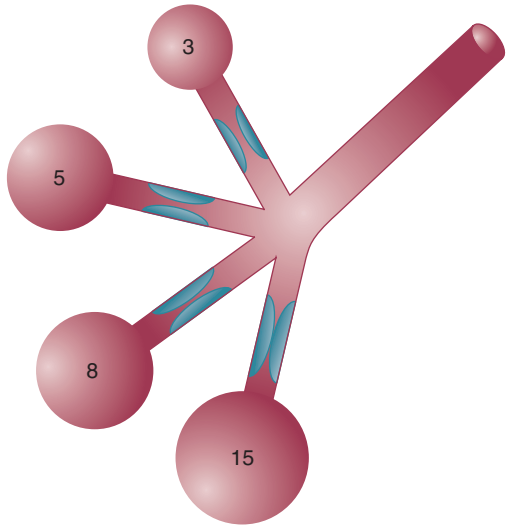
Assuming that both inspiration and exhalation proceed passively, the mechanical breathing workload can be quantified as the product of mean inflation pressure and minute ventilation. The mean inflation pressure (Pm) during constant inspiratory flow is approximated in a modification of the equation of motion of the respiratory system:

$$Pm = R\,(flow) + V_T/2C + PEEPi,$$

where R is resistance; V_T is tidal volume; C is respiratory system compliance (the inverse of elastance); and PEEPi is auto-PEEP, the positive end-expiratory alveolar pressure in excess of set PEEP because of dynamic hyperinflation (Fig. 10.1).



• **Fig. 10.1** Depiction of the elements of the inspiratory equation of motion and their associated work of breathing. The stippled area shows resistive work, and striped areas represent the elastic work associated with tidal volume and auto-positive end-expiratory pressure, respectively. *AP,* Auto-PEEP.



• **Fig. 10.2** The auto–positive end-expiratory pressure (PEEP) effect. Auto-PEEP is the positive flow driving the difference between alveolar and airway opening pressures at end-expiration. As depicted here, it can vary widely from site to site within the lung.

Increased resistance to airflow is responsible (directly or indirectly) for many of the physiologic disturbances that typify this disease. Flow resistance, an important determinant of Pm, is increased by both structural and functional narrowing of the airway. Structural changes include a reduced number of airway channels, as well as narrowed cross-sectional airway caliber. In this already narrowed tapering network of tubes, the additional reduction of airway caliber caused by mucosal edema, functional compression, increased bronchomotor tone, or secretion accumulation noticeably increases the work of breathing because resistance relates linearly to the airway length but inversely to the fourth power of airway radius. For similar reasons, resistance within these critically narrowed airways is highly volume dependent, so that loss of lung volume is accompanied by loss of elastic recoil tension, reduction of cross-sectional area, tendency for expiratory airway collapse, and major increases in the frictional workload.[1,2]

Although each factor just enumerated contributes to AO, functional compression of the airway during exhalation is of overriding importance in many patients with components of emphysema, massive obesity, or vigorous expiratory effort. Loss of elastic recoil encourages collapse of these narrowed bronchi as their transluminal distending pressure gradients decline (or reverse) during the course of exhalation. In most patients with COPD who require mechanical ventilatory support, dynamic airway collapse occurs even during tidal breathing, so the average expiratory resistance is often several times higher during exhalation than during the inspiratory phase of ventilation. This compressive mechanism underlies the phenomenon of air trapping and hyperinflation-related consequences such as loss of inspiratory muscle power and reduced compliance of the respiratory system.

Dynamic Hyperinflation (Air Trapping)

Expiration is normally a passive process that uses elastic energy stored during inflation to drive expiratory airflow. If the energy potential stored during inflation is insufficient to return the system to a relaxed equilibrium before the next inspiration begins, flow continues throughout expiration and alveolar pressure remains positive at end-expiration, exceeding the clinician-selected PEEP value applied within the external circuit (Fig. 10.2).[3–9] This positive-pressure differential distends the alveoli, enhances the pressure driving expiratory airflow, and increases lung recoil, thereby helping to offset and overcome airflow resistance. Unfortunately, such hyperinflation also places the expiratory musculature at a mechanical disadvantage. Furthermore, because the "excess" end-expiratory alveolar pressure (termed auto-PEEP or intrinsic PEEP [PEEPi]) encourages deflation even as inspiration is initiated, it must first be counterbalanced by positive pressure applied to the central airway or by negative pleural pressure before inflation can proceed.[10,11] Thus PEEPi adds to the other components of the equation of motion to elevate the mean inflation pressure and inspiratory work of breathing. The process of air trapping contributes to an increase in the respiratory work of breathing in at least two other ways. Hyperinflation drives the respiratory system upward toward the least compliant portion of the pressure volume relationship, incurring increased elastic work per liter of ventilation (see Fig. 10.1). At these higher volumes the lung approaches its elastic limit as the recoil tension of the distended rib cage becomes *expiratory* rather than inspiratory in nature. Finally, hyperinflation tends to convert more of the well-perfused (zone 3) lung into less-well-perfused tissue, thereby increasing ventilatory dead space and the minute ventilation requirement.

Generally, the resistance increase in patients with chronic AO and in many of those with severe asthma concentrates within small airways.[1] Yet for certain asthmatic patients, the central airways and larynx contribute impressively to total resistance, accounting for the helpfulness of helium-oxygen (heliox) mixtures in some (but not all) patients during exacerbated asthma.[12] According to some reports, heliox helps to reduce air trapping in patients with COPD as well. Although there is some concern regarding the generalizability and accuracy of such observations, several mechanisms can be invoked, even if the *primary* site of expiratory obstruction is too peripheral for helium to affect resistance there. These include reduced inspiratory turbulence, faster expiratory flow in non–flow-limited channels, modestly decreased carbon dioxide (CO_2) production and lower minute ventilation.

Of note, dynamically positive end-expiratory alveolar pressure can also exist without hyperinflation, provided that airway collapse does not occur. In these instances expiratory muscle contraction increases pleural pressure, alveolar pressure, and the speed of expiratory airflow, obviating the need for hyperinflation to complete

exhalation in the allotted time. Such mechanisms are used by normal subjects during heavy exercise or when faced with major respiratory workloads. Indeed, many untrained normal subjects expire to positions below the equilibrium point of the respiratory system in response to PEEP. In this way the respiratory muscles can begin contraction from a mechanically advantageous position, and the expiratory muscles can share in the ventilatory work. Using this strategy, PEEP actually provides a boost to *inspiration,* experienced early in the cycle when the *expiratory* muscles relax. This "work-sharing" strategy, although effective for a normal individual, cannot be implemented by patients who experience dynamic airway collapse during tidal breathing. Because forceful expiratory efforts succeed not only in raising alveolar pressure but also in intensifying dynamic airway collapse, flow rate is determined strictly by absolute lung volume and is not accelerated by expiratory muscle activity after the first third of expiration has been completed.

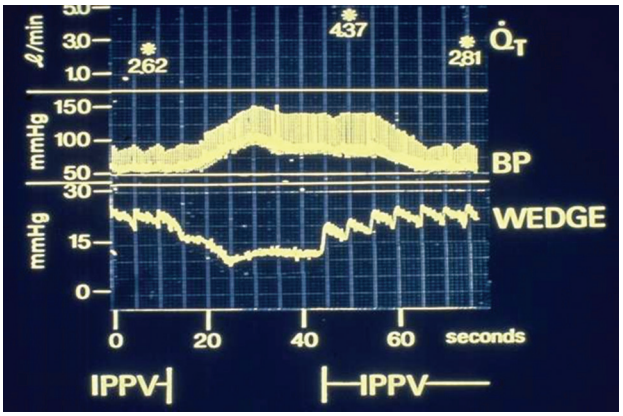
When dynamic collapse occurs during tidal respiration and breathing requirements are high, there is little alternative to hyperinflation, CO_2 retention, or both. At the chosen level of minute ventilation, maintaining the lower lung volume may be either too energy costly or physically impossible. For this reason, many patients with severe obstruction do not or cannot decrease their lung volumes when recumbent. Such considerations may help to explain the dyspnea experienced by most patients with severe AO on assuming horizontal positions. For the same recumbent angle, the lateral position may allow slightly more decompression than does the supine position.[13] Because lung volume influences airway caliber, airway resistance and tendency for collapse increase as the lung deflates.

Obesity and Airflow Obstruction

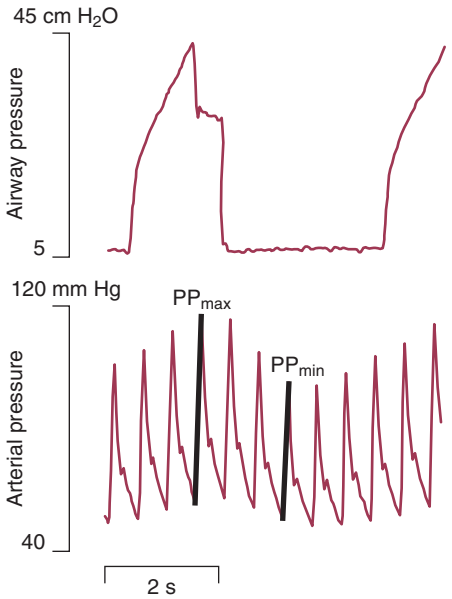
Patients with obesity normally have a lower functional residual capacity, or FRC, owing to the upward pressure of the abdomen upon the diaphragm, as well as the lower compliance of the chest cage. Consequently they exhibit higher airway resistance and a tendency for dependent atelectasis and symptoms when airways are narrowed by bronchoconstriction or disease. Likewise, patients with acute respiratory distress syndrome have higher than normal airway resistance in dependent zones. It is important to emphasize the value of upright positioning in obese bedridden patients. When the body mass index exceeds 35 kg/m^2, a transition to the horizontal position is associated with expiratory closure of dependent airways and auto-PEEP, even in otherwise healthy subjects.[14] As much as 10 to 15 cm H_2O PEEP is required to maintain airway patency throughout the breathing cycle in the horizontal position. Interestingly, assuming the horizontal prone position relieves much of the gas trapping that otherwise occurs when supine.[15]

The distribution of gas trapping in obstruction varies regionally throughout any diseased lung, depending on the local mechanical properties of the airways and the surrounding interstitial pressure. At the end of the expiratory cycle some zones remain patent, and some have sealed much earlier in the deflation cycle (Fig. 10.2). Consequently, the end-expiratory value of auto-PEEP detected at the airway opening may not reflect the magnitude of gas trapping.[16] Clues to the presence of regional closure are often seen when the airway is occluded at end-expiration; the auto-PEEP value shows an atypically slow rise to its final value as quasi-occluded small airways decompress into the common airway. In such cases, adding PEEP, a higher minute ventilation, or more upright position often eliminates or attenuates this characteristic. During volume-controlled ventilation (VCV), plateau pressure tracks hyperinflation more reliably than direct measurements of PEEPi.[5]

In some patients who passively receive ventilatory support, the problems presented by air trapping and dynamic hyperinflation are as much cardiovascular as pulmonary in nature. A relatively high fraction of the resulting positive alveolar pressure is transmitted to the pleural space, where it impedes venous return and confuses interpretation of hemodynamic pressure measurements made with pulmonary artery catheters (Fig. 10.3). Lung distention also adds to pulmonary vascular resistance, exacerbating the tendencies of patients with *cor pulmonale* to experience low cardiac output and hypotension. Marked respiratory variation of systolic and pulse pressures during passive inflation indicates phasically adverse cardiac loading and strongly implies the possibility of dynamic hyperinflation (Fig. 10.4).



• **Fig. 10.3** The hemodynamic impact of auto-auto–positive end-expiratory pressure (PEEPi) in a passively ventilated patient with severe airflow obstruction. A 40-second disconnection of the ventilator was associated with rising blood pressure and cardiac output despite a falling pulmonary artery wedge pressure. *BP,* Blood pressure; *IPPV,* intermittent positive-pressure ventilation; $\dot{Q}_t$, cardiac output.



• **Fig. 10.4** Marked respiratory variation of systemic arterial blood pressure, indicative of the relative variation in cardiac loading conditions associated with dynamic hyperinflation. *PP,* Pulse pressure. (From Michard F, Teboul JL. Using heart-lung interactions to assess fluid responsiveness during mechanical ventilation. *Crit Care.* 2000;4:282–289.)

Increased Minute Ventilation Requirement

Ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching is widespread in patients with severe AO, reducing the efficiency of CO_2 elimination.[1] It is not uncommon for the resting minute ventilation requirement to exceed 12 L/min (twice the normal value) in patients with exacerbated asthma or extensive emphysema and strong chemical drives to breathe. Not only do such increases in ventilation requirement act through frequency as a linear cofactor in the work of breathing per minute (power), but the high minute ventilation requirement itself increases most components of inspiratory pressure *per cycle*: flow, elastance (the reciprocal of compliance), VT, and auto-PEEP. It is not surprising, therefore, that enormous increases in the oxygen consumption rate of the ventilatory muscles have been observed in distressed patients with obstructive lung disease. Moreover, during exacerbations, the oxygen consumed by ventilation and the metabolic demands associated with heightened vigilance, agitation, or anxiety may double the total body oxygen consumption observed during fully supported breathing. The combination of impaired $\dot{V}/\dot{Q}$ matching, hypoventilation, and diffusion impairment results in arterial oxygen desaturation that generally responds well to modest supplementation of inspired oxygen.

Reduced Mechanical Efficiency

In patients with exacerbated COPD or decompensated asthma, the oxygen consumed in the ventilatory task is disproportionate to the amount of mechanical work actually performed. The muscles of the hyperinflated ventilatory system are inefficiently aligned, force-length relationships of the shortened end-inspiratory fibers are suboptimal, and normally efficient coordination among the various muscles of the ventilatory group is often disrupted.[16,17] The energy cost of breathing, therefore, is greatly increased for the pressure and mechanical work accomplished during the breathing effort.

Problems and Hazards of Ventilation With Positive Pressure

When NIV is not indicated or proves unimpressive and ineffective under direct observation, intubation of the airway and invasive ventilation should not be delayed, especially in patients with severe status asthma. Yet patients with AO who require invasive mechanical ventilation present special challenges to the clinician owing to their frequently underappreciated predisposition to adverse consequences that relate only loosely to the airflow resistance. For reasons that are not entirely clear, patients with COPD have been reported to have an increased incidence of gastrointestinal ulceration and bleeding, especially during stress periods. This tendency is accentuated to an important degree by chronically poor nutrition as well as therapeutic use of corticosteroids. In modern intensive care unit practice, the incidence of ulceration has been greatly attenuated by the use of H_2 blockers, proton pump inhibitors, enteral feeding, and other means of acid suppression.

Even when able to cough with maximal force, patients with severe AO have difficulty in clearing contaminated secretions from the central and peripheral airways, encouraging bronchial and lung infections. This tendency is accentuated when the airway is intubated or when NIV is provided with poorly humidified gas mixtures. These interventions accentuate the impediment to coughing efficiency, encourage secretion thickening, and promote entry of nonsterile bio-fluids from the upper airway. In conjunction with mucus plugging, air trapping, and the tendency toward parenchymal infections, markedly inhomogeneous ventilation predisposes the ventilated patient with severe AO to the varied forms of barotrauma—pneumomediastinum, subcutaneous emphysema, and tension pneumothorax. Because the lungs cannot collapse, even a small pneumothorax in a ventilated patient with severe AO can rapidly develop a tension component, leading to ventilatory and circulatory compromise.

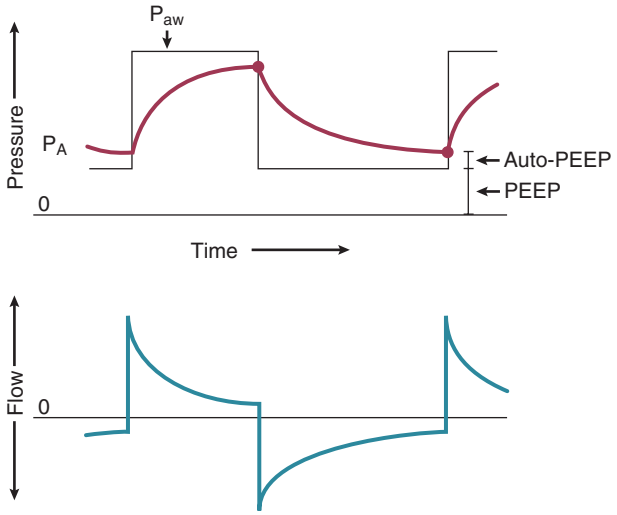
The hemodynamic sensitivity to positive-pressure ventilation of patients with AO arises from several sources.[18] The overexpanded lungs press outward on the chest wall, raising intrapleural pressure. When breathing efforts are silenced, as they are immediately after sedation and intubation, mean intrathoracic pressure abruptly changes from modestly negative to markedly positive. Increased pleural pressure raises the right atrial back pressure to venous return and encourages right ventricular dilation. Simultaneously, increased peripheral vascular capacitance (caused in part by the dilating effects of β_2-agonists) and reduced peripheral vascular tone limit the rise in mean systemic pressure, the upstream driver of venous return. Blood pressure routinely falls, and cardiac output declines disproportionately to oxygen demand. Absolute values of measured central vascular pressures (central venous and wedge) may be misleadingly high and do not necessarily reflect intravascular filling status or preload excess.[7] Marked respiratory variation of systolic and pulse pressures with the ventilatory cycle ("paradox," exceeding 12%–15%) is a hemodynamic marker of phasic alterations of preload and/or afterload (see Fig. 10.4). Either loading condition may cause such paradox, and ultrasonic assessment of the inferior vena cava as well as functional challenges may be required to determine the wisdom of adjusting fluid volume status. Depending on choice of VT, backup frequency, and set (and auto) PEEP, the afterload to right ventricular ejection may rise with any further lung expansion, coupled with the tendency for alveolar dead-space creation. Consequently, great care must be taken not to ventilate excessively and to provide adequate but carefully adjusted intravenous fluid support during this period. This advice pertains especially to patients with AO who require cardiac resuscitation.[19]

Interactions of Pressure-Targeted Modes With Auto-PEEP

Pressure-targeted modes of ventilation, exemplified by pressure control, airway pressure release ventilation, and pressure support, now occupy a central place in the care of intubated patients, as well as in those receiving NIV by face mask. Because the development of auto-PEEP reduces the pressure difference between airway opening and alveolus that drives inspiration, its rise and fall have a powerful influence on ventilation efficacy when these modes are used (Fig. 10.5). As already described, auto-PEEP varies not only with airway mechanics but also with the pattern of breathing and minute ventilation. For a fixed value of applied airway pressure, inspiratory VT in patients with AO will be more sensitive to the frequency and the inspiratory time fraction (an expression of the inspiratory:expiratory [I:E] ratio) than are normal subjects or those with restrictive disease[20,21] (Fig. 10.6). Faster breathing frequencies—for example, allow auto-PEEP to build—and this auto-PEEP must first be counterbalanced for inspiratory airflow to begin. If the patient is passive or the amount of inspiratory muscle force remains constant, delivered VT falls as the auto-PEEP builds.

This auto-PEEP/pressure differential relationship may result in an intriguing phenomenon resembling chaotic respiration during

NIV with a leaky mask interface.[21] The coupled PEEPi and VT form a "feed forward" system in which a building auto-PEEP of one cycle adversely influences the VT tidal volume of the next one. But this smaller VT also reduces the auto-PEEP that follows that restricted cycle, which in turn allows the subsequent breath—the third in the cycle—to have a larger effective airway pressure and VT, and the cycling variation continues. This may account for some of the wide variability in breathing rhythm often observed in these patients.[22] If the mask leak volume is a function of the I:E ratio, it can be shown mathematically and experimentally that fractal and chaotic VT delivery may occur, even when the patient's effort and mechanics remain unchanged (Fig. 10.7).[21] The consequences for comfort and sleep efficiency are likely to be significant, but clinical data are lacking on these issues at this time.



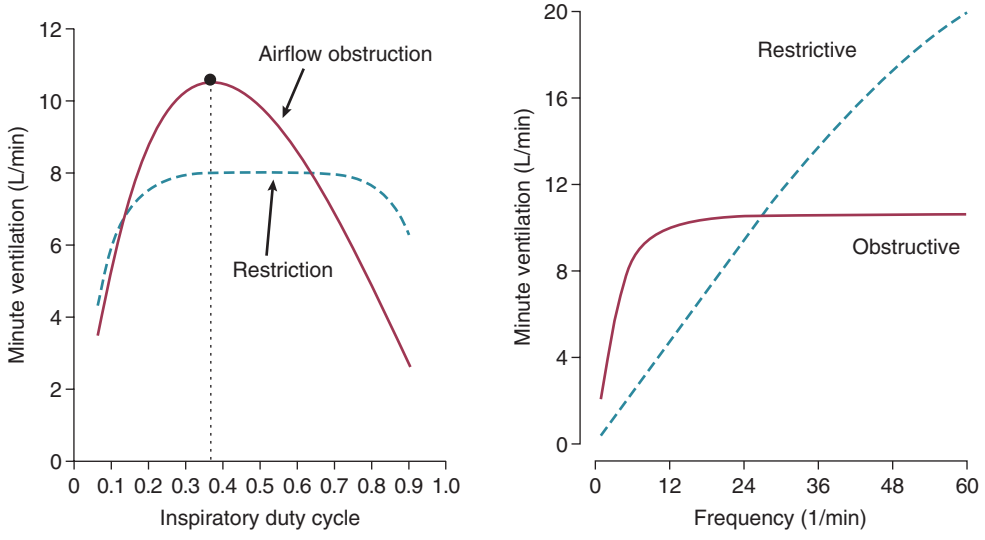
• **Fig. 10.5** Interaction of alveolar *(red line)* and applied airway *(fine line)* pressures in a patient ventilated with pressure-targeted ventilation. Auto-PEEP diminishes the driving pressure of the subsequent ventilatory cycle. P_A, Alveolar pressure; P_{aw}, airway pressure; *PEEP*, positive end-expiratory pressure.

Principles of Managing the Ventilated Patient With Severe Airflow Obstruction

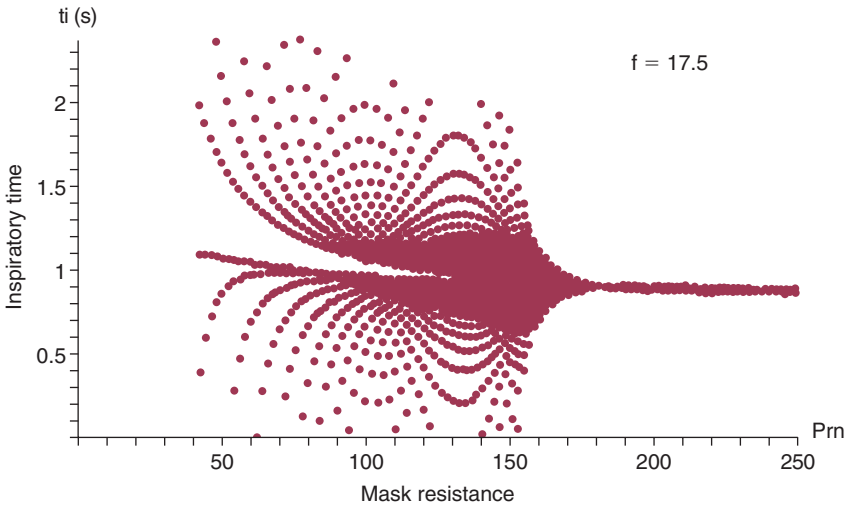
Most patients hospitalized with exacerbations of asthma or COPD can be managed effectively by regimens that incorporate aggressive secretion clearance techniques, antibiotics, corticosteroids, intensified bronchodilators, hydration, cardiovascular support, secretion lubricants (e.g., guaifenesin), and supplemental oxygen. NIV often helps as a temporizing measure for those with disease of *mild-moderate* severity, especially when cough is adequate to clear airway secretions and the patient remains both fully alert and accepting of a face mask interface.[23–28] Only a minority of such patients treated in this way need translaryngeal intubation and institution of mechanical ventilatory support unless the problem is complicated by coexisting cardiovascular, infectious, or neuromuscular problems. When invasive mechanical ventilation is required, however, the rationale underlying certain key management principles can easily be understood against a background of the physiologic derangements already described. These principles are (1) provide adequate support for muscle rest at adequate partial pressure of arterial oxygen (PaO_2) and pH; (2) do not overventilate; (3) minimize the minute ventilation requirement; (4) minimize risk of barotrauma; (5) maintain adequate bronchial hygiene; (6) prevent panic reactions; and (7) establish appropriate nutrition.

Principle 1: Provide adequate support to rest the ventilatory muscles, while avoiding hypoxemia and profound acidemia.

Poised at the edge of decompensation, the ventilatory muscles must be rested adequately before withdrawal of machine support can be considered. Rest may allow recovery of energy reserves and restore the balance between ventilatory capability and demand. Whereas sustained inactivity of the diaphragm encourages atrophy, excessively vigorous contractions of the diaphragm may eventually result in ventilator-induced diaphragmatic dysfunction.[29] Some evidence points to patient-ventilator dyssynchrony and eccentric muscular contractions as key contributors to this process. Both occur more often when ventilator demands are



• **Fig. 10.6** Relative sensitivity of patients with airflow obstruction to the settings of frequency and inspiratory time fraction for a fixed pressure target in pressure-controlled ventilation. This sensitivity is induced primarily by the impact of these settings on auto-PEEP.



• **Fig. 10.7** Theoretical behavior of tidal volume in response to pressure support by mask ventilation in a patient experiencing auto-PEEP. At a certain critical value of mask leak, there is wide cycle-to-cycle variation in tidal volume despite unchanging levels of pressure support and patient effort. Near "chaotic" behavior is a consequence of auto-PEEP. *f,* breath frequency; *PEEP,* positive end-expiratory pressure; *ti (s)*, inspiratory time in seconds. (From Hotchkiss JR, Adams AB, Dries DJ, et al. Dynamic behavior during noninvasive ventilation: chaotic support? *Am J Resp Crit Care Med.* 2001;163:374–378.)

high. Benefit may accrue to judicious muscle rest, even when it occurs intermittently on a chronic basis. Sufficient oxygen and mechanical support must be provided to permit restorative sleep and to avoid significant hypoxemia (arterial oxygen saturation <85%) and acidemia (pH < 7.2)—derangements that increase pulmonary vascular resistance; stimulate vigorous breathing; and inhibit mental, cardiac, and skeletal muscle functions.

Principle 2: Do not overventilate.

Profound respiratory acidosis and hypoxemia accentuate pulmonary hypertension, impair the right ventricle, and demand reversal. Nevertheless, although it is important to provide adequate ventilation and to reverse hypoxemia, overventilation is detrimental on several counts. Rapid reduction in the alveolar CO_2 tension tends to promote bronchoconstriction and impair neuromuscular and cardiovascular function. Furthermore, excess ventilation exacerbates dynamic hyperinflation and auto-PEEP, whereas moderate arterial partial pressure of carbon dioxide ($PaCO_2$) elevations are generally well tolerated.[30] Generally, it is a mistake to depress the $PaCO_2$ below the level that the patient chronically maintains. Such a strategy may temporarily reset chemical drives, effectively increasing respiratory workload intensity once spontaneous breathing resumes. If $PaCO_2$ falls sufficiently, the patient will not maintain unassisted breathing without intolerable effort, potentially delaying discontinuation of mechanical breathing assistance.

Principle 3: Minimize minute ventilation requirement.

Because hyperinflation, mean inflation pressure, and the adverse cardiovascular consequences of mechanical ventilation are intimately linked to the minute ventilation requirement, ventilatory dead space and CO_2 output must be minimized while both metabolic acidosis and iatrogenic hyperventilation are avoided or addressed. Relief from discomfort, anxiety, fever, and metabolic acidosis help achieve these objectives.

Principle 4: Minimize the risk of barotrauma.

The predisposition of patients with severe AO to barotrauma must be combated by intelligent choices for VT, ventilation frequency, PEEP, and machine settings of trigger sensitivity and flow. Reduction of the minute ventilation requirement decreases the mean or peak alveolar pressures, or both, reducing the incidence of barotrauma. The relative contributions of mean alveolar pressure, PEEP, dynamic cycling pressure, and peak static (plateau) ventilatory pressure to the risk of barotrauma are not clear. Based on epidemiologic evidence, however, peak airway pressures in a passively inflated lung should be kept below 40 cm H_2O whenever possible. Selecting a VT within the recommended range (6–8 mL/kg of predicted body weight) is probably best. The question of optimal flow setting is of no small importance: auto-PEEP and mean alveolar pressure are reduced by selection of relatively rapid flow settings when minute ventilation is high. If minute ventilation is normal, however, rapid inspiratory flow rates are much less effective in reducing gas trapping, at least in asthmatic patients.[31] Using less rapid inspiratory flows may improve ventilation-perfusion matching, as well. Finally, higher peak *dynamic* airway pressures engendered by unnecessarily rapid flows are not entirely without risk. Units served by low-resistance pathways are in jeopardy from associated overdistention. For the same tidal inspiratory time, a constant ("square") flow waveform often serves better than a decelerating one in patients with severe AO. The risk of barotrauma can also be minimized by maintaining the lungs free of infection and the airways clear of secretions.

Principle 5: Maintain effective bronchial hygiene.

Secretion retention may dramatically increase airflow resistance and effectively seal off entire banks of functional alveoli, preventing their effective participation in ventilation. Thickened central airway secretions are a particular risk during mechanical ventilation, whether invasive or noninvasive (Fig. 10.8).[32] Apart from raising the end-inspiratory pressure, the resulting dynamic hyperinflation can detrimentally affect cardiovascular function, work of breathing, and respiratory muscle function. In addition to effective suctioning, bronchodilators, adequate hydration, corticosteroids, mucolytics, mucolubricants, and infection control, frequent repositioning, mobilization, and tolerated forms of physiotherapy are fundamental to secretion management. Percussive ventilation or vibropercussive vest treatments often complement mobilization effectively when tolerated. Whether vibratory delivery of inhaled bronchodilators enhances their therapeutic effects has not been conclusively established. Tracheotomies not only reduce resistance and provide improved access to the lower airway but also eliminate the direct connection between the pharynx and trachea established by tracheal intubation. Yet because of their associated morbidity, tracheostomy is best avoided unless mandated by the ineffectiveness of other measures.[33]

Pressure-flow signatures of central-airway mucus plugging. *Crit Care Med.* 2006;34:223–226.)

Principle 6: Prevent panic reactions.

In patients susceptible to dynamic airway collapse, an abrupt need to augment ventilation often precipitates a downward spiral in which the capability of the patient is overwhelmed by the imposed workload. Not only is minute ventilation increased during such episodes, but the resulting augmentation of dynamic hyperinflation also impairs muscle strength and endurance. Respiratory acidosis, dyspnea, and anxiety unbalance the ventilation demand/capability relationship to encourage the need for aggressive intervention. Cardiac decompensation owing to increased demands, adverse loading conditions, and diastolic dysfunction is another potential consequence, especially in the elderly. Anxiolytics, although hazardous to use in patients who are not invasively ventilated, may be extremely helpful in carefully selected circumstances.

Principle 7: Maintain appropriate nutrition, ensure adequate hemoglobin concentration, and prevent obstipation.

In stressed and often malnourished patients, the nature and quantity of nutritional support can make the difference between expedient recovery and continued ventilatory insufficiency. Although reasonable caution is advisable, severe anemia (hemoglobin <8 gm/dL) should be reversed and an adequate number of calories should be provided, via the enteral route whenever possible. Care must be taken to ensure that bowel motility is normal. Patients with AO frequently develop breathing discomfort because of raised abdominal pressures within a compartment bounded by a hyperinflation-depressed diaphragm. Along a similar line, attention to upright positioning is also important to relieve infradiaphragmatic hydrostatic pressures.

Practical Management of the Ventilated Patient

Intubation

An understandable reluctance to initiate mechanical ventilation in patients with COPD or perennial asthma exists because ventilatory assistance may be needed for prolonged periods and because a minimalist palliative approach may be appropriate for individuals who are so chronically disabled as to be miserable or despondent at home—even when everything is going as well as possible from a physiologic viewpoint. The development of comfortable noninvasive systems, coupled with supportive trials and clinical experience, has given rise to the initial use of mask ventilation and HFNCs in those who are alert and can tolerate such approaches. However, the most severely affected patients, especially those with copious, thick, and retained secretions; claustrophobia; anxiety; cardiovascular decompensation; or irreversible somnolence continue to require intubation to stabilize their deteriorating conditions.[34]

A mounting load of secretions audibly retained within the central airways generally indicates that the patient is too weak or breathless to expectorate and often portends an imminent crisis. Hence, when this sign arises and cannot be easily reversed, most physicians consider it strong evidence favoring intubation for secretion management and ventilation support. Overt disorganization of the breathing rhythm and gasping or ataxic respirations strongly suggest approaching exhaustion.

Initial Support

Postintubation Problems

The first 24-hour period after tracheal intubation and initiation of positive-pressure ventilation may be highly dynamic for the patient with AO. Many of these individuals have depleted intravascular volume and impaired cardiovascular reflexes—features that prepare them poorly to compensate for the suddenly increased pleural pressure and impediment to venous return that usually accompany initiation of mechanical support. In this postintubation phase there is an understandable but unfortunate tendency for the physician to intentionally overventilate the patient, and asynchrony often develops as patients cough vigorously or fight against the rhythm imposed by the machine.

One reason for the agitation that some patients experience is a sudden rise of positive intrathoracic pressure through the process of dynamic hyperinflation. When these intubated patients are deeply sedated and paralyzed, respiratory efforts cease and vasodilation occurs related to hypercapnia and sedation. The consequent buildup of intrathoracic pressure, coupled with a fall

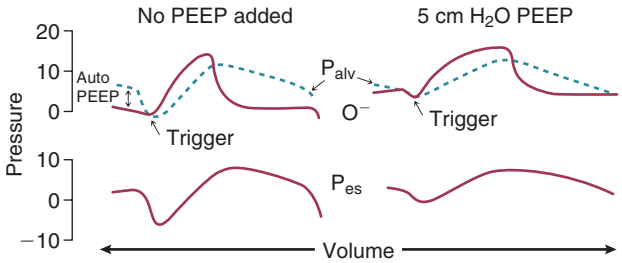
in mean systemic vascular pressure, almost routinely depresses venous return and cardiac output (see Fig. 10.3). Therefore the physician is well advised to remain alert to the predictable development of cardiovascular depression and hypotension after intubation or sedation and be prepared to intervene to reduce ventilation or to support the circulation at the initially selected level, or both. A catastrophic error is to misinterpret the development of sudden hypotension as the uncloaking of tension pneumothorax and then to undertake needle puncture of the chest wall. In such individuals it is also wise to remember the potential contribution of auto-PEEP to hypotension during cardiopulmonary resuscitation attempts.

Shortly after intubation there may be agitation, coughing, and retching related to tube insertion. When this interferes with comfort or ventilation, many lightly sedated patients benefit from 3 to 5 mL of 1% to 2% lidocaine instilled through the endotracheal tube. Instillation may be repeated one or two times, but care should be exercised, as lidocaine is easily absorbed via the lung. Fortunately, intolerance of tube placement gradually abates with sedation and the passage of time.

Machine Settings

As a general rule, ventilation should be adequately supported during this initial phase, but it is better to underventilate cautiously than to overventilate the patient. One reasonable approach is to use assisted flow-regulated volume-controlled mechanical ventilation, delivered with a square wave profile, with the backup rate set to provide about two-thirds of the estimated minute ventilation requirement. Although the flow setting is adjusted empirically to coordinate the cycle lengths of the patient and the ventilator, an initial peak flow setting of approximately four to six times the minute ventilation requirement (depending on whether the flow profile is square or decelerating, respectively) usually suffices to meet expiratory time requirements and minimize auto-PEEP without imposing undue risks that attend extraordinarily high peak cycling pressures. Assuming a minute ventilation of 10 L/min, a constant flow setting of about 40 to 60 L/min is usually appropriate. This yields an I:E ratio of approximately 1:4, which is considerably shorter than customary in a patient with normal mechanics who breathes at this level of minute ventilation. Reducing the I:E ratio still further may not improve gas trapping noticeably at modest levels of ventilation, as terminal rates of airflow are predictably very low.[5] On the other hand, increasing airflow carries a high airway pressure cost in patients with such severe AO. For similar reasons, a constant inspiratory flow is preferable to a decelerating one when flow-controlled, volume-cycled ventilation is in use. Pressure-targeted ventilation is a sensible choice only when it is monitored closely or adjusted automatically by the ventilator to maintain VT in response to changing airflow impedance.

The triggering threshold of the ventilator is set to be as sensitive as possible, and the auto-PEEP level is estimated when feasible to do so. (Measurement typically requires passive inflation to allow predictable occlusion of the circuit at end-expiration.) If auto-PEEP exceeds 5 cm H_2O and expiratory flow is limited during tidal breathing (which is almost invariably the case during the initial phase), an uncomfortable patient who makes spontaneous breathing efforts may benefit from the addition of a low level of end-expiratory pressure to counterbalance auto-PEEP, reduce the incidence of ineffective triggering efforts, and reduce the breathing workload (Fig. 10.9). PEEP levels in excess of 15 cm H_2O may be necessary in some unusual instances to reestablish patency of some air channels.



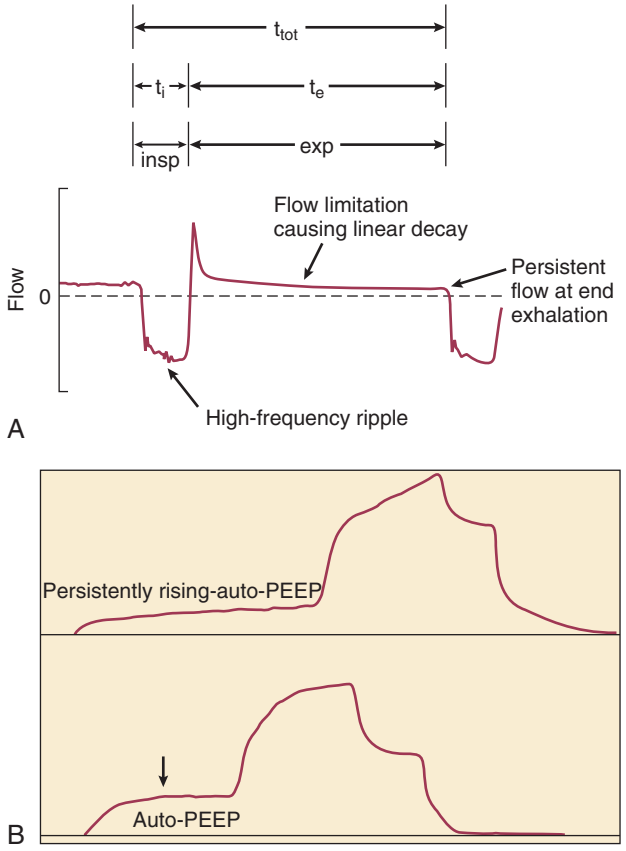
• **Fig. 10.9** Work of breathing and ventilatory effort are improved in patients with tidal flow limitation by the addition of PEEP marginally less than the original value of auto-PEEP. Airway pressure *(top)* and intrapleural pressure *(bottom)*. P_{alv}, Alveolar pressure; P_{es}, esophageal pressure.

The plateau pressure is a better guide to the degree of hyperinflation than is the measured level of auto-PEEP, for reasons of heterogeneous mechanics already discussed. First, most machines do not allow estimation of auto-PEEP in a patient who is spontaneously triggering the ventilator and varies the length of the respiratory cycle. On the other hand, a plateau pressure estimate is usually recordable during triggered, as well as during controlled, volume-cycled breathing. Just as importantly, the auto-PEEP estimated by central airway occlusion is simply the volume-weighted average of those airways that remain open at end-expiration, which generally have shorter time constants and better mechanical properties than those that seal earlier in the expiratory period at higher pressure (see Fig. 10.2).

The flow tracing gives some indication of the underlying presence of gas trapping but does not indicate its severity. For example, a severely obstructed airway may be totally occluded and therefore unable to transmit its high pressure to the pressure sensor located within the machine circuitry. Similarly, a severely narrowed airway may give rise to almost imperceptible flow at end-expiration. Several features of the flow tracing are of value: high-frequency variations of the flow tracing during exhalation suggest the presence of retained central airway secretions or water in the external tubing. An abrupt transition between the earliest part of expiration and what follows ("hockey-sticking") indicates a flow limitation during tidal breathing and the potential value of added PEEP if flow persists to the onset of the next breathing cycle (Fig. 10.10). Several signs appearing in the monitored airway pressure and flow signals have been reported to be signatures of partial central airway occlusion, as by mucus plugging (see Fig. 10.8).[32]

Support Phase Management

After the first hours of ventilatory support, rational management focuses not only on reversal of the underlying problems of infection, bronchospasm, secretion retention, and cardiac insufficiency, but also on replenishing spent nutritional reserves and building endurance. It makes sense to support ventilation fully in patients intubated for ventilatory failure while fundamental pathologic processes and precipitating causes are being addressed—at least for the initial 24 to 48 hours. Because it is not known what intensity of ventilatory effort is best for patients with AO to undertake during the support phase of the illness, controversy exists as to the optimal mode of ventilation. During the support phase, the major ventilation objective while the acute problems causing deterioration are being addressed should be to provide sufficient breathing assistance to alleviate discomfort while not risking deconditioning of the



• **Fig. 10.10** A, Typical flow tracing of a patient demonstrating flow limitation during tidal breathing. High-frequency ripple suggests secretions or circuit fluid, whereas "hockey-sticking" and linear flow decay during expiration characterize flow limitation. • **Fig. 10.11** Adjustment of the expiratory flow trigger during pressure support can help to compensate for a slowly decelerating inspiratory flow profile that typifies patients with severe airflow obstruction. The appropriate adjustment in this schematic drawing might be from 25% to 50%.

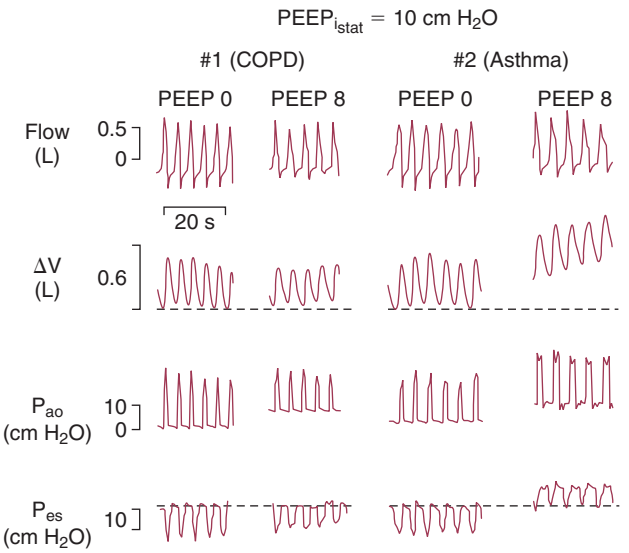
ventilatory muscles. To this end, it is reasonable to use volume- or pressure-targeted assist-control (assisted mechanical ventilation) or even synchronized intermittent mandatory ventilation (SIMV). Although the latter has seen decreasing use in recent years, it still proves helpful when a consistent back-up rate is needed while reducing the asynchrony otherwise encountered with purely time-cycled modes such as VCV or pressure-controlled ventilation (PCV). In patients who are not deeply sedated and who breathe chaotically, the latter mode applied with pressure support sufficient to replicate the VT of the mandated breaths may reduce the number of dyssynchronous "collisions" between the rhythms of patient and machine. Adequate sedation must be provided to ensure comfort and reduce the minute ventilation requirement as other fundamental elements of ventilatory therapeutics are addressed (e.g., antibiotics, corticosteroids, regulation of intravascular volume, secretion expulsion or extraction, cardiovascular support).

Ensuring adequate oxygenation, ventilatory muscle rest, and restorative sleep deserve emphasis. Deep sedation and muscle relaxants, although occasionally necessary in achieving therapeutic objectives early in the ventilatory process, may prove detrimental when their use is prolonged unnecessarily. Not only does sedation present risks of muscle deconditioning and even neuromyopathy, but secretions tend to pool in dependent areas when breathing efforts and coughs are suppressed. As a general rule, deep sedation and paralysis should not be continued for longer than 40 to 72 hours after intubation.

Decelerating flow profiles are often poorly tolerated by the patient with severe AO who makes spontaneous efforts, because the latter half of the inspiratory period may require higher flows than imposed by the tightly regulated and stereotyped flow waveform of the ventilator. Raising the flow criterion off-switch that triggers expiration can help manage this problem during pressure-supported ventilation (Fig. 10.11).

PEEP and CPAP in Severe Airflow Obstruction

The deliberate use of PEEP in patients with AO historically has been considered undesirable, but there is now ample reason to believe that most of these patients benefit from the application of low levels of PEEP or continuous positive airway pressure (CPAP).[5,10,11] When applied downstream of airways that collapse dynamically during the exhalation phase of tidal breathing, PEEP helps to improve the effective triggering responsiveness of the machine without significantly increasing the alveolar pressure or hyperinflation (Fig. 10.12). Most benefit is provided to patients receiving VCV who do not experience proportionate increases of peak static or peak dynamic cycling pressures after PEEP application.[10,11,35] When using a fixed level of targeted pressure (pressure control or pressure support), VT may increase after PEEP is applied. This occurs because the added PEEP counterbalances auto-PEEP to allow the applied inspiratory pressure to more effectively drive inspiratory flow. In effect, PEEP improves the pressure gradient that drives *inspiratory* flow and delivers VT. (Should minute ventilation increase with PEEP application, total PEEP may also rise.) Applied PEEP may also help to keep airways more widely patent, and thereby improve secretion clearance and bronchodilator deposition. Finally, the application of external PEEP theoretically may help to even the distribution of ventilation among multiple units with heterogeneous time constants, but this potential benefit has not been definitively shown (Fig. 10.13).



• **Fig. 10.12** Differing responses of a flow-limited patient with chronic obstructive pulmonary disease *(COPD)* and a non–flow-limited patient with asthma to the application of PEEP. The increases of lung volume *(V)* and airway opening pressure (P_{ao}) in asthma and the relative absence of these features in the patient with COPD are demonstrated. *PEEP,* Positive end-expiratory pressure. (From Ranieri VM, Giuliani R, Cinnella G, et al. Physiologic effects of positive end-expiratory pressure in patients with chronic obstructive pulmonary disease during acute ventilatory failure and controlled mechanical ventilation. *Am Rev Respir Dis.* 1993;147:5–13.)

Newer Modes of Ventilatory Support in Airflow Obstruction

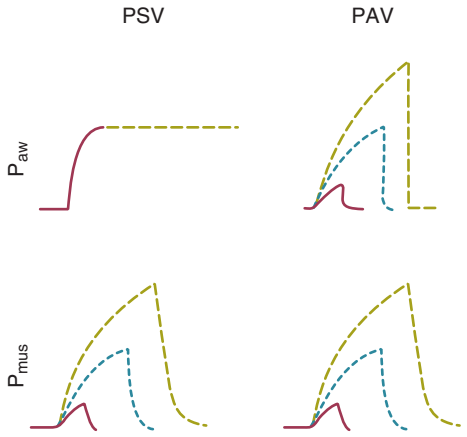
Currently the majority of ventilatory support of AO is still provided with modes of ventilation that are now decades old—flow-controlled, volume-cycled ventilation ("assist-control"); pressure assist control (pressure control, PCV); pressure support (PSV); and SIMV. When combined with PEEP/CPAP and an attentive provider, these time-tested options suffice for the majority of patients. Increasingly, however, practitioners have recognized the need to offload to the ventilator responsibility for minute-by-minute and even intrabreath adjustment of settings for flow and pressure delivery in response to changing conditions of mechanics or ventilatory demand. Patients with dyspnea generally need a faster rise of pressure and flows to their target values, unimpeded inspiratory flow, and precise termination of the ventilator's inspiratory phase to avoid collisions between the patient's neural and the ventilator's mechanical cycling rhythms. Once set, however, a specified flow pattern regulates the ventilator's gas delivery, whereas pressure control caps airway pressure at the targeted value. Just as importantly, these time-cycled assist-control modes (whether flow or pressure regulated) disregard the duty cycle rhythm variations of the patient's own drive center; therefore asynchrony occurs commonly in these modes, and asynchrony may result not only in dyspnea but also in adverse outcomes.[36,37] Avoidance of the triggering, power, and cycling dyssynchronies that are so common among acutely ill patients has now become a key focus of optimized ventilator care. Appropriate moment-by-moment intracycle adjustment of flow or pressure is not an option with "traditional" modes of ventilation. Logic dictates that better synchrony between patient and machine would require continuously monitored feedback and flexibility to adjust to the vagaries of patient need. Of the newer modes of ventilation, four with implications for AO have garnered considerable attention and have been incorporated into some of the latest equipment.

Airway Pressure Release Ventilation and Bilevel Ventilation

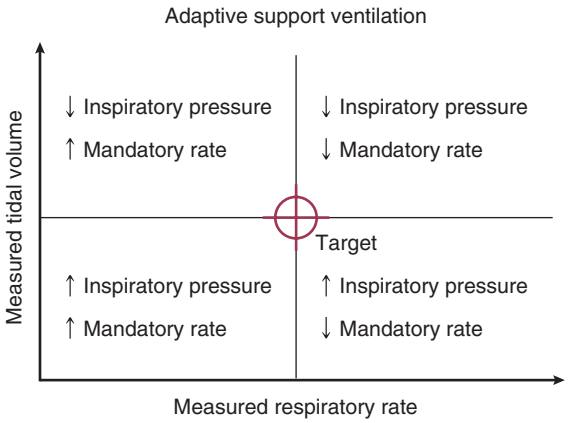
These modes were neither designed nor intended for patients with lengthy expiratory time constants. Airway pressure release ventilation does not take full advantage of its release phase in patients with lengthy expiratory time constants and therefore ineffectively ventilates unless the release frequency is high. At the same time, maintaining mean alveolar pressure relatively high is a priority. The machine's inspiratory phase pressure is generally higher than that encountered during conventional ventilation, introducing the problems associated with sustained hyperinflation in patients with relatively flexible lungs. Wide variations of auto-PEEP and of release cycle volumes are to be expected. The addition of PEEP to airway pressure release ventilation may not prove effective in mitigating this variation during release cycles unless the release phase had been prolonged sufficiently to encounter flow limitation during tidal breathing. Bilevel ventilation alternates ventilation around two levels of CPAP and may take better advantage of PEEP's work-offsetting effect. Again, however, this mode holds little advantage over more conventional options for patients with AO.

Proportional Assist Ventilation

Proportional assist ventilation (PAV)—a mode based on the equation of motion of the respiratory system that regulates delivered pressure in proportion to externally sensed inspiratory flow and volume—effectively mimics the actions of an auxiliary muscle in patients without gas trapping.[38–40] Quite unlike pressure support, which targets the same pressure for every breath, PAV takes resistance and compliance into account and is meant to provide help breathing in proportion to patient effort according to a percentage designated by the provider (Fig. 10.14). Unfortunately, ventilatory impedance varies considerably in patients with AO, and a considerable fraction of inspiratory muscle effort is spent in counterbalancing variable auto-PEEP, an event that precedes the onset of inspiratory flow. Given the strong dependence of dynamic hyperinflation on minute volume ($\dot{V}E$) and the expiratory time constant, the original version of PAV could not easily fulfill its intended function in patients with severe OA and changing mechanics or minute ventilation needs. Despite these theoretical disadvantages, a modern adaptation of PAV (e.g., PAV+)—which monitors respiratory mechanics several times or more per minute on an ongoing basis—has shown at least equivalent comfort in patient trials, as well as no greater incidence of missed triggering events and greater V_T variability



• **Fig. 10.14** Comparison of pressure support ventilation *(PSV)* and proportional assist ventilation *(PAV)* in response to muscular efforts of varying intensity. The machine pressure mirrors the patient's muscular effort during PAV but not during PSV. P_{aw}, Airway pressure. (From Younes M. Proportional assist ventilation, a new approach to ventilatory support. Theory. *Am Rev Respir Dis.* 1992;145:114–1120.)



• **Fig. 10.15** Regulation of ventilation by adaptive support. By changing the number of mandated pressure-controlled breaths and by regulating the pressure applied to each triggered cycle, adaptive support aims to keep breathing frequency and tidal volume within acceptable physiologic ranges (see text).

than pressure support, both in invasive and noninvasive settings.[41] Although reassuring, no outcome advantage over PSV has yet been convincingly demonstrated in any AO setting.

Neurally Adjusted Ventilatory Assist

Neurally adjusted ventilatory assist (NAVA) is similar in concept to PAV in that it attempts to regulate the machine's power support moment by moment by sensing inspiratory effort from the patient.[40,42] The difference is that the diaphragmatic electromyogram provides the pressure-controlling signal for the machine, so that the electrical intensity of phrenic nerve traffic regulates the amplitude and the pattern of the inflation pressure delivered. NAVA depends on the patient's drive to breathe, not the lung's mechanical response. A thin, multielectrode esophageal catheter is used to pick up the strength and contour of the electromyogram signal, and failure to detect it has not proven a major problem. The dynamic hyperinflation drawbacks of PAV in patients with AO are theoretically nullified by placing the "effort detector" closer to the respiratory drive controller—inspiratory efforts related to auto-PEEP are tracked and supported before inspiratory flow actually begins. Inherent protective reflexes are believed to help the patient avoid overdistention, even if the machine's power boost factor is set inappropriately high. Despite its intuitive appeal, NAVA is still too recently deployed in the clinical arena to confirm its theoretical advantage over other options.

Adaptive Support Ventilation

Adaptive support ventilation (ASV) regulates machine output with pressure-targeted breaths delivered at a variable frequency and with variable pressure in accordance with the clinician-set minute ventilation target and the breathing pattern across a sequence of multiple breaths (Fig. 10.15). It can be used during triggered (pressure-supported) or controlled (pressure-controlled) ventilation. Its intent is to minimize the work of breathing and auto-PEEP while avoiding both hypoventilation and hyperventilation. ASV attempts this by optimizing the VT and frequency combination that comprises the targeted minute ventilation. As such, ASV is one step closer to "closed-loop" ventilation, in which clinical goals are set, monitored, and accomplished automatically. Once the clinician has determined the PEEP, fraction of inspired oxygen, and cycling ramps and triggers for pressure support, he or she must input the patient's predicted body weight or height and age as well as the fraction of the estimated "normal" minute ventilation (approximately 100 mL/kg per minute) the machine should provide for that disease state. It then varies the mandatory breath number and the pressures of a pressure-regulated SIMV algorithm to stay within the desired breathing pattern zone. All the while, the machine tries to nudge the patient toward the ventilatory pattern optimum that *should* minimize dead space, work of breathing, and auto-PEEP.

In observational studies ASV appears to regulate VT and total breathing frequency effectively, without the need for clinician intervention.[43] As with all advanced modes, however, its performance in severely stressful settings has not been validated and no convincing outcome benefit has yet been reported. As originally implemented, ASV lacked gas exchange feedback, did not calculate total physiologic dead space, and did not account for adjustment to the ideal optimum breathing pattern incurred by disease or deformity.

A refinement of ASV (Intellivent-ASV, Hamilton Medical, Reno, NV) incorporates end-tidal CO_2 and pulse oximetry data and is somewhat more complicated to set up as the ranges for three controllers must be specified. Nonetheless, it is a promising approach that modifies machine output in response to changing need and patient response and may prove to reduce the gas trapping that dysfunctional patterns of AO engender.

Extracorporeal Carbon Dioxide Removal

While still in its initial stage of clinical deployment, extracorporeal CO_2 removal by intravascular catheter holds undeniable logical appeal for use in the most severely ill and/or refractory patients with AO.[44] Because blood flowing through the external circuit can be virtually scrubbed free of its CO_2 content, relatively low blood flows are required in exchange for considerable benefit regarding the pulmonary workload associated with any given metabolic state. In turn, reduced ventilating burden attenuates dyspnea and conceptually may spare the need for airway intubation and invasive mechanical ventilation, especially when used in conjunction with NIV. Moreover, in patients with adequate hemodynamics, blood flow through the external CO_2 exchanger may be driven by the

arteriovenous pressure gradient. Mechanical pumps are clearly more effective and would be required in patients with limited cardiac reserve, but the associated apparatus is inherently more complex. Although the hazards of this methodology currently remain very significant and reliability needs further enhancement, recent improvements in anticoagulation, catheters, exchangers, and circuitry suggest that variations of this promising methodology will offer a viable as well as logical consideration for many severely ill patients with life-threatening ventilatory failure in the relatively near future.

Weaning ("Liberation") Phase

Protracted ventilator dependence is perhaps the most feared consequence of intubating patients with exacerbated COPD and perennial asthma. Not only are breathing workloads high, but the ability of the patient to sustain them is compromised by muscle weakness, hyperinflation, disadvantageous thoracic geometry, blunted ventilatory drive, and abnormal cardiovascular function. Rational management of the patient with AO includes provision of adequate rest and nutritional support; enhancement of mental, neuromuscular and cardiovascular function; and minimization of the breathing workload. Maintenance of positive mental attitude and avoidance of sedation excess can greatly speed the weaning process. It has been argued that few if any patients benefit from the gradual removal of ventilator support.[45] Although this argument holds validity for many patients, those with life-threatening exacerbations of AO are among those most likely to benefit.

Patients remain dependent on mechanical ventilation for a wide variety of reasons (failure to wean). Among these are hypoxemia, cardiac arrhythmias, hemodynamic instability, and psychological dependence. However, imbalance between ventilatory capability and demand is perhaps the most common reason for failure to wean in patients with ventilatory failure either of itself or because it provokes worsening of one or more of the other factors just mentioned.[46,47]

Predicting Readiness for Spontaneous Breathing

In clinical practice a panel of indices has long been used to predict the outcome of the weaning trial. Most individual elements of these demand and/or capability panels can be classified as indicators of either one or the other, but not both. Some capability indicators depend on voluntary effort as well. Thus a maximal inspiratory pressure measurement exceeding negative 30 cm H_2O and a minute ventilation requirement of less than 10 L/min are standard components of the traditional predictive battery. Although minute ventilation has been criticized as unreliable when used alone, it is still a highly useful observation, particularly when referenced to blood gas measurements, body size, gender, and integrated into an evaluation of other panel elements. When the patient is calm, a high degree of variation of minute ventilation suggests some degree of ventilatory reserve.[48] Because the product of minute ventilation and the average inspiratory pressure per breath are the main components of the breathing workload, minute ventilation must not be disregarded, even when more integrative indices are in use, such as the frequency-to-VT ratio (rapid shallow breathing index [RSBI]).[49] For example, a high RSBI does not necessarily portend failure if the patient has restrictive physiology of lung or chest wall and/or minute ventilation rises from the baseline value as well. Such an observation may simply reflect the most efficient breathing pattern during tolerable exercise. A steadily rising RSBI during the trial is more concerning, especially if the patient exhibits signs of distress. Published criteria for RSBI lose some reliability in the presence of neuromuscular weakness, severe restriction, or chronic illness requiring ventilator support.[47]

Numerous other weaning outcome indices have been suggested over the years, but none stands alone as infallible, including the RSBI. The most successful of these indicators reliably relate power requirement for ventilation to the ability of the patient to sustain it. Certain physiologic measurements such as the $P_{0.1}$ (a measurable indicator of ventilatory drive now offered on some of the newest ventilators) have predictive appeal. These are not universally available, however, and cannot be relied on for definitive judgment in every case. Because many factors may limit the patient's ability to be removed from the ventilator, more than one single indicator is usually necessary to observe. Alertness, degree of cardiovascular compensation, clinical trajectory over the preceding days, oxygenation status, secretion load, upper airway patency, coughing efficiency, and psychological well-being are as important as any single predictive measure based on mechanics and muscle strength. Successful weaning protocols take all such factors into account.[46,47,49]

Repeated failure to wean is often explained by cardiovascular factors such as ischemia and diastolic dysfunction, particularly among elderly patients with COPD. This is especially true when parameters based on ventilation appear favorable. Clues may appear in the form of cardiac dysrhythmias and an unfavorable excess of fluid intake over output. In part for such reasons, weaning protocols must be constructed and applied carefully; failure to meet weaning criteria must be considered a cue to undertake a careful review of all potential factors that prevent success, not necessarily an indication to allow a bit more time with unchanging therapy.

Weaning Approaches

Preparations

Preparations for ventilator withdrawal should include ensuring adequate nocturnal rest with fully supported breathing, adequate nutrition, good circulatory reserve, avoidance of excessive intravascular volume and edema, treatment of infection, appropriate body positioning, and judicious sedation.[46,49] Obstipation, urinary retention, pleural effusions, gastric distention, musculoskeletal pain, severe anemia, and chemical imbalances must be avoided or reversed. During the full support phase of ventilation, care must be taken not to allow sedatives to accumulate or secretions to collect within the airways. Intermittent "as-needed" dosing is preferred to steady infusion or scheduled dosing of sedatives, and if used at all, interruption of sedation should be implemented daily. Heat-moisture exchangers do not hydrate the airway secretions reliably, especially in low humidity environments or when high inspired concentrations of oxygen have been in use. Active humidification often proves the better choice when secretion load or clearance is problematic. Inspection of the central airway before attempted extubation may be rational in tenuous patients when intubation has continued for more than a few days, as thickened or inspissated secretions may not have been adequately removed by routine suctioning. The patient must not depend on high levels of PEEP for either oxygenation or comfort. It must be remembered that PEEP and CPAP aid ventilation in patients with flow limitation and auto-PEEP.

The use of frequent wake-ups, intermittent dosing, and short-acting sedatives (especially in the hours before spontaneous breathing trials and weaning attempts) has helped to avoid the common problem of benzodiazepine metabolite hangover; lingering sedative

effects may persist for up to a week after the last benzodiadepine dose was given. As a complement or alternative to minimized and low-dose benzodiazepines, dexmedetomidine (Precedex), a sedative agent with relatively little hypnotic action, has proved helpful when calm alertness is desired but difficult to otherwise achieve.[41] In well-selected cases, alertness-enhancing drugs such as modafinil (Provigil) have been helpful. Delirium should be addressed to the extent possible by nonpharmacologic means, such as verbal redirection, restoration of diurnal wake and sleep schedules, minimized sedation, repositioning, and mobilization. Delirium that interferes with weaning occurs commonly and may benefit from such agents as quetiapine and olanzapine.[50,51] The highly effective interventions of noninvasive ventilation and high-flow nasal cannulas often act as effective "bridges" to fully spontaneous breathing once the tube is removed.

Specific Modes for Weaning

Considerable effort has gone into the delineation of the optimal weaning technique. It is generally true that the majority of patients do not need a lengthy period of gradual machine withdrawal once the primary problems that brought the patient to medical attention have been treated and the adverse effects of fluids and drugs given during their acute problems have been addressed.[52] It is also true, however, that a distinct subset of these patients with underlying AO or other chronic impairments not amenable to therapy cannot tolerate abrupt transitions to spontaneous breathing. More graded reloading is sometimes necessary because of fragile cardiovascular status, neuromuscular weakness, or psychological factors. Pressure support ventilation is generally to be preferred to SIMV, as the muscle and cardiovascular reloading process tends to be less sudden and more predictable. Use of intermittent T-piece weaning makes little sense in patients like this; each transition to fully spontaneous breathing abruptly imposes a full stress workload. All patients, however, should be *tested* with low-level pressure support or T-piece breathing before any gradual withdrawal of support is undertaken, as the latter may not be necessary.[53] Once the patient is breathing with a low level of pressure support or from an oxygenated T-piece, observation should be continued at least 30 minutes, but generally less than 2 hours before decannulation of the airway is attempted. During the attempt at spontaneous breathing, the patient must be watched carefully and not allowed to fatigue because recovery from that condition may require more than a day to restore energy reserve.[54] Although careful implementation of weaning protocols by a dedicated team is highly effective, it is worth noting that two modes that have recently been introduced to accelerate and automate weaning—namely, Smartcare/PS (Draeger Medical, Lübeck, Germany) and ASV—have met with some success in facilitating that process. For settings in which appropriate protocols are not rigorously applied or patient surveillance not closely maintained, both approaches hold strong appeal.[55]

Periextubation Phase

In intubated patients in whom upper airway obstruction is suspected, a cuff deflation test should be conducted before decannulating the airway. This is performed by elevating PEEP to 10 cm H_2O immediately in advance of deflation. An audible leak should be heard if the glottic space is not prohibitively tight. With the tube cuff deflated and no audible leak, the sitting position, manipulation of head position, slight (1–2 cm) caudal displacement of the tube, and a temporary increase of PEEP during ventilation may help break a "mucus seal" that otherwise prevents gas leakage. In questionable cases, advance preparations should be made for urgent intervention, should that prove necessary after tube extraction.[33]

The immediate postextubation phase should be as carefully managed as the ventilated one. The first 24 hours off the ventilator are often difficult, but in successful cases there should be progressive improvement. Coughing, deep breathing, adequate oxygenation, avoidance of arrhythmias, adequate bronchodilation, airstream hydration, maintenance of a clear central airway, and a mechanically efficient posture are crucial. Oral refeeding must be undertaken with extreme caution because swallowing difficulty and dysfunction can persist days to weeks after extubation in patients who have been ventilated for lengthy periods. CPAP and intermittent NIV may be especially helpful in selected patients,[33,56] especially in the nighttime hours. Interfaces for NIV have improved remarkably in recent years, facilitating NIV use. In some patients with AO who require only modest ventilation assistance, well-hydrated high flow nasal cannulas (HFNCs) (30–50 L/min of blended gas) can provide a well-tolerated and effective option.[57,58] The mechanisms for therapeutic ventilation effect with this modality may include (1) an modest upper airway CPAP effect that helps dilate the upper and lower airways; (2) CO_2 washout from the pharynx and upper trachea; (3) reflexes that reduce the sensation of dyspnea, slow the breathing rate, and improve ventilating efficiency; and (4) an expiratory retard similar to the effect of pursed lips breathing (HFNC physiology). This comparatively comfortable methodology allows for speech, eating, and expectoration.

NIV (often referred to by its now generic but once commercial designation of Bi-pap [biphasic positive airway pressure]) affords greater ventilating power than HFNC, helps maintains patency of an edematous upper airway, and provides ventilation support during all phases of sleep. This often proves important in patients who have received sedating medications and/or are sleep deprived. It must be used judiciously, however, and carefully applied. Ventilation by pressurized mask impedes secretion clearance, and if a humidifier is not used, mouth-breathing during Bi-pap dries secretions and encourages displacement of oral material into the central airway. Therefore it is not uncommon for patients who receive mask ventilation after extubation to require reintubation for clearance of thickened airway mucus.

Key Points

- By assuming a major portion of the ventilator workload, mechanical ventilation affords the opportunity to rest the respiratory muscles while maintaining pH homeostasis and oxygenation, thereby averting progressive ventilatory failure or respiratory arrest, or both.
- Increased resistance to airflow and gas trapping is responsible (directly or indirectly) for many of the physiologic disturbances that typify AO.
- When dynamic collapse occurs during tidal respiration and breathing requirements are high, there is little alternative to hyperinflation, CO_2 retention, or both.
- Ventilation-perfusion mismatching is prevalent in patients with severe AO, reducing the efficiency of CO_2 elimination but allowing for hypoxemia reversal by relatively low levels of oxygen supplementation.

- Pressure-targeted modes of ventilation, exemplified by pressure control and pressure support, have become increasingly popular in the care of intubated patients, as well as those receiving NIV by face mask.
- Most patients hospitalized with exacerbations of asthma or COPD can be managed effectively by regimens that incorporate aggressive secretion clearance techniques, antibiotics, corticosteroids, intensified bronchodilators, hydration, cardiovascular support, and supplemental oxygen.
- The first 24-hour period after tracheal intubation and initiation of positive-pressure ventilation is a highly dynamic one for many patients with AO.
- The majority of ventilatory support of AO is still currently provided effectively with modes of ventilation that are now decades old—flow-controlled, volume-cycled ventilation (assist-control); PCV; PSV; and SIMV. However, newly developed ventilator modes and nonventilatory innovations point the way toward more effective and comfortable life support.
- Careful attention to the nature and quantity of sedation, coupled to daily attempts to awaken and test spontaneous breathing, accelerates liberation from mechanical ventilation.
- The postextubation phase should be as carefully managed as the ventilated one. The first 24 hours off the ventilator are often difficult and tenuous. During this phase, close attention to secretion clearance, quality sleep, upper airway patency, appropriate upright positioning, and fluid management help avert the need for reintubation.
- NIV and HFNC are valuable adjuncts to care both before and after intubation.

Review Questions

1. For patients with chronic obstructive pulmonary disease (COPD), dyspnea during exertion best correlates with which one of the following?
- **a.** Heavy secretion load
- **b.** Dynamic hyperinflation
- **c.** Elevated airway resistance
- **d.** High tidal driving pressure

Answer: b. Many patients with airflow obstruction experience low levels of dyspnea until the tidal volume approaches the inspiratory capacity. Breaths taken from high chest volumes require more work to perform and inspiratory muscles are mechanically disadvantaged. Dynamic hyperinflation reduces the reserve between end-expiration and total lung capacity. Further increases of lung volume cannot be accomplished without encroaching on total lung capacity. Although secretion load, elevated airway resistance, and high tidal driving pressures all increase the breathing workload, dyspnea depends most directly on the workload-to-work capacity ratio.

2. For hospitalized patients with massive obesity which one of the following is most correct?
- **a.** Lung volume is predictably increased.
- **b.** Gas trapping is reduced by upright positioning.
- **c.** External positive end-expiratory pressure (PEEP) increases regional gas trapping in the supine position.
- **d.** Gas trapping seldom occurs in those without COPD or asthma.

Answer: b. Patients with massive obesity tend to collapse airways and gas trap upon assuming the horizontal position. The upward thrust of the abdominal pressure is reduced by assuming an upright posture, relieving the tendency for expiratory collapse. Adding PEEP to the supine patient helps keep the airways open and also relieves tidal gas trapping. Although positional gas trapping may occur, the overall tendency is for overall lung volume (as measured by FRC) to decline.

3. In patients who are passively inflated by volume-controlled mechanical ventilation, changes in gas trapping are best indexed by which one of the following?
- **a.** Difference between peak dynamic and static airway pressures
- **b.** End-expiratory esophageal pressure
- **c.** End-inspiratory plateau pressure
- **d.** End-expiratory flow rate

Answer: c. The extent and severity of regional auto-PEEP vary from site to site, influenced by local variations in pleural pressure. Thus some airways seal at relatively high airway pressures, whereas others remain open throughout the entire respiratory cycle. Measurements made at end-exhalation tend to underestimate the pressures in the units that closed earlier in the expiratory cycle. During inflation, reversibly closed units reopen as the airway pressure builds. Therefore the end-inspiratory plateau pressure during volume-controlled ventilation is influenced by the pressures in all lung units and will better reflect the difficulty of inflation owing to dynamic hyperinflation. End-expiratory flow is influenced by airway resistance in the units that remain in communication with the airway opening as well as by the auto-PEEP in those units. The end-inspiratory difference between peak dynamic and plateau pressures will reflect the end-inspiratory resistance of open channels but does not index auto-PEEP.

History

Extensive reviews on the history of mechanical ventilation of acute respiratory distress syndrome (ARDS) can be found elsewhere.[1,2] In the 1970s mechanical ventilation was recommended and performed with low positive end-expiratory pressure (PEEP) and high tidal volume (VT): "larger tidal volumes (10–15 per kilogram) are preferable, having been used in several thousand ventilated patients with no evidence of development of pulmonary damage."[3] Today this advice seems inconceivable. At that time, the main concerns were the putative harm of high inspiratory oxygen fraction and the hemodynamic impairment. It was later recognized in experimental and clinical settings[4–6] that high-volume/high-pressure mechanical ventilation could severely damage the lung parenchyma. Such lesions, primarily attributed to the excessive airway pressure, were collectively classified as *barotrauma*. In the same period, Suter and colleagues[7] published a report that, for the first time, systematically described the interaction between PEEP, lung mechanics, gas exchange, and hemodynamics.

In the 1980s, based on the work of Dreyfuss,[8,9] the focus progressively shifted from the potential harm of pressure to the harm of volume (overdistention), a concept that was popularized as *volutrauma*.[10] In the mid-1980s the application of computed tomography (CT)[11,12] and the quantitative approach to CT analysis[13] led to the concept of *baby lung*,[14,15] which accounted for most of the previous observations on respiratory mechanics, gas exchange functionality, and potential harm of mechanical ventilation. The premise of this line of thought is that high pressure or excessive distention applied to a small fraction of the lung parenchyma (with a size similar to the lung of a baby) unavoidably leads to structural lesions of the lung regions open to ventilation. Total *lung rest* was achievable with the use of extracorporeal carbon dioxide (CO_2) removal, targeted to prevent the damages of high-pressure/high-volume ventilation.[16–18] The target of mechanical ventilation shifted toward lung protection, rather than normal gas exchange functionality. Hickling and associates[19] proposed the "permissive hypercapnia" strategy for ARDS, providing "gentle treatment" of the portion of the lung that remains open to ventilation (the baby lung) through less aggressive mechanical ventilation, at the acceptable price of an abnormally higher arterial partial pressure of carbon dioxide ($PaCO_2$).

Substantial experimental and clinical data over the years have supported the approach of a *lung protective strategy*.[20–24] Low VT prevents the excessive global stress and strain of the baby lung, whereas higher PEEP prevents the regional excessive stress and strain by avoiding alveolar collapse and reopening during mechanical ventilation.[25] These mechanical events are associated with an inflammatory reaction of the epithelial and endothelial lung cells *(biotrauma/atelectrauma)* as shown by the seminal study of Tremblay and colleagues[26] (see also work of Dreyfuss and Saumon[10] and Tremblay and Slutsky[27]). The literature supports the thought that the harm of mechanical ventilation is due to excessive global or regional stress and strain.[28] This situation leads to two results—a physical rupture of the lung and a mechanically induced inflammation of the lung parenchyma, constituting ventilator-induced lung injury (VILI). The best "mechanical ventilation" would provide adequate gas exchange with the lowest amount of VILI.

Up until recent times, little consideration has been dedicated to the flow and the respiratory rate, although both may have a significant role in the generation of VILI. Flow may be considered as the rate at which a given strain occurs into the lung, proportional to the energy dissipated into the lung parenchyma. Theoretical considerations[29,30] and experimental evidence[31] suggest that during mechanical ventilation the importance of flow cannot be neglected. Moreover, the effects of respiratory rate are quite intuitive. In a series of experiments on healthy pigs, Cressoni et al. found that a strain considered lethal (i.e., >2) was only fatal when delivered at 15 breaths/min, not at rates of 3 to 6 breaths/min. In addition, the tidal strain was more related to injury than the static strain.[32] In this scenario, the concept of ergotrauma has been recently introduced.[33] Given these data, it can be concluded that the cause of VILI could be described as a single physical entity, which combines volume, pressures, flow and respiratory rate, the mechanical power.

Physiologic Basis of Mechanical Ventilation

Driving Force

Force is required to ventilate the respiratory system. The driving force for ventilation under normal circumstances is provided by the respiratory muscles. During spontaneous breathing, the thoracic cage expands. This causes a decrease in intrathoracic pressure (pleural pressure, Ppl) relative to the atmosphere (in normal conditions approximately 2 mm Hg of ΔPpl is sufficient to expand the thoracic cage by 0.5 L). Because the lungs are connected in series with the thoracic cage, their volume is expanded to a nearly equal extent (not considering the blood shift[34]). The force that distends the lung is the pressure difference between the alveoli and the pleural cavity (the transpulmonary pressure, PL). As the lung expands, the alveolar pressure becomes subatmospheric and gas flow is generated (*inspiration*). When the respiratory muscles relax, the potential energy accumulated in the respiratory system (lung and chest wall) returns the chest wall and the lung parenchyma to the resting position (*expiration*). In spontaneously breathing subjects, the driving force (muscular pressure, ΔPmusc) is spent partly to expand the chest wall (ΔPpl), partly to expand the lung (ΔPL), and partly to overcome the resistances to the gas flow. In *quasi-static* conditions, in which the resistances to gas flow are negligible,

$$\Delta Pmusc = -\Delta Ppl + \Delta PL$$

During positive-pressure mechanical ventilation, the rules are exactly the same, with the exception that ΔPmusc is substituted by the force provided by the ventilator, and the force is applied to the lung parenchyma and not to the chest wall. The airway pressure at plateau during an end-inspiratory pause (in quasi-static conditions), is spent first to expand the lung and second to expand the chest wall:

$$\Delta P_{aw} = \Delta PL + \Delta Ppl,$$

where ΔP_{aw} is the change in airway pressure.

In spontaneous breathing and during positive-pressure mechanical ventilation, the distending force of the lung is the transpulmonary pressure. During spontaneous breathing, pleural pressure is negative (facilitating venous return), whereas during mechanical ventilation it is positive (impairing venous return). What matters from the pulmonary perspective is the distending force (i.e., the transpulmonary pressure [ΔPL]), whereas what matters from the hemodynamic perspective is the pleural pressure (ΔPpl).

Transpulmonary Pressure

At the same driving force applied to the whole respiratory system (lung and chest wall), the resulting transpulmonary pressure may be extremely variable. If the lung is relatively "stiff" and the chest wall is relatively "soft" (e.g., during pulmonary fibrosis or ARDS of pulmonary origin), a greater fraction of the airway plateau pressure is spent to distend the lung (high transpulmonary pressure). In contrast, if the lung is relatively soft but the chest wall is relatively stiff (e.g., in the presence of an abdominal disease or severe obesity), most of the driving force is spent to move the chest wall (high pleural pressure).

To express this phenomenon quantitatively, it is convenient to consider the concept of *elastance*. The elastance of the whole respiratory system is the driving force (ΔP_{aw}) required to increase the lung and the chest wall 1 L above their resting position (total elastance of the respiratory system [Etot] = ΔP_{aw}/1 L). Part of this driving force is spent to increase the lung volume of 1 L (lung elastance [EL] = ΔPL/1 L), and part is spent to increase the chest wall by the same amount (Ecw = ΔPpl/1 L, where Ecw represents the chest wall elastance). Transpulmonary pressure (ΔPL) can be expressed as the driving force times the ratio between lung elastance and total elastance of the respiratory system:

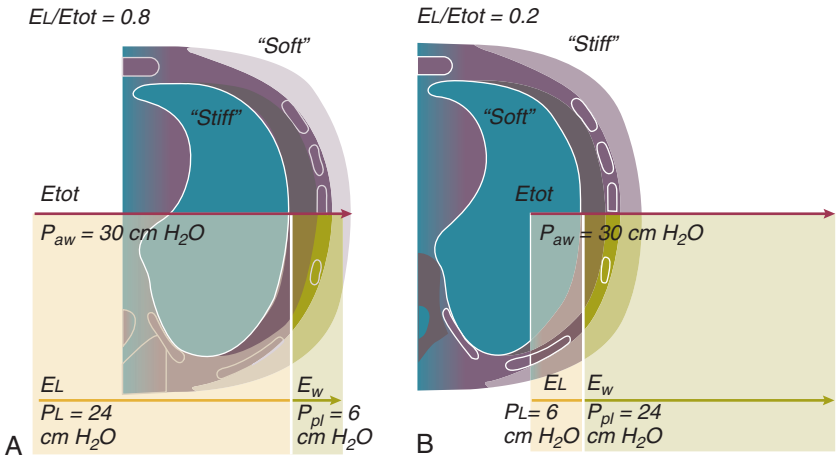
$$\Delta Pl = \Delta Paw \times EL/Etot$$

The transpulmonary pressure for a given plateau pressure uniquely depends on the ratio of lung elastance to respiratory system elastance. In normal subjects EL/Etot is approximately 0.5, whereas in patients with ARDS it may range from 0.2 (e.g., in obese patients or in patients with high intraabdominal pressure) to 0.8 (e.g., in patients with a very small baby lung and a normal chest wall elastance). This variability implies that for the same driving force applied and read on the ventilator display (e.g., 30 cm H_2O), the resulting transpulmonary pressure may range from 6 to 24 cm H_2O (Fig. 11.1).

Force-Bearing Structure of Lung Parenchyma

The transpulmonary pressure is applied to the force-bearing structure of lung parenchyma, the extracellular matrix, which constitutes the *lung skeleton*.[35] The lung skeleton is a complex and metabolically active structure that includes a network of several components—elastin, collagen, and proteoglycans. All these molecules are involved in determining the mechanical characteristics of the respiratory system. The elastin may be considered as an elastic spring, whereas the inextensible collagen, which is folded at end-expiration and completely unfolded at a lung volume equal to total lung capacity, acts as a stop-length fiber.[36,37] The proteoglycans stabilize the collagen-elastin network, contributing to lung elasticity and alveolar stability at low and medium lung volumes.[38]

The matrix of elastin, collagen, and proteoglycans is arranged in two main fiber systems: (1) the *axial* system, which originates from the pulmonary hilum and runs deeply into the lung parenchyma down to the alveolar level, where it joins (2) the *peripheral* system, which originates from the visceral pleura and runs centripetally within the lung parenchyma.[35] The lung skeleton may be considered a continuous elastic structure that reaches its extension limits at total lung capacity, a lung volume equal to about threefold the lung resting volume. At this level of alveolar distention, the collagen is completely unfolded and further expansion is prevented. The epithelial and endothelial cells do not directly bear the applied forces because they are anchored to the extracellular matrix by a



• **Fig. 11.1** Two examples of EL/Etot variability in patients with acute lung injury/acute respiratory distress syndrome. A, EL/Etot = 0.2. B, EL/Etot = 0.8. This variability implies that for the same airway pressure applied (e.g., 30 cm H_2O), the resulting transpulmonary pressure (PL) may range from 6 to 24 cm H_2O. *EL,* Lung elastance; *Etot,* total elastance of the respiratory system; P_{aw}, airway pressure; *Ppl,* pleural pressure.

series of structural proteins (integrins), which are connected to the cytoskeleton. During lung expansion, the epithelial and the endothelial cells modify their shape.

It is well documented that mechanically induced cellular deformation activates a series of mechanosensors with the production of several inflammatory mediators, such as cytokines (interleukin 6, tumor necrosis factor α, and interferon γ),[26,39] metalloproteinases (enzymes involved in the remodeling of the matrix),[40] leukotrienes,[41] and interleukin 8,[42–44] the most powerful attractor of neutrophils.[45] Gross barotrauma (e.g., pneumothorax) is due to the stress at rupture of the lung skeleton, whereas intrapulmonary inflammation is primarily due to the excessive strain of the epithelial and endothelial cells.

Concept of Stress and Strain

Stress is the applied force, and strain is the linear deformation of material. In the whole lung, the rough approximation of stress is the transpulmonary pressure, whereas the approximation of the average strain is the change in volume relative to the lung resting volume. The ratio between alveolar stress and strain is defined as *lung-specific elastance* (Espec), which is mathematically defined as

$$\Delta P_L = Espec \times \Delta V / V_0,$$

where ΔV is the volume variation applied to the lung (i.e., the VT), and V_0 is the lung resting volume (i.e., the functional residual capacity at atmospheric pressure [without any application of PEEP]). The lung-specific elastance is the transpulmonary pressure required to double the lung resting volume (i.e., the ΔP_L when $\Delta V/V_0$ is equal to 1). In ARDS, lung-specific elastance is similar to normal,[15,46] reinforcing the concept of the baby lung (lung is small and not stiff), and questions the use of normalizing the VT to the ideal body weight. The same VT per kilogram may result in completely different strain according to the size of the baby lung (the V_0 of the previous equation). For example, a 70-kg man with ARDS may have, according to the severity of the lung injury, a residual baby lung equal to 60%, 40%, or 20% of his normal lung size. If the ventilator is set to deliver 10 mL/kg, the actual delivered VT would generate an alveolar strain, which would result from the application, in normal lung, of a VT equal to 17 mL/kg, 25 mL/kg, and 50 mL/kg, values associated with a significant lung injury in laboratory studies.[10,28]

Recently we attempted to quantify the relationship between stress-strain and VILI in healthy animals. We found that edema formation was a threshold phenomenon, induced by mechanical ventilation when the global strain reaches a critical value of about 2.[47] This threshold roughly corresponds to the point where the stress-strain curve loses its linearity and starts an exponential growth, indicating that some lung regions reach their own total capacity and cannot expand any further. At this level of strain, in a period of 24 to 48 hours the mechanical ventilation is lethal and the increased lung weight (two to three times the baseline) is associated with a striking impairment of respiratory mechanics, gas exchange, hemodynamics, inflammation, distal organs damage, and 100% mortality rate. This lethal strain and associated stress, however, are rarely applied in clinical practice. To explain VILI in a diseased lung, therefore, alternative phenomena must be taken into account as the lung dishomogeneity and the presence of stress rise, which is discussed later.

Driving Pressure

Recently it has been suggested that VT should be scaled to compliance, introducing the concept of driving pressure (ΔP = Pplat – PEEP, where Pplat indicates the plateau pressure). Indeed, driving pressure is the ratio of VT to compliance, the latter indicating the "functional" size of the lung.[48,49] It is important to remember that driving pressure is one of the causes of VILI included in the computation of mechanical power, a single physical entity that combines volume, pressures, flow, and respiratory rate.[50]

Patient Characterization

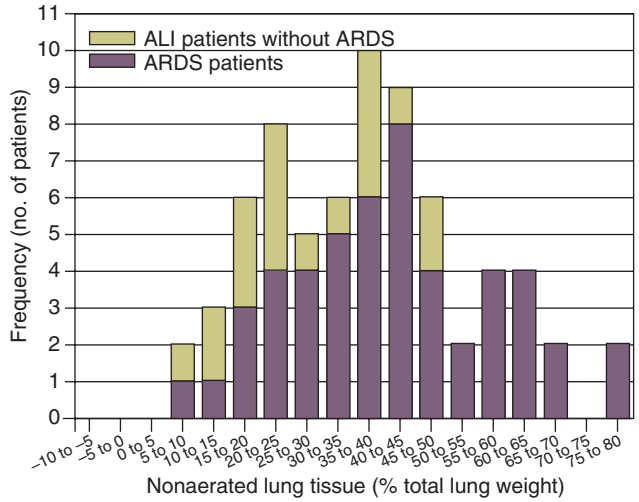
Using the least harmful mechanical ventilation setting requires a preliminary knowledge of the main pathophysiologic characteristics of the patient. The most relevant characteristics are the kind and amount of the lung injury, the chest wall elastance, and the lung recruitability.

Gas Exchange

Oxygen

The partial pressure of arterial oxygen (PaO_2), PaO_2-to-fraction of inspired oxygen (FIO_2) ratio (PaO_2/FIO_2), and Riley's shunt fraction[51] are the most commonly used variables to assess the severity of lung injury. In particular, the PaO_2/FIO_2 thresholds of 300 and 200 were originally used to define acute lung injury (ALI) (300) and ARDS (200) according to the 1994 American-European Consensus Conference on ARDS.[52] Consequently, the PaO_2/FIO_2 ratio is perceived as a key variable by most intensive care unit (ICU) physicians: The lower the PaO_2/FIO_2 ratio, the greater the lung injury. This equivalence is highly questionable. First, in most large studies on ARDS, no association was found between hypoxemia and outcome.[53] In the large study showing a better outcome with low VT compared with higher VT, the PaO_2/FIO_2 ratio was significantly lower in the low VT group despite ending with better outcome.[24] Finally, the PaO_2/FIO_2 ratio was not different in patients with early, intermediate, and late ARDS, suggesting that oxygenation was not dependent on the structural changes of lung parenchyma occurring with time.[54] In a study[55] in which the lung severity was assessed by CT scan (and defined as a fraction of the gasless tissue), we did not find significant changes of PaO_2/FIO_2 ratio over a wide range of nonaerated tissue (Fig. 11.2), and the PaO_2/FIO_2 ratio was not associated with outcome.

Most data suggest that PaO_2/FIO_2 ratio is a weak indicator of the overall lung severity, with compensatory rearrangement of perfusion during ARDS limiting the deterioration of oxygenation. The same limits apply when PaO_2/FIO_2 ratio changes are used to assess lung recruitment. Because this maneuver is unavoidably associated with changes of perfusion (global or regional), the increase of the PaO_2/FIO_2 ratio may be partly due to decrease of perfusion, as shown in the 1980s.[56–58] Most data suggest that the use of oxygenation variables alone to assess lung severity is misleading.



• **Fig. 11.2** Frequency distribution of nonaerated lung tissue, expressed as a proportion of the total lung weight, recorded at 5 cm H_2O positive end-expiratory pressure in 68 patients with acute lung injury/acute respiratory distress syndrome *(ALI/ARDS)*. *Green columns* represent patients with partial pressure of arterial oxygen (PaO_2)/fraction of inspired oxygen (FIO_2) ratio less than 300 (ALI without ARDS), whereas *purple columns* represent patients with PaO_2/FIO_2 ratio less than 200 (ARDS). The nonaerated lung tissue was defined as the lung tissue with a physical density at computed tomography scan image analysis between +100 Hounsfield units (HU) and −100 HU, representing the portion of lung parenchyma that is consolidated or collapsed or both (i.e., the lung injury severity). (From Gattinoni L, Caironi P, Cressoni M, et al. Lung recruitment in patients with the acute respiratory distress syndrome. *N Engl J Med.* 2006;354:1775–1786.)

Carbon Dioxide

Although less considered, the variables derived from CO_2, as the total or alveolar dead space, seem to be of greater value in assessing lung severity. It has been shown in patients with ALI/ARDS that dead space at entry is a strong predictor of outcome,[59] and that $PaCO_2$ for the same total ventilation steadily increases from early to intermediate and to late ARDS, reflecting the lung structural changes.[54] The PCO_2 response to prone position (in contrast to the partial pressure of oxygen [PO_2] response) is a strong prognostic index of mortality.[60] Most data suggest that CO_2-related variables (dead space), more than PaO_2/FIO_2 ratio, reflect the severity of lung injury (and associated mortality rate) at the time of presentation and the structural changes of lung parenchyma occurring with time (fibrosis, *Pneumocystis* infection, and possibly perfusion defects).

Respiratory Mechanics, Chest Wall Elastance, and Lung Volume

In the original description of ARDS,[61] the low compliance (i.e., high elastance) of the respiratory system was a landmark of the syndrome. The respiratory system compliance is not considered in the current definition of ARDS, however.[52] For years, the low compliance was attributed uniquely to the lung component (lung stiffness and lack of surfactant). Quantitative CT shows, however, that the respiratory system compliance primarily reflects the size of lung open to gases (the baby lung[13,15]), suggesting that the intrinsic functioning lung elasticity in ARDS is close to normal (the lung is "small" rather than "stiff"). More than gas exchange, the respiratory system compliance indirectly assesses the lung injury severity (the smaller the baby lung, the greater lung injury),[62] as confirmed in animal experiments.[63] Another variable also must be taken into account—the elastance of the chest wall. It has been shown in a significant portion of patients with ALI/ARDS that the chest wall elastance is greater than normal because of increased intraabdominal pressure, obesity, or severe edema.[64] In patients with extrapulmonary ARDS[65] and in obese patients,[66] the high elastance of the respiratory system may be due to the chest wall and to the lung derangement. Measurement of intraabdominal pressure should be considered when selecting mechanical ventilator settings.

Severity of Lung Injury and Lung Recruitability

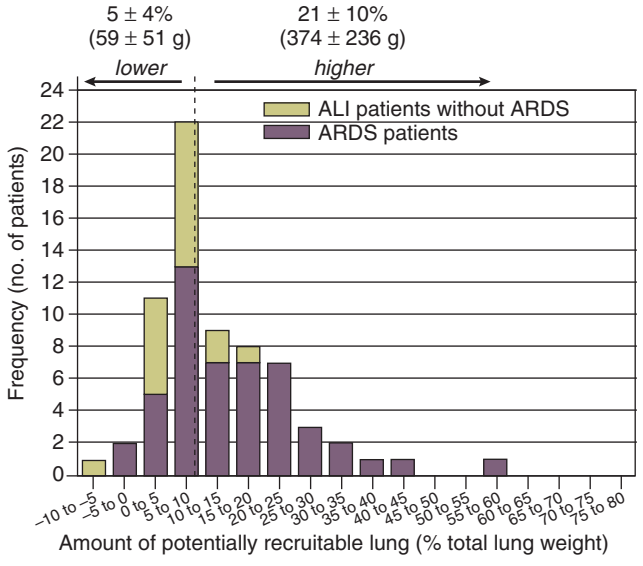
CT can be used to assess the severity of lung injury by measuring the fraction of nonaerated lung tissue at end-expiration (end-expiration pause at 5 cm H_2O). This fraction includes the lung tissue that is "consolidated" (i.e., not openable at 45 cm H_2O airway pressure) and the tissue that is collapsed but openable at 45 cm H_2O. These values were chosen to produce a minimal risk during the maneuver and because this is the most frequently used in the literature for recruitment maneuver.[67] In patients with elevated chest wall elastance, the resulting transpulmonary pressure could be insufficient, however, to overcome the opening pressure of some pulmonary units.

The total fractions of nonaerated lung tissue (consolidated plus recruitable) and the recruitable tissue alone (tissue that regains aeration at 45 cm H_2O airway pressure) are strongly associated with mortality rate. The data of Fig. 11.2 show the inadequacy of the

term ALI/ARDS, as currently defined, to describe the lung injury.[55] The data refer to a population of ALI/ARDS patients, classified according to the American-European Consensus Conference on ARDS (AECC),[52] in which a CT-based quantitative analysis of the whole-lung parenchyma at 5 cm H_2O PEEP was performed. As shown in Fig. 11.3, the fraction of the nonaerated lung tissue (consolidated or collapsed or both) may range from 5% to 70% of the entire lung parenchyma. Patients meeting ALI/ARDS criteria may have a baby lung size very close to that of normal subjects, or a baby lung that is just a small fraction of the expected normal lung. When the distending force is applied to the lungs by the mechanical ventilator, previously collapsed lung regions may open. Lung recruitability may be expressed as the amount of lung tissue regaining aeration when increasing the applied driving force from 5 to 45 cm H_2O. As shown in Fig. 11.3, in some patients lung recruitability was almost negligible, whereas in others it was equal to 25% to 35% of the entire lung parenchyma. Lung recruitability was strongly associated with the fraction of nonaerated tissue, suggesting that the greater the inflammatory edema, the greater the lung collapse. It seems that the best way to assess the overall lung severity and the related lung recruitability, both strongly associated with mortality rate, is the CT scan analysis. Physiologic variables are poor indicators of the severity of the lung injury. This relationship is shown in Fig. 11.4—that for a large variation of lung injury ranging from 20% to 60% of the lung parenchyma—the values of PaO_2/FIO_2 ratio, lung compliance, and $PaCO_2$ greatly overlap.

ARDS Classification

Although, in our opinion, the definition of ARDS should include a quantitative estimate of the lung edema, because this is not feasible in most of the ICU, alternative ways for defining ARDS have been sought. ARDS was first defined by Ashbaugh and coworkers in 1967.[61] Several other definitions have been introduced afterward, up to the AECC in 1994.[52] This conference defined ARDS as the acute onset of hypoxemia ($PaO_2/FIO_2 \leq 200$) with bilateral infiltrates seen at x-ray study and no evidence of left atrial hypertension, and these parameters were largely used for the enrollment of patients in clinical trials. In 2011 a panel of experts, under the initiative of the European Society of Intensive Care Medicine endorsed from the American Thoracic Society and Society of Critical Care Medicine, convened to develop what has been called the "Berlin definition."[68] The final Berlin definition is reported in Table 11.1. Stages of mild, moderate, and severe ARDS were related to increased mortality rates and increased median duration of mechanical ventilation in survivors.



• **Fig. 11.3** Frequency distribution of 68 patients with acute lung injury/acute respiratory distress syndrome (ALI/ARDS) according to the percentage of potentially recruitable lung, expressed as the percentage of total lung weight. ALI without ARDS was defined by a PaO_2/FIO_2 ratio less than 300, but not less than 200; ARDS was defined by a PaO_2/FIO_2 ratio less than 200. The percentage of potentially recruitable lung was defined as the proportion of lung tissue in which aeration was restored at airway pressures between 5 and 45 cm H_2O. *FIO_2,* Fraction of inspired oxygen; *PaO_2,* partial pressure of arterial oxygen. Mechanical Ventilation in ARDS: Available Evidence

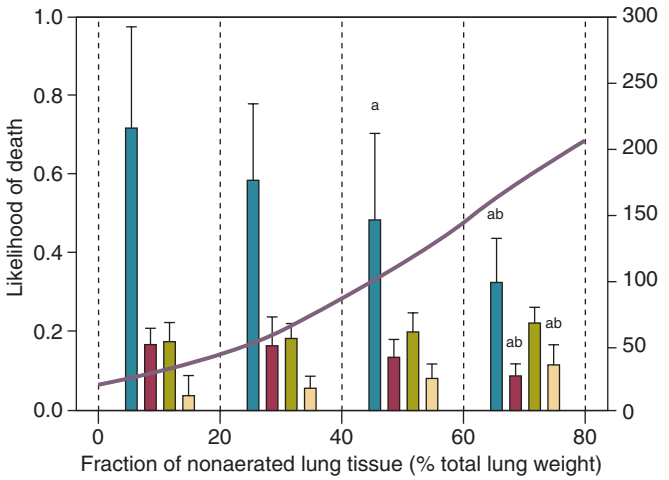
Setting Tidal Volume

The main results of several outcome studies specifically designed to compare different VTs are summarized in Table 11.2. A survival benefit was found in the study comparing 6 mL/kg VT versus 12 mL/kg, the highest VT range tested,[24] whereas no survival



• **Fig. 11.4** Mean ± standard deviation values of respiratory variables of a population of 68 patients with acute lung injury/acute respiratory distress syndrome. *Blue columns* represent PaO_2/FIO_2 ratio at positive end-expiratory pressure (PEEP) 5 cm H_2O (mm Hg). *Red columns* represent respiratory system compliance at PEEP 5 cm H_2O (mL/cm H_2O). *Green columns* represent dead space fraction (%), *Gold columns* represent alveolar dead space fraction (%). [a]$P < 0.05$ versus patients with a fraction of nonaerated tissue recorded at 5 cm H_2O PEEP less than 0.2. [b]$P < 0.05$ versus patients with a fraction of nonaerated tissue recorded at 5 cm H_2O PEEP ranging from 0.2 to 0.4. The *continuous purple line* represents the likelihood of death predicted by the fraction of nonaerated lung tissue recorded at 5 cm H_2O PEEP ($P = 0.015$). Weight is a poor surrogate of strain because ARDS patients with similar body weights may have completely different lung sizes and consequently different levels of strain at equal tidal volumes. This is confirmed by the plateau pressures measured in these different studies (see Fig. 11.5). As shown for the same tidal volume per ideal body weight, the plateau pressures are widely distributed with huge overlap between the studies. This reflects a wide distribution of the respiratory system compliance and consequently of the lung size.

differences were found in the other studies, which compared intermediate values of VTs.[20,22,23] As previously discussed, the VT per ideal body weight is a poor surrogate of strain because ARDS patients with similar body weight may have completely different lung sizes and consequently different strain at equal VT. This is confirmed by the plateau pressures measured in these different studies (Fig. 11.5). As shown for the same VT per ideal body weight, the plateau pressures are widely distributed with huge overlap between the studies. This reflects a wide distribution of the respiratory system compliance and consequently of the lung size.

Despite the lack of information about stress and strain in each individual patient, most available data strongly suggest that a gentle ventilation is safer than the application of high volumes and pressures. This evidence does not mean that 6 mL/kg ideal body weight represents the ideal VT. In a patient with a very small baby lung, it still may be harmful, inducing excessive strain, whereas if applied to a lung characterized by a large ventilatable area, it may be low. There is little doubt, however, that 12 mL/kg ideal body weight is excessively high and unnecessary. It is evident that low VT ventilation, decreasing the global alveolar stress and strain, is advantageous compared with high VT ventilation in different patients.

It has been suggested that a plateau pressure of 30 cm H_2O represents the safe limit for plateau pressure.[69] In a retrospective analysis, such a safe limit has been challenged, however.[70] A safe upper limit for plateau pressures in patients with ALI/ARDS could not be identified. This is understandable if we consider that the airway plateau pressure is a poor surrogate of stress owing to the high variability of the chest wall compliance. The same plateau pressure, 30 cm H_2O, may result in completely different stress values in different patients.

TABLE 11.1 The Berlin Definition of ARDS

Defining Features	Criteria
Timing	Within 1 week of a known clinical insult or new/worsening respiratory symptoms
Chest imaging[a]	Bilateral opacities, not fully explained by effusions, lobar/lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload Need for objective assessment (e.g., echocardiography) to exclude hydrostatic edema if no risk factor is present
Oxygenation[b]	
Mild	200 < Pao_2/FIo_2 ≤ 300 with PEEP or CPAP ≥ 5 cm H_2O[c]
Moderate	100 < Pao_2/FIo_2 ≤ 200 with PEEP ≥ 5 cm H_2O
Severe	Pao_2/FIo_2 ≤ 100 with PEEP ≥ 5 cm H_2O

[a]Chest x-ray study or computed tomography scan.
[b]If altitude is higher than 1000 m, the following correction factor should be used: Pao_2/FIo_2 × (barometric pressure/760).
[c]This may be delivered noninvasively in the "Mild" group.

Setting Positive End-Expiratory Pressure

The available evidence on the effects of higher versus lower levels of PEEP in ALI/ARDS with ALI/ARDS is summarized in Table 11.3. As shown, despite the fact that the experimental data provide striking evidence that PEEP may reduce the damages of mechanical ventilation, the largest studies comparing higher versus lower PEEP levels in unselected patients with ALI/ARDS were unable to find any difference in outcome.[71–74] It has been suggested that PEEP should be of benefit in patients with higher lung recruitability and useless or harmful in patients with low lung recruitability.[75] Patients with greater severity are those with a lower PaO_2/FIO_2 ratio and higher recruitability as well as greater lung weight and, in general, worse CT scan findings. Two meta-analyses seem to confirm this

• **Fig. 11.5** Distribution of tidal volume *(VT)* per ideal body weight (mL/kg) *(left column)* and of plateau pressure *(right column)* (the *red line* indicates the treated group; the *blue line* indicates the control group) in five randomized trials (computed from the reported mean ± standard deviation assuming a Gaussian distribution). Data from the following studies: A and B, Acute Respiratory Distress Syndrome Network[24]; C and D, Multicenter Trial Group on Tidal Volume Reduction in ARDS[22]; E and F, Pressure- and Volume-Limited Ventilation Strategy Group[20]; G and H, Brower et al.[23]; I, Amato et al.[21] (From Gattinoni L, Carlesso E, Cadringher P, et al. Physical and biological triggers of ventilator-induced lung injury and its prevention. *Eur Respir J.* Suppl 2003;47:15s–25s.)

hypothesis—that is, that higher PEEP improves outcome in more severe ARDS. The meta-analysis by Phoenix and associates[76] showed a trend toward improved survival in more severe ARDS treated with high PEEP group with no evidence of increase in barotrauma. The other meta-analysis by Briel and colleagues[77] of the largest three trials reported no treatment effect on hospital survival between higher and lower PEEP groups, whereas a significant improved survival rate was found in patients in presence of ARDS defined as PaO_2/FIO_2 ratio equal or less than 200. In contrast, in patients with mild and moderate ARDS, higher PEEP seemed harmful. These results roughly account for what we know about the ARDS pathophysiology. In fact, the putative beneficial effect of PEEP on survival should be related to the prevention of excessive regional stress and strain by keeping open lung regions that would otherwise collapse.[25,78] When we studied lung recruitability in an unselected ALI/ARDS population, we found that it varied from 0% to more than 50% of the whole lung.[67] We found that severity of lung injury was associated with higher lung recruitability and more severe hypoxemia, greater dead space, and lower compliance of the respiratory system. By arbitrarily dividing the study population into patients with higher or lower lung recruitability, we first observed that in the latter group, the amount of recruitable lung was almost negligible, amounting to about 50 g of tissue weight. The response to the application of higher levels of PEEP was minimal and much lower than that observed in patients with higher lung recruitability. This suggests that correct patient characterization is needed before PEEP setting. Selection criteria may include lung recruitability, end-expiratory transpulmonary pressure, respiratory system compliance, and driving pressure. A large randomized trial[79] tested the open lung approach performed by aggressive recruitment maneuvers followed by PEEP selection according to the compliance changes measured during the deflation. Surprisingly, the mortality rate was significantly lower in the control group in which the PEEP was selected according to a National Institutes of Health table than in the patients treated according to the open lung approach. These results cast serious doubts on the application of high PEEP level. Moreover, a high PEEP level may contribute to explaining the high-frequency oscillatory ventilation trial failure, in which the PEEP applied was close to the pressure needed to reach total lung capacity (i.e., >30 cm H_2O).

TABLE 11.3 Summary of Available Evidence on the Effects of Higher PEEP in Patients With ALI/ARDS

Setting Respiratory Rate

Although extensive work has been devoted to understanding better how to set VT and PEEP in ARDS, the potential importance of respiratory rate in the development of VILI has been scarcely investigated. Technology allows the use of respiratory rate from near zero breaths per minute using extracorporeal techniques to remove CO_2 to 2000 to 3000 breaths/min by using high-frequency oscillation. Each VT delivered may be considered as a stress cycle. Increasing the number of stress cycles may increase the lung damage. In experimental ARDS models, it has been observed that decreasing the respiratory rate decreases edema formation in isolated rabbit lung,[80] whereas an increase in respiratory rate during spontaneous breathing leads to an increase in edema formation.[81] It is conceivable that the respiratory rate may play a role in the pathogenesis of VILI when associated with a harmful VT or inadequate PEEP. A different issue is the use of high-frequency oscillatory ventilation (HFOV), a technique that uses very high respiratory frequencies in association with very low VTs and very high mean airway pressure, minimizing inspiratory overdistention and end-expiratory lung collapse.[82] Most patients treated with HFOV improved PO_2/FIO_2 ratio and reduced oxygenation index over time. Clinical trials were not able to prove a survival benefit; however, a recent meta-analysis of six randomized controlled trials comparing HFOV to conventional ventilation suggested a survival benefit at 30 days.[83] Two recent trials—the OSCILLATE (Oscillation for Acute Respiratory Distress Syndrome Treated Early) and OSCAR (Oscillation in ARDS) trials—did not show survival benefits. The OSCILLATE trial was stopped because of increased in-hospital mortality and found that, in adults with moderate to severe ARDS, early application of HFOV, compared with a ventilation strategy of low VT and high PEEP, does not reduce, and may increase, in-hospital mortality.[84] The OSCAR trial concluded that the use of HFOV had no significant effect on 30-day mortality in patients undergoing mechanical ventilation for ARDS.[85] The editorial accompanying the two trials suggests that "for now clinicians should be cautious about applying HFOV routinely in patients with ARDS."[86] A recent meta-analysis suggested that HFOV may be of potential advantage in patients with very severe ARDS (PaO_2/FIO_2 < 70 mm Hg).[87]

Setting Inspiratory-to-Expiratory Ratio

Mechanical ventilators provide a wide range of inspiratory-to-expiratory (I:E) ratios. Setting an adequate I:E ratio may be of great importance when ventilating patients with structural alterations of lung parenchyma, such as chronic obstructive pulmonary disease and emphysema, and during asthmatic exacerbation. In these conditions characterized by a time constant of the respiratory system greater than normal, a longer expiratory time must be provided to allow deflation of gas from the lungs before the next respiratory cycle, avoiding dynamic hyperinflation and intrinsic PEEP.[88] During ALI/ARDS, no convincing evidence has been provided for the advantages of setting an I:E ratio different from 1:1.

In the past, inverse ratio ventilation[89] was advocated as a tool to improve the effects of mechanical ventilation in ARDS.[90–92] Studies primarily showed an improvement of arterial oxygenation. Increased mean airway pressure, intrinsic PEEP, and a decrease in

cardiac output were problematic.[93] Extreme forms of manipulating I:E ratio are not recommended; an I:E ratio in ALI/ARDS of 0.5 to 1.5 is appropriate.

Individualizing Mechanical Ventilation in Patients With ARDS

General principles underlying the application of mechanical ventilation in patients with ALI/ARDS have been discussed. We now present the sequence of interventions that we believe are most appropriate for tailoring mechanical ventilation in an individual patient.[94]

The first intervention after admission to the ICU is to determine whether the patient has the criteria for ARDS diagnosis, keeping in mind that this syndrome consists of diffuse inflammatory lung edema. Patient history (research for possible etiologic factors leading to ARDS) and clinical observation (cyanosis, higher respiratory rate, use of accessory respiratory muscles, inspiratory crackles at lung auscultation mainly in the dependent lung regions) may suggest a possible lung inflammatory edema. Blood gas analysis and chest x-ray studies may confirm the initial diagnosis of the syndrome. The choice between an attempt of noninvasive respiratory support (face mask continuous positive airway pressure or noninvasive ventilation) or endotracheal intubation should be made on a clinical basis, according to the severity of illness, and whether the patient's condition is stable or deteriorating. We pay particular attention to the improvement of PaO_2 after oxygen administration and to $PaCO_2$. The lack of remarkable response in oxygenation to increased FIO_2 indicates a remarkable fraction of right-to-left intrapulmonary shunt, which is typical of ARDS. Low $PaCO_2$ suggests that the respiratory muscles of the patient are still able to deal with the decreased compliance of the respiratory system (i.e., sustaining the increased respiratory effort), whereas normal or high levels of $PaCO_2$ suggest a near exhaustion of the respiratory muscles and need of immediate ventilatory support.

Clinicians should be aware of the immediate possible consequences of intubation and initiation of mechanical ventilation. Sedation, either by itself or in association with muscle paralysis, produces a loss of respiratory muscle tone and a cranial shift of the diaphragm, promoting further lung collapse with immediate consequences in gas exchange. Mechanical ventilation produces an increase in intrathoracic pressure and decreased venous return. The intravascular volume status of the patient should be assessed before intubation, and hypovolemia should be corrected. The rate and the amount of fluid replacement should be decided for each individual patient. Inadequate fluid replacement may lead to a severe hemodynamic impairment immediately after beginning positive-pressure ventilation. An excessive fluid replacement in an inflamed lung with leaking capillaries may result in a dramatic increase of pulmonary edema with devastating consequences on gas exchange. Wiedemann and coworkers,[95] in a study published in the *New England Journal of Medicine,* compared a conservative and a liberal strategy of fluid management in 1000 patients with ALI. Although the primary endpoint (60-day mortality) was not significantly different, patients treated with the conservative strategy had better lung function and shorter duration of mechanical ventilation and intensive care without increasing nonpulmonary organ failures. For these reasons, we prefer to tailor fluid replacement according to the results of a fluid challenge test. Echocardiography also may be helpful in assessing the volumetric status.[96] After endotracheal intubation, the initial ventilatory setting used is blind because the pathophysiologic characteristics of the patient have not yet been assessed. We usually set the ventilator (volume-controlled) with a VT equal to 6 to 8 mL/kg ideal body weight, FIO_2 equal to 0.7, and a respiratory rate of 15 breaths/min, with an I:E ratio of 1:1. As soon as hemodynamic stability is obtained, a PEEP trial (preceded by a recruitment maneuver) is performed by applying in a random sequence of 5 to 15 cm H_2O PEEP with the patient under sedation and, sometimes, muscle paralysis. At each level of PEEP, we maintain VT, respiratory rate, FIO_2, and I:E ratio constant for about 20 minutes, after which we measure (1) arterial oxygenation, (2) respiratory system compliance, and (3) alveolar dead space. Patients who, after the application of higher PEEP, show improvement in at least two of these three parameters have a greater likelihood of having a higher lung recruitability. Alternatively, it is possible to target a specific saturation on the basis of pulse oximetry, if available, aiming at a hemoglobin oxygen saturation of 90%.

The improvement in arterial oxygenation alone, although commonly used, may be misleading for the assessment of lung recruitment because it may be the result of a slight decrease in cardiac output or a modification of regional distribution of pulmonary blood flow or both. It has been shown that improvement in respiratory physiologic variables from a PEEP trial has low sensitivity (71%) and specificity (59%) in assessing lung recruitability[67]; we prefer to obtain whole-lung CT scanning. In the CT scan facility, while maintaining the baseline ventilator setting, whole-lung CT scanning is performed at 5 cm H_2O PEEP at end-expiration and 45 cm H_2O at end-inspiration. The subsequent quantitative analysis of the CT scans allows us to obtain a precise assessment of lung recruitability. In patients with higher recruitability we apply PEEP greater than 15 cm H_2O, up to 20 cm H_2O and exceptionally greater than 20 but not exceeding 25 cm H_2O, whereas in patients with lower lung recruitability we apply a PEEP level not greater than 10 cm H_2O.

If CT scan is unavailable and only the PEEP trial has been performed, we assign to the high-recruitment group patients with either a baseline PaO_2/FIO_2 ratio less than 150 when measured at 5 cm H_2O PEEP or patients who respond to 15 cm H_2O PEEP compared with 5 cm H_2O with a positive response of two of the following three variables: increased PaO_2, decreased alveolar dead space, or increased compliance of the respiratory system.

We attempt to keep the plateau pressure less than 30 cm H_2O by modifying VT and respiratory rate. As discussed earlier, however, VT and plateau pressure are inadequate surrogates for alveolar stress and strain. We now measure, in each patient with severe ARDS, the transpulmonary pressure by helium dilution technique using an esophageal balloon (lung resting volume of 0 cm H_2O or 5 cm H_2O PEEP). With mechanical ventilation, a global pulmonary strain greater than about 1.5 (strain is dimensionless because it is the ratio of two volumes), or an end-inspiratory transpulmonary pressure greater than 20 cm H_2O, may cause VILI, with irreversible respiratory failure to follow.[10,28] These values of alveolar stress and strain are the ones at which the residual ventilatable lung reaches its near-total lung capacity, with a full extension of the collagen fibers of the lung skeleton.

In some patients, we have observed that a VT of 8 to 10 mL/kg ideal body weight determines a lung strain value less than 1 and a transpulmonary pressure value less than 14 cm H_2O. In these patients, we use a VT greater than 6 mL/kg ideal body weight, avoiding excessive hypercapnia or need for sedation. In contrast, in the patient with the most severe disease, in which the baby lung

is extremely small, even a ventilation with 6 mL/kg ideal body weight may result in values of alveolar stress and strain higher than those required to reach total lung capacity. Evidence from the literature and physiologic reasoning strongly indicate that for these patients a safe form of mechanical ventilation does not exist.[97,98] We reserve to them the use of extracorporeal support. We acknowledge that measuring alveolar stress and strain may seem to be a physiologic curiosity or a research tool. Nonetheless, we have introduced them in our clinical practice as the most logical approach for VILI prevention.

Some authors advocate the use of other forms of mechanical ventilation in patients with ARDS.[99,100] The rationale of pressure support ventilation in ARDS relies on the possibility of decreasing the need for sedation, while preserving the contribution of spontaneous breathing, and with possible advantages on gas and flow pulmonary distribution.[84] During the full-blown phase of the illness, we prefer to keep the patient well sedated. This approach may help to reduce energy requirement and oxygen consumption and CO_2 production.

The onset of recovery is characterized by the control or reversal, or both, of the cause of ARDS. An increase of systemic oxygenation and respiratory system compliance follows. When a PaO_2 value greater than 80 mm Hg is obtained at FIO_2 of 0.4, we start the weaning from PEEP application, decreasing the PEEP level no more than 1 cm H_2O every 4 to 6 hours, and suspending the process if the oxygenation consistently deteriorates. Subsequently, after an appropriate adjustment of sedation, we shift from pressure-controlled or volume-controlled to pressure support ventilation, initially setting the support at the same inspiratory pressure used during controlled ventilation. According to the patient's response, pressure-support level is progressively decreased, and the final phase of weaning is initiated at pressure support of 5 to 10 cm H_2O, FIO_2 lower than 0.4, and PEEP level equal to 5 cm H_2O.

Possible Adjuncts to Mechanical Ventilation

Prone Position

Prone positioning, first proposed in 1974[101] and first applied in patients with ARDS in 1976,[102] results in improved arterial oxygenation in most patients. After the introduction of CT scanning, showing lung consolidation located in the dependent lung regions and the aerated baby lung in the nondependent lung regions,[12,16] we integrated prone positioning as standard practice in clinical treatment of patients with ARDS to improve systemic oxygenation.[103] The initial hypothesis was that better perfusion of the baby lung, located in the dependent lung regions after prone positioning, would provide advantages in gas exchange. The picture observed was quite different, however. We did observe an improvement in arterial oxygenation, but the mechanism was likely different because CT scans taken in the prone position showed a density redistribution toward the dependent lung areas.[104]

This observation led to our introduction of the "sponge model" as our pathophysiologic understanding of ARDS.[105] Regardless of the patient's position, the increased weight of the nondependent lung tissue squeezes the gas out of the dependent regions of the lung.[46] The mechanisms of improved gas exchange were different from that first hypothesized. It is not the aim of this chapter to discuss the possible physiologic mechanisms of prone positioning, which may be found elsewhere.[106–110] Taken together, all of the studies, including small and large series of patients, consistently showed that in 70% of the patients systemic oxygenation improves in prone positioning compared with supine positioning,[110,111] without any change in the applied airway pressure. There is no doubt that in life-threatening severe hypoxemia a trial in the prone position is indicated.

A different issue is the effectiveness of the prone position in improving ARDS outcome. Is mechanical ventilation in ARDS less harmful in the prone position compared with the supine position? Does mechanical ventilation induce less alveolar stress and strain in the prone position? There is a consistent physiologic rationale to believe that this is the case. In experimental settings[112–115] and in normal subjects and patients affected by ARDS, CT scan shows a more homogeneous distribution of gas throughout the lung parenchyma in the prone position compared with the supine position.[110] This observation strongly suggests that the distribution of alveolar stress and strain is more homogeneous in the prone position. In experimental models of ARDS, there is evidence that prone positioning prevents or significantly delays the development of VILI.[115,116] Two large randomized studies on prone positioning were unable to show a significant benefit on outcome[109,117]; however, prone positioning was applied for only about a quarter of the day, and mechanical ventilation was not controlled. In a more recent trial,[118] in which prone positioning was applied for 20 hours per day and mechanical ventilation was strictly controlled, a positive benefit was found for the patients treated with prone positioning. On these bases the Prone-Supine II study[119] was organized to detect potential survival benefit of prone positioning avoiding the limitations of previous trials. Although the study was not able to show a significant survival benefit in the general population, a favorable trend was detected in the subgroup of patients with severe ARDS. In a meta-analysis including 10 clinical trials on adults and children, Sud et al.[120] found that prone ventilation reduced mortality in severely hypoxemic patients ($PaO_2/FIO_2 \leq 100$ mm Hg, $P = 0.01$; but not in patients with $PaO_2/FIO_2 > 100$ mm Hg, $P = 0.36$). The authors' suggestion was that prone position may provide benefits in severe hypoxemic but it should not be routinely used in all patients affected by acute hypoxemic respiratory failure. In a pooled analysis[119] of the four largest databases[111,117–119] of trials on prone position, the absolute mortality reduction in severe ARDS treated in prone position was approximately 10% (log-rank 0.03). On the contrary, in patients with moderate ARDS prolonged prone position may be useless or possibly harmful. Finally, a recent clinical RCT by Guerin et al. tested the effects of prone positioning on mortality in patients with severe and persistent ARDS.[121] The criteria for the enrollment included $PaO_2/FIO_2 < 150$, FIO_2 60% or higher, PEEP 5 cm H_2O or higher, and the prone position was applied for at least 16 hours/day. The study showed a survival benefit in patients treated with the prone position, with a reduction in mortality of nearly 50%. Therefore the prone position has its definite role in the treatment of patients with severe ARDS.

Extracorporeal Support

Extracorporeal support of ARDS was first applied in 1972.[122] The first randomized trial ever performed in ALI/ARDS showed that patients treated with extracorporeal support or with conventional ventilation had similar mortality, equal to about 90%.[123] In the 1980s, our center introduced extracorporeal CO_2 removal in ARDS, aiming at lung rest with a suggestion of benefit.[124,125] A randomized study performed in 1994 did not show any survival benefit with extracorporeal CO_2 removal support.[126] The results of this trial may have been significantly influenced by bleeding complications

in patients undergoing extracorporeal CO_2 removal. Despite the discouraging results, in Europe few centers continued to use venovenous extracorporeal support as a last resource in selected series of patients.[127] In the United States, Kolla et al.[128] and Bartlett et al.[129] continued to provide extracorporeal support associated with mechanical ventilation with less strict entry criteria and with encouraging results. Interest in extracorporeal membrane oxygenation (ECMO) was renewed after the publication of CESAR (Conventional ventilatory support vs. extracorporeal membrane oxygenation for severe adult respiratory failure) trial in 2009,[130] which showed clear benefits on outcome when severely hypoxemic patients were treated within an expert high–case volume center (with ECMO capability) when compared with nonspecialized hospitals. The rebirth of the technique, however, was due to its use as a rescue therapy during H1N1 flu epidemics in Australia and New Zealand in severely hypoxemic patients untreatable with conventional methods.[131] The approach vas venovenous with high blood flows. This report showed a survival rate higher than 70% and an impressive number of centers in Europe, United States, South America, Canada, and Asia started to use ECMO in severely hypoxemic patients who do not benefit from maximal mechanical ventilation.[132–137] The survival rate ranged between 56% and 79%.

The impressive diffusion of ECMO led to the great improvement of this technology, and there are increasing numbers of reports describing simple forms of extracorporeal support, primarily aiming at CO_2 removal.[138] The actual indications for ECMO depend on the patient's need and the physician's request. The choice of the technique may vary from low-flow bypass with CO_2 removal to high-flow ECMO with total oxygenation support. If the aim is the treatment of life-threatening hypoxemia, the clear-cut indication is high-flow venovenous ECMO. If the patient, however, presents with severe cardiac failure, venoarterial ECMO must be used.

A simplified schema of the possible intervention is shown in Fig. 11.6, which underlines the recent ARDS Berlin definition. As shown, the recent ARDS Berlin definition may be helpful in dictating the sequence of possible intervention when ARDS severity is increasing.

Therapeutic Options According to the Berlin Definition

	ARDS		
	MILD	MODERATE	SEVERE
ALTERNATIVE TREATMENTS			ECMO
		$ECCO_2$-R	
			Neuromuscular Blockade
			Prone Position
Airway Plateau Pressure	≤30 cm H_2O		
Transpulmonary Pressure	≤20 cm H_2O		
PEEP	≈10 cm H_2O		>15 cm H_2O
Tidal Volume	6 mL/kg IBW		
Strain	≤1.5–2		

• **Fig. 11.6** Simplified schema of possible ARDS intervention. *ARDS,* Acute respiratory distress syndrome; *ECMO,* extracorporeal membrane oxygenation; *$ECCO_2$-R,* extracorporeal CO_2 removal; *PEEP,* positive end-expiratory pressure; *IBW,* ideal body weight. Key Points

- The targets of mechanical ventilation in ARDS have shifted from providing normal gas exchange to protecting the lung from VILI.
- Mechanical ventilation replaces the action of the respiratory muscles. The driving force of mechanical ventilation (airway pressure displayed on the ventilator) is spent partly to overcome the resistances to flow, partly to inflate the lung, and partly to inflate the chest wall.
- The distending force of the lung (the trigger of VILI) is the transpulmonary pressure (PL)—the difference between the airway pressure (P_{aw}) and the pleural pressure (Ppl). For the same driving force, in normal conditions, the transpulmonary pressure equals the driving force multiplied by the ratio between the lung elastance and the respiratory system elastance (lung elastance + chest wall elastance): $PL = P_{aw} \times EL/Etot$. In normal subjects, this ratio is approximately 0.5; in patients with ARDS, it may be 0.2 to 0.8. Consequently, the airway pressure alone may be misleading to assess the transpulmonary pressure imposed on the lung by mechanical ventilation (i.e., to assess the stress). We used airway pressure to indicate end-inspiratory pressure.
- The delivered VT increases the lung volume and in the process produces strain on the lung. The ratio of change in lung volume over resting lung volume ($\Delta V/V_0$) is a rough approximation of the strain. Excessive strain causes shape changes of endothelial and epithelial cells, inducing an inflammatory reaction. Because the resting volume (V_0, the baby lung) may vary largely in ARDS, the same VT per ideal body weight may induce largely different strain values.
- Stress and strain, the triggers of VILI, are linked by a constant, specific lung elastance (Espec), accounting for the following relationship: PL (stress) = Espec × $\Delta V/V_0$ (strain). The specific lung elastance is similar in normal subjects and in patients with ARDS.
- Flow may be considered as the rate at which a given strain occurs into the lung, proportional to the energy dissipated into the lung parenchyma.
- VT can be scaled to compliance using the concept of driving pressure (ΔP = Pplat − total PEEP). The lower the driving pressure for a fixed VT, the more compliant is the lung. Physiologic variables are generally poor indicators of the severity of

lung injury, with the alveolar dead space being the only variable associated with outcome. The severity of lung injury may be assessed by CT scan. The fraction of nonaerated lung tissue is strongly associated with mortality risk. The greater the lung injury, the smaller the baby lung, and the greater the stress-strain induced by mechanical ventilation.

- Among outcome studies testing different VTs, only the study comparing the two extreme values tested (6 mL/kg vs. 12 mL/kg) showed a significant benefit of lower VT. Data from clinical studies and rationale from physiologic studies are strongly in favor of using the lowest VT possible, likely associated with lower stress and strain, accepting hypercapnia as a side effect.
- All studies comparing lower versus higher PEEP randomly applied to *unselected* ARDS populations failed to show benefits on survival. In contrast, benefits of higher PEEP were found in more severe *selected* ARDS patients.
- The lung recruitability may vary greatly within the ARDS population (5%–50% of the lung parenchyma) and is correlated with the overall lung injury severity. Higher PEEP possibly should be reserved only for patients with higher recruitability.
- When treating patients with ARDS, individual characteristics (lung injury severity, gas exchange, lung mechanics, abdominal pressure) should be assessed to tailor the least harmful mechanical ventilation setting according to the available evidence and physiologic rationale, providing the lowest stress and strain possible.
- In severe ARDS, in which mechanical ventilation is more harmful, associated therapy such as prone positioning and extracorporeal support must be sought.

Review Questions

1. A 55-year-old male is admitted to the intensive care unit with respiratory failure. The patient has presumed bacterial pneumonia, chest x-ray shows bilateral diffuse opacities, and an echocardiogram shows normal heart function with no signs suggestive of heart failure. The patient is supported by mechanical ventilation and his partial pressure of arterial oxygen/fraction of inspired oxygen (PaO_2/FIO_2) ratio is less than 200. Given the current clinical scenario, which of the following statements regarding stress and strain on the lungs is most correct for this patient?

a. Stress refers to the injury caused by high airway pressures.
b. Strain is the applied force to the lung and is correlated best with esophageal pressures.
c. Lung-specific elastance is the ratio between alveolar stress and strain.
d. In this patient the lung-specific elastance will be significantly lower than in a normal lung.

Answer: c. The concepts of stress and strain were introduced by Gattinoni et al.[28] and help provide a conceptual framework for better understanding ventilator-induced lung injury in acute respiratory distress syndrome (ARDS). Stress is the applied force, and strain is the linear deformation of material (lung tissue). In the whole lung, the best approximation of stress is the transpulmonary pressure and the best approximation of the average strain is the change in volume relative to the lung resting volume. The lung-specific elastance is defined by the ratio between alveolar stress and strain. The lung-specific elastance is the transpulmonary pressure required to double the lung resting volume. In ARDS, the lung-specific elastance is similar to normal, reinforcing the concept of the baby lung (normal lung is small and not stiff). Furthermore, this concept raises questions regarding normalizing the tidal volume to the ideal body weight. Depending on the severity of ARDS and the size of the residual normal lung (baby lung), a given tidal volume can result in a wide range of levels of strain.

2. Which of the following variables is most strongly associated with a poor outcome in patients with ARDS?

a. Arterial pressure of oxygen (PaO_2)
b. PaO_2/FIO_2 ratio with 100% oxygen
c. PaO_2/FIO_2 ratio with PEEP above 5 cm H_2O
d. Initial amount of dead space

Answer: d. Although most clinicians (and current definitions) equate severity of disease in ARDS with PaO_2/FIO_2, and other oxygenation-related variables, studies have shown poor correlation between these and outcomes in ARDS. Most data suggest that the use of oxygenation variables alone to access lung severity can be misleading. On the other hand, variables derived from carbon dioxide (CO_2) as the total alveolar dead space seem to be of greater value to assess lung severity. Studies have shown that in ARDS dead space at entry is a strong predictor of outcome.

3. Which of the following interventions has been associated with improved mortality in clinical trials of patients with ARDS?

a. Ventilation with low tidal volumes (6 mL/kg of ideal body weight)
b. Ventilation with high PEEP (>10 cm H_2O)
c. Ventilation with inspiratory-to-expiratory ratio (I:E ratio) greater than 2:1
d. High-frequency oscillatory ventilation (HFOV)

Answer: a. Multiple clinical trials have evaluated therapeutic strategies in ARDS. To date the only therapy that has been demonstrated to be associated with a significant improvement in survival in a wide range of patients with ARDs is the use of lower tidal volumes (6 mL/kg of ideal body weight). Other strategies such as higher positive end-expiratory pressure (PEEP) may be of use in selected groups of patients. HFOV has not been demonstrated to improve outcomes. There are no clinical data supporting the use of inverse ratio ventilation (increased I:E ratios) in ARDS.

4. Which of the following patients is most likely to have a mortality benefit from ventilation in the prone position?

a. A 54-year-old female with severe cardiogenic pulmonary edema supported by mechanical ventilation requiring high FIO_2.
b. A 45-year-old male with multifocal pneumonia and ARDS supported by mechanical ventilation (FIO_2 0.7, PEEP 10, PaO_2/FIO_2 90).
c. A 35-year-old female with ARDS postaspiration pneumonia supported by mechanical ventilation (FIO_2 1.0, PEEP 5, PaO_2/FIO_2 250).
d. A 76-year-old male with severe influenza and ARDS supported by mechanical ventilation (FIO_2 0.8, PEEP 12, PaO_2/FIO_2 180).

Answer: b. Prone positioning has been used in ARDS for several decades. Prone positioning has been shown to produce improved oxygenation in up to 70% of patients with ARDS. However, several clinical trials evaluating a wide range of patients with ARDS were unsuccessful in demonstrating improved survival with prone positioning. More recent meta-analyses and clinical trials have shown a mortality benefit with prone position ventilation in patients with severe ARDS. Based on this and considering the most recent definitions for ARDS (see Table 11.1), the patient in option c is most likely to benefit from prone position ventilation.

Bronchoscopy and Lung Biopsy in Critically Ill Patients

THADDEUS BARTTER, MELVIN R. PRATTER, AND WISSAM ABOUZGHEIB

CHAPTER OUTLINE

Fiberoptic Bronchoscopy-Induced Physiologic Changes
- General Considerations
- Special Considerations: Bronchoscopy in Mechanically Ventilated Patients
- Special Considerations: Hypoxemia
- Physiologic Changes With Bronchoscopy Summary

Airway Evaluation and Management
- Intubation and Endotracheal Tube Management
- Percutaneous Dilational Tracheostomy
- Airway Obstruction and Atelectasis
- Trauma
- Smoke Inhalation
- Hemoptysis

Diagnosis of Infection

Lung Biopsy: Surgical, Transbronchial, and Cryobiopsy
- Placement of Endobronchial Valves

Special Situations
- Immunocompromised Host
- Thrombocytopenia

Complications and Death

Summary

Bronchoscopy plays an important role in the care of critically ill patients. Since the introduction of the flexible fiberoptic bronchoscope in 1968, flexible bronchoscopy has slowly gained importance as a diagnostic and a therapeutic tool. It has largely replaced rigid bronchoscopy in the intensive care unit (ICU) for several reasons: the lack of need for complete anesthesia, the ease of use, and the fact that flexible bronchoscopy allows one to perform procedures on a critically ill ventilated patient through an endotracheal tube (ETT) or tracheostomy tube.

Lung biopsy is often a procedure of last resort in a critically ill patient with lung disease who is not responding to therapy. Whereas many of these patients are treated with mechanical ventilation, the potential benefits of biopsy need to be carefully weighed against the potential risks.

This chapter reviews bronchoscopy and lung biopsy in critically ill patients. By definition, a critically ill patient has one or more organs that are under stress and has limited functional reserve. Stresses that are usually well tolerated by healthy individuals may have serious or even fatal consequences for a patient in the ICU. This chapter first reviews the physiologic stresses induced by bronchoscopy. It then reviews diagnostic and therapeutic indications for bronchoscopy in the ICU. Finally, we review the potential role of bronchoscopic and nonbronchoscopic approaches to lung biopsy.

Fiberoptic Brochoscopy-Induced Physiologic Changes

General Considerations

The act of cannulation of the airway is not a physiologically neutral event.[1–5] It stimulates both cardiovascular and respiratory responses. In the ICU, there are three common stimuli that provoke these reflexes: intubation, bronchoscopy, and suctioning. Even after the use of sedation and application of topical anesthesia, the passage of a bronchoscope through the larynx typically results in a 30% increase in mean arterial blood pressure and cardiac index, a 40% increase in heart rate, and an 86% increase in pulmonary arterial occlusion pressure.[1] The response seems to represent a reflex to mechanical stimulation of the larynx. A significant hemodynamic response occurs even when patients are anesthetized and paralyzed before the passage of a bronchoscopy through the larynx and into the trachea, with conflicting data as to whether there is a difference in hemodynamic response between the nasal and the oral routes.[3,4] Topical anesthesia of the upper airway with lidocaine attenuates (but does not ablate) the cardiovascular responses.[3,5]

The significance of the cardiovascular changes associated with bronchoscopy is related primarily to their potential impact on the heart and the brain. The increase in rate-pressure product has the potential to cause cardiac ischemia in patients with limited cardiac perfusion. In one small study, 3 of 10 monitored patients undergoing bronchoscopy, all of whom were 55 years of age or older, developed electrocardiographic changes of ischemia.[2] In another study designed specifically for older patients, the incidence of ischemia was 17%.[6] Despite these findings, bronchoscopy has a low rate of ischemic mortality. In studies describing complications from bronchoscopy (ranging from as few as 10 to as many as 48,000 procedures), the rate of death from ischemic events ranged from 0% to approximately 0.01%.[6–11]

A second potential cardiac complication of bronchoscopy is the triggering of arrhythmias. One study looking specifically for arrhythmias during bronchoscopy found an 11% incidence of "major arrhythmias."[12] As with ischemia, however, reported mortality from arrhythmias has been very low; in two large studies of complications of bronchoscopy the mortality from arrhythmias ranged from 0% to 0.04%.[10,11]

With respect to the brain, both bronchoscopy and endotracheal suctioning cause significant increases in intracranial pressure.[2,13] Because mean arterial pressure and intracerebral pressure increase roughly in parallel, there is little overall change in cerebral perfusion pressure.[2,13] This may explain why no adverse intracerebral sequelae have been reported despite the observed increase in intracerebral pressure.[13] Nevertheless, we believe that close attention to intracerebral pressure is warranted whenever possible in brain-injured individuals undergoing bronchoscopy.

Bronchoscopy also affects the work of breathing, respiratory pressures, and lung volumes. Transnasal cannulation of the trachea leads to a decrease in inspiratory and expiratory flow, a decrease in vital capacity, and an increase in functional residual capacity.[14] Bronchoscopy through an ETT in a sedated, but not ventilated, patient leads to significant further decreases in flows and vital capacity and a marked increase in the work of breathing.[14,15]

Special Considerations: Bronchoscopy in Mechanically Ventilated Patients

Before planning a bronchoscopy in the ICU on an intubated patient, it is crucial to know the ETT size while keeping in mind the primary indication of the bronchoscopy. This will avoid patient-related complications as discussed in the following text and bronchoscope-related injuries and damages.

In general, we prefer to use a therapeutic bronchoscope in intubated patients, as we often encounter thick secretions that may hinder the completion of the procedure. However, for patients intubated with an ETT size 7.5 and below, it is advisable to use a diagnostic bronchoscope with an outer diameter (OD) of 5.1 mm. Using a therapeutic bronchoscope with an OD of 6.0 mm requires at least an ETT size 8.0. In addition, the operator needs to ensure the use of a bite block regardless of the level of sedation to avoid accidental biting of the scope and adequate lubrication of the entire length of the scope, which facilitates maneuverability of the bronchoscope through the ETT.

Mechanical ventilation adds additional complexity to the physiologic effects of bronchoscopy. The details were elegantly delineated in a study by Lindholm and colleagues.[15] The first notable change is a dramatic increase in upper airway resistance. Airway narrowing related to ETT insertion by itself increases airway resistance. The subsequent introduction of a bronchoscope through the ETT greatly increases that resistance. The actual degree of increased airway resistance observed is related to the cross-sectional areas of both the ETT and the bronchoscope being inserted.[15] The increased resistance has implications for ventilator gas delivery. The first is a potential decrease in delivered volume. With a volume-cycled mode, pressure increases as needed to deliver the specified volume, but the set volume may not be delivered owing to a pressure pop-off set in the alarm/safety parameters of the ventilator. (Although peak pressures of 60 to 80 cm H_2O can be reached at the airway opening, note that the pressure gradient from the proximal obstruction limits the pressure delivered to the lung parenchyma.)[15] With a pressure-cycled mode of mechanical ventilation, the increase in upper airway resistance caused by bronchoscopic cannulation leads to an immediate decrease in delivered volume, the severity of which again depends on the cross-sectional diameters of both the ETT and the bronchoscope. This effect can be countered by raising the applied pressure and the associated inspiratory airway pressure.

Whereas the driving pressure for inspiratory volumes depends on external force (generated by the ventilator), exhalation is largely dependent on the passive recoil of the lungs. The increase in airway resistance caused by introduction of the bronchoscope into the ETT thus has a disparate and more potentially dramatic effect on expiratory volumes than on inspiratory volumes. Sequential delivered volumes may be incompletely exhaled, causing a gradual buildup of intrathoracic volume and intrinsic positive end-expiratory pressure (auto-PEEP). Lindholm and colleagues[15] documented several cases of auto-PEEP greater than 18 cm H_2O. In one patient undergoing bronchoscopy through an ETT with an internal diameter of 7 mm, auto-PEEP was recorded at 35 cm H_2O.

Suctioning adds another layer of complexity. In addition to the cardiovascular changes stimulated by suctioning mentioned above, suctioning can cause profound changes in intrathoracic pressures and lung volumes. Not only can the auto-PEEP induced during bronchoscopy be eliminated, but with prolonged suctioning negative intrathoracic pressure can be created.[15] This can lead to clinically relevant decreases in functional residual capacity, tidal volume, and minute ventilation, with potential for alveolar collapse, hypercarbia, and hypoxemia.

Special Considerations: Hypoxemia

That bronchoscopy can cause hypoxemia is clear. The degree of hypoxemia ranges from mild to severe, and a variety of potential mechanisms are involved. The administration of benzodiazepines and narcotics can cause hypoxemia and respiratory depression in normal volunteers,[16] and one study showed a 35% incidence of desaturation after sedation even before bronchoscopy was performed.[17] The desaturation may not be completely due to central nervous system depression; Chhajed and coworkers[18] showed that hypoxemia during bronchoscopy could be corrected in most of their lung transplant patients by the insertion of a nasopharyngeal tube, indicating that upper airway collapse was a major cause of hypoxemia in their population. Apart from the effects of sedation on oxygenation, bronchoscopy itself can cause hypoxemia, Changes in airway resistance and the impact of suctioning on functional residual capacity are probably major factors.[19–22] Higher incidences of hypoxemia have been shown to correlate with the degree of prebronchoscopy pulmonary impairment, extent of suctioning, and performing a bronchoalveolar lavage (BAL).[20–25] Furthermore, the hypoxemia induced by bronchoscopy often does not resolve immediately on removal of the bronchoscope; it can persist for more than 2 hours.[17,24,25] Hypoxemia represents another stress in addition to the cardiovascular reflex changes cited early and may have a negative impact on organs at risk. Hypoxemia may play a significant role in cardiac ischemia and arrhythmias associated with bronchoscopy.[1]

Bronchoscopy through the ETT of a patient assisted by a ventilator has been reported to cause an increase in the partial pressure of oxygen (Po_2) with an increase in Pco_2 and a decrease in Po_2 with no change in the partial pressure of carbon dioxide (Pco_2).[14,15] The seemingly contradictory differences in findings probably reflect individual differences in how much patients are suctioned and the degree to which suctioning affects functional residual capacity.

Physiologic Changes With Bronchoscopy Summary

In summary, bronchoscopy and other airway cannulations almost always trigger a reflex response that includes tachycardia and an increase in blood pressure. Bronchoscopy frequently causes hypoxemia, which may be of prolonged duration. For patients supported by ventilators, disparate physiologies can be created based on the mode of ventilation, the size of the ETT, the size of the bronchoscope, the duration of suctioning, and the flow rate that the suction channel of the bronchoscope is able to attain. Bronchoscopy can cause significant physiologic stress, and the critically ill patient may be less able to tolerate such stress than an otherwise healthy individual.

Airway Evaluation and Management

Intubation and Endotracheal Tube Management

Bronchoscopy can be an asset in the insertion and subsequent management of ETTs.[26,27] For patients with difficult airways, an ETT can be placed over a bronchoscope and slid into the trachea after direct visual intubation with the bronchoscope. A similar technique can be used for changing the ETT in a tenuous patient, especially if switching from nasal to oral or oral to nasal route.[27] Bronchoscopy is valuable in the placement of tubes for single-lung ventilation or placement of double-lumen tubes.[27] Bronchoscopy also allows the bronchoscopist to position the tip of an ETT at a point approximately 2.5 cm above the carina under direct visualization or, when there is a process such as tumor compression of the trachea, to place the tube wherever needed for optimal ventilation.[26]

Percutaneous Dilational Tracheostomy

Percutaneous dilational tracheostomy (PDT) has emerged as a primary method of tracheostomy for ICU patients. It has a lower incidence of overall complications than does open surgical tracheostomy, and it can be performed at the bedside, avoiding the risks of transporting a critically ill patient.[28–31] It also is more cost-effective.[29] PDT can be performed not only by surgeons, but also by trained intensivists and pulmonologists[29]; it has become a standard intensivist procedure in many institutions.[32,33] Although its overall safety profile is better than for open surgical tracheostomy, PDT does have a higher risk of posterior tracheal wall injury and false passage.[34] Bronchoscopy can be combined with PDT to allow direct endobronchial guidance for the procedure. Bronchoscopy has been suggested by several authors to be an important safety factor in PDT,[30,31,33a,34–39] although its use is not universally practiced.[32,40,41] Direct visualization is a protection against inadvertent tracheal injury and a means of assessing an injury for intervention should it occur.[34,35,37] The most logical approach to PDT is a team approach[39a] with at least two principal operators—one managing the bronchoscope and ETT and the second working at the neck to insert the tracheostomy tube.[30,31,34,38] The risk of using bronchoscopy for PDT is that of increased hypoventilation because the patient is being ventilated through the ETT during the procedure.[36] This can be obviated with the use of a pediatric bronchoscope for guidance; a large working channel is not needed for this application.

Airway Obstruction and Atelectasis

The upper airway can become obstructed via several mechanisms. Bronchoscopy is valuable in diagnosing all of them. When an ETT is inserted, it becomes part of the airway. Kinking of the ETT or luminal blockage by hardened, inspissated secretions causes the same physiologic problems as a primary tracheal process. Granulation tissue at the proximal end of a tracheostomy tube or at the distal end of a tracheostomy tube or ETT can cause obstruction and difficulty with inflation or deflation of the lungs. (This is much less common with ETTs than with tracheostomy tubes because of Murphy's eye [the distal side port] on ETTs.) Benign or malignant processes can cause strictures or compression of the trachea. Finally, edema of the vocal cords and periglottic structures can lead to upper airway obstruction that is not evident with an ETT in place but which can cause recurrent respiratory failure after extubation; performing extubation over a bronchoscope allows immediate evaluation of the upper airway as the ETT is withdrawn with immediate diagnosis of this problem.[27]

Foreign bodies can cause obstruction at various points in the airways. Traditionally, rigid bronchoscopy was used for management of foreign bodies given its capacity for airway control and the availability of tools larger than those that can be passed through a flexible bronchoscope.[42] Flexible bronchoscopes are the only choice, however, in an intubated patient, and the combination of larger channel scopes (2.8 mm and larger) for the passage of instruments and of different baskets and grasping tools makes flexible fiberoptic bronchoscopy a viable option in many cases.[26,42,43] For nonintubated patients, a flexible bronchoscope through a rigid bronchoscope is sometimes an optimal approach.[42]

Atelectasis is a common ICU problem and has been one of the most common indications for bronchoscopy in ICUs.[44,45] The argument is obvious: if standard "blind" suctioning is effective and useful, why not use suctioning under direct visualization for local airway obstruction caused by secretions? One key study done by Marini and coworkers[46] challenged the assumption that bronchoscopy is an optimal approach to atelectasis. In their study of patients with radiologically evident atelectasis, one group underwent a regimen of initial bronchoscopy followed by regular chest physiotherapy while a second group received regular chest physiotherapy alone followed by delayed bronchoscopy at 48 hours only if atelectasis persisted. The authors showed early bronchoscopy to be the inferior approach; there was no difference in rate or degree of improvement between the two groups, and bronchoscopy led to more significant decreases in oxygenation.[46] The authors also looked at the presence or absence of air bronchograms, postulating that patients with air bronchograms had more distal consolidation (as opposed to proximal obstruction causing atelectasis) and would be more refractory to any attempts to reexpand consolidated lung. Their results strongly supported their postulate.[46]

These data are valuable and should lead to initial trials of chest physiotherapy in most cases of atelectasis, but they do not apply universally in clinical medicine. Some patients with chest trauma or spinal cord injury are not candidates for chest physiotherapy.[47] Some patients have atelectasis and a severe refractory hypoxemia as a result of shunting of blood through the atelectatic lung. In these patients, a 24-hour wait may be inappropriate, and bronchoscopy sometimes leads to marked improvement. Judicious use of bronchoscopy for atelectasis is thus a clinical decision involving the art of medicine.[47] Some patients with atelectasis have severe refractory hypoxemia as a result of shunting of blood through the atelectatic lung. In these patients, trying chest physiotherapy may

be inappropriate because bronchoscopy often can lead to marked improvement almost immediately. Decisions on use of bronchoscopy for atelectasis thus depends on the clinical situation and combining the art and science of pulmonary medicine. For patients who have a bronchoscope inserted for atelectasis, one technique that has been moderately successful is that of isolated segmental inflation; the bronchoscope or a ballooned catheter is wedged into the atelectatic segment, and pressure of at least 30 mm H_2O is applied through the bronchoscope or catheter.[44,47] This focal approach is more rational for focal atelectasis than are recruitment maneuvers applied to the whole chest because recruitment maneuvers are more likely to overdistend compliant alveoli than to open atelectatic alveoli.[44]

Trauma

The value of bronchoscopy for the evaluation of chest trauma was defined in a landmark paper by Hara and Prakash.[48] The authors investigated 53 cases of blunt trauma to the chest, neck, or both in which bronchoscopy was performed within 3 days of injury. Bronchoscopy was believed to be of clinical value in 53% of the 53 cases. They documented injury and tears of the upper and lower airways, contusion or hemorrhage, aspirated material, and plugging or secretions. Only one of eight major tracheal injuries was not completely diagnosed. These data provide compelling evidence for visual bronchoscopic evaluation of the bronchial tree in all cases of significant blunt chest trauma.

Smoke Inhalation

Inhalation injury is a unique form of trauma to the bronchial tree. Most inhalation injuries are due not to heat alone, but to the deposition in the bronchial tree of soot and gases, the products of combustion.[49] Early ventilatory support and aggressive pulmonary toilet probably improve outcomes for inhalation injury,[50,51] but the severity of inhalation injury may not become fully manifest for up to 5 days (usually 3 days).[51] Bronchoscopy has been advocated in the evaluation of patients with possible inhalation injury.[50–52] Some patients have mucosal injuries that are obvious to even an inexperienced bronchoscopist, but sometimes even when there is significant injury, the bronchoscopic appearance of the airways may be minimally abnormal. For patients who have relatively normal-appearing mucosae, biopsy specimens from segmental or subsegmental carinae can yield pathologic information that is predictive of the degree of inhalation injury (or lack thereof) and can be used to guide aggressiveness of management.[50,51] Another tool for evaluation of inhalation injury is the ventilation-perfusion scan,[49,52] but the objectivity and reproducibility of bronchoscopic endobronchial biopsy could lead one to argue that it should be the current standard of care for the diagnosis of possible inhalation injury.

Hemoptysis

Hemoptysis can run the gamut from scant to massive. There are several definitions of massive hemoptysis, with varying quantities of blood specified over different intervals. The best definition of massive hemoptysis is functional: massive hemoptysis is bleeding in quantities that threaten to cause death by asphyxiation from filling of the bronchial tree with blood or by exsanguination.[53,54] Patients with massive hemoptysis should always be admitted to the ICU.

Bronchoscopy plays two roles in massive hemoptysis—diagnostic and therapeutic. Most authors recommend bronchoscopy as soon as possible to localize the site of bleeding.[53–55] Rigid bronchoscopy and flexible bronchoscopy each have their advocates. The argument for rigid bronchoscopy is that it allows better visualization of the major airways, more aggressive suctioning, removal of clots, and local tamponade with packing materials.[55,56] The argument for flexible bronchoscopy is that it does not require the operating room or general anesthesia, it allows more thorough evaluation of the bronchial tree, and it allows directed intubation.[53,55] Intubation may be with a regular ETT in the trachea or in the left lung or with a double-lumen tube. (The right upper lobe takeoff is too proximal in the right bronchial tree to allow selective right main bronchus intubation.) If bleeding is too great, flexible bronchoscopy is of limited value; small amounts of blood can obscure the relatively small lens of a bronchoscope.[53] For massive hemoptysis, the goals of bronchoscopy are to identify the bleeding site and to stabilize the patient enough to allow arterial embolization, surgery, or a sequence of the two; embolization and surgery are usually the two most effective therapies. Several temporizing endobronchial therapies have been advocated: iced saline solution lavage, topical 1 : 20,000 epinephrine, endobronchial tamponade with packing or a Fogarty catheter, and endobronchial laser therapy.[53–55]

Diagnosis of Infection

Bronchoscopy is a valuable tool for the diagnosis of pulmonary infection in a critically ill patient. A variety of organisms, including *Mycobacterium tuberculosis, Pneumocystis jiroveci* (formerly *P. carinii*), fungi, viruses, and bacteria are capable of causing severe pneumonia in critically ill patients. Given the broad differential diagnosis, it is commonly important to try to determine the specific etiology. Bronchoscopy offers access to lower airway secretions, which can lead to accurate diagnosis, focused therapy, and sometimes the withdrawing of unnecessary therapy. BAL is the most useful diagnostic modality and can be performed in a patient who cannot or will not produce expectorated sputum or who is intubated. BAL samples alveoli more reliably than induced sputum. BAL fluid also is helpful for a broader range of diagnoses than induced sputum. In some cases, BAL recovery of organisms is not adequate alone, and biopsy is needed to confirm tissue invasion.

For BAL, the bronchoscope is wedged into a peripheral airway, and aliquots of sterile saline solution totaling at least 120 mL are instilled to ensure that alveolar spaces are reached. Box 12.1 summarizes the recommended method for BAL. Fluid retrieved via suctioning is sent for diagnostic studies. The BAL technique samples about 1 million alveoli, or 1% of the lung.[57] For some infections, the presence of an organism in the lung is pathognomonic for active infection, whereas for others quantitative cultures are needed to distinguish lower respiratory tract infection from upper airway contamination.

M. tuberculosis is a cause of pneumonia that should not be forgotten in critical care medicine. BAL is a sensitive tool for the diagnosis of *M. tuberculosis,* one of the organisms whose presence always means active infection.[58,59] BAL is more sensitive than gastric washings for the diagnosis of tuberculosis.[60] BAL or protected specimen brushings are often positive in patients who have pulmonary tuberculosis but negative sputum smears,[58,61,62] and BAL is also more sensitive than transbronchial biopsies for diagnosis of tuberculous pneumonia.[63] (For miliary tuberculosis, biopsy is of great value.[64]) The addition of molecular techniques such as

• BOX 12.1 Bronchoalveolar Lavage

- Wedge the bronchoscope into a peripheral area of whatever segment is most suspect radiologically. If there is no such segment, wedge into an upper lobe segment if *Pneumocystis* pneumonia is suspected or into a posterior lower lobe segment otherwise.
- Instill 30- to 60-mL aliquots of sterile nonbacteriostatic saline solution through the wedged bronchoscope until some fluid can be retrieved using suction. Discard approximately the first 20 mL of fluid.
- Attach a sterile specimen cup in line with the suction tubing, and instill further aliquots until at least 120 mL have been instilled and at least several milliliters of fluid have been obtained.
- Bilateral lavage has a higher yield than unilateral lavage.
- Have the fluid divided into two aliquots. One is plated using quantitative techniques; the second is centrifuged, stained, and examined for intracellular organisms and other diagnostic findings.
- Time from obtaining bronchoalveolar lavage fluid to plating of quantitative specimen should be <4 hours.

polymerase chain reaction (PCR) can further increase the sensitivity of BAL for *M. tuberculosis*.[65]

P. jiroveci is a pathogen in immunocompromised individuals. Its incidence increased dramatically in the 1980s with the emergence of AIDS. In the 1960s and 1970s, only about 100 cases were diagnosed per year in the United States.[66] In the 1980s, thousands of cases were diagnosed.[66] Because the organism cannot be cultured, its detection depends on identification in respiratory secretions. BAL greatly increases the yield for *Pneumocystis* pneumonia over bronchial washings and brushings and is the diagnostic procedure of choice.[63,67,68] As with *M. tuberculosis, P. jiroveci* is an organism that can sometimes be difficult to see on smears, especially in patients with *Pneumocystis* pneumonia who do not have AIDS or who have AIDS but have received inhaled pentamidine.[69,70] PCR can increase the sensitivity of fluid examination with the caveat that some patients can have *Pneumocystis* colonization without infection, and the PCR method is sensitive enough to detect those cases.[71,72] In patients without AIDS or patients with AIDS receiving inhaled pentamidine, transbronchial biopsy increases the diagnostic yield.[69,73]

The diagnosis of fungal pulmonary infection is more problematic; some fungi can colonize the bronchial tree without being a cause of active infection. Fungal infection is a major issue in the immunocompromised host, but it can occur in immunocompetent individuals and can be community-acquired.[74] *Candida* species often colonize the respiratory tract in critically ill patients; their isolation from BAL fluid alone is not diagnostic of tissue invasion.[74,75] *Aspergillus* runs the gamut of possibilities; it can colonize the upper airways without infection, and it can be difficult to detect sometimes when it is the cause of deep tissue infection. In the appropriate clinical and radiologic setting, a BAL positive for *Aspergillus* would be a reasonable criterion for starting therapy, but a BAL negative for *Aspergillus* is inadequate to rule out infection.[76] PCR would seem promising to increase sensitivity for *Aspergillus,* but published results have been variable, and it is not a standard tool.[77–79] Because of the possibility of colonization with *Aspergillus* and *Candida* species, lung biopsy showing tissue invasion is needed to confirm active infection by these fungi.[75,79] In contrast, *Cryptococcus neoformans,* although ubiquitous, does not routinely colonize the respiratory tract; its detection in samples of lung fluid is strong presumptive evidence for an active role in pulmonary infection.[80,81]

The endemic fungi, *Histoplasma capsulatum, Blastomyces dermatitidis,* and *Coccidioides immitis,* are capable of causing fulminant infection and cannot be ignored as diagnostic possibilities for pneumonia in patients who live in or travel through endemic areas.[80–85] Diagnosis is sometimes difficult, although the organism may be more plentiful and easier to identify in pulmonary secretions of patients who have fulminant disease. BAL fluid has a much higher yield than sputum.[86] If organisms are not seen on smear, fungal cultures can take weeks, an unacceptable interval for seriously ill patients. For *H. capsulatum,* an antigen can be detected in bodily fluids (including BAL) and is of clinical value.[85] The other two endemic fungi are more problematic when not demonstrable on staining of fluids or biopsy material, but promising techniques with antigen detection, DNA probes, and PCR are evolving and should become clinically available soon.[82,84,87,88]

Similar to fungi, viral pneumonias occur more frequently in immunocompromised hosts, but viruses play a role in community-acquired pneumonias as well.[89–91] In a multinational study, viruses alone were identified in 9% of community-acquired pneumonias, and viruses as copathogens were identified in an additional 9% of community-acquired pneumonias.[91] Viral pneumonia is relevant to the critical care setting; in the multinational study, 8% of patients with pure viral pneumonia were admitted to the ICU owing to severity of disease.[91] In another study using the most sensitive available virus detection technique, reverse transcriptase PCR, viruses were present as pathogens or copathogens in 23% of patients hospitalized for community-acquired pneumonia.[89] Analogous to the atypical pneumonias, no clinical characteristics reliably differentiate viral from bacterial pneumonia.[89,91,92]

The virology of viral pneumonia is different for pneumonia in immunocompetent and immunocompromised hosts. In immunocompetent individuals, the most common viruses are influenza A and B, parainfluenza, respiratory syncytial virus, and adenovirus.[92] In immunocompromised patients, the herpesviruses—herpes simplex, varicella zoster, and cytomegalovirus—are most common, with adenovirus, respiratory syncytial virus, and measles also occurring.[92,93] BAL is useful in the diagnosis of viral pneumonia; BAL fluid is an ideal substrate for most studies done to detect viral infection.[94,95] For all but herpes simplex virus and cytomegalovirus, the presence of the virus is diagnostic of infection.[94,96] Cytomegalovirus and herpes simplex virus can be present in BAL fluid in the absence of pneumonia; proof of tissue invasion is far more specific for active infection.[94,96] Viral pneumonias are often difficult to diagnose, and cultures can take days to weeks. Newer diagnostic techniques such as reverse transcriptase PCR offer a far more sensitive diagnostic tool.[97]

BAL is of major utility in the diagnosis of bacterial pneumonias. It has long been recognized that patients in the ICU often have colonization of the upper airways by several potentially pathogenic organisms, and that culture of upper airway secretions cannot be used to diagnose infections of the lower airways and lung parenchyma. Quantitative culture of BAL specimens has been proven to best obviate the issue of upper airway colonization, and BAL has thus emerged as the best currently available diagnostic test for bacterial pneumonia.[57,98] An alternative to BAL is the protected specimen brush (PSB). BAL allows the sampling of a much larger area of lung than does the PSB and logically would be a better diagnostic modality. Although the two modalities are equally accurate in some studies, for several reasons BAL has become the diagnostic procedure of choice for bacterial pneumonia

• BOX 12.2 Reasons to Use Bronchoalveolar Lavage Over Protected Specimen Brush for the Diagnosis of Lung Infiltrates

BAL has a higher sensitivity.
BAL is less expensive.
BAL has a lower complication rate (pneumothorax or bleeding with protected specimen brush).
BAL allows Gram stain of concentrated smear to look for extracellular organisms.
BAL offers the opportunity to evaluate cells for intracellular organisms, additional proof of active infection.
BAL is a tool for the diagnosis of infections other than bacterial infections.
BAL yields specimens that can be used for probe techniques such as polymerase chain reaction.
BAL is a tool for the diagnosis of other infiltrative processes (e.g., alveolar bleeding) that can mimic infection radiologically.

BAL, *Bronchoalveolar.*

(Box 12.2).[57,98] A third technique, the blind passage of a protected brush into the airways without bronchoscopic guidance, has been described.[99] This technique has a relatively lower sensitivity than BAL, which probably depends on which lobe is most involved with infection. For example the catheter cannot be passed into the upper lobes.[57,99] For this reason and the reasons cited in Box 12.2, BAL has evolved as the procedure of choice.[98]

Two quantitative methods for bacterial growth of samples obtained by BAL have been described. The first is a simple log count; any bacteria present in greater than or equal to 10^4 colonies by quantitative methods is a pathogen unless proven otherwise.[57] (If PSB is used, a smaller area of lung is sampled and a concentration of $>10^3$ colonies is considered diagnostic of infection.[57]) The second, called the bacterial index, was described by Johanson and colleagues.[100] This method recognizes the fact that in careful studies numerous patients with pneumonia have more than one infecting organism.[23,91,100,101] For the bacterial index, the log numbers of each cultured organism are summed (10^4 *Staphylococcus aureus* + 10^3 *Pseudomonas aeruginosa* = bacterial index of 7). With this system, a bacterial index greater than 6 was a sign of moderate to severe pneumonia.[100] Although the bacterial index system seems more rational, single-organism quantification has become the de facto standard in current clinical practice.

Reinforcing the value of BAL for clinical management of bacterial infection is a study by Rodriguez and associates.[73] The authors performed quantitative cultures on BAL fluid and PSB from 32 ventilated patients not suspected to have pneumonia. There were six "false-positive" results, with quantitative cultures in the pneumonia range. Four of the six patients subsequently developed clinical pneumonia.

If a patient with suspected bacterial pneumonia has already been given antibiotics, the quantitative culture of distal airway secretions loses sensitivity.[102,103] A decrease in recovered organisms becomes significant within 12 hours of initiation of antimicrobial therapy and reaches 50% between 24 and 48 hours.[104] This is not surprising because even quantitative cultures of lung tissue have a dramatic loss of sensitivity and specificity for patients who have received prior antibiotic therapy.[105] Despite this loss in sensitivity, BAL may make sense in the evaluation of critically ill patients with lung infiltrates who are receiving antibiotics as long as these limitations are recognized. BAL can detect organisms not being covered by the current antibiotic regimen, and BAL could help to define nonbacterial infectious agents or other noninfectious processes responsible for the clinical presentation.

When discussing the diagnostic utility of bronchoscopy for the diagnosis of severe lung infection, it is important to mention diagnoses that may be missed by the techniques discussed above. The "atypical pneumonias"—principally *Legionella pneumophila, Mycoplasma pneumoniae,* and *Chlamydia pneumoniae* and *C. psittaci*—can be community acquired. The myth that "atypical' and "typical" pneumonias can be distinguished clinically has been refuted. *Legionella* is particularly capable of causing severe disease, and the other organisms can be present as coinfectants in severe disease.[106–108] *Legionella* is not typically visible on Gram stain, does not grow on standard bacterial culture, and requires about 1 week to grow on special media when it is present. BAL material in a patient being evaluated for severe community-acquired pneumonia should be sent for direct fluorescent antibody staining for *Legionella* and for culture.[109] The direct fluorescent antibody staining is reasonably sensitive and very specific for *Legionella,*[106] and direct fluorescent antibody staining of pulmonary secretions and of urine are the most rapid diagnostic tools available. The direct fluorescent antibody of pulmonary secretions remains positive for at least 48 hours after institution of appropriate therapy.[109]

There is an importance to negative BAL for quantitative bacterial culture. A prospective study comparing management based on quantitative cultures from invasive diagnostic techniques (BAL or PSB) with management based on clinical data without quantitative cultures showed that the patients whose therapy was started or withheld based on quantitative bacterial studies had less antibiotic use, lower mortality, and less sepsis-related organ failure.[110] The importance of negative bacterial studies lies not only in the capacity to withhold or discontinue treatment for bacterial pneumonia, but also in the implication that other types of pulmonary infection or injury should be sought, and that, in some cases, extrapulmonary sources of bacterial infection may be present.[57,110] The implications of BAL for a critically ill patient thus extend beyond the lungs.

In summary, bronchoscopic techniques for the diagnosis of pulmonary infection are valuable tools in intensive care medicine. BAL is the most valuable single tool, with diagnostic implications dependent on the organism being evaluated. It is important to remember that a wide spectrum of organisms can cause pneumonia in critically ill patients; the intensivist needs to consider tuberculosis, *Pneumocystis*, viruses, fungi, and atypical organisms in addition to typical bacteria.[111] When BAL fluid has been obtained, the diagnostic techniques of greatest value vary with the infecting organism. For some infecting organisms, detection of a causative organism can be difficult even in the presence of severe infection, and sensitive assays such as PCR can help in the rapid detection of the etiologic agent. In other cases, such as bacterial infection, organisms abound and it can be difficult to separate colonization from infection; in these cases, quantitative cultures are of greatest value. For other organisms, tissue samples are needed for definitive diagnosis. Table 12.1 summarizes diagnostic methods relevant to different lung infections. BAL fluid is the optimal substrate for almost every listed study with the exception of titers and biopsy material.

Lung Biopsy: Surgical, Transbronchial, and Cryobiopsy

The decision of whether or when to perform an open lung biopsy is difficult and a matter of debate. Open lung biopsy is the gold

TABLE 12.1 Diagnostic Techniques for Important Potentially Severe Pulmonary Infections

Important Organism	Presence in BAL Diagnostic?	Culture	Serology	Detection With Antibodies	Gene Amplification	Cytology/Pathology/ Other
M. tuberculosis	Yes	Usually positive—slow			PCR	Necrotizing granulomas
Legionella	Yes	Special media, slow	≥1:256 or 4-fold increase	IF of sputum or BAL	PCR±	DFA of urine or pleural fluid
"Typical" bacteria	No	BAL $>10^4$ PSB $>10^3$ BI >6				DFA—urinary pneumococcal antigen
Influenza (A, B, and C)	Yes	Positive—slow	4-fold increase	IF ELISA (A and B)	PCR	Hemadsorption testing
Herpes simplex	No	Cell culture—cytopathic effects		IF ELISA		Nuclear inclusions (Cowdry A bodies)
Cytomegalovirus	No	Cell culture—cytopathic effects		ELISA		Nuclear inclusions ("owl's eye")
Varicella zoster	Yes	Cell culture—cytopathic effects				Nuclear inclusions (Cowdry A bodies) Typical rash helpful Tzanck preparation
Respiratory syncytial virus (rare)	Yes	Cell culture—cytopathic effects		IF	PCR	Eosinophilic cytoplasmic inclusions
Parainfluenza (1–4)	Yes	Cell culture—cytopathic effects		IF	PCR	Hemadsorption testing Small eosinophilic cytoplasmic inclusions
Adenovirus	Yes	Cell culture—cytopathic effects		IF	PCR	Variable inclusion pattern
Cryptococcus	Yes	Slow				Antigen-serum Tissue invasion
Aspergillus	No					Tissue invasion
Candida	No					Tissue invasion
Coccidioides	Yes		High or increasing

standard for the diagnosis of severe cryptogenic lung disease.[112,113] When performed, it has a high diagnostic accuracy although it is not 100%; in one study with 25 patients who had biopsies and subsequent autopsies, the autopsy confirmed the open lung biopsy diagnosis in 76% of cases.[114] Open lung biopsy is useful not only in the diagnosis of infection (particularly infections for which tissue invasion is essential to prove clinical relevance), but also in the diagnosis of primary lung involvement by diseases such as malignancy, nonspecific inflammatory lung disease, and lung-related toxicities of therapeutic interventions. Box 12.3 demonstrates the breadth of possible diagnoses that can be made with open lung biopsy after other diagnostic studies are negative.

Open lung biopsy leads to a change in therapy in 57% to 75% of cases in which it is performed.[112,113,115–117] Open lung biopsy can be performed in patients with respiratory distress and patients supported by ventilators with a reasonable rate of perioperative

complications; death attributed to the biopsy procedure itself is rare, and complications such as persistent air leak usually resolve over time.[113,115,116] Complication rates have been reported to be the same with video-assisted thoracic surgery as with thoracotomy.[117] Several recent studies have reported the frequent use of bedside open lung biopsy, which avoids transport of a critically ill patient and appears to have a morbidity similar to that of doing the biopsy in the operating room.[117–121]

Although the procedure sounds promising, open lung biopsy has several drawbacks. First, authors who separated open lung biopsy results into "specific" (allowing focused therapy thought or known to have some efficacy) and "nonspecific" (a pattern of injury such as diffuse lung damage with no clear cause and no documented effective therapy) found that 38% to 46% of patients had nonspecific injury and no specific therapeutic benefit from the procedure.[113,117] Second, mortality is extremely high in this group despite specific diagnoses and the previously mentioned changes in therapy, particularly if the patients have respiratory compromise; for those patients, the short-term mortality ranges from 52% to 70%.[115–117] (Note that short-term mortality is believed by most authors to be related far more to the underlying disease than to the open lung biopsy procedure.[115–117]) Third, most patients already have received appropriate therapy; in most cases, the change in therapy would be discontinuation of unnecessary drugs or increased dosing of a drug already being given (usually steroids). In some, the benefit of open lung biopsy would be acknowledgment of end-stage disease and withdrawal of all therapy. The most important outcome of open lung biopsy would be a change in therapy that altered outcome from death to survival. Institution of a new potentially lifesaving therapeutic intervention as a result of open lung biopsy is uncommon.[113,115,116] In 1988, Warner and colleagues[116] discussed open lung biopsy in patients with respiratory compromise and said, "any complications of a procedure of unknown benefit is of concern." Some authors hold this opinion to this day. Most patients have received anti-infective drugs, steroids, or both before open lung biopsy is considered, and one could argue that most patients who could respond would have responded before open lung biopsy. Nevertheless, that the controversy is "alive and well" is illustrated by a quote from Chuang and associates[112]: "It is not ethical to avoid open lung biopsy in patients with unclear diagnoses, as open lung biopsy is known to be the most sensitive and specific test available at this time."

Another controversy with respect to open lung biopsy is when to perform it. Two groups have reported open lung biopsy relatively early in the course of respiratory failure with diffuse infiltrates and have withheld therapies until and unless biopsy results demonstrated a specific indication.[120,121] Not unexpectedly, this approach led to a high number of new therapies, usually steroids and/or antivirals. Papazian et al. argued that their approach improved survival.[121] The data provide valuable support for a counterargument—that all patients with idiopathic diffuse lung disease should be treated with both steroids and antiviral drugs. If this had been done in these two series, the added benefit of open lung biopsy would have been very small.

Given the controversies and the available data, a few principles would seem appropriate in considering whether or not open lung biopsy should be performed. First, in most cases, BAL (and perhaps transbronchial biopsy; see later text) should be performed before open lung biopsy is considered. Second, patients who have three or more organs failing (lung plus two more) probably should not undergo biopsy; the prognosis is too poor.[113] Third, decisions about open lung biopsy should be based more on the prior condition of the patient and the potential utility of the study than on the degree of ventilatory distress or compromise of the patient; short-term mortality from the procedure is acceptable. Open lung biopsy in a critically ill patient with undiagnosed pulmonary infiltrates remains a valuable tool that is uncommonly indicated but that will occasionally provide a diagnosis that results in lifesaving therapy.

Bronchoscopic transbronchial lung biopsy may fill the gap between "nontissue" procedures such as BAL and open lung biopsy with its large amount of tissue for pathology and culture. Open lung biopsy by definition requires anesthesia and by definition causes a breach in pleural integrity and requires chest tube placement, with many patients having air leaks after the procedure.[115–117] Transbronchial lung biopsy requires only conscious sedation and would require chest tube placement only if a complication occurred, not as a matter of routine. As noted earlier in the discussion of infection, some diagnoses, such as invasive aspergillosis, *Candida* pneumonia, and cytomegalovirus pneumonia require tissue samples showing tissue invasion. Tissue samples can increase the diagnostic yield for other organisms such as *M. tuberculosis* and *P. jiroveci*.[122]

Diagnoses such as cryptogenic organizing pneumonia and several others listed in Box 12.3 cannot be made without tissue. Transbronchial lung biopsy is reasonable with BAL or after a negative BAL in compromised patients with infiltrates of unknown etiology.[122–125] The available data challenge this concept. It was formerly thought that performing transbronchial lung biopsy in a patient supported by a ventilator carried too high a risk of complications to be warranted. Two early studies[126,127] and several more recent studies[68,124,128,129] have evaluated the yield and complications of transbronchial lung biopsy in ventilated patients. All of these studies showed high yields similar to the yields for open lung biopsy. The pneumothorax rates varied from 0% to 24%. Bleeding

was considered to be significant in 6% to 20%, with all cases self-limited. No fatalities occurred. When transbronchial lung biopsy in ventilated patients is compared with open lung biopsy—for which general anesthesia, incisions, violation of the visceral pleura, and a chest tube are requisites—it is apparent that transbronchial lung biopsy is underused in this population; it has a favorable risk/benefit ratio.

Recently the use of cryoprobes for transbronchial cryobiopsy has gained acceptance, especially in the diagnosis of interstitial lung disease. The cryoprobe concept follows the Joule-Thomson effect, which occurs when a compressed gas is released at a high flow, it expands rapidly and leads to a very low temperature. The cryoprobe is introduced through the bronchoscope channel, extended into the lung parenchyma. The foot pedal is then activated for 3 seconds, leading a "frozen ball" effect around the tip of the probe. Then the specimen, cryoprobe, and bronchoscope are retracted en bloc. Several studies using transbronchial cryobiopsy have documented larger specimens compared with regular transbronchial forceps and with less crush artifacts. Significant bleeding and loss of bronchoscopic visual field are a concern, considering the need to remove the bronchoscope en bloc with the cryoprobe and the frozen specimen to retrieve the specimen. This leaves the airways and potential bleeding "unattended" and may lead to grave consequences.[130–135] Considering that cryobiopsy practice has been often done in patients under general anesthesia, intubation, and mechanical ventilation, the use of transbronchial lung cryobiopsy can be performed in ICU patients with acceptable oxygen requirements. To anticipate and tamponade any potential serious bleeding, a Fogarty balloon is passed to the opening of the targeted bronchus then advanced to occlude the bronchus when the biopsy specimen and bronchoscope are removed.

Placement of Endobronchial Valves

Critically ill patients with bronchopleural fistulae and prolonged air leaks often require longer mechanical ventilation duration, longer ICU length of stay, and are often poor surgical candidates. Bronchoscopic placement of one-way endobronchial valves could be a minimally invasive option. The procedure is easily done in the ICU at bedside. The chest tube drainage system is placed at a bedside table to monitor changes in the degree of air leak. To localize the culprit segment or lobe responsible for the air leak, a sequential bronchoscopic balloon occlusion maneuver is performed while monitoring the air leak. The balloon sequentially occludes the proximal to distal airway to attempt accurate localization of smallest airway possible with either cessation or significant reduction of the air leak. This is followed by bronchoscopic placement of one-way valves (IBV, Spiration Inc., Redmond, WA). Different sized valves are available (5, 6, 7, and 9 mm) and are placed depending on the size of the airways. Several studies have demonstrated the efficacy of those valves in controlling bronchopleural fistulae in critically ill patients supported by mechanical ventilation.[136–138]

Special Situations

Immunocompromised Host

Immunocompromise is a recognized risk factor for respiratory infection. Years of elegant work have helped to define classic types of immunocompromise and patterns of infection that are more typical for the different types.[139–141] Long-recognized diseases causing immunocompromise include solid tumors on chemotherapy, hematologic malignancies, organ transplantation, chronic diseases for which cytotoxic or steroid therapy is given, human immunodeficiency virus infection, and other less common acquired or congenital diseases.[125,141] Although immunocompromise definitely includes the previously mentioned diseases, it has no clear boundaries. Patients with chronic insulin-dependent diabetes, alcoholics, patients with severe malnutrition, and patients using drugs such as infliximab, a tumor necrosis factor antagonist, almost certainly have degrees of immunocompromise that affect their susceptibility to infection.[142–146] The stresses of critical illness and organ dysfunction coupled with the broaching of natural defense systems (skin by central lines, lungs by intubation, urinary tract by catheters) put critically ill patients at increased risk for infection.

Many chronic illnesses probably also carry an increased risk for infection. Shelhamer and colleagues[141] recognized the difficulty with this issue and defined immunocompromise as "any condition, congenital or acquired, temporary or chronic, in which the response of the host to a foreign antigen is subnormal." For patients with classic known forms of immunocompromise, special diagnostic attention must be paid to the possibility of *Pneumocystis* pneumonia, invasive fungal infection, infection with the herpesviruses, and tuberculosis. Three factors make this area gray rather than black-and-white. First, the lack of knowledge that a patient is immunocompromised does not rule out immunocompromise. Second, degrees of immunocompromise exist. And third, most of the pathogens discussed are capable of causing disease in "normal" hosts. For these reasons, some specific issues related to immunocompromise have been mentioned throughout this chapter, but in the clinical approach to a patient with severe respiratory disease, it makes sense to assume that any patient might be immunocompromised; the diagnostic workup should, as mentioned, cast a wide net.

Thrombocytopenia

Thrombocytopenia is an obvious risk factor for bleeding from invasive procedures. BAL has been shown to be safe and clinically useful in thrombocytopenic patients.[147] Bronchoscopic procedures and open lung biopsies have been performed safely in patients with thrombocytopenia.[117,148] Historically, procedures have been limited to BAL, or platelets have been given before bronchoscopic or surgical procedures.[117,148] In our practice, we use platelet count $\geq 50{,}000\ \mu L$ as an absolute cutoff before considering transbronchial bronchoscopic lung biopsy.

Complications and Death

The true incidence of complications of bronchoscopy in the ICU is poorly defined. Most reviews of the topic[27,39,149–152] cite several older studies of bronchoscopy in general,[7–9,11,153] not specifically in critically ill patients. The two largest and most-cited reports are by Credle and colleagues[7] and Suratt and coworkers[11] and reviewed 24,521 (Credle et al.) and "approximately 48,000" (Suratt et al.) procedures. These were retrospective reports based on mailed questionnaires. Death rates were 0.01% and 0.03%, respectively.[7,11]

The next largest study was a retrospective single-institution study of 4273 bronchoscopies, which reported 0% mortality and a 0.5% frequency of major complications (pneumothorax, bleeding, respiratory failure requiring intubation).[9] Three prospective studies reported on 205 to 1146 flexible bronchoscopies and reported mortality rates of 0%,[9] 0.1%,[153] and 0.5%.[8] The highest reported

mortality rate is in a study from a consortium of expert bronchoscopists studying autofluorescence.[154] The study included the requisite of at least two endobronchial biopsies, and in a series of 300 cases the immediate postbronchoscopic mortality was 0.7%. Two retrospective studies[45,155] and one prospective study[68] reviewed bronchoscopies performed specifically in patients in the ICU. No procedure-related mortality was reported. Throughout these studies, only death rates are consistently noted; major and minor complications are variably defined.

Several principles emerge from the previously cited studies. The complication rates depend on the invasiveness of the procedure. The highest incidence of complications occurs with lung biopsy and then, in descending order, with brushings, BAL, and simple observation. For the patients expected to have the highest complication rate—patients supported by ventilators who underwent transbronchial biopsies—there is a pneumothorax rate of 24%, but no fatalities have been reported.[68,124,126–129] None of these studies involved large numbers of patients; it is inevitable that fatalities would occur in this subset of high-risk cases. Nevertheless, many years of experience with flexible fiberoptic bronchoscopy have led to the conclusion that its benefits outweigh its risks. No bronchoscopy should be done in a critically ill patient without a reason, but when a reason is present, bronchoscopy is often the unique or the safest method known of obtaining data that may affect care.

Summary

Since its inception in 1968, flexible fiberoptic bronchoscopy has evolved into a major tool in the evaluation and management of critically ill patients. The bronchoscope allows evaluation of and sometimes management of airway problems. The bronchoscope follows the most natural pathway into the lung—the airway—and allows sampling of secretions and tissues from the alveolar level. The basic techniques have been defined for many years. What has been refined is our understanding of their utility and testing methodologies; increasing sensitivities and specificities over the years have greatly enhanced our capacities, particularly in the diagnosis of lung infections. Some lung infections require lung tissue for definitive diagnosis, as do several diagnoses that can cause diffuse lung disease and can sometimes mimic infection. Open lung biopsy is a time-honored approach with high diagnostic accuracy that may sometimes be an optimal approach. Transbronchial lung biopsy, even in a ventilated patient, has a clinical impact similar to that of open lung biopsy and is probably underused in critically ill patients with diffuse infiltrates in whom empiric therapies fail. It is clear that the more ill the patient, the higher the risk of any invasive procedure, but the literature points the risk/benefit ratio of bronchoscopy in favor of performing bronchoscopy for the indications outlined in this chapter.

Key Points

- Bronchoscopy has become a major tool in the evaluation of the airways and lung parenchyma of critically ill patients.
- Bronchoscopy stimulates a series of reflexes affecting blood pressure, heart rate, and intracerebral pressure, but this is true for any cannulation of the upper airway (e.g., suctioning). Bronchoscopy for the evaluation of lung problems in critically ill patients has a favorable risk/benefit ratio.
- Inserting a bronchoscope through an ETT causes upper airway obstruction and can cause hypoventilation or hyperinflation or both; the physiologic changes caused by the bronchoscope need to be understood and possibly compensated for.
- Bronchoscopy is a valuable tool for the diagnosis and management (especially intubation and percutaneous tracheostomy) of upper airway problems.
- Bronchoscopy with BAL is the most effective and accurate clinical tool currently available for the diagnosis of pulmonary infection in critically ill patients.
- The potential of bronchoscopy for the diagnosis of infection is being advanced at present not by bronchoscopic techniques, but by the development and clinical application of extremely sensitive tools such as PCR assays.
- Critically ill patients with undiagnosed infiltrates occasionally benefit from lung biopsy; the results often affect management but rarely affect outcome. Available data suggest that bronchoscopic transbronchial lung biopsy has yields similar to those for open lung biopsy with a more favorable risk/benefit ratio.

Review Questions

1. Which of the following is most correct concerning conscious sedation during bronchoscopy:
- **a.** It is not associated with hypoxemia in healthy volunteers.
- **b.** It is associated with hypoxemia in healthy volunteers only after prolonged bronchoscopy >30 minutes.
- **c.** It is associated with hypoxemia even before bronchoscopy starts in healthy volunteers.
- **d.** It is associated with hypoxemia only in patients with underlying lung diseases.

Answer: c. Conscious sedation during bronchoscopy using benzodiazepines and narcotics can lead to hypoxemia in healthy volunteers even before bronchoscopy starts. We recommend the use of supplemental oxygen in all patients undergoing bronchoscopy regardless of whether they have underlying lung diseases or not.

2. You are consulted to perform a therapeutic bronchoscopy in the ICU on a patient with significant right-sided-atelectasis. After reviewing all clinical information, you notice that the patient has not undergone any chest physiotherapy. You inform the consulting physician of the following:
- **a.** You agree to perform the bronchoscopy as it has been shown to be superior to chest physiotherapy in patients with atelectasis in the ICU.
- **b.** Bronchoscopy is equal to chest physiotherapy and associated with the same adverse events.
- **c.** Chest physiotherapy is preferred as initial therapy considering that bronchoscopy could be associated with complications
- **d.** There is no role for bronchoscopy in ICU patients with atelectasis as they are too sick to undergo a bedside bronchoscopy.

Answer: c. Atelectasis is common in the ICU, especially in patients receiving invasive mechanical ventilation. Chest physiotherapy remains first-line therapy for atelectasis as it is proven to be as effective as bronchoscopy as an initial intervention; bronchoscopy is associated with more significant decreases in oxygenation compared with chest physiotherapy. We recommend initiating chest physiotherapy before attempted bronchoscopy. However, some patients have contraindications for chest physiotherapy—such as chest trauma, spinal cord injury, or immediate postthoracotomy—and may require bronchoscopy first.

3. When compared with conventional transbronchial forceps biopsy for interstitial lung disease, cryobiopsy
- **a.** Is associated with increased risks of bleeding
- **b.** Is safer than transbronchial forceps biopsy and provides equal size samples
- **c.** Should be performed only with rigid bronchoscopy
- **d.** Obeys the Pascal law of transmission of fluid-pressure

Answer: a. Cryobiopsy for interstitial lung disease has gained popularity recently as it leads to larger samples compared with transbronchial forceps biopsy during a workup for interstitial lung disease. However, it is associated with increase bleeding complications when retrieving the specimen as the bronchoscope, the cryoprobe, and the specimen need to be retrieved en bloc considering that the "frozen ball" would not fit through the bronchoscope channel. Cryoprobe biopsy can be performed with flexible bronchoscopy and does not require rigid bronchoscopy. It obeys the Joule-Thomson effect.

Noninvasive Respiratory Monitoring

AMAL JUBRAN AND MARTIN J. TOBIN

CHAPTER OUTLINE

Gas Exchange
- Pulse Oximetry
- Transcutaneous Blood Gas Monitoring
- Capnography

Respiratory Neuromuscular Function
- Airway Occlusion Pressure
- Maximal Inspiratory Airway Pressure
- Breathing Pattern
- Changes in End-Expiratory Lung Volume

Respiratory Mechanics
- Elastance (Compliance)
- Pressure-Volume Curves
- Resistance
- Intrinsic Positive End-Expiratory Pressure
- Airway Pressure Profile
- Flow-Volume Curves

Various devices are available for effective and noninvasive monitoring of the patient's gas exchange function, respiratory neuromuscular capacity, and respiratory mechanics. Such measurements are helpful in characterizing the pathophysiology of an underlying respiratory disorder, tracking the course of illness and the effects of treatment, minimizing the risk of complications, and determining the patient's readiness for the withdrawal of therapeutic interventions and support devices.

Gas Exchange

The human eye is poor at recognizing hypoxemia.[1,2] With the availability of pulse oximetry, episodic hypoxemia has been found to be more common than was previously suspected, with an incidence ranging from 20% to 82%.[3] Patients experiencing hypoxemia have a threefold higher risk of death compared with patients who do not display desaturations.[4]

Pulse Oximetry

Pulse oximeters determine oxygen (O_2) saturation by measuring light absorption of arterial blood at two specific wavelengths, 660 nm (red) and 940 nm (infrared).[5,6] The ratio of absorbencies at these two wavelengths is calibrated empirically against direct measurements of arterial blood oxygen saturation (SaO_2), and the resulting calibration algorithm is used to generate the pulse oximeter's estimate of arterial saturation (SpO_2) (Fig. 13.1).[3,7]

Accuracy

Compared with the measurement standard (multiwavelength oximeter) for measuring SaO_2, pulse oximeters have a mean difference (bias) of less than 1% and a standard deviation (precision) of less than 2% when SaO_2 is 90% or above.[6,8] Although pulse oximetry is accurate in reflecting 1-point measurements of SaO_2, it does not reliably predict changes in SaO_2.[9] In 1085 simultaneous measurements of SaO_2 and SpO_2 in 41 ICU patients, changes in SaO_2 correlated moderately with changes in SpO_2 ($r = 0.6$), and the pulse oximeter tended to overestimate actual changes in SaO_2.[10]

The accuracy of pulse oximeters deteriorates when SaO_2 falls to 80% or less.[9,11] In critically ill patients, poor agreement between the oximeter and a CO-oximeter was observed, with bias ranging from −12% to 18%; and oximetry tended to systematically underestimate SaO_2 when it was less than 80%.[12]

Conventional pulse oximeters use probes that are usually placed on the earlobe, finger, or toe.[13] More recently, reflectance technology has been used to develop probes that can be placed on the forehead.[9] When tested in critically ill patients with low perfusion, the forehead reflectance probe had lower bias and precision than did the finger probe.[14,15] However, the response to change in O_2 saturation was faster for the forehead probe than for the finger probe in patients undergoing anesthesia.[16]

Limitations

Oximeters have several limitations that may lead to inaccurate readings (Box 13.1). Pulse oximeters target measurement of SaO_2, which is physiologically related to arterial oxygen tension (PaO_2) according to the O_2 dissociation curve. Because the dissociation curve has a sigmoid shape, oximetry is relatively insensitive in detecting hypoxemia in patients with high baseline levels of PaO_2.[6,17]

Pulse oximeters use only two wavelengths of light; accordingly, they can discriminate only two substances, oxyhemoglobin and reduced hemoglobin. Elevated carboxyhemoglobin and methemoglobin levels can therefore cause inaccurate oximetry readings.[18–21] Recently multiwavelength oximeters have been developed that can estimate blood levels of carboxyhemoglobin and methemoglobin.[22,23] When tested in patients with suspected carbon monoxide poisoning, the bias between oximetric measurement of carboxyhemoglobin and laboratory measurement of carboxyhemoglobin was less than 3%.[24,25] The limit of agreement between the measurements, however, was large (−11.6% to 14.14%),[25] raising questions as to whether these new oximeters may be a reliable substitute for standard laboratory measurements of carboxyhemoglobin.[9,25,26]

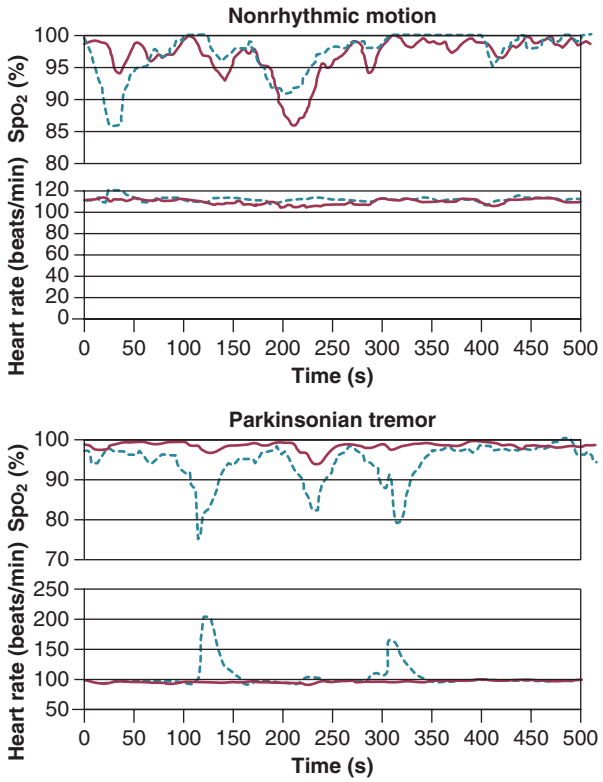
Physiologic limitations
- Shape of oxyhemoglobin dissociation curve

Interference from substances
- Dyshemoglobins: carboxyhemoglobin, methemoglobin
- Dyes
- Nail polish
- Ambient light
- Skin pigmentation

Limitation in signal processing
- Low-perfusion state
- Motion artifact
- False alarms
- Limitation in knowledge of the technique



• **Fig. 13.2** Pulse oximetry signals with motion artifact; *top panel,* recorded during nonrhythmic motion (i.e., gross arm motion); *lower panel,* recorded during parkinsonian tremor. The *red line* denotes Masimo Signal Extraction Technology (SET), aimed at minimizing spurious pulse oximetry readings due to motion artifact; the *blue line* denotes conventional pulse oximetry. Spurious changes in measured oxygen saturation (Spo_2) are less with Masimo SET than with conventional pulse oximetry. (From Dumas C, Wahr JA, Tremper KK. Clinical evaluation of a prototype motion artifact resistant pulse oximeter in the recovery room. *Anesth Analg.* 1996;83:269–272.)

Intravenous dyes can cause falsely low SpO_2 readings.[3,9] In critically ill patients requiring mechanical ventilation, nail polish has been shown not to affect the accuracy of SpO_2 readings.[27] Falsely low and falsely high SpO_2 readings occur with fluorescent and xenon arc surgical lamps.[28]

Skin pigmentation can affect the accuracy of pulse oximetry.[29,30] In critically ill patients,[11] bias plus precision was greater in black patients (3.3% + 2.7%) than in white patients (2.2% + 1.8%); also, a bias greater than 4% occurred more frequently in black patients (27%) than in white patients (11%).

Low-perfusion states, such as low cardiac output, vasoconstriction, and hypothermia, may impair peripheral perfusion, making it difficult for a sensor to distinguish a true signal from background noise. In patients experiencing hypothermia and poor perfusion during cardiac surgery, only 2 of 20 oximeters (Criticare CSI 503 [Criticare Systems, Inc., North Kingstown, RI] and Datex Satlite [Datex Instrumentarium Corp., Helsinki, Finland]) provided measurements within +4% of the CO-oximeter value.[13]

Motion artifact is a frustrating problem, and it results in inaccurate readings and false alarms. An innovative technological approach, termed Masimo Signal Extraction Technology, was introduced to extract the true signal from artifact secondary to noise and low perfusion[31] (Fig. 13.2). When tested in healthy volunteers, the new generation of pulse oximeters that incorporated new technology to filter out artifacts outperformed conventional oximeters in reducing nuisance alarms and ensuring alarm reliability.[8]

Despite their popularity for continuous monitoring of O_2 saturation, pulse oximeters fail to provide valid data in a variety of settings, accounting for almost half of false alarms[32–35]; such alarms were secondary to low perfusion, cardiac arrhythmias, and motion artifacts.[36] An underrecognized and worrisome problem with pulse oximetry is that many users have a limited understanding of how the oximeter functions and the implications of the measurements obtained.[9] One survey revealed that 30% of physicians and 93% of nurses thought that the oximeter measured PaO_2.[37] Some clinicians did not recognize that SpO_2 values in the high 80s represent seriously low values of PaO_2. More recent studies suggest that the knowledge about pulse oximetry is increasing.[9,38] When 551 critical care nurses were interviewed, 86.5% knew that SpO_2 readings are not as accurate when signal quality is poor, and 70% knew that SpO_2 was not a replacement for arterial blood gas analysis in the care of critically ill patients.[39]

Clinical Applications

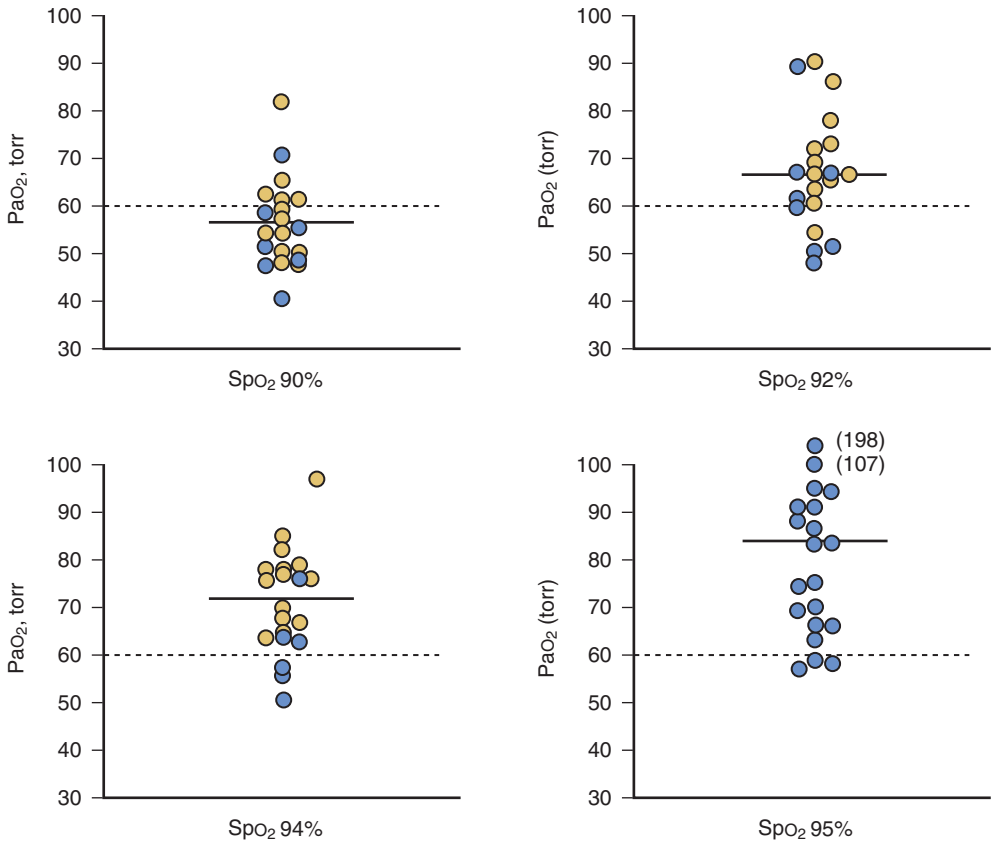
With the introduction of pulse oximetry, hypoxemia (defined as an SpO_2 value <90%) is now detected more often in critically ill patients[40] and in patients undergoing surgery.[41,42] Changes in SpO_2 may not accurately reflect changes in PaO_2. Accordingly, caution is required in clinical decision making in critically ill patients based solely on pulse oximetry. Although pulse oximetry is a suitable way of measuring arterial oxygenation, it does not assess ventilation. Indeed, measurements of SpO_2 have been shown to be inaccurate in assessing abnormal pulmonary gas exchange, defined as an elevated alveolar-arterial O_2 difference.[3]

Pulse oximetry can assist with titration of fractional inspired oxygen concentration (FIO_2) in ventilator-dependent patients, although the appropriate SpO_2 target depends on a patient's pigmentation.[11] The SpO_2 target value that predicts a satisfactory level of oxygenation is 92% in white patients and 95% in black patients (Fig. 13.3).

Pulse oximetry has been evaluated as a means of screening for respiratory failure in patients with severe asthma.[43] Respiratory failure was unlikely in patients with SpO_2 greater than 92%. Of interest, this threshold value of 92% is the same target value that reliably predicted a satisfactory level of oxygenation during titration of FIO_2 in ventilator-dependent patients.[11] Pulse oximetry may be useful in predicting outcome in patients with pulmonary embolus. In patients with documented pulmonary embolism, a room-air SpO_2 less than 95% had an overall diagnostic accuracy of 67% in predicting mortality.[44]

Moller and associates[45] conducted the first prospective, randomized study of pulse oximetry on the outcome of anesthesia care in 20,802 surgical patients. Detection of hypoxemia (defined as an SpO_2 <90%) was 19-fold higher in the oximeter group than in the control group. Myocardial ischemia was more common in the control group than in the oximetry group, occurring in 26 and 12 patients, respectively. Pulse oximetry, however, did not decrease the rate of postoperative complications or mortality.

The lack of proven efficacy of pulse oximetry in the study by Moller and associates[45] was related to the sample size. These investigators concluded that it would take at least 500,000 patients to show a reduction in a rare event such as myocardial infarction, and 1,900,000 patients to show a reduction in anesthesia-related deaths. When anesthesiologists in the study were surveyed, 80% of them reported feeling more secure when they used a pulse oximeter.[46] It is this mindset that has established pulse oximetry as an essential component of the standard of care despite a failure to achieve a level of proven efficacy with a *P* value of less than



• **Fig. 13.3** Arterial oxygen tension *(Pa_{O_2})* values at pulse oximetry oxygen saturation *(Sp_{O_2})* values of 90%, 92%, 94%, and 95%. The inspired oxygen concentration was adjusted to achieve a particular steady-state SpO_2 value in a group of 54 critically ill patients. The *solid horizontal line* represents the mean PaO_2 value obtained at each SpO_2 target. The *orange* and *blue circles* represent values obtained in white and black patients, respectively. In white patients, a SpO_2 target of 92% resulted in a satisfactory level of oxygenation, whereas a higher SpO_2 target, 95%, was required in black patients. (Modified from Jubran A, Tobin MJ. Reliability of pulse oximetry in titrating supplemental oxygen therapy in ventilator-dependent patients. *Chest.* 1990;97:1420–1425.)

0.05. The lack of concurrence between randomized trial proof of efficacy of pulse oximetry and its requirement as part of the standard of care has major ramifications for all monitoring techniques.[47]

Cost-Effectiveness

Studies evaluating the cost-effectiveness of pulse oximetry have reported that fewer arterial blood gas samples were obtained if SpO_2 data were available to the caregivers.[48–50] The effect of implementing pulse oximetry in an ICU without any specific plan for its appropriate use was examined in 148 patients before the implementation of oximetry and 141 patients after its implementation.[51] The number of blood gas samples decreased from 7.2 to 6.4 per patient per day—a reduction of only 10.3%—compared with average reductions of 39% in the previous studies.[3] This suggests that without explicit guidelines, the pulse oximeter was used in addition to, rather than instead of, blood gas sampling.

Transcutaneous Blood Gas Monitoring

Transcutaneous measurements of O_2 tension ($PtcO_2$) are made by placing a heated Clark polarographic electrode directly on the skin and measuring the O_2 that diffuses from the blood to the skin.[52] This technique is used more commonly by neonatologists because neonatal skin is thin.[53] During low-perfusion states, $PtcO_2$ measurements may not reflect changes in PaO_2. In critically ill patients, the $PtcO_2/PaO_2$ ratio decreased from 0.79 ± 0.1 when the cardiac index was greater than 2.2 L/min per m^2 to 0.12 ± 12 when the cardiac index was less than 1.5 L/min per m^2.[54]

Transcutaneous monitoring of the partial pressure of carbon dioxide ($PtcCO_2$) can be performed using a modified Severinghaus electrode. The underlying skin is heated to 44°C to enhance carbon dioxide (CO_2) diffusion through the skin.[54] The correlation of $PtcCO_2$ with the arterial partial pressure of carbon dioxide ($PaCO_2$) usually is good: $r = 0.93$.[53]

The accuracy of $PtcCO_2$ as a surrogate measure for $PaCO_2$ was evaluated in 50 critically ill patients in a medical ICU.[55] Of the available 168 measurements, the mean difference between $PaCO_2$ and $PtcCO_2$ was −0.2 ± 4.6 mm Hg; the correlation between two measurements was 0.92. A strong correlation was observed between changes in $PaCO_2$ and $PtcCO_2$ ($r^2 = 0.78$). These data suggest that transcutaneous PCO_2 may be reliable in monitoring changes in arterial PCO_2, provided that no major vasoconstriction is present.

Capnography

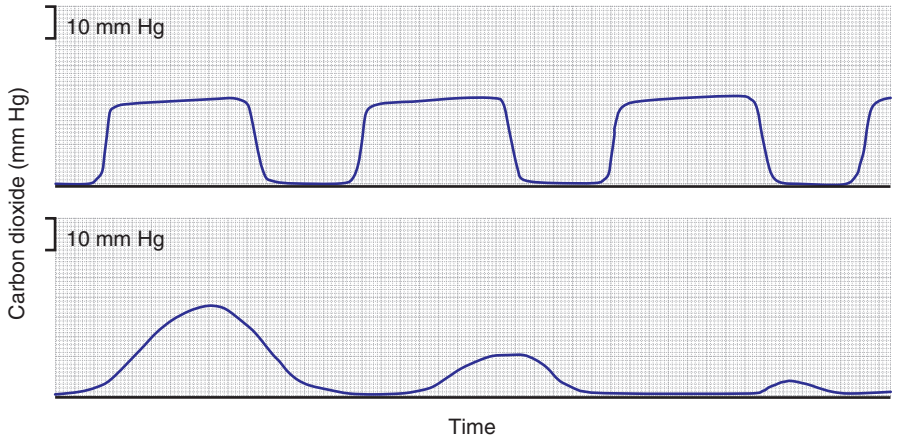
The CO_2 concentration at the end of a tidal breath—end-tidal CO_2—can be used as a continuous, indirect measure of $PaCO_2$. In intubated patients with respiratory failure, correlation between end-tidal CO_2 and $PaCO_2$ was good ($r = 0.78$).[56] The correlation between changes in end-tidal CO_2 and changes in $PaCO_2$ from baseline, however, was considerably weaker ($r = 0.58$). The change in end-tidal CO_2 incorrectly indicated the direction of change in $PaCO_2$ in 43% of patients being weaned from mechanical ventilation after cardiac surgery.[57]

Capnometry commonly is used in detecting esophageal intubation (Fig. 13.4).[58–60] When the trachea of a patient with an intact pulmonary circulation is intubated, end-tidal CO_2 is recorded. When, however, the endotracheal tube is erroneously placed in the esophagus, end-tidal CO_2 will be zero. Other conditions that produce a flat-line waveform on capnometry include obstruction within or distal to an endotracheal tube and prolonged cardiac arrest. Monitoring of end-tidal CO_2 has been compared with three other methods—auscultation, negative-pressure testing using a self-inflating bulb, and transillumination—for verifying tracheal tube placement, and it was found to be the most reliable.[61] During cardiac arrest, capnometry is useful in assessing the adequacy of chest compressions and the return of spontaneous circulation.[62,63]

Respiratory Neuromuscular Function

Airway Occlusion Pressure

Measuring airway pressure 0.1 second after initiation of an inspiratory effort against airway occlusion ($P_{0.1}$) provides a measure of respiratory drive.[64] In ventilator-dependent patients, $P_{0.1}$ has been



• **Fig. 13.4** End-tidal carbon dioxide (CO_2) tracing and esophageal intubation. *Upper panel:* End-tidal CO_2 tracing in a patient in whom an endotracheal tube was inserted correctly in the trachea. During inhalation, end-tidal CO_2 is 0 mm Hg. During exhalation, the CO_2 tracing rises steeply, attains a near plateau, and then quickly returns to the baseline. *Lower panel:* End-tidal CO_2 tracing in a patient in whom an endotracheal tube was erroneously inserted in the esophagus. The expected shape of the CO_2 tracing has been replaced by small transient rises in the CO_2 tracing, which progressively decrease with each squeeze of the Ambu bag.

shown to correlate significantly with work of breathing during pressure-support ventilation ($r = 0.87$).[65] By taking advantage of the decrease in airway pressure (P_{aw}) to open the demand valve during triggering, investigators have demonstrated that commercially available ventilators can measure $P_{0.1}$ accurately.[66] Several studies[66–68] have indicated that an elevated $P_{0.1}$ predicted weaning failure, but the threshold separating success from failure differed among the studies.[69]

Maximal Inspiratory Airway Pressure

Maximum inspiratory pressure (PImax), a global measure of inspiratory muscle strength, is measured using a one-way valve that allows exhalation but prevents inhalation.[70,71] PImax is one of the standard measurements used to determine a need for the continuation of mechanical ventilation. Values that are more negative than −30 cm H_2O are considered predictive of weaning success; values that are less negative than −20 cm H_2O are predictive of weaning failure. These criteria, however, frequently are falsely positive and falsely negative.[72]

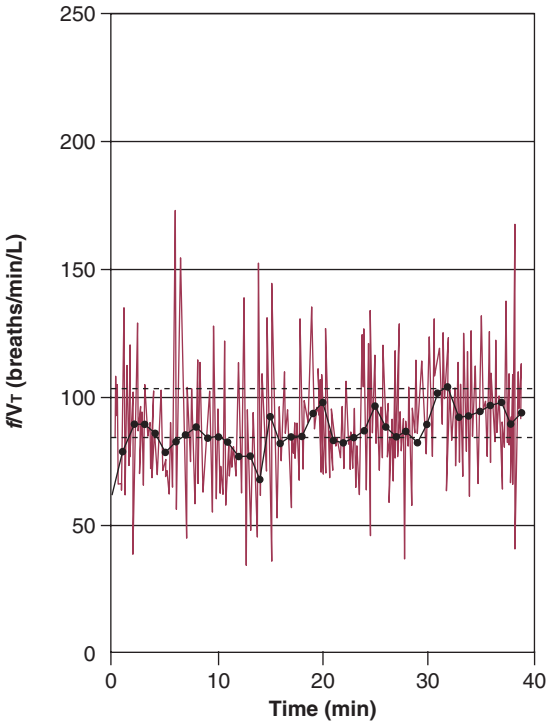
Breathing Pattern

Rapid shallow breathing is a common respiratory pattern in patients in whom a trial of weaning from mechanical ventilation fails,[73] and this can be quantitated in terms of the frequency/tidal volume ratio (f/V_T). An f/V_T above 100 breaths/min per liter suggests that a trial of weaning is unlikely to be successful.[72] When prospectively evaluated, f/V_T was found to be superior to nine other weaning predictors: sensitivity was 0.97, specificity 0.64, positive predictive value 0.78, and negative predictive value 0.95.[69]

The usefulness of f/V_T in predicting weaning outcome was challenged. Using a meta-analysis, an American College of Chest Physicians Task Force concluded that f/V_T was unreliable.[74–77] In their evaluation of published reports on f/V_T, the Task Force ignored the important influence of pretest probability on the interpretation of a test results. The implications of pretest probability are greater for weaning than for many clinical situations because weaning involves a sequence of three diagnostic tests: measurement of predictors, followed by a weaning trial, followed by an extubation trial. The undertaking of three diagnostic tests in a sequential manner poses an enormous risk for the occurrence of test referral and spectrum bias.[78] The introductions of such biases, will, in turn, increase the pretest probability.[79,80] Indeed, the mean pretest probability of weaning success was 75% in the studies included in the meta-analysis. When data from studies included in the Task Force meta-analysis were entered into a Bayesian model with pretest probability as the operating point, the observed posttest probabilities were closely correlated with the values predicted by the original study on f/V_T: $r = 0.86$ for positive predictive value and $r = 0.82$ for negative predictive value.[81]

It has been suggested that measurements of f/V_T at 30 minutes into a weaning trial more accurately predict outcome than measurements in the first minute.[82,83] Although it is true that including data for the first 30 seconds or so may be unrepresentative, this does not mean that it takes 30 minutes to establish a steady state.

Jubran and colleagues[83] studied the time required for f/V_T to reach a point of equilibration in 17 weaning failure and 14 weaning success patients. The median time (plus interquartile range) to reach +10% of the final value of f/V_T was 2 (1 to 2) minutes in both the weaning success and the weaning failure patients (Fig. 13.5). Within 2 minutes of the onset of the T-tube trial, 77% of the weaning failure patients and 73% of the weaning success patients had reached +10% of the final value of f/V_T. As indicated by these data, a reasonable strategy is to commence measurement of f/V_T at 60 seconds after removal of the ventilator and then continue the measurement for another 60 seconds.

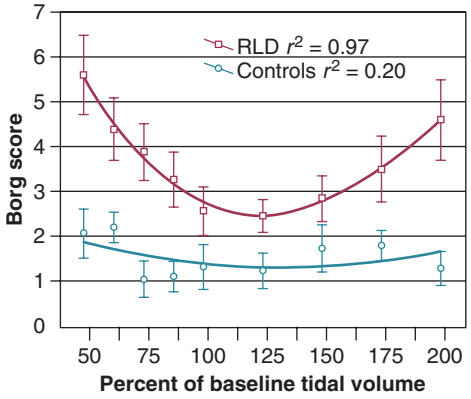


• **Fig. 13.5** Time-series plot of frequency/tidal volume ratio *(f/V_T)* during a T-tube trial of spontaneous breathing in a weaning failure patient. The *black dots* represent 1-minute averages. The *solid line* indicates the average value of f/V_T of the final minute of the trial. The *dashed horizontal lines* indicate +10% of the final minute values of f/V_T. The time taken to reach +10% of the final value of f/V_T was 2 minutes. (From Jubran A, Grant BJ, Laghi F, et al. Weaning prediction: esophageal pressure monitoring complements readiness testing. *Am J Respir Crit Care Med.* 2005;171:1252–1259.)

Continuous recording of breathing pattern provides an important approach for assessing the ability of the respiratory controller to maintain or adjust its response over time.[64] Simple measurements, such as coefficients of variation, indicate that healthy subjects display considerable variation in tidal volume and respiratory cycle time from one breath to the next.[84] Signal analysis techniques reveal that this variability is composed of random and nonrandom fractions.[85–90] The predominantly random character of the variability makes it possible for the respiratory system to engage in tasks other than gas exchange. A smaller fraction of variability is nonrandom; moreover, tidal volume and respiratory cycle time of one breath are significantly related to those of the preceding breath.[85,86,88,89] When healthy subjects are faced with external chemical or mechanical loads, however, the random fraction decreases significantly.[86,88,89] This decrease in random variability may lessen the freedom of the respiratory system to undertake behavioral tasks.[88,89,91]

Using autocorrelation analysis and fast-Fourier transformation, patients with restrictive lung disease display a marked decrease in breath-to-breath variability of breathing.[64,92] The random fraction

of variability was approximately $^1/_{27}$ of that found in healthy subjects, and the nonrandom correlated fraction was as much as three times higher in the patients. Slight variations from the average resting tidal volume caused large increases in dyspnea in the patients, but not in the healthy subjects (Fig. 13.6).[92] In patients undergoing a weaning trial, a higher gross variability of breathing (quantitated in terms of coefficient of variation) was noted in patients who were successfully weaned than in patients in whom the trial failed.[93] These data suggest that an increase in the ability to vary breathing may be associated with a favorable weaning outcome.[94]



• **Fig. 13.6** The relationship between variation in tidal volume and dyspnea *(Borg score)* in patients with restrictive lung disease *(RLD)* and in control subjects. Dyspnea scores were higher in the patients than in the control subjects ($P < 0.01$, analysis of variance [ANOVA]); dyspnea varied with tracked volume in the patients ($P < 0.05$, ANOVA) but not in the control group. The regression between dyspnea and tidal volume was parabolic in the patients ($y = 10.3 - 0.12x + 0.0005x^2$; $P < 0.0001$), but not in the control subjects ($y = 2.76 - 0.02x + 0.00008x^2$; $P = 0.5$). *Bars* represent ± standard error of the mean. (From Brack T, Jubran A, Tobin MJ. Dyspnea and decreased variability of breathing in patients with restrictive lung disease. *Am J Respir Crit Care Med.* 2002;165:1260–1264.)

Changes in End-Expiratory Lung Volume

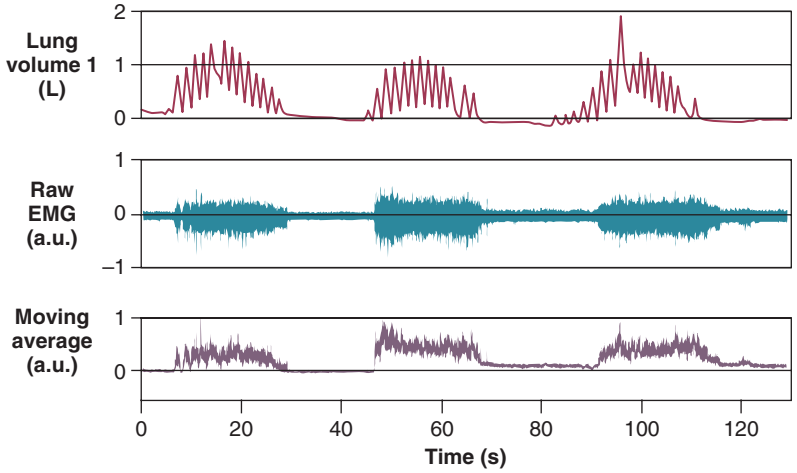
Alterations in the end-expiratory level of signal from an inductive plethysmograph can provide a measurement of the change in functional residual capacity provided that motion artifact is absent (Fig. 13.7).[95,96] Inductive plethysmography has been used to estimate a patient's level of auto-PEEP.[56] By noting the level of external PEEP at which end-expiratory lung volume increased, a close estimate of the patient's original level of auto-PEEP (positive end-expiratory pressure) can be obtained. An attractive feature of this technique is that it does not disturb expiration, unlike the occlusive technique, in which foreshortening of expiratory time is unavoidable.[97]

Respiratory Mechanics

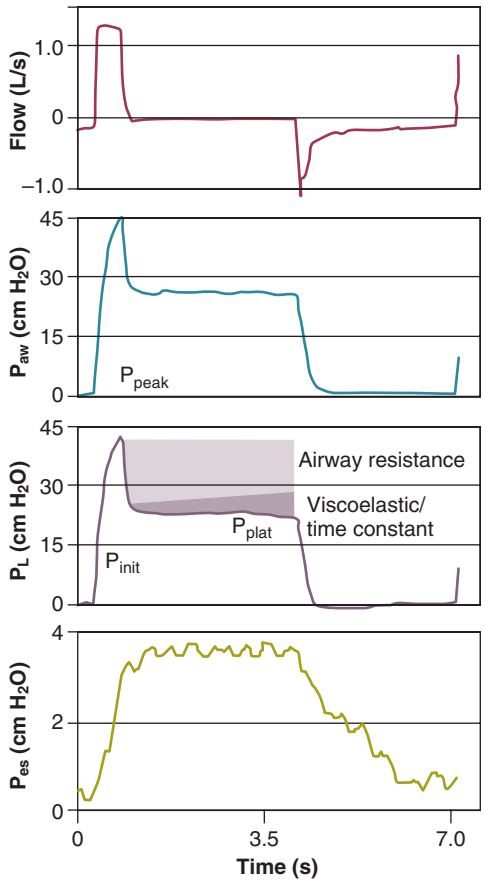
Measurements of respiratory mechanics in a relaxed ventilator-dependent patient can be obtained using the technique of rapid airway occlusion during constant-flow inflation.[84,98] Rapid airway occlusion at the end of a passive inflation produces an immediate drop in both P_{aw} and transpulmonary pressure (P_L) from a peak value (P_{peak}) to a lower initial value (P_{init}), followed by a gradual decrease until a plateau (P_{plat}) is achieved after 3 to 5 seconds (Fig. 13.8).[99,100] P_{plat} on the P_{aw}, P_L, and esophageal pressure tracings represents the static end-inspiratory recoil pressure of the total respiratory system, lung, and chest wall, respectively.

Performing an end-inspiratory occlusion maneuver to measure plateau pressure can help the physician determine immediately the reason a patient is fighting the ventilator (Fig. 13.9).[101] An increase in peak airway pressure without a proportional increase in plateau pressure indicates narrowing of the airway.[101] Narrowing may arise from bronchoconstriction, an increase in secretions, a collection of fluid in the inspiratory limb of the ventilator circuit, kinking of the tubing, a foreign body, or herniation of the cuff of the endotracheal tube over its distal tip.[101]

An increase in peak airway pressure accompanied by a proportional increase in plateau pressure indicates a decrease in thoracic



• **Fig. 13.7** Changes in lung volume measured by inductive plethysmography *(top tracing),* raw electromyographic signal of scalene muscle activity *(EMG) (middle tracing),* and moving time average *(bottom, integrated signal)* during three consecutive cycles of Cheyne-Stokes breathing in a representative patient. Note the repeated increases in end-expiratory lung volume with each hyperpnea. (From Brack T, Jubran A, Laghi F, et al. Fluctuations in end-expiratory lung volume during Cheyne-Stokes respiration. *Am J Respir Crit Care Med.* 2005;17:1408–1413.)



• **Fig. 13.8** Flow (inspiration upward), airway pressure *(P_{aw})*, transpulmonary pressure *(P_L)*, and esophageal pressure (P_{es}) tracings in a representative patient during passive ventilation. An end-inspiratory occlusion produced a rapid decline in both P_{aw} and P_L from a peak value *(P_{peak})* to a lower initial pressure *(P_{init})*, followed by gradual decrease to a plateau pressure *(P_{plat})*. P_{plat} on the P_{aw}, P_L, and P_{es} tracings represents the static end-inspiratory recoil pressures of the total respiratory system, lung, and chest wall, respectively. Using this technique, total resistance can be partitioned into ohmic airway resistance and tissue resistance, which reflects the viscoelastic properties (stress relaxation) and time-constant inhomogeneities within the respiratory tissues. (Modified from Jubran A, Tobin MJ. Passive mechanics of lung and chest wall in patients who failed and succeeded in trials of weaning. *Am J Respir Crit Care Med.* 1997; 155:916–921.)

compliance. A decrease in lung compliance may arise from pulmonary edema, early stages of acute respiratory distress syndrome (ARDS), dynamic hyperinflation associated with intrinsic PEEP, atelectasis, collection of fluid (hemothorax, parapneumonic effusion, or transudative effusion), or a pneumothorax.

Elastance (Compliance)

The end-inspiratory airway occlusion method is used clinically to measure the static compliance, or its reciprocal, elastance, of the respiratory system ($E_{st,rs}$) according to the following equation[102]:

$$E_{st,rs} = P_{plat} - PEEP_{tot}/V_T,$$

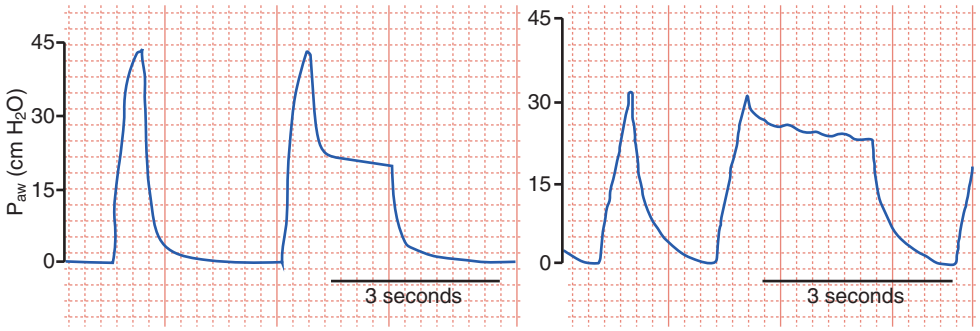
where P_{plat} is plateau pressure obtained after occlusion of the airway, $PEEP_{tot}$ is the sum of external and intrinsic positive end-expiratory pressures if present, and V_T is tidal volume (see Fig. 13.8).

Mechanical ventilation in itself can produce or aggravate lung injury in patients with ARDS.[103–105] Injury may be decreased by minimizing alveolar overdistention. Alveolar volume is reflected by peak alveolar pressure, which can be assessed indirectly by measuring the plateau pressure during an end-inspiratory hold maneuver. It has been recommended that plateau pressure not exceed 32 cm H_2O.[106,107]

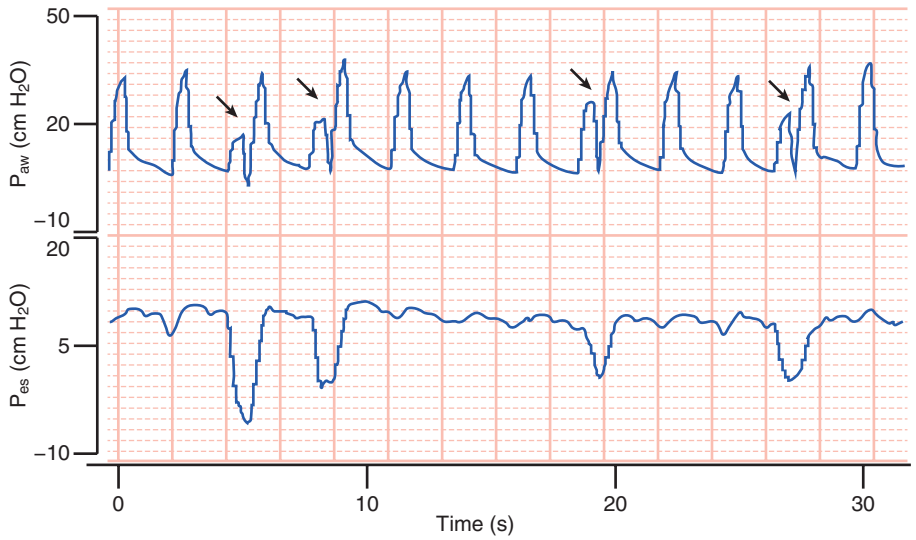
A new era of ventilatory management began in 1990, when a report demonstrated that lowering tidal volume caused a 60% decrease in the expected mortality rate among patients with ARDS.[108] Subsequently, randomized trials were undertaken[109–112] that revealed that use of a high tidal volume (12 mL/kg) is associated with an increased mortality in patients with ARDS.[106,113] To minimize alveolar distension (i.e., limit plateau pressure to 32 cm H_2O or lower), it has become standard practice to lower tidal volume.[106] A low tidal volume is typically accompanied by a short mechanical inspiratory time and thus these patients are especially susceptible to double triggering (Fig. 13.10).[101] Accordingly, conscious attempts to lower tidal volume can paradoxically result in greater alveolar distension than occurs with conventional tidal volume settings.[64,101]

Pressure-Volume Curves

A pressure-volume curve of the respiratory system in a paralyzed patient can be constructed by measuring the airway pressure as



• **Fig. 13.9** End-inspiratory occlusion maneuver during passive ventilation in two patients. In each patient, the second displayed breath was occluded for 2 seconds—a period that was not sufficient to achieve a complete plateau in either patient. *Left panel*: Airway pressure (P_{aw}) drops by 24 cm H_2O during the end-inspiratory occlusion maneuver, indicating the presence of increased airflow resistance. *Right panel*, P_{aw} drops by 5 cm H_2O during the end-inspiratory occlusion maneuver, indicating decreased respiratory compliance consequent to noncardiogenic pulmonary edema secondary to sepsis. (From Tobin MJ, Jubran A, Laghi F. Fighting the ventilator. In: Tobin MJ, ed. *Principles and Practice of Mechanical Ventilation.* 3rd ed. New York: McGraw-Hill; 2012:1237–1258.)



• **Fig. 13.10** Four incidents of double triggering, each indicated by an arrowhead symbol (↑). Airway pressure *(P_{aw})* and esophageal pressure *(P_{es})* during assist-control ventilation at the following settings: tidal volume 600 mL, inspiratory flow 60 L/min, trigger sensitivity −2 cm H_2O, and positive end-expiratory pressure 5 cm H_2O. The duration of neural inhalation of the double-triggered breaths, roughly equivalent to the width of the associated swings in P_{es}, was substantially longer than the neural inhalation of the normally triggered breaths. (From Tobin MJ, Jubran A, Laghi F. Fighting the ventilator. In: Tobin MJ, ed. *Principles and Practice of Mechanical Ventilation*. 3rd ed. New York: McGraw-Hill; 2012:1237–1258.)

the lungs are progressively inflated with a 1.5- to 2-L syringe. A lower inflection point and an upper inflection point may be seen on the pressure-volume curve.[114] The lower inflection point is thought to reflect the point at which small airways or alveoli reopen, corresponding to closing volume. In patients with acute lung injury, investigators have recommended that PEEP be set at a pressure slightly above the lower inflection point.[115]

When an "open-lung approach," consisting of use of a lower tidal volume (<6 mL/kg) with PEEP individually titrated to be consistently above the inflection point on the pressure-volume curve, was compared with a conventional approach, consisting of use of tidal volume of 12 mL/kg and a low PEEP level, the mortality rate was significantly reduced in the group managed with the new approach.[109,116]

A National Institutes of Health–sponsored trial of high versus low PEEP failed to demonstrate a significant survival advantage for patients randomly assigned to the high PEEP group.[117] Methodologic considerations cast doubt on the conclusions of the investigators.[118] First, PEEP-induced recruitment was estimated by improvement in oxygenation. It is well known that changes in oxygenation depend not only on recruitment but also on cardiac output.[119] Thus oxygenation may have improved without any lung recruitment. Second, recruitment potential was not stratified, so that patients who were not likely to benefit were assigned to both groups.[120]

The importance of individualizing PEEP in ventilator management in patients with ARDS was confirmed in a Spanish trial.[121] One patient group was randomly assigned to a treatment group in which PEEP was titrated to 2 cm H_2O above the lower inflection point. The mortality rate was lower in these patients than in control group patients who did not receive customized titration of PEEP.[121]

Two subsequent randomized trials were performed in which PEEP was titrated to oxygenation or plateau pressure, failed to show improved survival with higher PEEP[122,123]; high PEEP, however, decreased the number of patients with severe hypoxemia and was associated with greater ventilator-free days and organ failure–free days.[119]

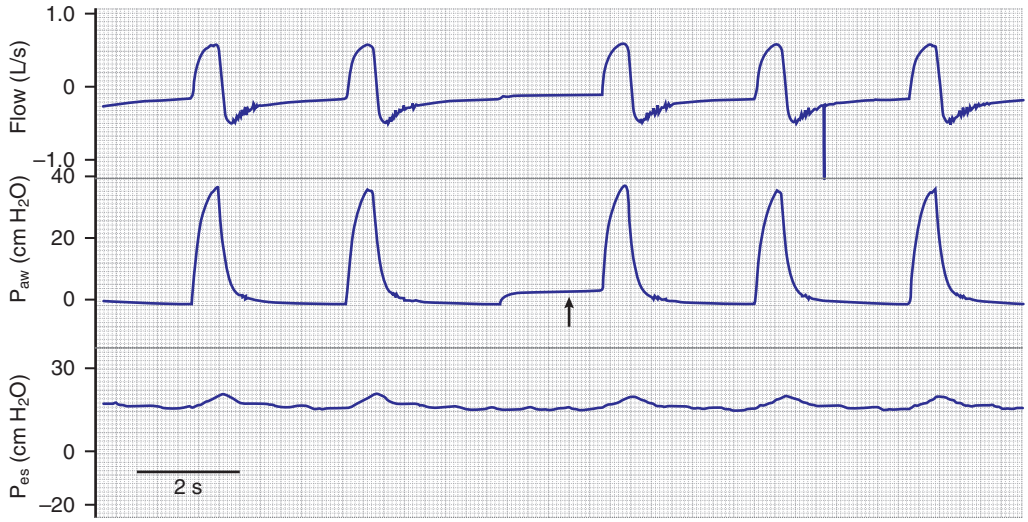
Resistance

Airway resistance can be measured in ventilator-dependent patients using the technique of rapid airway occlusion during constant-flow inflation (see Fig. 13.8).[98,99,102,124] Measurements of airway resistance are helpful in assessing the response of patients to bronchodilator therapy. In a study in ventilator-dependent patients with chronic obstructive pulmonary disease, a significant decrease in airway resistance occurred after giving 4 puffs, with no additional effect after the addition of 8 and 16 puffs (cumulative doses of 12 and 28 puffs).[125,126]

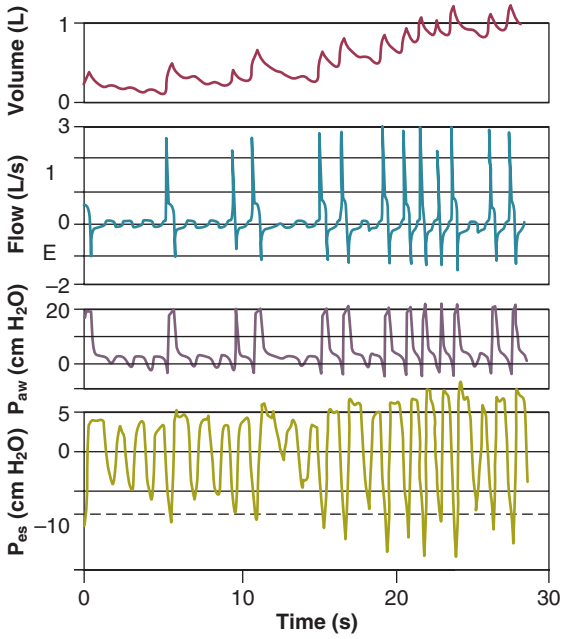
Intrinsic Positive End-Expiratory Pressure

The static recoil pressure of the respiratory system at end-expiration may be elevated in patients receiving mechanical ventilation.[102] This positive recoil pressure, or intrinsic PEEP (static $PEEP_i$), can be quantified in relaxed patients using an end-expiratory hold maneuver on a mechanical ventilator immediately before the onset of the next breath (Fig. 13.11).[47,127]

$PEEP_i$ poses a significant inspiratory threshold load that must be fully counterbalanced by increasing inspiratory muscle effort to generate a negative pressure in the central airway and trigger the ventilator. Thus $PEEP_i$ adds to the triggering pressure such that the total inspiratory effort needed to trigger the ventilator is the set trigger sensitivity plus the level of $PEEP_i$. This is one of the factors that may account for the not infrequent observation of a patient who is unable to trigger a ventilator despite obvious respiratory effort (Fig. 13.12).[128–133]



• **Fig. 13.11** Recordings of flow, airway pressure *(P_{aw}),* and esophageal pressure *(P_{es})* in a patient receiving controlled mechanical ventilation. After the third breath, the airway was occluded at end-expiration using the end-expiratory hold function on the ventilator. During the period of zero flow, pressure in the alveoli and in the ventilator circuit equilibrates, and the plateau pressure reflects auto–positive end-expiratory pressure (PEEP or intrinsic PEEP, indicated by the *arrow*).



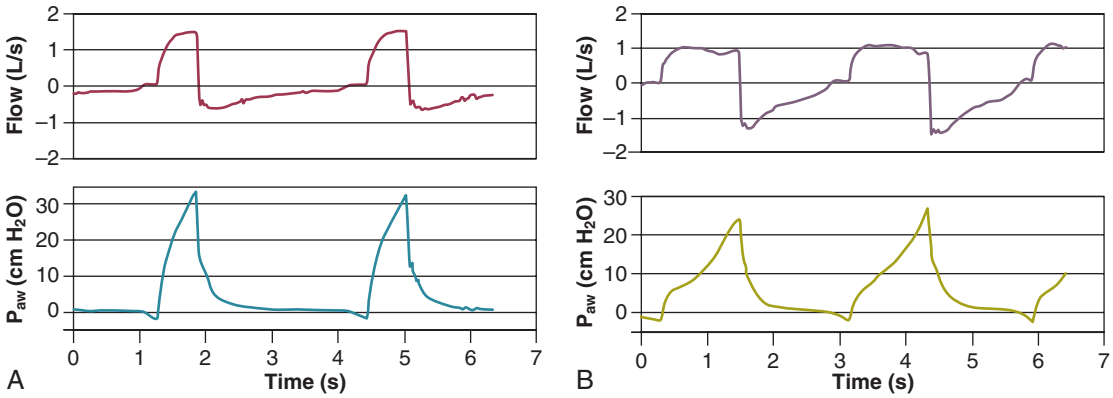
• **Fig. 13.12** Recordings of tidal volume, flow, airway pressure *(P_{aw}),* and esophageal pressure *(P_{es})* in a patient with chronic obstructive pulmonary disease receiving pressure-support ventilation. Approximately half of the patient's inspiratory efforts do not succeed in triggering the ventilator. Triggering occurred only when the patient generated a P_{es} less than 8 cm H_2O (indicated by the *dashed line*), which was equal in magnitude to the opposing elastic recoil pressure. (From Tobin MJ, Jubran A. Pathophysiology of failure to wean from mechanical ventilation. *Schweiz Med Wochenschr.* 1994;124:2139–2145.)

In a study of ventilator-dependent patients, Leung and colleagues[130] reported that ineffective triggering occurred with all assisted modes of mechanical ventilation. The ineffective or wasted efforts were significantly related to resistance ($r = 0.85$), elastance ($r = -0.61$), and static $PEEP_i$ ($r = 0.77$). A decrease in the magnitude of inspiratory effort at a given level of assistance was not the cause—indeed, effort was 38% higher during nontriggering attempts than during the triggering phase of attempts that successfully opened the inspiratory valve. Significant differences, however, were observed in the breaths before the triggering and nontriggering attempts. Breaths before nontriggering attempts were associated with shorter respiratory cycle time and expiratory time and higher static $PEEP_i$ compared with the breaths before triggered attempts. These findings suggest that ineffective triggering resulted not from a decrease in the magnitude of effort but rather from inspiratory efforts that were premature and insufficient to overcome the elevated elastic recoil pressure associated with dynamic hyperinflation.

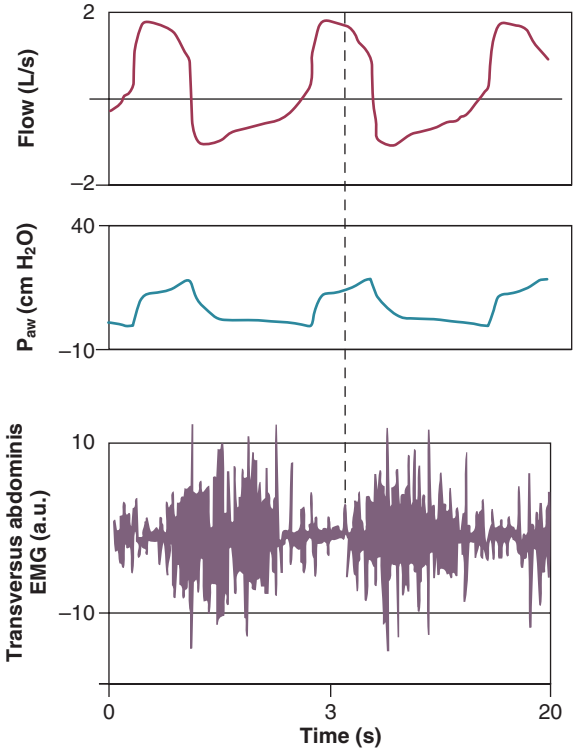
Airway Pressure Profile

A continuous recording of airway pressure provides helpful information about the amount of respiratory work being performed by a patient receiving ventilator assistance. Ideally the waveform should show a smooth rise with a convex appearance during inspiration.[47,134] By contrast, a prolonged negative phase with excessive scalloping of the tracing reflects increased inspiratory effort; this pattern indicates unsatisfactory sensitivity and inappropriate flow settings (Fig. 13.13).[47] A "bump" on the airway pressure tracing observed while the ventilator is still pumping gas in the patient may reflect recruitment of expiratory muscles (Fig. 13.14).[131]

Use of a flow setting that does not meet a patient's ventilatory demands will cause inspiratory effort to increase. Sometimes the flow is increased to shorten the inspiratory time and increase the expiratory time. An increase in flow, however, can cause immediate and persistent tachypnea; if this happens, the resulting decrease in expiratory time may lead to $PEEP_i$.[135,136] In general, however,



• **Fig. 13.13** Flow and airway pressure *(P_{aw})* during assist-control ventilation at different flow rates: 60 L/min (A) and 30 L/min (B). In A, the small negative phase, coupled with the smooth rise and convex appearance of the P_{aw} waveform, indicates that the patient is making a slight inspiratory effort to breathe. In B, the more pronounced negative phase, together with excessive scalloping of the P_{aw} waveform, indicates that the patient is making a strenuous effort to breathe as a result of the inadequate flow setting. (From Jubran A, Tobin MJ. Monitoring during mechanical ventilation. In: Tobin MJ, ed. *Principles and Practice of Mechanical Ventilation.* New York: McGraw-Hill; 2006:1051.)

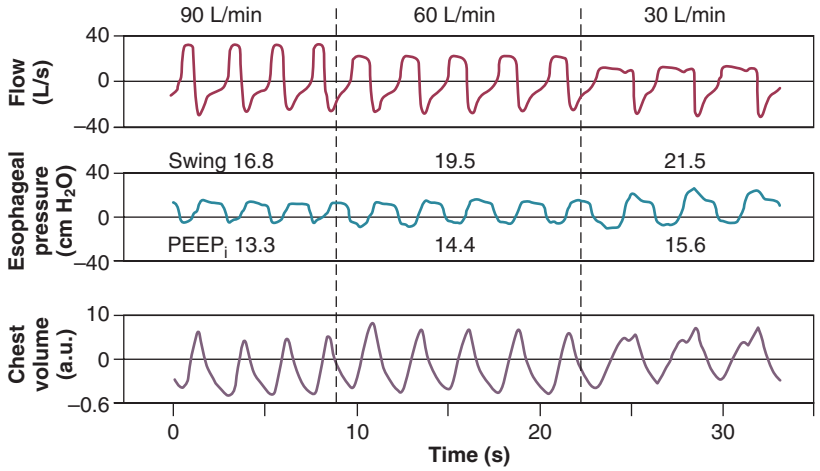


• **Fig. 13.14** Recordings of flow *(top)* and airway pressure *(P_{aw}; middle)* and transversus abdominis electromyogram (*EMG*; *bottom*) in a critically ill patient with chronic obstructive pulmonary disease receiving pressure support of 20 cm H_2O. The onset of expiratory muscle activity *(vertical dashed line)* occurred when mechanical inflation was only partly completed. (From Parthasarathy S, Jubran A, Tobin MJ. Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. *Am J Respir Crit Care Med.* 1998;58:1471–1478.)

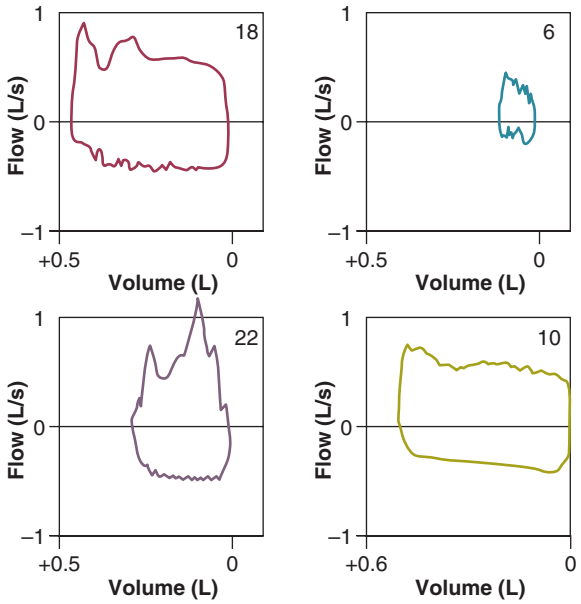
an increase in inspiratory flow does not lead to an increase in $PEEP_i$ (Fig. 13.15).[136]

Flow-Volume Curves

Flow-volume curves may be helpful in indicating a need for endotracheal suctioning. In 50 intubated patients, Jubran and Tobin[137] found that the presence of a sawtooth pattern strongly suggested the presence of secretions (positive predictive value, 94%), and the absence of this pattern suggested that secretions are unlikely to be present (negative predictive value, 77%) (Fig. 13.16). Clinical examination had much higher false-positive and false-negative rates (42% and 43%, respectively) than the flow-volume curves (12% and 14%, respectively). The usefulness of a sawtooth pattern for detecting secretions was confirmed in a study of 62 patients who were receiving pressure-support or assist-control ventilation.[138]



• **Fig. 13.15** Continuous recordings of flow, esophageal pressure (P_{es}), and the sum of rib cage and abdominal motion in a patient with chronic obstructive pulmonary disease receiving assist-control ventilation at a constant tidal volume. As flow increased from 30 L/min to 60 and 90 L/min (from *right* to *left*), frequency increased (from 18 breaths/min to 23 and 26 breaths/min, respectively); intrinsic positive end-expiratory pressure *(PEEP$_i$)* decreased (from 15.6 cm H_2O to 14.4 and 13.3 cm H_2O, respectively); and end-expiratory lung volume also fell. Increases in flow from 30 L/min to 60 and 90 L/min also led to decreases in the swings in P_{es} from 21.5 cm H_2O to 19.5 and 16.8 cm H_2O, respectively. *a.u.,* Arbitrary units. (From Laghi F, Segal J, Choe WK, et al. Effect of imposed inflation time on respiratory frequency and hyperinflation in patients with chronic obstructive pulmonary disease. *Am J Respir Crit Care Med.* 2001;163:1365–1370.)



• **Fig. 13.16** Flow-volume curves obtained in four patients with secretions. Note the presence of a sawtooth pattern on both the inspiratory and expiratory flow-volume curves. (The numbers to the *upper right* in each grid are the original patient numbers.) (From Jubran A, Tobin MJ. Use of flow-volume curves in detecting secretions in ventilator-dependent patients. *Am J Respir Crit Care Med.* 1994;150:766–769.)

Key Points

- Pulse oximetry can accurately measure oxygen saturation at levels of 90% or above; its accuracy deteriorates when the saturation falls to 80% or less.
- Inaccurate readings from pulse oximetry can occur as a result of interference from substances or from problems in signal processing.
- Hypoxemia is detected more frequently in patients monitored with pulse oximetry than in patients in whom this modality is not used.
- Transcutaneous monitoring of P_{CO_2} may be reliable in monitoring changes in arterial P_{CO_2} in the absence of major vasoconstriction.
- Capnometry is reliable in verifying tracheal tube placement after intubation.
- Measuring airway pressure at 0.1 second after initiating an inspiratory effort against an occluded airway is closely associated with increased work of breathing during mechanical ventilation.
- One-time measurements of breathing pattern (frequency and tidal volume) are helpful in predicting weaning outcome; continuous measurements of breathing pattern can provide information about the function of the respiratory controller.
- Measurements of respiratory mechanics in a ventilator-dependent patient can be easily performed at the bedside using the rapid airway occlusion technique.
- Continuous recordings of airway pressure can provide useful information about the respiratory work performed by a patient receiving mechanical ventilation.
- Flow-volume curves may be helpful in indicating a need for endotracheal suctioning.

Review Questions

1. A 56 year-old man with a history of drug abuse is being managed in the intensive care unit for respiratory failure and bacteremia. The patient continues to be febrile despite broad-spectrum antibiotics. On the fifth day, transesophageal echocardiography was done to rule out vegetation on the valves. The patient received midazalom, fentanyl, and benzocaine spray for the procedure. An hour later, you are called to his bedside because the pulse oximeter is reading a saturation of 86% with a good pulse waveform. On examination, the patient is breathing comfortably at a rate of 18 breaths/min on the following ventilator settings: assist-control mode, tidal volume 500 mL, backup rate 12 breaths/min, and positive end-expiratory pressure 5 cm H_2O. Vital signs are stable. Bilateral breath sounds are present. Arterial blood gas values show a pH 7.34, partial pressure of carbon dioxide 46 mm Hg, partial pressure of oxygen 72 mm Hg, and oxygen saturation is 94%. What should you do next?

a. Increase the backup rate on the ventilator to 16 breaths/min.
b. Measure oxygen saturation with a multiple-wavelength co-oximetry.
c. Increase the fraction of inspired oxygen to 100%. Obtain arterial blood gas samples 1 hour later.
d. Perform a computed tomography pulmonary angiogram.
e. Administer naloxone.

Answer: b. Methemoglobinemia should be suspected when the pulse oximeter estimate of arterial saturation is significantly less than the calculated arterial oxygen saturation as seen in this patient. The patient had a transesophageal echocardiogram in which benzocaine, a common cause of methemoglobinemia, was used. Multiwavelength oximetry will confirm methemoglobinemia as the cause of erroneous pulse oximetry readings.

2. When using capnometry to confirm the position of an endotracheal tube, a flat waveform on capnometry in an intubated patient indicates all of the following *except:*

a. Prolonged cardiac arrest
b. Foreign body obstruction
c. Bronchospasm
d. Esophageal intubation

Answer: c. A flat-line waveform on capnometry indicates that the endotracheal tube is in the esophagus. Other situations that produce flat-line waveforms include obstruction within or distal to an endotracheal tube, prolonged cardiac arrest, or technical malfunction of the monitoring device. Bronchospasm will produce detectable levels of end-tidal carbon dioxide.

3. A 76-year-old man has been improving on assist-control ventilation for adult respiratory distress syndrome associated with sepsis. Ventilator settings are fraction of inspired oxygen of 0.40, tidal volume of 0.6 L, inspiratory flow rate 60 L/min, respiratory rate 20 beats/min, and positive end-expiratory pressure of 8 cm H_2O. Arterial blood gas measurements are pH 7.42, arterial partial pressure of carbon dioxide 37 mm Hg, and arterial partial pressure of oxygen 70 mm Hg. Peak pressure is 35 cm H_2O and plateau pressure is 32 cm H_2O. Suddenly, the ventilator alarm goes off, indicating high peak airway pressures. Peak pressure is now 65 cm H_2O and plateau pressure is 34 cm H_2O. Breath sounds are decreased slightly on the right. The patient remains hemodynamically stable. An immediate chest x-ray is obtained. What is the most likely cause of patient distress?

a. Kinking of the endotracheal tube
b. Right mainstem intubation
c. Pneumothorax
d. Auto–positive end-expiratory pressure as a result of dynamic hyperinflation

Answer: a. This patient developed an increase in peak airway pressure without a proportional increase in plateau pressure, indicating narrowing of the airway. The narrowing of the airway occurred because of kinking of the endotracheal tube. The other options listed will occur because of a decrease in thoracic compliance; accordingly, the increase in peak airway pressure should be accompanied by a proportional increase in plateau pressure.

Summary

Definition

Tracheostomy is the creation of an opening in the anterior neck into the trachea with insertion of an indwelling tube to facilitate airflow or evacuation of secretions. The procedure is most often an elective measure, rarely an emergency, and should be well planned. Although rare, serious complications can result in severe consequences. Tracheostomy placement in critically ill patients is best performed at the bedside to avoid the logistical challenges and added costs associated with using the operating room. Two major techniques, percutaneous and surgical, have been widely used at bedside and are discussed in detail in this chapter.

History

The first description of tracheostomy goes back nearly 6000 years. The word "trachea" is derived from the Greek term *trakheia arteria* (rough artery), or "windpipe," as the ancient Greeks thought the arteries were filled with air.[1,2] Tracheostomy refers to a permanent opening, whereas tracheotomy refers specifically to an incision in the trachea. These terms are often used interchangeably in reference to the procedure of tracheostomy, but tracheostomy is the correct term for an artificial airway established in this manner and is in more common use. Two Egyptian tablets from Abydos and Saqqara dating to about 3600 BCE have been interpreted as depicting tracheostomy.[3] Alexander the Great used the point of his sword to open the trachea of one of his soldiers who was choking, according to a description by Homerus of Byzantium.[4] Tracheostomy was successfully performed to relieve airway obstruction in the second century but remained controversial. Paul of Aegina described the technique of tracheostomy in the seventh century and recommended its use for airway obstruction.[5] The technique was also described in the Arabic surgical literature of the period. During the Dark Ages in Europe, the technique of tracheostomy was abandoned.[6,7] During the Renaissance, European surgeons applied tracheostomy in cases of injury or obstruction caused by a foreign body, drowning, or Ludwig angina.

The clinical importance of tracheostomy became evident during sporadic diphtheria epidemics.[7] Fear of tracheostomy was quite prevalent in America, as evidenced in the death of George Washington in 1799, when bloodletting won over tracheostomy to relieve an epiglottitis-related upper airway obstruction.[6,8]

The development of the modern intensive care unit (ICU) and the frequent need for prolonged mechanical ventilation have resulted in the acceptance of tracheostomy as a standard procedure in the ICU. Tracheostomy has become one of the most frequently performed procedures in critically ill patients. The need to perform this procedure at the bedside in the ICU has led to the development of new methods of percutaneous dilational tracheostomy (PDT) using the Seldinger technique, most notably by Ciaglia and colleagues in 1985.[9] Several modifications of those techniques have improved the efficiency and safety over the past 30 years. Bedside tracheostomy by surgeons and intensivists has become the norm for ICU care, rather than the exception.

Epidemiology

Tracheostomy is a common procedure in the ICU. About 800,000 patients require mechanical ventilation for acute respiratory failure in the United States annually.[10] More than 100,000 tracheostomies are performed in the United States every year,[11] and it is estimated that 10% of patients receiving mechanical ventilation for at least 3 days eventually need tracheostomy.[12]

• BOX 14.1 Indications for Tracheostomy

1. Prolonged mechanical ventilation
2. Failure of extubation
3. Inability to clear secretions/pulmonary toiletry
4. Severe traumatic brain or cervical spine injury
5. Upper airway obstruction

• BOX 14.2 Contraindications for Tracheostomy

Absolute

1. Inexperienced operator
2. Infected insertion site
3. Uncorrected coagulopathy
4. No informed consent

Relative Contraindications (Favoring Surgical Tracheostomy)

5. Difficult anatomy
6. Unstable cervical spine
7. Presence of pulsatile vessels at the insertion site
8. High PEEP or F_{IO_2} requirements
9. Enlarged thyroid gland

F_{IO_2}, Fraction of inspired oxygen; *PEEP*, positive end-expiratory pressure.

Indications

With advances in critical care, more patients are supported by mechanical ventilation for a longer duration. Most of these patients require prolonged intubation and will eventually be considered for tracheostomy.[13] Although the decision for, and the timing of, tracheostomy must be adapted to each patient, the general indications are listed in Box 14.1. The primary indication remains prolonged mechanical ventilation and failure of extubation, followed by traumatic brain injury and inability to clear airway secretions. Upper airway obstruction is not a common indication in the ICU setting. Many factors are involved in the decision-making process: balanced consideration of the projected recovery course, risks and contraindications, and the patient's and family wishes relative to overall outcomes.

Over the years the guideline recommendations have progressively changed. In 1989 the American College of Chest Physicians indicated that tracheostomy is preferred over endotracheal tube (ETT) placement if the need for an artificial airway is expected to be longer than 21 days.[14] The European consensus in 1998 recommended that when intubation is anticipated to last between 10 and 21 days, daily assessment should occur regarding the need for continued intubation.[15] More recent guidelines from the American College of Chest Physicians suggest that tracheostomy should be considered within 3 to 7 days when it becomes apparent that prolonged mechanical ventilation is likely.[16]

Contraindications (Box 14.2)

Bedside percutaneous or surgical tracheostomies are elective procedures involving a vital organ system where errors can be deadly. The most important contraindications in this setting are operator inexperience, followed by difficult anatomy, active site infection, and uncorrected coagulopathy. When planning the procedure, appropriate history, including a history of previous tracheostomy, coagulation factors review, and physical examination—particularly of the neck anatomy—are crucial. More importantly, discussion with the patient or family members and answering their questions regarding risks and benefits need to occur before obtaining an informed consent. If the patient is unable to consent and has an advance directive or physician order for life-sustaining treatment, this should also be reviewed to ensure that the patient's wishes are known.

Neck anatomy should be carefully examined when deciding on technique—percutaneous versus surgical. Patients with cervical spine injury require extra attention to spine immobilization during the procedure. In the past this was considered a relative contraindication for percutaneous tracheostomy,[17] although one recent study demonstrated feasibility and safety. The examination needs to include identification of midline neck masses, such as goiter and crossing vessels around the surgical site. If needed, preoperative ultrasound examination may lead to fewer complications by delineating vascular anatomy.[18]

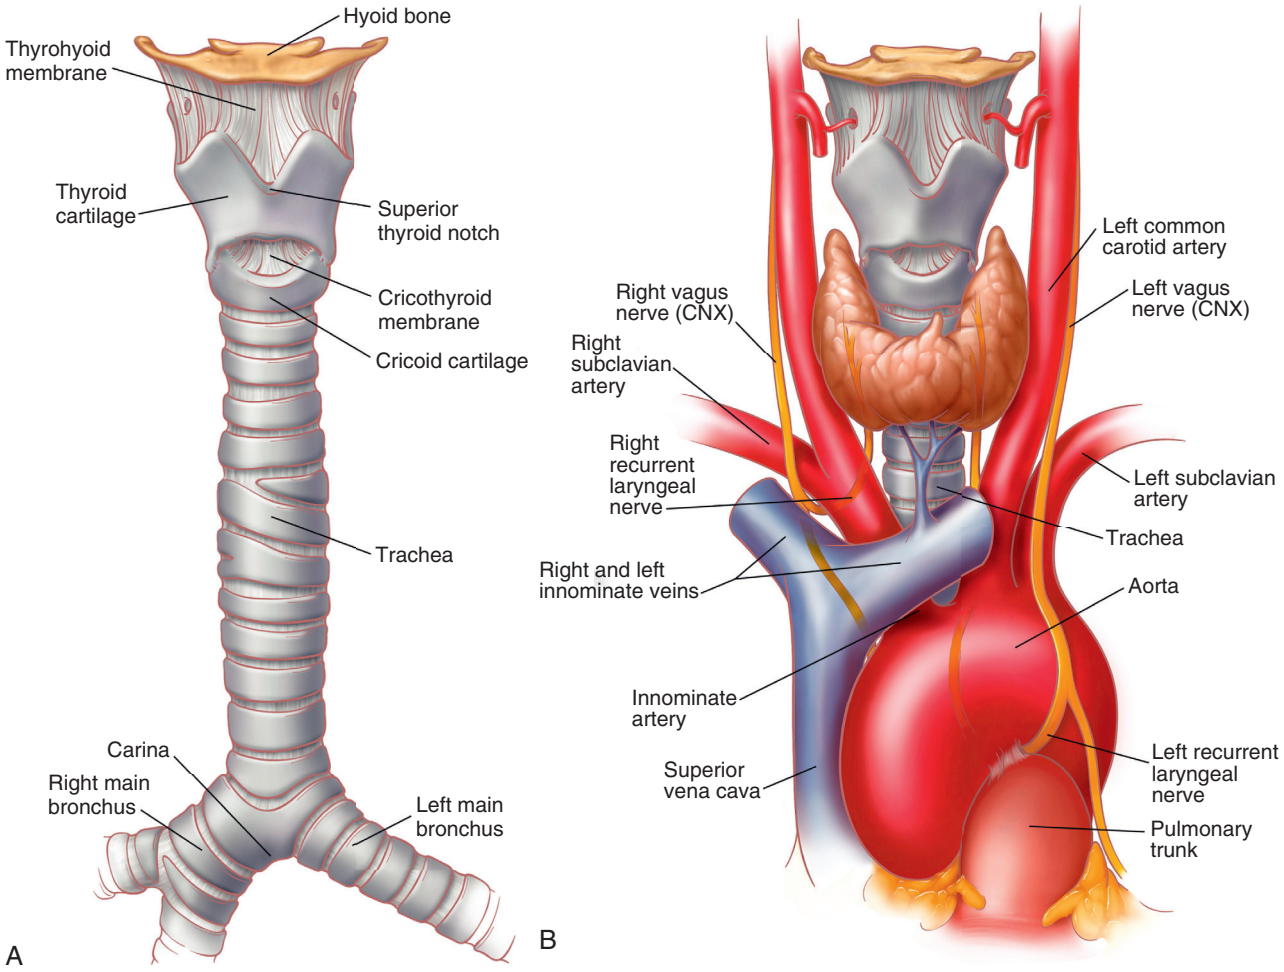
Common concerns in ICUs that affect the timing of tracheostomy are oxygen requirements and high levels of positive end-expiratory pressure (PEEP) during mechanical ventilation. Breaking the circuit and pulling the ETT to the subglottic area during the procedure may lead to worsening oxygen saturation levels. One must exercise caution in approaching tracheostomy in patients requiring a high fraction of inspired oxygen (F_{IO_2}) or advanced ventilator modes such as airway pressure release ventilation. One study documented the safety of performing bronchoscopy-guided percutaneous tracheostomy in patients with high PEEP (average of 16 cm H_2O) with no significant change in oxygenation at 1 hour and 24 hours after the procedure; however, most apply lower thresholds in practice.[19]

Tracheal Anatomy

Knowledge of the patient's anatomy is crucial before any surgical procedure. In the case of tracheotomy, there are two main factors to consider: (1) the site of the procedure, which is surrounded by major vessels and vital organs, and (2) the critical role of the trachea itself.[20] The trachea begins at the lower edge of the cricoid cartilage and extends to the level of the carina. It consists of 18 to 22 anterior C-shaped tracheal rings lined by a posterior membranous wall. It starts anterior and midline in the neck below the cricoid cartilage and then it dives posterior in the mediastinum. The esophagus starts at the same level and lies at the left posterior border of the trachea. The thyroid gland is found anterior and lateral to the proximal trachea with the isthmus projecting apically at the level of the second or third tracheal ring. The structure associated with this procedure's deadliest complications is the innominate artery. It crosses the anterior aspect of the trachea in an oblique fashion inferior to the third or fourth tracheal ring[20] (Fig. 14.1).

Timing

The advantages of tracheostomy in the setting of prolonged mechanical ventilation are well established. However, the timing of replacing a temporary artificial airway (ETT) with a tracheostomy has been controversial[14] because of two main challenges. One is the inability of clinicians to predict the need for prolonged mechanical ventilation accurately within several days of initiation. There is also ongoing debate regarding early versus late tracheostomy. Early timing has been generally defined as within 3 to 10 days,



• **Fig. 14.1** A, Principal features of the larynx and trachea. Anterior view. Tracheobronchial angles vary widely. (B) Relationships of trachea to surrounding structures. Anterior view. *CNX,* Cranial nerve X. (From Minnich DJ, Mathisen DJ. Anatomy of the trachea, carina, and bronchi. *Thorac Surg Clin.* 200717:571–578.)

whereas late is beyond that period. Although numerous studies have evaluated this subject, the majority were observational or retrospective, and only a few recent ones were well-designed prospective randomized trials. The most positive study on early tracheostomy was a prospective randomized trial involving several centers by Rumbak et al.[21] In this study, early tracheostomy was associated with significantly lower mortality, nosocomial pneumonia rate, and shorter duration of ICU stay and mechanical ventilation. Several other studies have demonstrated no difference in mortality but decreased duration of mechanical ventilation.[22,23] Systematic reviews and meta-analysis of randomized trials have also shown no difference in rates of mortality[24,25] but were variable relative to mechanical ventilation duration and ICU length of stay. More recently, a large prospective randomized trial (TracMan trial) compared early tracheostomy (within 4 days of intubation) to late tracheostomy (after 10 days if still indicated).[26] This trial was one of the largest to date exploring the timing of tracheostomy and found no advantage to early tracheostomy with regard to 30-day mortality or other secondary outcomes such as duration of mechanical ventilation, ICU length of stay, or hospital length of stay. Furthermore, this study showed that more than half of patients in the late group did not require tracheostomy by day 10.

Patients with severe head trauma often require tracheostomy for airway protection because of poor cough and clearance of secretions, rather than the need for mechanical ventilation. This group has been the subject of studies of the timing of tracheostomy.[23] One well-designed, prospective randomized trial comparing early tracheostomy to prolonged intubation found no difference in frequency of pneumonia or mortality between the two groups. However, early tracheostomy decreased total days of mechanical ventilation and specifically the duration of mechanical ventilation after development of nosocomial pneumonia in this group of patients.

The biggest challenge in designing trials regarding the timing of tracheostomy is the ability of treating physicians to predict duration of mechanical ventilation. In several randomized trials comparing early versus late tracheostomy, about 20% of patients randomly assigned to the late group did not ultimately require tracheostomy in the late group; this reflects the difficulty in predicting need for prolonged mechanical ventilation.

Organization of Care and Safety During Bedside Tracheostomy

Tracheostomy is one of the most hazardous procedures performed in the ICU. Although intraprocedural complications are rare, vascular injury resulting in hemorrhage, loss of airway control, or airway injury is catastrophic and may rapidly result in death, with

rates as high as 75%[27,28] for loss of airway control. It is prudent to take appropriate precautions to avoid these problems or manage them when they arise. A number of measures have been demonstrated to reduce complication rates, and some commonsense steps that can prepare the team for safer practice and handling of emergencies.[29]

The first step is appropriate patient selection. There are few absolute contraindications and a small number of relative contraindications (described elsewhere in this chapter).[30] The practitioner evaluating the patient for possible bedside tracheostomy must exercise judgment regarding the risks of location and technique to eliminate preventable complications.

The development of a team approach and a safety checklist for bedside tracheostomy has been demonstrated to decrease complications.[31] This should include a well-trained lead physician and assistant; an airway management practitioner who is capable of reintubation if necessary and will manage the ventilator; a nurse or other provider to administer sedation and pain medication and monitor the patient's clinical status; and a circulator who can run for supplies. If bronchoscopic support is planned, a skilled bronchoscopist should be included. Some practitioners consider that such bronchoscopic assistance is required for PDT, but the literature does not support improved complication rates.[32] The bronchoscope should be available immediately for emergencies, even if not used routinely. Ultrasound has also been used as an adjunct to avoid vascular injury but it has not yet been demonstrated to be of benefit in this setting.[33] If the primary proceduralist is not a surgeon, it is appropriate to have surgical "backup" in the hospital. It is therefore wise to plan elective bedside tracheostomy during daytime hours to ensure the availability of maximum personnel support in an emergency.

The equipment for the procedure should be in the room before starting, as well as any equipment that may be needed to deal with unplanned events. An assortment of tracheostomy tube sizes should be available as well as endotracheal tubes and laryngoscopes for reintubation. Electrocautery may be necessary and should be in the ICU, at least with grounding pads applied to the patient before the procedure. If PDT is planned, a surgical tracheostomy tray should be in the unit, as well as equipment for cricothyrotomy should the need arise. Good lighting is essential and headlamps may be of benefit.

The team should prepare for bedside percutaneous or surgical tracheostomy as they would for any operation. This includes discussion of the plan for sedation, the procedure itself, the roles of the team members, and any particular concerns regarding the individual patient. Structuring this practice with the use of a World Health Organization style checklist has been demonstrated to reduce complication rates significantly for bedside tracheostomy.[34]

Techniques

Percutaneous (Box 14.3)

PDT, also known bedside tracheostomy, is the placement of a tracheostomy tube. This technique uses a small skin incision and dilation of the subcutaneous tissue into the tracheal lumen without direct surgical visualization of the trachea. It is considered minimally invasive and is often done at the bedside in the ICU, avoiding the risks of transporting a critically ill patient and the costs of the operating room. PDT is done with continuous monitoring of the patient's vital signs and often is performed under direct bronchoscopic visualization.

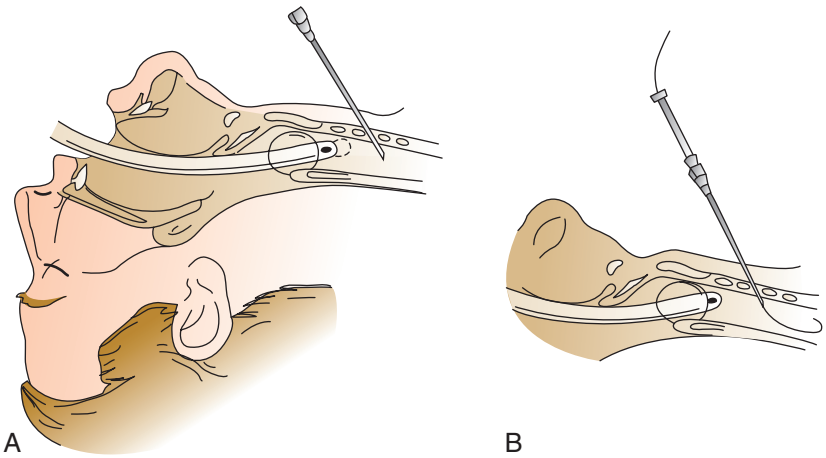
• BOX 14.3 Steps for Percutaneous Dilatational Tracheostomy

1. Hold tube feeding at least 4–6 hours prior to procedure
2. Hold anticoagulation appropriately to agent used
3. Keep patient on 100% FiO_2
4. Properly position the patient with maximum neck extension
5. Ensure adequate sedation and paralysis of the patient
6. Place bite block to avoid injury to teeth or bronchoscope
7. Deflate the ET cuff and withdraw ET under laryngoscopic vision until cuff is visualized just below cords, then reinflate the cuff
8. Clean, drape the patient as per protocol
9. Identify the site of insertion
10. Infiltrate the skin with local anesthetic containing a vasoconstrictor
11. Make a 2–2.5 cm transverse incision at the proposed insertion site
12. Advance a sheathed introducer needle into trachea stabilizing the trachea during the process
13. Tracheal placement of needle is confirmed by aspirating air bubbles into the saline solution–filled syringe attached to the needle, and by direct visualization through the bronchoscope
14. Withdraw the needle and insert Seldinger guidewire through the plastic sheath which is withdrawn out
15. Dilate the insertion site with the help of a small tracheal dilator
16. Single graduated dilator is moisturized with saline and then loaded over the guiding catheter
17. The whole assembly is then loaded over the guidewire and advanced as a unit into trachea in a sweeping action
18. After adequate dilatation, dilator is removed and tracheostomy tube with appropriate adapter is inserted into trachea over the guiding catheter
19. Placement of tracheostomy tube is confirmed by direct visualization of carina through the bronchoscope or by $EtCO_2$ graph
20. Connect tracheostomy tube to ventilator and ensure volume return
21. Suture tracheostomy to the skin and secure using a trach tie

ET, Endotracheal tube; $ETCO_2$, end-tidal carbon dioxide; FiO_2, fraction of inspired oxygen.

Classically the ability to hyperextend the neck is important in preoperative planning, but recent literature suggests that PDT is applicable in patients with spine injury whose necks cannot be hyperextended. There must be sufficient space between the cricoid cartilage and the suprasternal notch to allow tracheostomy tube placement.

Several different systems and approaches for PDT are available. The most common technique used is the Ciaglia technique (Video 14-1). With this technique, there is no sharp dissection involved beyond the skin incision. The patient is positioned and prepared in the same way as for the standard operative tracheostomy. Deep sedation is administered and all steps are done under bronchoscopic vision. The endotracheal tube is withdrawn under bronchoscopic guidance about 1 to 2 cm below the vocal cords to expose the space below the first tracheal ring by using digital pressure at 2 cm above the sternal notch while looking at the bronchoscopic view. The incision site is selected to correspond to the space between the second and third tracheal rings. Lidocaine 2% with epinephrine is used for local anesthesia and then a 2-cm incision is made. The pretracheal tissue is then cleared with blunt dissection. The operator enters the tracheal lumen below the second tracheal ring with an introducer needle through the incision (Fig. 14.2). The tract between the skin and the tracheal lumen is then serially dilated over a guidewire and stylet. A tracheostomy tube is placed under direct bronchoscopic vision over a dilator. Placement of the tube is also confirmed by visualizing the tracheobronchial tree through the



• **Fig. 14.2** A, Insertion of a 15-gauge needle into the trachea. B, The guidewire is inserted through the needle into the trachea. (From Friedman Y, Franklin C. The technique of percutaneous tracheostomy. Using serial dilation to secure an airway with minimal risk. *J Crit Illn.* 1993;8:289–297. Copyright Margulies Medical Art, Miami, FL.)

tracheostomy. The tracheostomy tube is then secured to the skin with sutures and a tie or device encircling the neck.

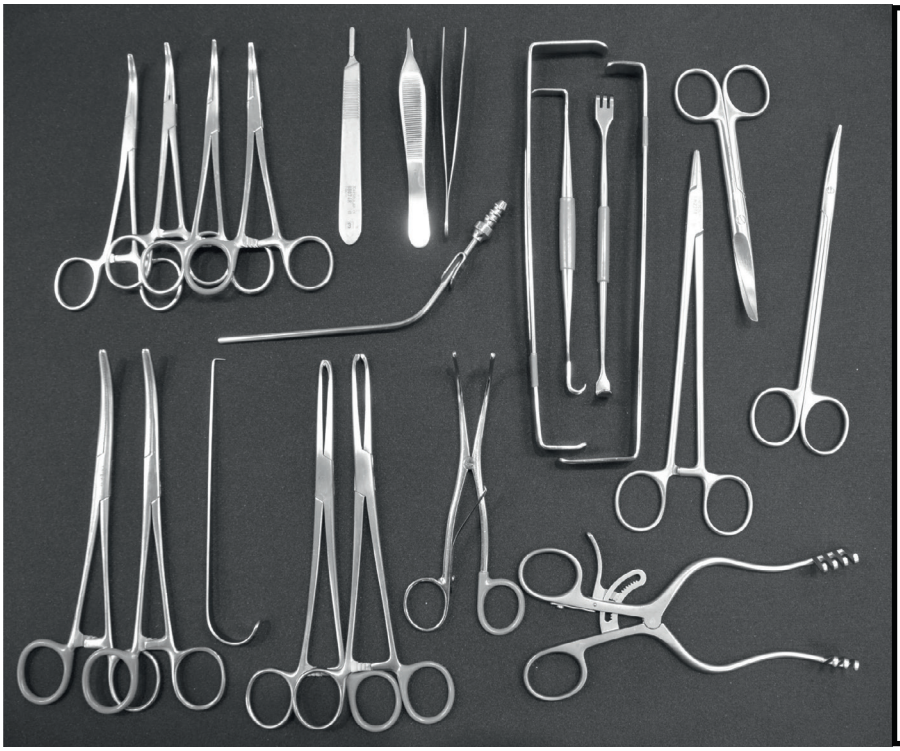
Although there is a learning curve to the technique, there are several advantages of PDT. The time required for bedside PDT is considerably shorter than that for an open tracheostomy. The elimination of operating room scheduling issues and costs, as well as the risks of transport, provide benefit to the patient and critical care team. In fact, the cost of performing PDT at the bedside is roughly half that of performing open surgical tracheostomy in the operating room.[35]

Surgical

Elective open surgical tracheostomy has been performed at the bedside in ICUs since the 1960s.[36] The performance of these procedures at the bedside remained controversial,[37] but as intensive care improved and more and sicker patients required tracheostomy for ongoing mechanical ventilation, the practice became more common. Concern for transport of critically ill patients from the ICU to the operating room,[38] as well as logistic concerns, prompted evaluation of this practice. Reported technical and long-term complications were not found to be different than those performed in the operating room.[39,40] Although early studies since the acceptance of percutaneous tracheostomy suggested that the surgical technique offered safety and cost advantages,[41] meta-analysis has suggested that they are equivalent from the standpoint of mortality and operative complications.[42] Open tracheostomy at bedside may be an alternative to open tracheostomy in the operating room for patients with normal neck anatomy; however, potential difficulty in reintubation via the oral route—such in those with oral pathology or with cervical spine fractures—could be the deciding factor to move the patient to the operating room. The ability to directly visualize the withdrawal of the endotracheal tube via the tracheotomy site itself reduces (but does not eliminate) the risk of accidental extubation during the procedure. The surgeon must be experienced and comfortable with the procedure at the bedside; otherwise, the procedure should be performed in the operating suite. Patients with neck pathology—such as those with head and neck masses or goiter or those in halo devices—should not be considered candidates for bedside tracheostomy.

The technique of open tracheostomy is generally the same as in the operating room. The general requirements for patient management during the procedure do not differ from those of the percutaneous method. The patient should be supported by a controlled method of ventilation and receiving 100% oxygen concentration while receiving monitored sedation with appropriate analgesia. A nurse should be available at bedside at all times for ongoing monitoring and sedation management. Continuous pulse oximetry and end-tidal carbon dioxide monitoring should be in place. The decision for paralysis during the procedure is the proceduralist's choice. Some practitioners recommend nonparalysis as a safety measure to maintain spontaneous ventilator effort if there is difficulty with the procedure, but many use paralytic agents. Local anesthetic should be used liberally for the area of incision and dissection, even with sedation and paralysis. Good lighting is critical, and the use of headlamps is advisable. Electrocautery should be available, but caution should be exercised to not use it to open the trachea or while the tracheotomy is open. Use of electrocautery in the presence of 100% oxygen is a fire risk.

It is best to perform the procedure with a surgeon and assistant, as well as an experienced airway management practitioner (respiratory therapist or a member of the anesthesia team). The minimum instrumentation for the procedure is listed and shown in Fig. 14.3. A variety of sizes of tracheostomy tubes and airway rescue equipment should be immediately available. In the absence of cervical spine injury or pathology precluding extension, a roll should be placed behind the patient's shoulders to hyperextend the neck, allowing better exposure of the trachea. An incision midway between the cricoid and the sternal notch is made. A vertical incision is advisable to reduce the risk of division of branches of the anterior jugular veins and the attendant bleeding. Bleeding vessels may be controlled with suture ligature or electrocautery as needed. The dissection is carried out by blunt and sharp dissection to expose the trachea. The thyroid isthmus, if it is in the way, may need to be divided and controlled with suture ligatures. The third tracheal ring is identified and elevated into the wound with a Jackson Tracheal Hook (Skflar Surgical Instruments, West Chester, PA). The third ring is incised with a variety of techniques, based on the training and experience of the surgeon. Complex techniques, such as suturing a tracheal flap to the skin, should be avoided in bedside



• **Fig. 14.3** Instruments for bedside surgical tracheostomy tray.

tracheostomy. The tracheotomy is dilated with the tracheal dilator, the endotracheal tube withdrawn to just above the tracheotomy under direct visualization of the operator, and the tracheostomy tube inserted and the cuff inflated. The patient is then ventilated via the tracheostomy and once correct placement is confirmed by end-tidal carbon dioxide and breath sound auscultation, the endotracheal tube can be removed. The tube is secured with a tracheostomy tie encircling the neck, and the tracheostomy tube is sutured to the skin, and if necessary the skin wound is approximated. Some practitioners will obtain a postprocedural chest x-ray, but in the absence of clinical suspicion of new pathology this is unnecessary.[43]

Complications of Tracheostomy (Table 14.1)

Elective tracheostomy, whether surgical or percutaneous, is relatively safe and well tolerated.[44] This procedure involves maneuvering the ETT and pulling it to just below the vocal cords with the risk of accidental extubation. It also involves performing incision and deep dilation or dissection in a location surrounded by major vessels and vital organs. The reported mortality is less than 1%, and morbidity ranges between 4% and 10%.[44,45] Complications may be intraprocedural (during insertion procedure), early postprocedural (<7 days or before stoma maturation), or late procedural (>7 days).

Several of these complications are serious and warrant extra attention. Two immediate intraprocedural complications are critical and require swift intervention. One is surgical site bleeding, which can be significant. It is typically caused by soft tissue dissection and small vessel injury. It is often self-limited and managed by applying pressure to the site until the bleeding stops. We have also used 2% lidocaine with epinephrine injection around the site, which works almost immediately. Electrocautery may be useful for small branches of the anterior jugular veins, and occasionally these will require ligation during either PDT or surgical tracheostomy. Occasionally it is due to major vessel injury, in which case it can be massive and lethal, requiring immediate surgical intervention.

The second potentially lethal complication is loss of airway control during the procedure. This may be due to premature extubation, in which case rapid recognition and either reintubation or immediate completion of the tracheostomy is effective treatment. This may also be a result of the technical misadventure of false

TABLE 14.1 Complications of Tracheostomy

Intraoperative	Early	Late
Bleeding	Bleeding	Subglottic stenosis
Accidental extubation	Accidental decannulation	Accidental decannulation
False tract	Infection	Infection
Pneumothorax/ pneumomediastinum		Tracheo-innominate fistula
Posterior wall puncture/ esophageal injury		
Hypoxia		

cannulation,[46] which occurs in fewer than 1% of patients and is linked to wire kinking. This complication is often associated with a poor visual bronchoscopic field while attempting to apply too much pressure trying to advance the tracheostomy tube through the fresh stoma over a kinked wire.[46] Once again, rapid recognition and ensuring a controlled airway are critical in this setting. Then the procedure can be completed.

Another immediate serious, yet preventable, complication is puncture of the posterior tracheal wall. This complication may occur during percutaneous tracheostomy but is easily preventable when bronchoscopy is guiding intraluminal insertion of the wire, dilation, and placement of the tracheostomy tube.[47]

The most dramatic and life-threatening late complication—tracheo-innominate artery fistula—is delayed (within 3 weeks) and very uncommon. It can occur with either open or percutaneous tracheostomy and its incidence varies between 0.3% and 0.8%.[48] The risk factors include a low insertion site (below the third tracheal ring), the tracheostomy tube tip abutting against the anterior tracheal wall and eroding through the airway, or an overinflated cuff at the level of the artery. This complication is an absolute surgical emergency and is associated with a high mortality rate.

Posttracheostomy Care

After tracheostomy, weaning from mechanical ventilation and the tracheostomy begins. As in other mechanically ventilated patients, frequent assessment for liberation is conducted. The decrease in sedation requirements frequently leads to a rapid weaning process. Trials of tracheostomy collars may be initiated as tolerated as soon as the patient's oxygen requirements allow. Once mechanical ventilation is no longer needed, tracheostomy tube downsizing/capping and decannulation should be undertaken. In patients with neurologic compromise (e.g., stroke, traumatic brain injury) the assessment for initiating this process must include the patient's cough and swallowing function. Inability to maintain a safe airway may preclude decannulation. The rationale behind downsizing/capping a tracheostomy tube is to allow airflow around the tube through the vocal cord and detect any potential upper airway stenosis caused by the presence of an artificial airway—whether the ETT or tracheostomy tube.[45] Strategies and specifics of a weaning/decannulation protocol are usually institution dependent. Our decannulation protocol includes bedside evaluation with "digital occlusion" of the initial tracheostomy tube while observing any signs of respiratory distress or upper airway obstruction. If well tolerated, initial cuffed tracheostomy tube is downsized to a smaller uncuffed tube. If well tolerated, 24 hours later the tracheostomy tube is then capped for another 24 to 48 hours followed by decannulation.[49] The need for frequent suctioning or poor clearance of oral secretions should be assessed during the capping trial as these factors need to be considered in the decision to decannulate. Any signs of respiratory distress during any stage of tracheostomy tube occlusion should be followed by bronchoscopic evaluation of upper and lower airways.

During the first week after initial tracheostomy, an inadvertent decannulation should be treated as an emergency. The immature stoma can close rapidly, and blind reinsertion attempts can easily lead to a false tract and severe respiratory consequences. When inadvertent decannulation occurs, this should be treated by immediate orotracheal intubation unless a practitioner experienced in performing tracheostomy is present at the bedside. The practitioner may choose to attempt reinsertion of the tracheostomy tube with or without using a guide wire or modified Seldinger technique.[45]

Summary

Bedside tracheostomy is frequently performed in the ICU for patients requiring prolonged ventilation or an artificial airway for secretion or aspiration control. Both percutaneous and open surgical techniques have been used at the bedside in critical care units and have been demonstrated to be safe and effective with no difference in outcomes and the rate of complications. The timing of tracheostomy has been explored in a number of studies with marginal advantages to early compared with late (2–3 weeks). Bedside tracheostomy is associated with a low rate of complications if performed by an experienced operator, regardless of specialty, and a dedicated team.

Key Points

- Tracheostomy is a common procedure in the ICU and often done at the bedside whether it is percutaneous or open.
- Both techniques have similar safety profiles and are associated with a low complication rate.
- Timing of tracheostomy placement has been studied extensively; early tracheostomy has fewer minor advantages with no effect on major outcomes such as mortality or ventilator associated–pneumonia.
- A team approach and preset checklists are crucial when performing bedside tracheostomy.
- In case of accidental decannulation within the first week, preparation for orotracheal intubation should be initiated and tracheostomy reinsertion should be attempted only by an experienced operator.
- After weaning from mechanical ventilation, downsizing and capping should be initiated before decannulation. If not tolerated, bronchoscopic airway evaluation should be performed.

Review Questions

1. You are supervising your senior fellow who is performing a bedside percutaneous tracheostomy using the Ciaglia technique while another trainee is performing the bronchoscopy. The fellow performing the tracheostomy informs you that he is only able to push the tracheostomy tube partially over the tapered dilator into the tracheal lumen and is meeting resistance. He had already ensured that the guidewire was inside the tracheal lumen and this was confirmed by the bronchoscopist. What is the next best step?

a. Order a smaller tracheostomy tube immediately.
b. Abort the procedure and close the wound.
c. Ask your fellow to apply more pressure to get the tracheostomy tube inside the tracheal lumen.
d. Pull back the tracheostomy tube, tapered dilator, and guidewire en bloc as the guidewire may have kinked and caused a false channel anterior to the trachea.

Answer: d. The most common reason for creation of a false passage is failure to use a true Seldinger technique. Just as in placement of a central venous line, if the device is advanced with the wire, rather than keeping the wire stationary and advancing over it, the wire frequently kinks, resulting in the clinical situation as outlined. The solution is to withdraw the device, pull the kinked wire back into the introducer, and advance the device and introducer over the wire. Applying more pressure will only worsen the condition. If this complication results in desaturation or hemodynamic instability, it may be appropriate to convert to an open approach or abandon the procedure with replacement of the orotracheal tube. The wound should not be closed. A smaller tube will still result in the same outcome unless the technique is corrected.

2. You are reconsulted to evaluate a patient for decannulation after a tracheostomy for prolonged mechanical ventilation (about 4 weeks with orotracheal intubation). The critical care team has already downsized the tracheostomy to a cuffless Shiley No. 6, and the patient has not required mechanical ventilation for more than 10 days. You perform a digital occlusion maneuver and notice significant respiratory discomfort after only 10 to 15 seconds. What is the next step?

a. Continue with decannulation.
b. Downsize the tracheostomy one more time to a cuffless Shiley and then reassess.
c. Perform a diagnostic bronchoscopy through the tracheostomy and through vocal cords to assess for upper airway stenosis likely caused by the prolonged orotracheal intubation.
d. Order a one-way valve.

Answer: c. Respiratory embarrassment caused by airway obstruction (complete or partial) is an absolute contraindication to decannulation in this setting. After prolonged endotracheal intubation, the most frequent cause is likely to be related to laryngeal edema and/or scarring, but vocal cord paralysis or granuloma may be present at that level. Subglottic stenosis caused by prolonged intubation with high cuff pressures is less likely but should be evaluated by endoscopy.

3. You are asked to evaluate a 34-year-old female with severe acute respiratory distress syndrome (ARDS) secondary to pneumonia for an "early tracheostomy." She has been intubated for only 4 days. The intensivist informs you that the patient is expected to require long-term mechanical ventilation considering the severity of her illness and would like the patient to have a tracheostomy. She has had a recent drop in positive end-expiratory pressure (PEEP) (12 cm H_2O) and oxygen (a fraction of inspired oxygen of 50%) requirements; the intensivist wants to take the opportunity to place the tracheostomy as the patient's condition might worsen, precluding the procedure. What are the factors to consider when making a decision about tracheostomy in this patient?

a. It is imperative to wait and not perform a tracheostomy in patients with ARDS requiring high PEEP as it may lead to loss of recruited alveoli and severe oxygen desaturation.
b. Tracheostomy with bronchoscopic guidance is contraindicated in patients with more than 10 cm H_2O of PEEP as inserting the scope through the endotracheal tube may lead to excessive airway pressures.
c. The ability of practitioners to predict long-term mechanical ventilation is not very high; this patient may eventually get extubated without the need for a long-term artificial airway.
d. Proceed with tracheostomy as requested as the advantages of tracheostomy have been very well established and may decrease the risk of mortality in this patient.

Answer c. Many studies have been conducted in an attempt to help identify clinical factors that predict the duration of mechanical ventilation in the critically ill patient. None have provided sufficiently accurate prognosis to be applied to the individual patient. The benefits of early tracheostomy are restricted to a few specific populations but they do not include those with ARDS.

Chest Tube Thoracostomy

ZIAD BOUJAOUDE AND DAVID SHERSHER

CHAPTER OUTLINE

Historical Perspective

Anatomy and Physiology of the Pleural Space

Physiologic Changes With Pleural Effusions and Pneumothorax

Indications for Tube Thoracostomy
- Pneumothorax
- Noninfectious Pleural Effusions
- Hemothorax
- Complicated Parapneumonic Effusions and Empyema
- Malignant Pleural Effusions

Contraindication to Tube Thoracostomy

Drainage Systems

Optimal Chest Tube Size for Drainage

Technique of Chest Tube Insertion
- Small-Bore Tube Thoracostomy
- Large-Bore Tube Thoracostomy

Management of the Chest Tube and Troubleshooting

Complications

Chest tube thoracostomy consists of a percutaneous insertion of a small- or large-bore tube into the pleural cavity. The procedure is primarily used to drain fluid or air from the pleural space and can be lifesaving in certain conditions. Patients requiring chest tubes are often acutely ill with multiple comorbidities and the procedure could be associated with serious complications. It should be performed only by experienced or adequately supervised operators who are familiar with the indications and the potential risks of the procedure. In this chapter we review the historic development of chest tubes, discuss the indications, contraindications and complications of chest tube insertion, outline the technique of insertion, and review the evidence-based management of chest tubes after insertion.

Historical Perspective

Hippocrates was the first to drain an empyema of the pleural space with a metal tube 2400 years ago.[1] Playfair described an underwater seal in 1872, and in 1876 Hewitt designed the first closed tube drainage system with a rubber catheter that drained into a glass jar filled with a weakly antiseptic solution.[2,3] Because of technical problems, this procedure was not widely accepted until 1917, when chest tubes were extensively used for the treatment of pleural empyema associated with the influenza pandemic.[4] Emergency tube thoracostomy became an extremely frequent procedure in treating hemothorax and tension pneumothorax during both the Second World War and the Korean War, and the drain was connected for the first time to a two-bottle water seal system.[5] Thereafter synthetic and more flexible and easier to place tubes replaced metal tubes, and modern three-chamber drains have been used since 1952.[6]

Anatomy and Physiology of the Pleural Space

The pleural cavity is the space formed between the visceral and parietal pleurae, which is crucial for efficient pulmonary and chest wall function. Each pleura is formed from a single layer of mesothelial cells.[7] The parietal pleura covers the inner surface of the thoracic cage including the mediastinal surface and the diaphragm. The visceral pleura covers the outer surface of the lung including the interlobular fissures. The parietal pleura is richly supplied with arterial blood derived from systemic arteries (intercostal, internal mammary, subclavian, and mediastinal arteries), whereas the blood supply of the visceral pleura is divided between the bronchial (mediastinal and interlobular surface) and the pulmonary circulation (costal and diaphragmatic surface). The majority of the venous drainage of the parietal pleura is through the azygos vein and eventually the superior vena cava, whereas the greater part of the visceral pleura is drained through the pulmonary veins. The lymphatic circulation of the visceral pleura is divided into a superficial plexus and a deep plexus composed of a network of lymphatic capillaries and collecting vessels that drains to the hilum. The lymphatic system of the parietal pleura is more extensive and complex with a flow directed to the intercostal and mediastinal nodes. This system plays a key role in the formation and removal of pleural fluid in normal and pathologic states. The effective removal of fluid, cells, and debris relies on the presence of pleural-lymphatic communications including pleural stomata and lymphatic channels.[8]

The parietal pleura is innervated by somatic intercostal nerves and phrenic nerve, whereas the visceral pleura is innervated by the vagus nerve and sympathetic trunk. The pain resulting from irritation of parietal pleura is felt at the adjacent chest wall and may be referred to shoulder. The visceral pleura contains no pain fibers.

In a normal physiologic state, pleural fluid is produced mostly by the parietal pleura according to the net hydrostatic-oncotic pressure gradient, at an approximate rate of 0.5 mL/h in adults.[9]

Drainage of fluid and proteins occurs almost exclusively via the parietal pleural stomata and the pleural lymphatics. Pleural effusion occurs when these homeostatic mechanisms are disrupted, affecting transit of pleural fluid across the pleural space. Movement of fluid between the pleural space and the alveolar or pulmonary interstitium is restricted by tight junctions between visceral mesothelial cells. This barrier can be damaged in disease states such as congestive heart failure or acute respiratory distress syndrome.[10] Additionally, intercostal and diaphragmatic muscle activity influences the rate of lymphatic flow, and hypoventilation and anesthesia can reduce lymphatic flow and the rate of absorption of protein, altering the physiology of the pleural space.

Physiologic Changes With Pleural Effusions and Pneumothorax

The effects of a pleural effusion on pulmonary function are difficult to determine. Generally speaking, it imposes a restrictive ventilatory defect on the patient. One study showed a 20-mL increase in forced vital capacity for every 100 mL of pleural fluid withdrawn, but there was large interindividual variability.[11] For patients supported by mechanical ventilation, one study showed immediate improvement of compliance and the partial pressure of arterial oxygen/fraction of inspired oxygen (PaO_2/FIO_2) ratio, but another study showed no effect.[12,13] The presence of a large pleural effusion can lead to diaphragmatic inversion and marked dyspnea and can compress the heart and lead to a compromised cardiac output.

A pneumothorax occurs when air enters the pleural space through a communication between the alveoli or the ambient air and the pleural space. Information on the effect of pneumothorax on pulmonary function is limited as most patients are symptomatic. However, it has been shown to adversely affect blood gases in humans. In one study of 12 patients with pneumothorax, the PaO_2 was below 80 mm Hg in 9 patients and below 55 mm Hg in 2 patients.[14] The PaO_2 was lower in patients with pneumothoraces. The effect of a small pneumothorax on diaphragm and cardiac output is minimal; however, the effect exponentially increases when a tension pneumothorax develops. Tension pneumothorax occurs when air enters the chest with each mechanical or spontaneous breath, with no route for escape. Initially, the affected lung simply collapses, but as tension increases, the diaphragm flattens, and the mediastinum shifts toward the contralateral side. The contralateral lung is compressed, further decreasing effective ventilation. Most importantly with respect to acute hemodynamics, the great vessels also are compressed and venous return is reduced. This reduction in venous return results in rapid and disastrous cardiopulmonary collapse.[15]

Indications for Tube Thoracostomy

Chest tubes are primarily used to remove liquid or air from the pleural space, but they can also be used to instill sclerosing agents to induce pleurodesis. In the critically ill patients, they are frequently used to treat pneumothoraces, pleural effusions, parapneumonic effusions and empyema, hemothoraces, and malignant pleural effusions.

Pneumothorax

A pneumothorax can be spontaneous (primary or secondary), iatrogenic, or traumatic (non-iatrogenic). A secondary spontaneous pneumothorax is defined as a pneumothorax that occurs as a complication of underlying lung disease. In contrast, primary spontaneous pneumothorax occurs without a precipitating event in the absence of clinical lung disease. Patients with primary spontaneous pneumothorax who are symptomatic or who have a distance greater than 2 cm from the surface of the lung to the inside of the chest wall should undergo drainage.[16] Simple aspiration with a 14- to 16-gauge catheter is as effective as a large-bore chest drain and may be associated with fewer days of hospitalization.[17,18] The patient may be observed for a few hours and then discharged home if the pneumothorax does not recur. Small-bore chest tubes have been shown to be as effective as large-bore catheters if a tube is indicated.[19] Most spontaneous secondary pneumothoraces are related to chronic obstructive pulmonary disease. In these patients, needle aspiration is usually not sufficient, and most require drainage with a small-bore chest tube.[16] One nonrandomized study demonstrating equivalence of size of tube thoracostomy compared the results in 61 patients treated with pigtail catheters (10F–14F) and 22 patients receiving large-bore chest tubes (22F–28F), reported that the success rate was 72.5% with the pigtail catheters and 72.7% with the large-bore catheters.[20] In our practice and consistent with these data, we prefer to use small-bore chest tubes for simple pneumothoraces.

Traumatic (non-iatrogenic) pneumothorax can result from either penetrating or nonpenetrating chest trauma. Tube thoracostomy may not be necessary for patients with occult or small pneumothoraces. Knottenbelt and van der Spuy observed 333 patients with small (<1.5 cm from lung to chest wall) pneumothoraces and reported that only 33 required subsequent drainage for an enlarging pneumothorax.[21] An occult pneumothorax is a pneumothorax that is not visible on the chest radiograph but is visible on the computed tomography CT scan. This accounts for 40% of all traumatic pneumothoraces and does not require treatment with a chest tube unless patients require positive-pressure ventilation while using mechanical ventilation (to avoid the risk of development of tension pneumothorax). Although there are no controlled studies, small-bore rather than large-bore chest tubes are recommended for traumatic pneumothoraces that are not associated with pleural effusion that may be a hematoma related to the mechanism of injury. After placing a small-bore chest tube, if the lung does not expand a large-bore chest tube should be inserted. If the pneumothorax is not resolved after this, consideration should be given to performing video-assisted thoracic surgery to control air leak and/or prevent development of a trapped lung.[22,23]

The most common causes of iatrogenic pneumothoraces are transthoracic needle aspiration, subclavian vessel puncture, thoracentesis, pleural biopsy, and mechanical ventilation.[24] Asymptomatic iatrogenic pneumothorax may be treated with supplemental oxygen. If symptomatic, needle aspiration is effective in more than 90% of patients.[25] A small-bore tube is indicated if the lung does not expand and a large-bore chest tube should be inserted if no resolution occurs.[22] One special situation with iatrogenic pneumothorax is in patients supported by mechanical ventilation. In general, all such patients should receive a chest tube because of the possibility of the development of a tension pneumothorax.[26] The decision to place a large-bore or small-bore chest tube in this situation is largely determined by training paradigm and institutional preference. Lin and associates reported their experience with 70 patients supported by mechanical ventilation who developed a pneumothorax. When the pneumothorax was due to thoracentesis, central line insertion, or central venous access stick, pigtail catheters were successful in 35 of 40 (87.5%) patients. However, when the

pneumothorax was due to barotrauma, pigtail catheters were successful in only 13 of 30 (43.3%) patients.[27] The results of this study suggest that if a pneumothorax is due to barotrauma in mechanically ventilated patients, it is probably better to insert large-bore chest tubes.

Tension pneumothorax is a life-threatening emergency that requires immediate decompression. In the absence of hemodynamic compromise, the diagnosis should be confirmed on chest radiograph before drainage, but often the diagnosis is made clinically without radiographic support. Unstable patients should be treated immediately with needle decompression of the second intercostal space at the mid-clavicular line using a 14- or 16-gauge long angiocatheter, followed by formal insertion of chest tube. A 14F to 16F chest tube is successful in our experience.

Noninfectious Pleural Effusions

Transudative and exudative pleural effusions are common in the intensive care unit (ICU). The incidence varies with screening methods, from approximately 8% for physical examination to more than 60% for routine ultrasound.[28] Several factors contribute to the occurrence of pleural effusions in ICU patients. Large amounts of intravenous fluid are often administered during the first few days to patients admitted for shock. Heart failure, atelectasis, hypoalbuminemia, and liver disease are present in many ICU patients. Cardiac or abdominal surgery is often complicated by pleural effusion; the majority of effusions are small and if clinical suspicion for infection is low, observation of these effusions is warranted initially. Most effusions are caused by noninfectious processes that should resolve with treatment of the underlying disease.[29] However, drainage with a small-bore chest tube may be indicated when an effusion is large and symptomatic. Drainage of large pleural effusions may result in a significant improvement in oxygenation for mechanically ventilated patients in acute respiratory failure who are poorly responsive to treatment with mechanical ventilation and positive end-expiratory pressure.[13]

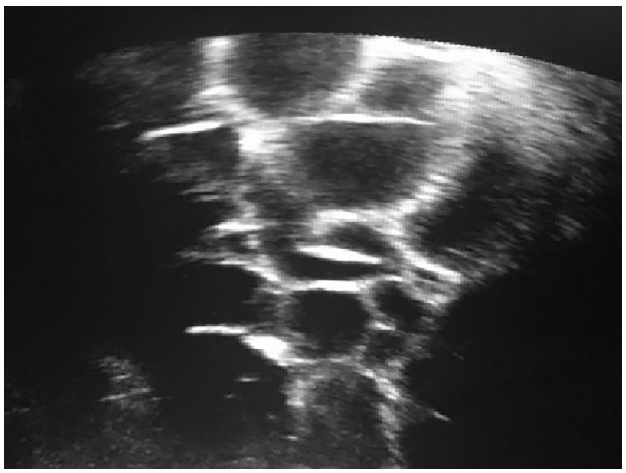
Hemothorax

A hemothorax is defined by a hematocrit of the pleural fluid of at least 50% of the peripheral hematocrit. Most hemothoraces are due to trauma, and some are due to malignancy, anticoagulation, or other conditions.[22] The presence of a hemothorax requires immediate insertion of a chest tube. Insertion of the tube allows complete evacuation of blood and quantification of the amount of bleeding. It helps to stop the bleeding if caused by pleural laceration as the two pleural surfaces come into apposition and decrease the incidence of subsequent infection, empyema, and fibrothorax.[30] In general, a large-bore tube is recommended. Massive hemorrhage (>1500 mL) or drainage of more than 250 mL/h is an indication for surgical exploration.[31]

Complicated Parapneumonic Effusions and Empyema

Empyema is defined by the presence of frankly purulent pleural fluid. Conversely, the criteria for a complicated parapneumonic effusion are broader and include the presence of pus, gram stain–positive or culture-positive pleural fluid, pleural fluid pH less than 7.20, and pleural fluid lactate dehydrogenase level greater than three times the upper limit of normal of serum lactate dehydrogenase. The British Thoracic Society guidelines recommend that patients with frankly purulent or turbid/cloudy pleural fluid on thoracentesis sampling should receive prompt pleural space chest tube drainage. In addition, the presence of organisms identified by Gram stain and/or culture from a nonpurulent pleural fluid sample indicates that pleural fluid is infected and should lead to prompt chest tube drainage. The guidelines also state that patients with parapneumonic effusion and pleural fluid pH less than 7.20 or patients with loculated parapneumonic effusions should also receive early chest tube drainage.[32] Loculation is defined by the presence of one or more pockets of fluid in the pleural space. A loculated effusion tends to have a lower pH and glucose level and the fluid analysis in the majority of patients with loculations indicates that tube thoracostomy should be performed (Fig. 15.1). There is no consensus on the optimal size of the chest tube, and it is reasonable to start with a smaller size and proceed to surgical tube placement if the effusion does not improve. Masket et al. collected data on the size and the complications of chest tubes on 405 patients who participated in the Multicenter Intrapleural Streptokinase Trial that was designed to assess the efficacy and safety of streptokinase in patients with complicated parapneumonic effusions.[33] The group reported that there was no significant difference in the frequency with which patients either died or proceeded to surgery for source control when comparing chest tubes of varying sizes.[34] Another study reviewed the results of tube thoracostomy in 103 patients who were treated with 8F to 12F pigtail catheters or 10F to 14F Malecot catheters (Cook Medical, Bloomington, IN) placed with the Seldinger technique. This study reported that the small catheters served as the definitive treatment in 78% of the patients.[35]

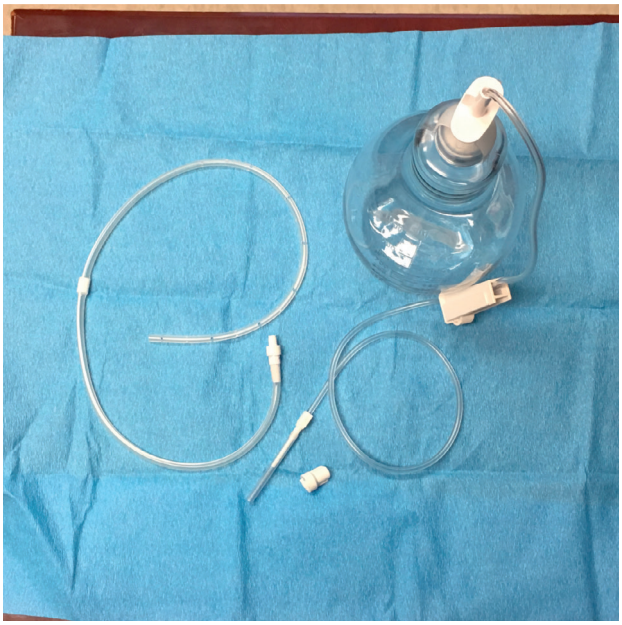
The British Thoracic Society guidelines state that a small-bore catheter (10F–14F) is adequate for most cases of complicated parapneumonic pleural infection. The guidelines recommend regular flushing of small-bore flexible catheters to prevent clotting with debris, using 20 to 30 mL of saline solution every 6 hours via a three-way stopcock. It should be noted that flushing larger-bore drains is technically more difficult as these do not routinely have three-way stopcock, and disconnection for irrigation might encourage the introduction of secondary infection.



• **Fig. 15.1** Ultrasound examination of a multiloculated pleural effusion. Pleural fluid with a pH of less than 7.20 in such patients with multiple loculations should be treated with early chest tube drainage.

Malignant Pleural Effusions

Chest tubes are often used in the management of malignant pleural effusions to perform pleurodesis or to drain the pleural fluid on a long-term basis. The available evidence suggests that small-bore catheters are as efficacious as large-bore catheters to effect pleurodesis.[36–38] Indwelling, tunneled catheters are used for long-term home drainage and are extremely comfortable and effective. The most commonly used is the Pleurx catheter (CareFusion, San Diego, CA) (Fig. 15.2). The PleurX catheter is a 15.5-F silicone rubber catheter that is 66 cm long. It has a one-way valve on the external part of the catheter that allows drainage of the pleural fluid when an adaptor attached to a vacuum bottle is inserted into the valve. Tunneled pleural catheters allow symptomatic improvement in 95% of the patients, reduce the length of hospitalization, and can induce spontaneous pleurodesis. They are associated with low obstruction and infection rates.[39] They can be combined with pleuroscopic talc pleurodesis to reduce the duration of hospitalization and to provide a backup mechanism in case of pleurodesis failure.[40]



• **Fig. 15.2** PleurX catheter (CareFusion, San Diego, CA) indwelling device that is inserted with a subcutaneous cuff for outpatient drainage of pleural effusion.

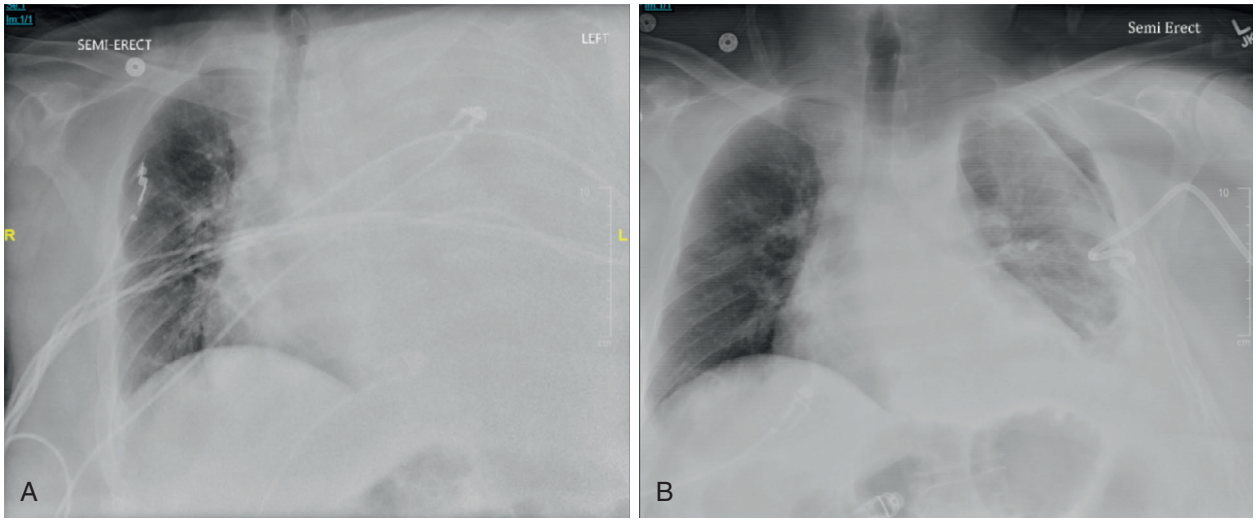
Contraindication to Tube Thoracostomy

With appropriate operator experience or experienced supervision, there are few technical contraindications to performing bedside tube thoracotomy. Relative contraindications are thrombocytopenia (platelet count <50,000/μL and international normalized ratio >1.5 IU), but these are more applicable to percutaneously placed tubes owing to inability to manually control periprocedural bleeding leading to hemothorax. In our institution's practice, we have safely placed chest tubes with a bedside cut-down approach in coagulopathic patients using appropriate hemostatic surgical principles and transfusion of blood products.

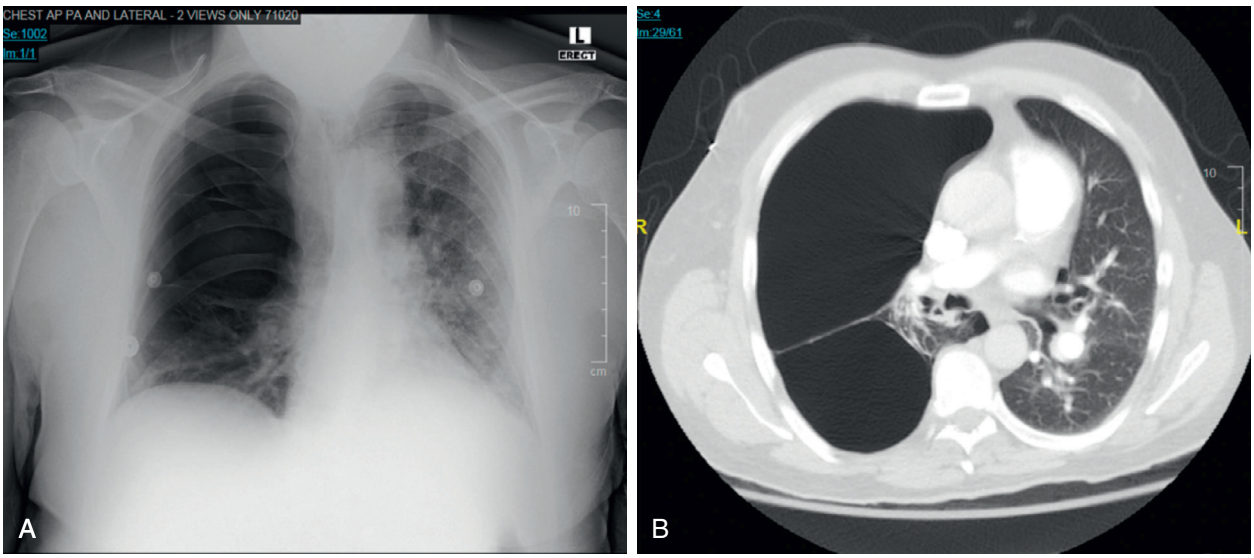
There are two specific contraindications to tube thoracostomy that are most often missed in the haste of radiology imaging review and procedural treatment of a sick patient: trapped lung and bullous disease mistaken for a pneumothorax. The former condition is often associated with a thickened pleural rind that can be seen on chest enterography and better demarcated on CT. Whether the trapped lung is due to chronic empyema, metastatic disease, or fibrothorax, placement of a chest tube will likely not expand the lung to create pleural apposition. The appropriate treatment is surgical decortication. Fig. 15.3 demonstrates a prefilm (part A) and postfilm (part B) image after incomplete pulmonary reexpansion in a patient with trapped lung. The latter condition, bullous disease, may be mistaken for a large pneumothorax on rapid radiographic evaluation of a hypoxic patient. The result of this "misread" can be dangerous, as placement of chest tube into a large bullae will result in a large bronchoatmospheric fistula that will likely need surgical control to seal. Fig. 15.4 demonstrates a chest radiograph and subsequent CT example of bullous disease.

Drainage Systems

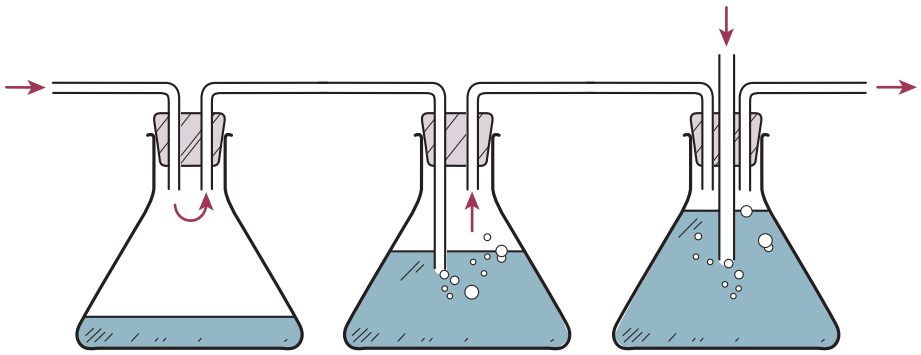
The original drainage system was a single-bottle system consisting of a water seal and drainage bottle. This was ultimately advanced



• **Fig. 15.3** Demonstration of a trapped lung: (A) shows appearance of chest radiograph before drainage of pleural fluid with tube thoracostomy and (B) afterward, now demonstrating trapped lung.



• **Fig. 15.4** Chest radiograph (A) and computed tomography scan (B) demonstrating giant bullae in the right lung. As demonstrated, chest radiography alone can confuse clinicians as to a potential diagnosis of pneumothorax with ensuing complication of large bronchopleural fistula if a chest tube is mistakenly inserted in the belief that the bullae is a pneumothorax.



• **Fig. 15.5** Historically the three-bottle collection system was used; the system consisted of (from *left* to *right*) trap bottle, water-seal bottle, and manometer bottle. These are now all integrated into a single self-contained collection system.

to a three-bottle system (Fig. 15.5), which allowed a separate chamber for fluid collection, air expulsion, and ultimately external suction connection to hasten evacuation of air and fluid from the pleural space (rather than relying solely on water seal pressure as a function of height differential between the chest tube tip and the water column). The modernization of this three-chamber system is found in single compartmentalized boxes such as those made by Atrium (Atrium Medical Corp., Hudson, NH) or Sahara (Teleflex Inc., Morrisville, NC) (Figs. 15.6A and B, respectively). Both allow connection to various degrees of suction that can be manipulated on the side of the device. The factory setting is −20 mm Hg, which corresponds to a negative pressure generated with a 20-cm column of water in the original three-bottle system. Advanced digital systems such as the Medela (Medela Healthcare, McHenry, IL) system are based on the same design principle but objectify air leak and quantity of drainage better than conventional analog systems (Fig. 15.7). Proponents argue that these devices lead to earlier chest tube removal and decreased hospitalization.[41] This was recently corroborated in a multicenter randomized trial with subjective improvement in patient satisfaction scores, especially considering that these portable devices could be used at home.[42] Opponents cite benefit/cost issues as a barrier to use.

Finally, water seal–equivalent options exist for patients with prolonged air leak, defined as leak persisting longer than 5 days after intervention, who can be discharged home with adequate control of the pleural space.[43] The two most common devices are demonstrated in Fig. 15.8, with the former device (part A) permitting efflux of air and the latter device (part B) also allowing capture of pleural fluid into a closed sterile chamber.

Optimal Chest Tube Size for Drainage

Chest drains are usually divided into two size categories: large-bore (>20F) or small-bore (≤20F). French refers to the outer diameter and (1F) is equivalent to 0.333 mm. Like all cylindrical tubes, pleural drains obey Poiseuille's law and the Fanning equation. The Fanning equation ($\nu = \pi^2 r^5 P/fl$, were ν is the flow, r is the radius, l is the length, P is the pressure, and f is the friction factor) determines the flow of the moist gas (such as in a pneumothorax) or liquid with turbulent flow through the tube.[44] Poiseuille's law

• **Fig. 15.6** Common modern self-contained pleural drainage systems are made by Atrium (A) or Teleflex (B). These function similarly and utilize the principles of the three bottle collection system.

• **Fig. 15.7** Modern digital drainage system (Medela; Medela Healthcare, McHenry, IL) can objectify air leak and quantity of drainage better than conventional analog systems.

• **Fig. 15.8** A, The Heimlich valve (Becton, Dickinson and Company, Franklin Lakes, NJ) and (B) Atrium Pneumostat devices are two ambulatory systems designed to allow one-way drainage of small air leaks and permit short-term outpatient management of patients. (B, Copyright [2004] Atrium Medical Corporation. All rights reserved.)

($\nu = \pi r^4 \Delta P / 8 \dot{\eta} L$, where ν is the flow, r the radius, $\dot{\eta}$ the liquid's viscosity, L the tube's length, and ΔP the difference between the tube's ends) determines the flow of corporeal fluids. If the diameter of the tube is doubled, flow increases by a factor of 16, implying that a small increase in the size of the drainage tubes would result in substantial improvements in the flow rates. The internal diameters (bore) and the length of the tube, which may vary according to the manufacturer, are obviously key determinants for the successful drainage of pleural collections. However, equally important are the characteristic of the drained material, its formation rate, the ability of the tube to remain patent, and for all or the majority of the collection being drained to be in communication with the tube. Patient safety and comfort should also be considered. A large-bore catheter would appear to fulfill most of the criteria, and traditionally large tubes are used whenever a high risk of drain

obstruction is expected as in cases of active bleeding or empyema. However, review of the published literature suggests that small-bore tubes are at least as effective as large tubes for most indications.[19,20,34–38] An experimental study compared the drainage capacity of a 19F and 28F tube in vivo and in vitro, showing that the larger tube had an in vitro capacity 9 times higher than the other, whereas in vivo both tubes had the same drainage capability over time.[45] Similar results were also found by Park and colleagues, who compared the catheters' drainage times according to their size, taking into account the characteristics of fluid including viscosity.[46] The authors observed that the tube's size was significantly different only for catheters smaller than 8F, whereas it was not so for the larger ones. Furthermore, small-bore tubes are easier to insert, they cause less pain for the patient both during insertion and while in place, and they appear to have a lower risk of complications.[31]

In our institution, small-bore tubes are routinely used for most indications, including initial drainage for complicated effusions and empyema, tension pneumothorax, and nontraumatic hemothorax with high success. Small-bore catheters may also complement larger tubes that have drained most of the chest but have left small residual pockets, which would be difficult to access blindly with large, less flexible tubes.

Technique of Chest Tube Insertion

Small-Bore Tube Thoracostomy

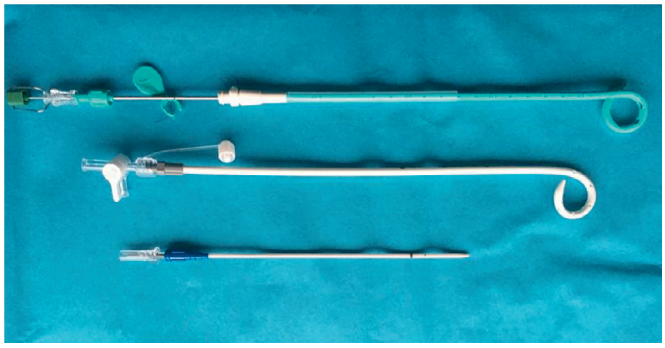
Small-bore chest tubes (<20F) are inserted using a catheter system such as the catheter-over-needle and the catheter-over-guidewire (Seldinger) technique. The procedure begins with patient positioning after explaining the procedure and obtaining informed consent.

Several positions are used; the most important issue is accommodating overall comfort of patient and operator. Patients could be positioned to sit on the bed with their back straight and upright with arms resting on a pillow placed on a table in front of them. For mechanically ventilated patients or those too ill to sit upright, the procedure could be performed with the patient in the supine or lateral decubitus position with arm raised overhead or reaching contralateral side (Fig. 15.9).

Physical examination allows safe selection of the insertion area in most cases. The general teaching approach is that insertion should be attempted one interspace below the spot where tactile fremitus is lost and the percussion note becomes dull. One must recognize, however, that the position of the diaphragm in the supine and lateral decubitus positions can be as high as the fourth intercostal space. In case of a pneumothorax, the catheter is inserted in the second anterior intercostal space, mid-clavicular line. Pleural ultrasonography is a safe and simple noninvasive technique for determining the presence of pleural fluid and identifying the insertion site. It can be performed at the bedside and can provide information about the quantity and the quality of pleural fluid, including the presence of loculations and the precise location of loculated pockets. Studies have shown that complications are decreased with ultrasound guidance, including in patients receiving antiplatelet agents.[47–49] As ultrasound is becoming more available in most ICU, we recommend its routine use to guide the insertion of small-bore tubes.

The selected site is cleaned thoroughly with antiseptic solution and sterile draping is applied. It is essential to anesthetize the skin, intercostal space, and the parietal pleura with a satisfactory amount of local anesthetic. A short 25-gauge needle is used to raise a small wheal with 1% lidocaine at the selected site. Then a long 22-gauge needle is advanced through the wheal directly over the rib with gentle aspiration. Lidocaine is injected every 2 to 4 mm as the needle is advanced until a small amount of fluid or air comes up into the syringe, at which point the needle is then removed. When

• **Fig. 15.9** Patient positioning for bedside thoracostomy is critical to adequately expose the axillary angle and permit safe insertion of a chest tube. Depicted are two common positions: (A) with arm across body and (B) with arm in abduction.



• **Fig. 15.10** Examples of commonly used small-bore chest tubes manufactured by *(top)* Skater (Argon Medical Devices, Frisco, TX); (*middle*) Wayne (Cook Medical, Bloomington, IN), and (*bottom*) Arrow (Arrow International, Reading, PA). Clinicians must be familiar with the type of tube and deployment system used to allow for safe tube thoracostomy.

the catheter-over-needle technique is used, the catheter sheath and needle are advanced until fluid or air is obtained and then the catheter is advanced while holding the needle in place. In case of a pneumothorax, the catheter is directed toward the apex, whereas in case of pleural effusion, it is directed inferiorly and posteriorly into the costal diaphragmatic recess. When the Seldinger technique is used, an 18-gauge hollow needle is advanced until fluid is obtained and then a guidewire is passed through the needle into the space. After removal of the needle, a small incision is made and then a dilating catheter is threaded over the guidewire and advanced using a twisting movement. The tube is next advanced over guidewire. A third technique for insertion uses a chest tube mounted on a sharp-tipped trocar. The whole unit is advanced until parietal pleurae are reached and then the catheter is advanced while the trocar is held in place. The distance to the pleura is premeasured with a 22-gauge needle. Examples of small-bore tubes that are inserted with the above techniques are Skater catheter (Argon Medical Devices, Frisco, TX), Wayne pneumothorax catheter (Cook Medical), and Arrow pneumothorax catheter (Arrow International, Reading, PA) (Fig. 15.10).

Large-Bore Tube Thoracostomy

All critical care proceduralists and surgeons must be familiar with large-bore tube thoracostomy, as this is the mainstay to initial and sometimes penultimate control of the pleural space in a critically ill patient. The procedure should be performed with an experienced proceduralist or supervisor after reviewing appropriate chest imaging, attaining consent, marking the appropriate site, and performing a timeout with nursing staff and equipment in the room. Patient positioning is important and can be performed in one of two ways as described earlier in Fig. 15.9.

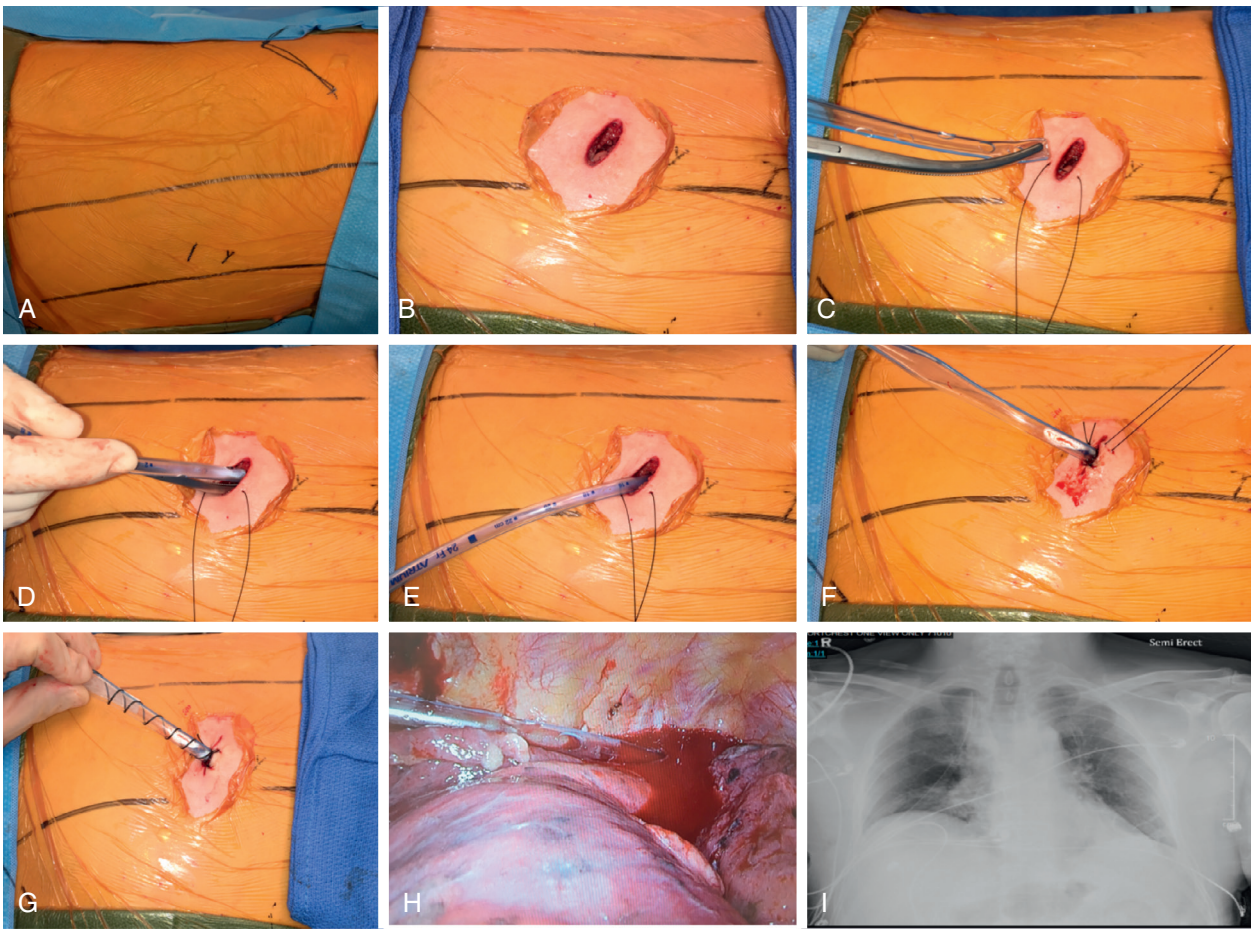
Each chest tube kit should contain the following components:

1. Lidocaine
2. Antiseptic solution
3. Sterile drape
4. Syringes (10 mL)
5. 21-gauge or smaller gauge needles
6. Scalpel
7. Size 0 silk sutures
8. Heavy scissors
9. Curved hemostat clamp
10. Larger Kelly hemostat clamp
11. Chest tube (24F for pneumothorax, 32F or larger for hemothorax or empyema)
12. Drain sponges, tape
13. Pneumovac canister

After obtaining consents and prepping and draping the patient, we routinely identify and mark the fifth intercostal space at the mid to anterior axillary line. This corresponds well to the inframammary crease demarcated by the Y (Fig. 15.11). The scapula is shown at the top of the screen, as are the posterior and anterior axillary lines along with the sixth intercostal space (which was used for this particular chest tube insertion). Occasionally, the fourth or sixth intercostal spaces may be used dependent on patient anatomy. We use local analgesia with 20 mL of 1% lidocaine (10 mL infiltration into incision and 10 mL as an intercostal nerve block) and intravenous sedation and analgesia if needed. We perform an intercostal nerve block of the site of interest using a long 21- or smaller gauge needle and marching up the bottom of the rib while infiltrating the parietal pleura. This avoids injury to the intercostal bundle. After making a 1-cm skin incision in the direction of the rib at the lower edge of the intercostal space, this incision is carried down to the intercostal muscle. A combination of controlled pressure and dissection using a curved hemostat just above the top border of the underlying rib permits safe entry into the pleural space. Using finger palpation, intrapleural loculations are gently disrupted and the pleural space is freed. Next, the chest tube (which should have been already prepared with a Kelly clamp at the tip and another hemostat at the end to prevent spillage of fluid around the sheets) is positioned posteroapically or in the direction of maximal pathology. The chest tube is secured to the skin with an anterior simple anchor stitch using size 0 silk suture. Additionally, to prevent accidental dislodging, the amount of chest tube leakage is decreased after the procedure and uncomplicated removal of the chest tube is facilitated; either a simple vertical stitch or a U-stitch is performed, tied down to the skin, and wrapped around the chest tube. The chest tube is then attached in a sterile manner to the pneumovac and dressed appropriately with gauze and tape. Fig. 15.9 demonstrates this sequence and also shows both an intrathoracic view of appropriate posteroapical placement and its radiographic postprocedure correlation.

Management of the Chest Tube and Troubleshooting

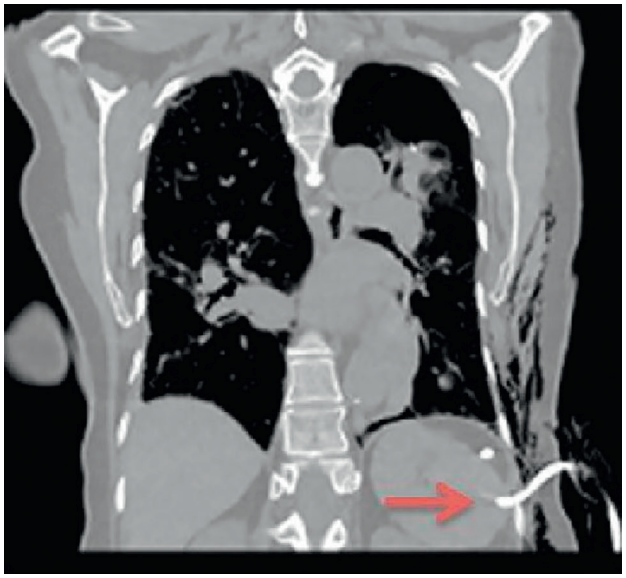
After chest tube insertion, our institution's practice is to immediately order a postinsertion chest radiograph with the chest tube to −20 mm Hg suction to confirm placement and either drainage of effusion and/or reexpansion of the lung. The appropriate use of pleural drainage systems as previously described is reported by the American College of Chest Physicians and does not discriminate between use of suction and water seal when effective.[50] However, the debate of water seal or suction is age-old; two recent meta-analyses published in 2010 and 2012 found no difference in terms of prolonged air leaks, duration of air leak, length of hospital stay, or length of indwelling tube thoracostomy when comparing suction to water seal.[51,52] Suction may hasten resolution of pleural effusion or pneumothorax in certain cases, but at the expense of increased risk of reexpansion pulmonary edema and possibly potentiating prolonged air leaks, without a decrease in duration of chest drain placement and hospital stay.[52,53]



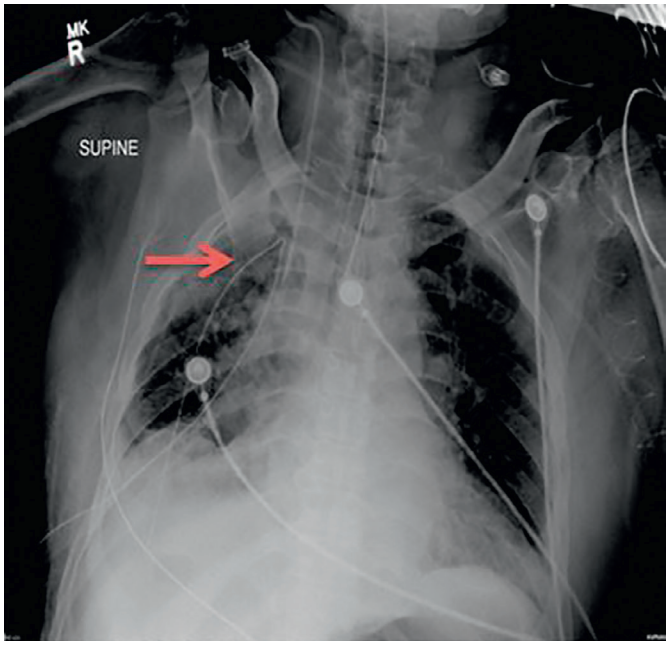
• **Fig. 15.11** Sequence of insertion of surgical tube thoracostomy (from A to G) with confirmation of placement intrathoracically (H) and radiographically (I) after the procedure. It is critical to identify patient landmarks between the anterior and posterior axillary lines. Obtaining a follow-up chest radiograph is a mandatory step to confirm position after tube placement.

Predictive tools have been created to best triage and treat prolonged air leaks, although these tools have not been adopted on a multiinstitutional scale.[53] In clinical practice, determination of the removal of the chest tube is made by the absence of worsening pneumothorax or subcutaneous emphysema (a prognosticator of pneumothorax) as well as absence of air leak with chest tube on water seal. In our practice, if pleural fluid drainage is less than 300 mL/day, the tube may be removed. Some other groups even recommend a threshold of drainage at less than 450 mL/day, demonstrating variability in clinical practice.[43] If the previous factors exist and the air leak is small and controlled on water seal, the clinician should ensure that there is no break in the tubing, and a provocative clamp trial can mimic removal of the tube. If pneumothorax worsens, then the chest tube is not ready to be removed. One must be aware of development of tension pneumothorax during the clamp trial and prepare the nursing staff and patient, with close monitoring during the duration of the trial. In our practice, we rarely perform provocative clamp trial (owing to patient safety), and subscribe to use of portable chest drainage systems such as a Heimlich valve (Becton, Dickinson and Company, Franklin Lakes, NJ) or Pneumostat chest drain valve (Maquet, Wayne, NJ), which allow resolution of air leak at home. Other groups use digital portable systems to monitor air leaks and send patients home without discontinuing the chest tube, although this is not commonplace across practice and quite expensive.[41,54] Finally, if air leak does not resolve, patients may require procedural interventions, including video-assisted thoracoscopy, thoracotomy, or endobronchial interventions, which are beyond the scope of this chapter.

Should a chest tube be removed at end-inspiration or end-expiration? At the end of expiration, the pleural and atmospheric pressure difference is minimized, decreasing the potential for "sucking air" into the pleural space. However, at end-inspiration, the lung is fully expanded, which may aid in pleural apposition and reduction of pneumothorax after the tube is removed. French and colleagues and others determined that there is no difference between the two strategies, as long as the patient maintains Valsalva maneuver throughout chest tube removal[55,56]; as such we recommend removing the chest tube at end-expiration. We do not obtain a radiograph after the chest tube is removed provided the removal was uncomplicated, because up to 25% to 30% of patients may have a clinically insignificant pneumothorax.



• **Fig. 15.12** A percutaneously placed chest tube entering the spleen *(arrow).* This complication can be avoided by choosing a higher intercostal space for insertion.



• **Fig. 15.13** Tubes can be malpositioned as seen on this postprocedure film. The nonfunctional kinked tube *(arrow)* should repositioned by pulling the tube back or replacing it.

Complications

Complications from tube thoracostomy insertion are avoidable in most cases. Described injuries include placement of the chest tube into bullae resulting in persistent air leak, placement in lung parenchyma with resultant bleeding, intercostal bundle trauma with bleeding, hemothorax, and insertion of chest tube into other organs (heart, liver, spleen, and so on) (Fig. 15.12). The most common complication is tube malpositioning (Fig. 15.13). With experience and proper technique and review of preprocedural imaging, these complications should be minimized.

Another unique complication is reexpansion pulmonary edema, which is related to the presence of mechanical injury to the alveolar-capillary membrane, resulting in reperfusion injury with reexpansion.[57] This may be related to the duration of the pneumothorax.[58] In the case of large, suspected long-standing pleural effusion or pneumothorax, some recommend slow reexpansion using lower suction or water seal, although it is likely the rate of reexpansion is more significant in creating lung injury than the amount of negative suction.

Key Points

1. Tube thoracostomy can be lifesaving but may be associated with serious complications. It should be performed only by experienced or adequately supervised operators.
2. The choice of the chest tube, including the size, the shape, and the insertion site, depends on the indication, the nature of the fluid to be drained, and its rate of formation.
3. Small-bore tubes are sufficient for the initial management of spontaneous and iatrogenic pneumothoraces, malignant and nonmalignant pleural effusions, parapneumonic effusions, and empyema.
4. Large-bore tubes are preferred for patients at risk for large air leak (e.g., mechanical ventilation, anastomosis dehiscence) or patients at high risk for tube obstruction (e.g., traumatic hemothorax).
5. Thoracic ultrasound should be routinely used to guide insertions of small-bore tubes.
6. In the hemodynamically unstable patient, the suspicion for tension pneumothorax should lead to immediate needle decompression followed by tube thoracostomy.
7. Blind insertion of chest tubes in patients with pleural adhesions, trapped lung, or suspected bullous disease can be dangerous. Imaging guidance with CT scan is recommended.
8. The most common complication of chest tube insertion is tube malpositioning.
9. Reexpansion pulmonary edema is a rare but serious complication, related to rapid drainage of air and fluid. Initial pleural fluid drainage should be limited to 1.5 L. Placement of the chest tube to water seal should be performed as soon as possible after tube insertion.

Review Questions

1. In a patient with a spontaneous primary pneumothorax, which of the following is incorrect?
   - **a.** A small stable pneumothorax can be treated with either needle aspiration or small-bore chest tube insertion.
   - **b.** The first intervention for tension pneumothorax with instability is tube thoracostomy.
   - **c.** Large-bore chest tubes are equivalent to small-bore chest tubes with respect to resolution of pneumothorax.
   - **d.** It is appropriate to manage some primary spontaneous pneumothoraces with supportive care and serial radiographic observation.

   Answer: b. See the "Indications for Tube Thoracostomy" section.
2. Which of the following steps is *not* involved for surgical tube thoracostomy?
   - **a.** Consent, review of imaging before the procedure, and timeout
   - **b.** Infiltration of the intercostal space as well as incision with lidocaine
   - **c.** Pleural entry into the seventh intercostal space
   - **d.** Positioning of patient's arm across body
   - **e.** Position of patient's arm with arm stretched to open the axillary angle

   Answer: c. See the "Technique of Chest Tube Insertion" section.
3. Which of the following is not a possible complication associated with tube thoracostomy insertion?
   - **a.** Splenic or hepatic laceration
   - **b.** Parenchymal injury and hemothorax
   - **c.** Reexpansion pulmonary edema
   - **d.** Inadequate drainage of fluid collection
   - **e.** Plural fluid embolus

   Answer: e. See the "Complications" section.
4. Which of the following is incorrect when choosing chest tube size?
   - **a.** If the diameter of the tube is doubled, flow increases by a factor of 16.
   - **b.** Important issues are the quality of the drained material, its formation rate, the ability of the tube to remain patent, and for all or the majority of the collection being drained to be in communication with the tube.
   - **c.** Patient safety and comfort should also be considered.
   - **d.** Small-bore tubes are not as effective as large-bore tubes for most indications.

   Answer: d. See the "Optimal Chest Tube Size for Drainage" section.
5. Which of the following statements is false with respect to removal of chest tubes?
   - **a.** At the end of expiration, the pleural and atmospheric pressure difference is minimized, decreasing the potential for "sucking air" into the pleural space.
   - **b.** At end-inspiration, the lung is fully expanded, which may aid in pleural apposition and reduction of pneumothorax after the tube is removed.
   - **c.** Chest tubes should not be removed at the end of expiration.
   - **d.** Occlusive dressings should remain in place for at least 24 hours after chest tube removal.

   Answer: c. See the "Management of the Chest Tube and Troubleshooting" section.

CHAPTER OUTLINE

Intracranial Pressure Monitoring
- Ventricular Catheter
- Fiberoptic Intracranial Pressure Monitors
- Catheter Tip Strain Gauge

Cerebral Blood Flow Monitoring

Brain Tissue Oxygenation Monitoring

Cerebral Microdialysis

Summary

Advancements in neuromonitoring techniques and improved understanding of the pathophysiology of brain injury have led to new developments in the field of neuro-critical care. This chapter reviews the fundamental tools of neuromonitoring: intracranial pressure (ICP), cerebral blood flow (CBF), brain tissue oxygenation, and cerebral microdialysis. These tools supplement the clinical neurologic examination and brain imaging in guiding patient care. Given that each tool has advantages and limitations, the choice of a single or combination monitoring strategies should be part of a rational management plan individualized for each patient.

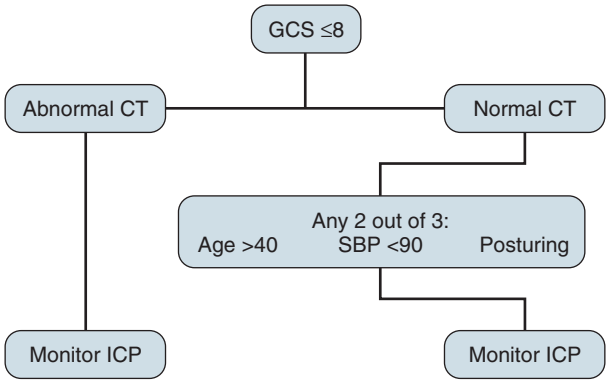
Intracranial Pressure Monitoring

The history of ICP monitoring dates to 1891, when Quincke measured the cerebrospinal fluid (CSF) pressure via a lumbar puncture.[1] Soon afterward, Cushing showed that as ICP increases and approaches systemic arterial pressure in an animal model, hypertension, bradycardia, and respiratory changes become evident.[2] The use of continuous ICP monitoring was first described by Guillaume and Janny[3] using an intraventricular catheter in 1951. Nine years later, Lundberg[4] published the first systematic observations of ICP and its response to medical and physiologic interventions. Using ventricular catheters, he showed the clinical value of direct ICP monitoring and described pressure waveforms, of which the Lundberg A wave has the most practical importance in the intensive care unit (ICU). These A, or plateau, waves were originally characterized by a steep increase in ICP to 60 to 80 mm Hg lasting 2 to 5 minutes or longer, followed by a rapid decrease to near-initial baseline pressures. This represents a pathologic response to decompensation of pressure controlling mechanisms.[4–6] Since these early investigations, CSF pressure and ICP measurement have been developed and refined further.

An ICP monitor is an invaluable research and clinical tool, contributing to the understanding of intracranial pathologic conditions and the assessment of therapeutic interventions. ICP monitoring can be used for patients with intracerebral hemorrhage, Reye syndrome, hepatic encephalopathy, encephalitis, stroke, hydrocephalus, near-drowning, and subarachnoid hemorrhage, but most of the clinical experience with ICP monitoring involves traumatic brain injury (TBI). In severe TBI, it is important to know if ICP is elevated. Early signs and symptoms of increased ICP include headache, lethargy, nausea, and vomiting. In critically ill patients, these clinical signs may be nonspecific and unreliable.[6] In addition, the positive trend toward early intubation and sedation, if not pharmacologic paralysis, eliminates the neurologic assessment of a patient with the exception of pupils. Even papilledema, a hard physical sign of increased ICP, is rarely seen acutely in patients with TBI.[7] Computed tomography (CT) is arguably the most useful diagnostic tool in patients with TBI, but may not reliably determine the ICP.

ICP monitoring in severe TBI has become routine because it facilitates rational management and provides prognostic information.[8–11] ICP monitoring can provide crucial information relative to cerebral perfusion pressure (CPP); detect the development or enlargement of a mass lesion, such as contusion or hematoma; facilitate the estimation of intracranial compliance; and be the only parameter to follow in a pharmacologically paralyzed patient, apart from the pupillary examination. It is rarely justifiable to treat a patient for intracranial hypertension empirically without a mechanism for measuring the effect of treatment, such as a clinical examination or ICP. The importance of clinical examination is highlighted by the findings of a study conducted in Bolivia and Ecuador that did not support the superiority of treatment based on ICP monitoring over treatment guided by neurologic testing and serial CT imaging in improving recovery in patients with severe TBI.[12] This study, referred to as the BEST:TRIP trial (Benchmark Evidence from South American Trials: Treatment of Intracranial Pressure), has been criticized; however, it does demonstrate the value of serial clinical examinations.[13]

There are well-defined guidelines from the Brain Trauma Foundation (BTF) for the use of ICP monitoring in TBI, which include patients with an abnormal CT scan and a Glasgow Coma Scale score of 8 or less after cardiopulmonary resuscitation. An abnormal CT scan is defined as one that reveals hematomas, contusion, edema, or compressed cisterns. It also is recommended to consider monitoring patients with severe head injuries with a Glasgow Coma Scale score of 8 or less even if the head CT scan



• **Fig. 16.1** Indications for intracranial pressure *(ICP)* monitoring. *CT,* Computed tomography; *GCS,* Glasgow Coma Scale score; *SBP,* systolic blood pressure. (From Brain Trauma Foundation, American Association of Neurological Surgeons, Joint Section on Neurotrauma and Critical Care. Management and prognosis of severe traumatic brain injury: Part I. Guidelines for the management of severe traumatic brain injury. *J Neurotrauma.* 2000;17:47–69.)

is negative if two of the following three criteria are met on admission: age older than 40 years, systolic blood pressure less than 90 mm Hg, or signs of posturing (Fig. 16.1).[14] The BTF guidelines for ICP monitoring were modified in 2016 based on the limited studies with relatively high levels of scientific evidence.[15] This approach resulted in focused conclusions limited by study design and are, therefore, carefully worded to reflect the specific methodology of the study used to support specific a recommendation, hence the level IIB recommendation for patients with TBI: ICP monitoring is recommended to reduce in-hospital and 2-week postinjury mortality. Likewise, the BTF 2016 update for monitoring CPP, important information obtained from an ICP monitor, is equally limited to a specific Level IIB recommendation for CPP monitoring to decrease 2-week mortality.[15] These limited recommendations have not changed clinical practice based on previous BTF recommendations to monitor ICP and CPP for severe TBI patients. Although ICP monitoring can be a useful tool in the ICU, this technology has limitations. It is crucial not to assign undue weight to a normal ICP if other clinical information suggests otherwise. ICP does not always increase in the presence of midline shift.[16,17] More specifically, a temporal lobe mass can herniate over the tentorial edge and cause brainstem compression without a concomitant increase in ICP.[18,19] Likewise, there is not good correlation between supratentorial and infratentorial pressures,[20] so it is imperative to remember that the condition of patients with a posterior fossa mass can deteriorate rapidly without a significant increase in ICP measured in the supratentorial compartment.[6]

ICP waveform analysis includes systolic and diastolic pressures with superimposed respiratory variation; however, the mean pressure is of practical importance. A normal adult mean ICP is 10 mm Hg or less with transient physiologic elevations above this value seen in a head-down position or during a Valsalva maneuver (see Chapter 63).[6] The Association for the Advancement of Medical Instrumentation developed standards for ICP monitoring devices that require a pressure range from 0 to 100 mm Hg, an accuracy of ±2 mm Hg in the range of 0 to 20 mm Hg, and a maximal error of 10% between 20 mm Hg and 100 mm Hg.[21] There are three basic types of contemporary, clinically useful monitoring systems: ventricular catheter, fiberoptic device, and catheter tip strain gauge.

Ventricular Catheter

A ventriculostomy is the gold standard for ICP monitoring. It can be inserted through a twist drill craniostomy at the bedside and can also be used to drain CSF or for the estimation of intracranial compliance. The catheter is connected to a fluid-filled system, which is connected to an external transducer. The transducer converts the measured pressure to an electrical signal, which provides a waveform and numerical value displayed on a monitor through a signal processor. A three-way stopcock is used to divert CSF from the monitor to a drainage bag if needed. This setup allows the catheter to be zeroed as frequently as necessary with the transducer positioned at the level of the center of the brain, which generally corresponds to the external auditory meatus. The BTF has a specific Level III recommendation stating continuous drainage of CSF may be considered to lower ICP burden more effectively than intermittent use. However, it is important to recognize that ICP cannot be accurately monitored when a standard ventricular catheter is open to drain.

This system has the potential to be contaminated and infected. The most significant risk of a ventriculostomy is infection; rates of 27% have been cited,[10,22–25] although most reported rates are in the 1% to 10% range.[24,26–29] Infection rates are similar regardless of procedure location (ICU or the operating room).[23,24,30] Tunneling the catheter subcutaneously to a distant skin exit site seems to reduce the infection risk. Other risk factors for infection include irrigation of the catheter or drainage system and the presence of intraventricular blood.[23,24,31] Duration of monitoring also may be a risk factor for infection. Some studies have found an increase in infection rates when ventriculostomies were left in place for longer than 5 days,[23,24,28] but more recent data reveal no significant reduction in infection rates when catheters were replaced before the fifth day.[32] Likewise, other investigators have found no significant relationship between duration of monitoring and rate of daily infection for 2 weeks.[33] The literature on the role of prophylactic antibiotics during external CSF drainage is also variable.[23,29,31,34] A BTF Level III recommendation discourages routine ventricular catheter exchange as well as prophylactic antibiotics for ventricular catheter placement.[35] Antibiotic-impregnated catheters have been shown to reduce infection rates[36] and are being used routinely in some centers.

Hemorrhage at the time of placement occurs about 1% to 2% of the time and only rarely needs to be surgically evacuated.[6,28,37] A more common problem with placement is difficulty in accessing small, compressed, or shifted ventricles, resulting in malposition and a poor waveform. Although a ventriculostomy is generally considered the most precise and accurate method of measuring ICP,[38] malfunction occurs if the ventriculostomy becomes clogged with air, blood, or debris, or if the ventricles are collapsed around the fenestrations in the catheter tip.

In addition to its primary use as an ICP monitor, a ventriculostomy is commonly used in the ICU as a drain for patients with TBI or hydrocephalus. Common causes of acute hydrocephalus in an adult ICU include cerebellar stroke or hemorrhage, intraventricular hemorrhage, and aneurysmal subarachnoid hemorrhage. A common and often debated concern regarding CSF drainage with a ventriculostomy is that it can cause subfalcine herniation in the presence of a hemispheric mass or upward herniation of the cerebellum in the presence of an infratentorial lesion.[39] Under these circumstances, we believe that surgical decompression of the primary mass also should be considered. Another potential risk of ventricular catheter insertion is aneurysmal rebleeding[40] after an

acute subarachnoid hemorrhage. Our group's opinion is that the benefit of treating hydrocephalus with high ICP outweighs the small, potential risk of aneurysmal rebleeding, and we have a low threshold for placing a ventriculostomy in these patients and carefully drain CSF.

If a ventriculostomy is primarily used for drainage of CSF, adequate spontaneous CSF resorption must be restored before the catheter can be safely removed. CSF resorptive capacity must be gauged according to the CSF drainage rate. Adjusting the height of the drainage system drip chamber controls the rate of external CSF drainage and the ICP that must be exceeded before drainage occurs. It can be assumed that 1 cm of CSF equals 1 cm H_2O. The height of the drip chamber is measured from the same external anatomic landmark as the ICP transducer, ranging from 0 to 20 cm (approximately 15 mm Hg) above the external auditory meatus in usual circumstances.

To reduce the amount of external CSF drainage, the drip chamber is usually raised by incremental amounts every 12 to 24 hours. As this is done, CSF resorptive mechanisms are gradually challenged. If CSF resorption is insufficient, most of the CSF continues to drain through the ventriculostomy, but if CSF resorption is sufficient, little CSF drains externally. When CSF resorption seems to be sufficient, CSF drainage is stopped, and ICP is monitored for 24 hours or more to confirm that spontaneous CSF resorption is adequate and ICP will not increase to dangerous levels. A confirmatory CT scan may also be useful.

We generally manage ventriculostomies for hydrocephalus by leaving the reservoir open to drain at a specific height above the ear and close it every hour for an ICP reading. In hydrocephalus, the ICP should never be significantly higher than the gradient the patient is draining against (i.e., the height of the drip chamber). We also specify our drainage gradient in millimeters of mercury to correlate the drip chamber to the monitor, and manually correlate the height of the CSF column in the drainage system with the monitor as a system check at least daily. A typical order may read: "leave ventriculostomy open to drain at 15 mm Hg (20 cm CSF) above the ear and monitor ICP every hour." ICP readings with the drain open are inaccurate as stated earlier, and the drainage port needs to be temporarily clamped when measuring an ICP. Likewise, the drain should be clamped and placed to monitor when changing position or during transport to avoid overdrainage, which may cause ventricular collapse and possibly subdural bleeding.

Fiberoptic Intracranial Pressure Monitors

Fiberoptic ICP monitors use miniature transducers that are coupled via fiberoptic cables to an external instrument. These monitors can be placed at the bedside through a standard twist drill craniostomy or through a smaller opening made with a 2.71-mm bit. The transducer is incorporated into the end of a tube and can be used alone or in combination with a ventriculostomy. Fiberoptic systems operate by projecting light through an optic fiber to a miniature, displaceable mirror in the catheter tip.[41] The amount of light reflected to a collecting optic fiber depends on the mechanical displacement of the mirror, which is a function of ICP. Fiberoptic devices can be inserted into the lateral ventricle, the brain parenchyma, or the subdural space. The greatest advantage of fiberoptic catheters is that they do not require fluid coupling for pressure transduction, which avoids the problems of waveform dampening and artifacts from poor coupling. Because they do not require fluid coupling, there also is less opportunity for contamination. The mechanism that does the actual pressure transduction is what is inserted into the patient; the system functions independent of head position and the monitor is zeroed once before it is placed. This feature also is a disadvantage because the transducer cannot be recalibrated to zero after insertion, although newer designs do not require zeroing. System accuracy compared with a ventriculostomy has been shown in the subdural space, brain parenchyma, and ventricles, although the parenchymal fiberoptic pressures may consistently exceed ventriculostomy pressures by nearly 10 mm Hg.[42–44] The fiberoptic device has an average daily drift of ±0.6 mm Hg. Over a 5-day period, there is an average drift of 2.1 mm Hg with a maximal drift of ±6 mm Hg. This drift over time may be enough to necessitate replacement if ICP monitoring is required for more than 5 days.[6,44,45]

Complications with the use of fiberoptic catheters relating to hemorrhage[46,47] and infection[46] have been reported, but our experience is that clinically relevant problems are unusual, particularly with intraparenchymal monitors. We do exercise caution, however, in patients with coagulopathy.

Catheter Tip Strain Gauge

The catheter tip strain gauge consists of a miniaturized solid-state pressure sensor mounted in a titanium case at the tip of a long, thin, flexible nylon tube. The transducer tip contains a silicon microchip with diffuse piezoresistive strain gauges that connect to tiny wires that travel the length of the tube. This is a small wire with a diameter of 1.2 mm that can be placed at the bedside. It can be incorporated into a ventricular catheter and used in any intracranial space. This device is accurate with a low daily drift range between −0.125 mm Hg and ±0.110 mm Hg. It shares many of the advantages and disadvantages of fiberoptic devices.[6,48,49]

Cerebral Blood Flow Monitoring

The primary objective concerning the ICU management of patients with brain injuries is the prevention and management of secondary injury in an effort to prevent ischemia. We typically monitor ICP and mean arterial blood pressure continuously, which allows us to calculate CPP; CPP = MAP − ICP, where MAP is mean arterial pressure. Under normal circumstances, knowing the CPP allows a good estimation of CBF, which is a more direct measure of blood supply to the brain. In head injury, the relationship between CPP and CBF is less predictable owing to local injury or to disruption of natural mechanisms of autoregulation. An ideal intracranial monitor would provide direct, continuous measurements of regional and global CBF at the bedside.

Measuring CBF outside the ICU began with Kety and Schmidt in 1948 and more recently has been done with xenon-enhanced CT,[50,51] but these methods provide only snapshots of CBF and do not allow for continuous monitoring at the bedside.[52] Continuous monitoring techniques in the ICU are classified as direct or indirect. Direct and continuous monitoring of CBF at the bedside includes laser Doppler flowmetry and thermal diffusion.

The laser Doppler flow sensor (1.5-mm diameter), which emits a monochromatic light, is placed into the white matter through a burr hole. The sensor measures the volume or concentration of red blood cells and their velocity and generates a flow signal. Although laser Doppler flow does allow continuous measurements of perfusion, the sample volume is small (1 mm^3) and only relative changes can be determined. Laser Doppler flow provides a qualitative estimate of regional CBF displayed in arbitrary units.[53] A

quantitative estimate of regional CBF can be acquired with the thermal diffusion method.[54] With this technique, a probe with two small thermistors is inserted into the brain to measure the tissue's ability to dissipate heat, and a microprocessor converts this into CBF displayed in the standard units of mL/100 g per minute.[52]

An indirect method for measuring blood flow at the bedside is transcranial Doppler ultrasound, which measures mean blood flow velocity in the basal cerebral vessels.[55] Although not equivalent to volume flow, changes in CBF can be inferred from changes in blood flow velocity.[56] Continuous transcranial Doppler monitoring is still cumbersome, however, because of problems of probe fixation to the head and computer interfacing.[52] Another indirect way of continuously monitoring CBF at the bedside is by measuring jugular venous bulb oxygenation.

Normal mean CBF is approximately 55 mL/100 g per minute with higher flow in the gray matter and lower flow in the white matter. When hemoglobin is fully saturated with oxygen, arterial blood carries approximately 20 mL of oxygen per deciliter to the brain. The oxygen content of venous blood draining the brain varies and depends primarily on how much oxygen the brain extracts. Normal internal jugular hemoglobin oxygen saturation ranges from 55% to 69%, and the normal difference between the arterial and jugular venous oxygen content (arteriojugular difference [$AJDO_2$]) is 6.3 ± 2.4 mL/dL. Stated differently, under normal circumstances, the brain extracts 6.3 ± 2.4 mL/dL of oxygen from the arterial blood to meet the metabolic needs of the brain.

Normally, the cerebral metabolic rate of oxygen ($CMRO_2$) is coupled to CBF; as demand increases, supply increases, and vice versa. In head injury, there may be a problem with supply (i.e., CBF may be compromised). If there is inadequate CBF to meet the metabolic demands of the brain, more oxygen is extracted from the available blood. Under this circumstance, the difference between blood going into the brain and blood coming out of the brain increases; $AJDO_2$ increases as the oxygen saturation in the jugular vein decreases.

$AJDO_2$ is proportional to $CMRO_2$ or inversely proportional to CBF or both.[57–60] Assuming that the $CMRO_2$ is constant, an increase in the amount of oxygen extraction—as reflected by a decrease in jugular oxygen saturation (increased $AJDO_2$)—implies that CBF has been compromised. Conversely, if $AJDO_2$ decreases and metabolism remains constant, we can infer an increase in CBF (i.e., hyperemia). Measuring jugular bulb oxygen can be a useful way to monitor a patient who requires hyperventilation for ICP control (see Chapter 63). Hyperventilation is a powerful tool for reducing ICP and enhancing CPP, but at the expense of increasing cerebrovascular resistance, with the consequent reduction of blood in the brain. The goal of treatment is to prevent ischemia, the ultimate and proximate cause of secondary injury. There is an obvious conflict when attempting to prevent ischemia by reducing the amount of blood delivered to the brain. $AJDO_2$ is sensitive to changes in cerebrovascular resistance; jugular vein monitoring may reveal inappropriate reductions of CBF as a result of hyperventilation.[57]

Most of the data concerning jugular bulb monitoring come from the trauma literature. In a prospective study of 353 patients with severe TBI, Cruz[61] found that outcome at 6 months was significantly better in the patients who had monitoring and management of cerebral extraction of oxygen along with CPP compared with the patients undergoing monitoring and management of CPP alone.

Increased $AJDO_2$ also can be detected during the early phases of head injury when CBF is pathologically reduced. Typically, the patient is being rescued at the scene, transported, and has triage during this early phase of injury, when CBF is low and ventilation is not carefully titrated. Hyperventilation is frequently used during this vulnerable period, often empirically and sometimes inadvertently.[57,62] Complicating this scenario is superimposed hypotension and hypoxia, which can occur during the early phases of resuscitation and later in the ICU.[63–65] Despite its usefulness, there are significant limitations to this monitoring technique. Measurements can be done by intermittent sampling, which is accurate but is limited by intermittent information, or continuous monitoring of oxygen saturation using fiberoptic catheters, which require careful maintenance and have reliability issues.[58,66]

It is easier to use the oxygen saturation of the venous blood in the jugular, rather than direct measurements of oxygen content, but because the percentage of oxygen saturation in the jugular bulb depends on hemoglobin concentration, it cannot be used independently for estimating the relationship between $CMRO_2$ and CBF. If the patient is anemic, more oxygen may be extracted from the available blood, even under conditions of normal CBF. When measuring oxygen saturation, $AJDO_2$ needs to be calculated, taking the hemoglobin concentration into consideration. Also, $AJDO_2$ is an overall estimate of the global relationship between CBF and $CMRO_2$ and cannot differentiate focal abnormalities. In addition, there is a limit to how much oxygen can be extracted from the available blood. If maximal extraction is reached and CBF continues to deteriorate, the $AJDO_2$ does not continue to increase. Under this circumstance, $AJDO_2$ appears stable despite a progressively worsening situation. Other pitfalls in monitoring $AJDO_2$ are observed under conditions in which oxygen extraction itself is impaired, such as in cases of mitochondrial dysfunction or a large stroke in which oxygen is not extracted at all.[57]

Several important technical factors are associated with $AJDO_2$ monitoring. The side chosen (right or left jugular bulb) for monitoring is important and can be affected by the side of the brain with the most injury regardless of whether it is the side of dominant venous drainage.[67–69] How high the tip of the catheter is positioned is another consideration and requires x-ray confirmation.[70] The speed at which samples are drawn also may affect the results.[71] Complications are uncommon and include carotid puncture[58,72] and subclinical internal jugular vein thrombosis.[72]

Ultimately, jugular bulb monitoring is geared toward the assessment of global CBF and cerebral oxygenation and can be useful in guiding therapeutic hyperventilation.[73,74] In severe TBI, there is enough evidence to recommend its use for titrating the level of hyperventilation[75]; however, some clinicians find jugular bulb monitoring to be cumbersome, to be prone to artifact, and to have other potential problems with poor data quality.[76–78] Because of all the problems involved with this technique, monitoring of $AJDO_2$ has not been universally accepted as a useful tool in the routine management of patients with head injuries, and the BTF 2016 update classifies the evidence for its support as Level III: "Jugular bulb monitoring of arteriovenous oxygen content difference ($AVDO_2$), as a source of information for management decisions, may be considered to reduce mortality and improve outcomes at 3 and 6 months post-injury."

Brain Tissue Oxygenation Monitoring

Brain tissue oxygen tension ($PbrO_2$) can be directly measured using a small flexible microcatheter (<0.5 mm in diameter) that is usually inserted into the frontal white matter and fixed onto a special bolt. The normal $PbrO_2$ is approximately 40 mm Hg.[79–83] Cerebral oxygen tension is generally reflective of CBF and local

oxygen extraction. In this sense, $PbrO_2$ may represent the "pool of oxygen" in brain tissue.[52,84,85] Changes in $PbrO_2$ can be used to monitor evolving disturbances of tissue metabolism.[76,86–88]

Ischemic damage seems to correlate to a $PbrO_2$ less than 8 to 10 mm Hg as measured by a Licox catheter (Integra Neuro Sciences, Plainsboro, NJ).[76] A systematic review of the literature on $PbrO_2$ monitoring found a total of 5676 patients across 6 studies where outcome measures, including mortality, Glasgow Outcome Scale, and Functional Independence Measure (FIM), at various time points showed inconsistent data to support the routine use of $PbrO_2$.[15] If $PbrO_2$ is being monitored, we recommend using it in conjunction with ICP and CPP monitoring and to set the threshold for intervention at $PbrO_2$ of 20 to 25 mmHg.

Local cerebral hypoxia in the presence of normal ICP, CPP, and mean blood pressure may be caused by insufficient arterial oxygenation,[86] a mismatch between supply (CBF) and demand ($CMRO_2$),[89] or hyperventilation-induced hypocapnia.[86,90] Hyperventilation can decrease $PbrO_2$ because of decreased CBF, which can negate the perceived benefit of improving ICP and CPP.[76,87,90–96] Hyperventilation has a particular risk of causing cerebral hypoxia when the partial pressure of carbon dioxide is less than or equal to 30 mm Hg, or within the first 24 hours[92,93] because of a further reduction of an already reduced CBF.[97] $PbrO_2$ has been shown not to be independently influenced by increases in CPP greater than 60 mm Hg,[78,87,96] which supports more recent evidence suggesting that maintaining a CPP greater than 60 mm Hg may be unnecessary,[98,99] and is consistent with current guidelines to keep CPP in the range of 60 to 70 mm Hg in severe TBI.[15]

When strategically placed, these monitors can detect local tissue hypoxia at the tip of the probe. An inherent problem with this technique (as with all focal monitors) is that placement of the probe into the area of interest becomes important.[52] There are rational arguments as to the best region to monitor. $PbrO_2$ values close to a contusion are smaller relative to a region that looks normal on a CT scan.[100] Some authors recommend monitoring the zone surrounding a contusion because of its high risk of tissue death. Other authors place the probes in uninjured brain with the idea being that a reduction in the $PbrO_2$ in the uninjured hemisphere is reflecting a diffuse decrease in arterial oxygenation, an increase in ICP, a decrease in CPP, overaggressive hyperventilation, or some other global event.[76]

Cerebral Microdialysis

Microdialysis is an established research tool to study the chemical composition of tissue extracellular fluids. The technology has been adapted for clinical use and to measure the extracellular concentration of standard neurochemicals at the insertion site within the brain tissue. This is achieved by the insertion of a double-lumen microcatheter fitted with a semipermeable membrane at the tip into or near the area of injured brain. Artificial CSF perfusate is pumped through the perfusion lumen at a standard rate of 0.3 μL/min and passes along the inside of the semipermeable membrane at the catheter tip. The chemical substances diffuse across the membrane according to their concentration gradient and the dialysate fluid is collected from the microdialysis catheter at a constant rate for analysis. Sampling can be done at 20-minute to 1-hour intervals. The concentration of extracellular glucose, lactate, pyruvate, glycerol, or glutamate can be measured from the dialysate at the bedside or in the laboratory, and lactate:pyruvate ratio (LPR) is a helpful calculation to estimate ischemia. The technology can also measure the concentration of other substances, such as proteins, cytokines, antibiotics, or drugs.[101] The normal value range for these substances are glucose ~2 mM, lactate ~2 mM, pyruvate ~120 μM, LPR 15 to 20, glycerol ~20 μM, and glutamate less than 10 μM.

Glucose levels should be interpreted in association with serum glucose levels. In the setting of ischemia or decreased cerebral perfusion, the **microdialysis** glucose (MD-glucose) level is low, the MD-lactate level is high, the LPR is high, and the MD-glutamate and MD-glycerol levels are also elevated owing to cell toxicity and destruction, respectively.

Microdialysis is a powerful research and clinical tool; however, its use has been limited to academic centers, and high-level evidence to support its use or correlate it with improved outcome is lacking.[15]

Summary

Most intracranial monitoring techniques are used for circumstances involving increased ICP, which has proven to be useful, reliable, and straightforward. As such, ICP and CPP monitoring has become a standard of care and both are widely used. It is much more difficult to obtain continuous, clinically useful information with CBF monitoring methods, and these methods have found limited use outside academic institutions. Newer advanced neuromonitoring techniques such as brain tissue oxygen monitoring and cerebral microdialysis are promising; however, evidence to justify their widespread use and impact on outcomes remains to be seen.

Key Points

- The primary objective concerning ICU management of patients with brain injuries is the prevention and management of secondary injury in an effort to prevent ischemia.
- ICP monitoring should be considered for patients with TBI and a Glasgow Coma Scale score of 8 or less.
- ICP monitoring in severe TBI has become routine because it facilitates rational management and provides prognostic information.
- It is crucial not to assign undue weight to a normal ICP if other clinical information suggests otherwise.
- A normal adult mean ICP is 10 mm Hg or less with transient physiologic elevations above this value, and normal CPP is generally 60 to 80 mm Hg.
- Ventriculostomies and fiberoptic intraparenchymal monitors are the mainstays of ICP monitoring devices.
- Local cerebral hypoxia in the presence of normal ICP, CPP, and mean blood pressure may be caused by insufficient arterial oxygenation, a mismatch between supply (CBF) and demand ($CMRO_2$), or hyperventilation-induced hypocapnia.
- Hyperventilation has a particular risk of causing cerebral hypoxia when the partial pressure of carbon dioxide is less than or equal to 30 mm Hg, or within the first 24 hours.
- Maintain CPP in the range of 60 to 70 mm Hg in severe TBI.

Review Questions

1. Which of the following statements regarding fiberoptic intracranial pressure (ICP) monitors and ventriculostomies is most correct?

a. Either device allows drainage of CSF.
b. The infection rates are equal in both devices.
c. The drift in measurements is equal in both.
d. Ventriculostomy is considered the gold standard for ICP monitoring.

Answer: d. Ventriculostomy is considered the gold standard for ICP monitoring and, in addition to measuring ICP, it allows for cerebral spinal fluid (CSF) drainage as an intervention to lower ICP. There is, however, a slightly higher risk of infection associated with ventriculostomy. Therefore a protocol for infection control should be in place for intravenous antibiotics before insertion, externalizing the drain 5 cm from the insertion site and the use of antibiotic-impregnated catheters are all measures that lower infection rate. The fiberoptic ICP monitor has the potential for drift (±0.6 mm Hg/day) and therefore the ICP measurements could become inaccurate after several days of insertion.

2. Which one of the following statements is most correct?

a. CPP (cerebral perfusion pressure) = MAP (mean arterial pressure) − ICP (intracranial pressure).
b. CBF (cerebral blood flow) can be accurately inferred from CPP despite brain injury.
c. The 2016 Brain Trauma Foundation guidelines for traumatic brain injury management recommend maintaining a CPP of 80 to 90 mm Hg.
d. Local brain swelling increases blood flow in that area.

Answer: d. The CPP is measured by subtracting the ICP from the MAP: CPP = MAP − ICP. CBF can be inferred from the CPP in the normal physiologic state. However, in the setting of brain injury when autoregulation is impaired, the CBF could be significantly increased for a given CPP or it could be decreased in the setting of local swelling or injury. The 2016 Brain Trauma Foundation recommendations are to maintain CPP of 60 to 70 mm Hg.

3. In a 26-year-old patient with severe head injury and a Glasgow Coma Scale score of 7, an emergent computed tomography scan showed blossoming contusions in the left frontal and temporal lobes with uncal herniation, and he received emergent left craniectomy. He now has a right-sided ventriculostomy. Which of the following statements is correct?

a. The ICP waves may be dampened or lose their triphasic character.
b. In the setting of craniectomy, we can accept higher ICP measurements before intervention.
c. The swelling over the craniectomy site is a reliable indicator of the ICP.
d. The risk of ventriculostomy site infection is high in this setting, and continuous prophylactic antibiotics should be given.

Answer: a. In the setting of craniectomy the ICP waves may be dampened or may lose the characteristic triphasic wave appearance. The mean ICP values, however, are useful in assessing the ICP and can guide management. ICP and CPP management protocols do not change after craniectomy, and high ICPs should be managed accordingly. The scalp and soft tissues over the craniectomy site can swell after surgery, and swelling in itself is not a reliable indicator of increased ICP. There is currently no evidence to support continued prophylactic antibiotics use to prevent ventriculostomy site infection.

Endoscopic Ultrasound
Endoscopy in the Pregnant Patient

History

The first gastroscopy procedure was performed in 1868 by German physician Adolph Kussmaul, with passage of a rigid metal tube down a patient's esophagus into the stomach. In 1932, Rudolph Schindler, in collaboration with a German engineer, Georg Wolff, developed a semiflexible instrument with a flexible distal shaft. Although this device was hailed as the first safe, workable gastroscope, it was not without limitation, including incomplete visualization of the esophagus and stomach, patient discomfort, and absence of photographic capability.[1,2] Fiberoptics were introduced into the endoscope in 1957 by Basil Hirschowitz, and in the 1960s and 1970s advancements were made with endoscope length, improved visualization, and greater control. Video cameras and monitors were subsequently incorporated into endoscopic technology, allowing others to view what was previously available only to the endoscopist.

Early experience with rigid and semiflexible proctosigmoidoscopes and colonoscopes was disappointing owing to the tortuous nature of the left colon, and early fiberoptic instruments fared no better. Bergein Overholt made adjustments in torque and control to develop a prototype flexible fiberoptic instrument in 1963.[3] The first total colonoscopy was performed in Sardinia, Italy, in 1965. Luciano Provenzale and Antonio Revignas instructed a patient to swallow a piece of polyvinyl tubing, which ultimately emerged from the anus. They attached a side-viewing gastroscope and gently pulled it through the entire colon to the cecum.[3] Further refinements were achieved in England, the United States, and Japan, and in 1969 Hiromi Shinya performed the first polypectomy, removing a 1.5-cm pedunculated polyp from the sigmoid colon of a 70-year-old Chinese gentleman.[4] Subsequently, colonoscopy has become a routine procedure performed by gastroenterologists and other health care providers.

Endoscopic cannulation of the duodenal ampulla was first accomplished in Chicago by William S. McCune and colleagues in 1968 and is considered the first reported case of endoscopic retrograde cholangiopancreatography (ERCP).[5] Sphincterotomy was initially performed in 1974, facilitating removal of common bile duct stones[6] and ushering in a new era of therapeutic pancreaticobiliary endoscopy.

The first transrectal ultrasound examination was performed by physician John Julian Wild and electrical engineer John Reid in 1956, when they developed the ultrasound probe.[7] The incorporation of ultrasound into a standard endoscope occurred in 1976, when Lutz and Rosch passed an ultrasound probe through the accessory port of an endoscope. Further improvements were achieved by Strohm and colleagues and Eugene DiMagno and coworkers, who introduced their own prototype echoendoscopes in 1980.[8] The first endoscopic ultrasound (EUS)-guided fine-needle aspiration was performed on a submucosal gastric lesion in 1991 by Giancarlo Caletti.[8]

Novel innovative endoscopic techniques continue to expand the field of gastroenterology. Peroral endoscopic myomoty was the first endoscopic procedure to go beyond the gastrointestinal (GI) lumen for therapeutic intervention. This was first performed by Inoue et al. in 2008 in Japan to treat severe achalasia. In 2010, Santiago Horgan continued the trend of extraluminal therapy by removing a gallbladder transorally using natural orifice transluminal endoscopic surgery.[8a] Endoscopic bariatric therapy is providing adjunctive therapy for obesity treatment, starting with transoral gastroplasty in 2008 by Eagon and Jonnalagadda in the United States.[8b] Development of antiobesity therapies are continuing to blur the lines between traditional surgical bariatric and endoscopic modalities.[9]

Endoscopic Equipment

Today's endoscopes have a control section that is grasped with the left hand to allow for scope control and passage of therapeutic instruments. An insertion tube extends from the bottom of the control section and is grasped with the right hand and inserted into the patient. Buttons on the control section allow for suction, insufflation, and washing of the lens. Channel ports distal to the hand controls on the control section allow for the passage of various accessories. Four-way tip deflection is accomplished through manipulation of control knobs, which are attached to a series of

TABLE 17.1 Levels of Sedation and Anesthesia

Anesthesia Management Component	Minimal Sedation (Anxiolysis)	Moderate Sedation (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation	Purposeful response after repeated or painful stimulation	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

Adapted from American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists. Practice guidelines for sedation and analgesia by non-anesthesiologists. *Anesthesiology.* 2002;96:1004–1017.

cables that run the length of the insertion tube. The distal end of all endoscopes contains lenses for imaging and channel openings for air, water, suction, and passage of instruments.

EUS equipment differs from that of standard endoscopes in that an ultrasound transducer is incorporated into the distal end of the insertion tube. The transducer emits sound waves that are directed at adjacent tissues that deflect different acoustic qualities back to the transducer. Radial and linear echoendoscopes are currently available. Interventional procedures, such as fine-needle aspiration, therapeutic injections, placement of radiopaque markers to guide radiotherapy, as well as stent deployment, may be performed safely.[10]

All video endoscopes have an image sensor called a charge-coupled device (CCD) mounted at the tip of the endoscope, which transmits an image to a video processor for display. Advances in CCD technology have resulted in the current high-resolution or high-definition endoscopes, which produce signal image resolutions that range from 850,000 pixels to more than 1 million pixels, allowing for detailed inspection of the GI mucosa.[11]

The wireless video capsule is a small disposable unit containing a small camera, short focal length lens, light source, two batteries, and a radio telemetry transmitter.[12] There are presently three types of video capsules: an esophagus-specific capsule incorporating two CCD chips oriented at 180 degrees, a small bowel video capsule using a single CCD chip with an 8-hour battery capacity, and experimental colonic video capsules. Two to six frames per second are captured by the small bowel camera and transmitted to a data recorder that is carried by the patient. The colonic video capsule can record up to 35 frames per second with a battery life of 10 hours or longer. Data are downloaded from the recorder to a personal computer and interpreted. Handheld devices have also been developed to allow real-time monitoring of video capsule images.

Anesthesia

The choice of anesthesia is based on the patient profile, the endoscopic procedure, and the preference of the endoscopist, anesthesiologist, and patient. Essential patient information includes prior adverse events from anesthesia, current medications, pertinent medical history, cardiopulmonary status, age, allergies, body habitus, and social history. Patients with alcohol or narcotic dependency may require high doses of opiates and benzodiazepines. Agents such as propofol may facilitate their sedation. Pregnancy should be excluded in any woman of childbearing age. The level of sedation required depends on the endoscopic procedure and expected length of time necessary to complete it. Flexible sigmoidoscopy and esophagogastroduodenoscopy (EGD) may require minimal or moderate sedation, whereas more complex and lengthier procedures, such as ERCP and EUS, may require deep sedation or even general anesthesia. Table 17.1 illustrates the different depths of sedation as defined by The American Society of Anesthesiologists Task Force.[13]

Regardless of the type of sedation, cardiopulmonary status should be monitored at all times. Standard equipment should include a pulse oximeter, continuous electrocardiogram, and cyclical blood pressure monitoring. Personnel trained in airway support should always be present. The cardiopulmonary complication rate is 0.005% for EGD and 0.01% for colonoscopy.[14]

Four medication classes are commonly used during endoscopic procedures: pharyngeal topical anesthesia, benzodiazepines, opiates, and propofol. Pharyngeal anesthetics, such as lidocaine, benzocaine, and tetracaine, are used to suppress the gag reflex during upper GI tract procedures. These agents, applied by spray or gargling, are active for approximately 1 hour. Potential risks include aspiration owing to loss of gag reflex and, rarely, methemoglobinemia.[15]

Benzodiazepines, such as midazolam and diazepam, are used to induce relaxation and amnesia by binding to receptors of the postsynaptic gamma-aminobutyric acid neurons. Both have similar properties, with the latter possessing a longer half-life and milder amnestic properties.[16] Onset of action occurs in 1 to 2.5 minutes with intravenous midazolam and 8 minutes with diazepam.[17] Adverse reactions include respiratory depression and hypotension. Overdoses can be reversed with flumazenil, although caution should be used because seizures secondary to acute withdrawal may occur.

Opiates such as fentanyl and meperidine are used for analgesia and sedation. A synergistic effect occurs when opiates are given concurrently with intravenous benzodiazepines. Fentanyl has a rapid onset (1.5 minutes) with a short duration of action (0.5–1 hour), whereas meperidine has an onset of 5 minutes and lasts 3 to 5 hours.[17] Common adverse reactions include respiratory depression, hypotension, constipation, nausea, and vomiting. Overdosage can be reversed with naloxone, an opioid antagonist. Long-term opiate users may experience acute withdrawal symptoms with naloxone. Serotonin syndrome may occur if monoamine oxidase inhibitors are used with meperidine.

Propofol, an ultrashort-acting anesthetic agent, has been increasingly used in recent years.[18] Propofol has a rapid onset of action, deeper level of sedation, and more rapid recovery time compared with narcotics and benzodiazepines.[19] Propofol use during

• BOX 17.1 Indications for Esophagogastroduodenoscopy

Persistent upper abdominal symptoms despite appropriate therapy
Upper abdominal symptoms associated with signs or symptoms suggesting serious organic disease (anorexia, weight loss) or new-onset symptoms in patients older than 50 years of age
Dysphagia or odynophagia
Esophageal reflux symptoms (persistent or recurrent despite appropriate therapy)
Persistent vomiting of unknown cause
Familial adenomatous polyposis syndromes
Confirmation and specific histologic diagnosis of radiologically shown lesions
  Suspected neoplastic lesions
  Gastric or esophageal ulcer
  Upper tract stricture or obstruction
Gastrointestinal bleeding
  Active or recent bleed
  Suspected bleed (chronic blood loss, iron deficiency anemia)
Sampling of tissue or fluid
Documentation or treatment of varices (banding, sclerotherapy)
Assessment of acute injury after caustic ingestion
Treatment of bleeding lesions such as ulcers, tumors, vascular abnormalities (electrocoagulation, heater probe, laser photocoagulation, injection therapy)
Removal of foreign bodies
Removal of selected polypoid lesions
Dilation of stenotic lesions
Placement of feeding or drainage tubes (percutaneous endoscopic gastrostomy, percutaneous endoscopic jejunostomy)
Management of achalasia (botulinum toxin, balloon dilation)
Palliative treatment of neoplasms (laser, multipolar electrocoagulation, stent placement)
Surveillance for malignancy in patients with premalignant conditions (Barrett esophagus)

Adapted from ASGE Standards of Practice Committee, Early DS, Ben-Menahem T, et al. Appropriate use of gastrointestinal endoscopy. Gastrointest Endosc. *2012;75:1127–1131.*

• BOX 17.2 Contraindications to Esophagogastroduodenoscopy

Risk to patient's health or life judged to outweigh most favorable benefits of procedure
Conditions in which adequate patient cooperation or consent cannot be obtained
Perforated viscus—known or suspected

Adapted from ASGE Standards of Practice Committee, Early DS, Ben-Menahem T, et al. Appropriate use of gastrointestinal endoscopy. Gastrointest Endosc. *2012;75:1127–1131.*

colonoscopy may carry a lower risk of cardiopulmonary complications compared with traditional agents.[20] Controversy exists as to its cost-effectiveness and the requirement that it be administered exclusively under the supervision of an anesthesiologist.

Esophagogastroduodenoscopy

EGD is one of the most commonly performed procedures in the world and has become the primary tool for evaluating the esophagus, stomach, and proximal duodenum. EGD is performed for a wide variety of indications and has both diagnostic and therapeutic roles (Box 17.1). There are relatively few contraindications to upper endoscopy (Box 17.2).

EGD is a safe procedure. Perforation occurs in approximately 0.04% of diagnostic endoscopies and up to 10% with therapeutic interventions, including dilation and endoscopic mucosal resection.[21] Clinically significant bleeding is a rare adverse event and may occur as a result of Mallory-Weiss tear, cautery injury, sclerotherapy injection, and after biopsy or polypectomy.

Before undergoing elective EGD, patients should be fasting for at least 6 hours. Motility agents, such as erythromycin, may be beneficial in clearing the stomach of blood or food.[22] In situations of possible airway compromise, elective intubation is reasonable. In a meta-analysis evaluating prophylactic intubation before endoscopy for upper GI bleeding, there was a higher rate of aspiration, pneumonia, and hospital length of stay in the intubated patients group.[23] Without published guidelines to direct use of endotracheal intubation in this group of patients, it is important to weight the risks and benefits of intubation for individual cases. Alternatives to intubation may include pre-endoscopy lavage, overtube placement, or the use of large-caliber endoscopes for suction.

Before administration of anesthesia, patients should be in the left lateral position, with the head elevated and supported by a pillow. Monitoring devices for vital signs, electrocardiogram, and pulse oximetry are attached, supplemental oxygen should be administered, and a bite guard should be placed in the mouth.

In addition to diagnostic capabilities, therapeutic interventions may be performed during upper endoscopy, particularly in the setting of GI hemorrhage. Several modalities are available for treating GI bleeding, including thermal cautery, electrocautery, needle injection, rubber band ligation, mechanical clips, laser therapy, argon plasma coagulation, and tissue adhesives.

Thermal cautery probes deliver predetermined pulses of heat (250°C) to an endoscopic catheter tip, which is transferred to tissue on contact.[24] Thermal probe coagulation can be applied to peptic ulcers, vascular lesions, and Mallory-Weiss tears. Another option for contact thermal coagulation is monopolar or bipolar electrocautery. With electrocautery, electrical current flows from electrode tip through contacted tissue. Monopolar cautery requires attaching an electrical ground to the patient and may cause burn injuries and tissue stickiness. Monopolar cautery is typically not used for hemostasis, but serves a role in snare polypectomy. Bipolar cautery consists of two active electrodes incorporated into a single catheter probe, allowing electrical current to pass from one electrode through the tissue and back to the other electrode. Consequently, bipolar cauterization allows for improved control of coagulation depth.

Injection therapy for nonvariceal and variceal bleeding is performed with sclerotherapy injector needles. Solutions commonly used are epinephrine in saline solution (1:10,000) and sclerosing agents, such as polidocanol and ethanolamine. Epinephrine reduces bleeding by vasoconstriction, vessel tamponade, and platelet aggregation.[25,26] The potential exists for systemic side effects from submucosal injections as plasma epinephrine levels can transiently increase four to five times above basal levels.[27] Sclerosing agents achieve hemostasis through inflammation and sclerosis and have been used in peptic ulcer hemorrhage and variceal bleeding. Mediastinitis, perforation, stricture formation, and infection are among reported complications.[28]

Injector needles are also used in nonbleeding situations. Polyps and superficial mucosal lesions can be raised with submucosal injection of saline solution, epinephrine, or osmotic agents before polypectomy. This technique reduces the likelihood of

postpolypectomy hemorrhage or perforation.[29] Lesions requiring surgery can be tattooed with ink to facilitate localization by the surgeon.

Rubber band ligation is an effective tool for hemostasis. The delivery system is loaded onto the endoscope tip, and current models allow for deployment of multiple rubber bands before reloading. For variceal bleeding, endoscopic variceal ligation has become the treatment of choice and is superior to endoscopic sclerotherapy in speed of variceal eradication, decreased risk of recurrent bleeding, and fewer complications.[30] Endoscopic banding may be used to treat gastric varices, bleeding peptic ulcers, Dieulafoy lesions, postpolypectomy hemorrhage, and internal hemorrhoids.

Metal clips, or endoclips, have been used successfully for GI bleeding,[31] closure of perforations,[32] anastomotic leaks,[33] and prevention of postpolypectomy hemorrhage.[34] The potential for significant tissue injury is small as only the mucosal and submucosal layers are involved in the grasping.[35] The procedure may be technically challenging if massive bleeding is present, or the angle of approach is tangential to the target lesion.[36]

Laser therapy, using neodymium:yttrium-aluminum-garnet (Nd:YAG) or argon, is delivered through probes passed via the endoscope to treat bleeding lesions and for tumor ablation. Nd:YAG and argon lasers differ in the width and depth of tissue effect, with the former having the greater effect.[37] Advantages of laser therapy include improved accuracy and no requirement of direct contact with the desired target.

Argon plasma coagulation is a noncontact method of hemostasis that delivers argon gas through a catheter probe. The argon gas is ionized, delivering thermal energy to adjacent target tissue. Large areas and tissue not in direct view, owing to the tangential arcing nature of the argon gas, can be treated rapidly. Clinical uses include adjunctive ablative therapy after piecemeal resection of colonic polyps, radiation proctopathy, GI vascular lesions, bleeding peptic ulcers, Barrett esophagus ablation, and palliation of GI malignancies.[38,39]

Tissue adhesives constitute a newer class of agents for GI hemostasis. The major types of tissue adhesives are fibrin sealants and cyanoacrylate. Fibrin sealants form a coagulum through the interaction of fibrinogen, factor XIII, and thrombin.[40] Extensively used in the surgical fields for tissue adhesion, hemostasis, and wound care, fibrin sealants have been used endoscopically in bleeding peptic ulcers,[41] variceal bleeding,[42] and for closure of GI fistulas.[43] Cyanoacrylate is synthetic glue that rapidly polymerizes into a solid complex when in contact with water or blood.[44] Cyanoacrylate has been successfully used for ablation of esophageal and gastric varices.[45,46] Serious complications of tissue adhesives include embolization and infarction.[47]

In addition to hemostasis, upper endoscopy is routinely used for other therapeutic situations. Foreign object ingestion and food bolus impaction occur commonly. Although most esophageal foreign bodies pass spontaneously, up to 20% of cases may require endoscopic intervention. Various types of endoscopy, ranging from rigid to flexible, and equipment (Box 17.3) are available for foreign body retrieval. An overtube is available for airway protection and frequent esophageal intubations. Retrieval should be performed within 24 hours or more urgently if the ingested object is sharp, is a disc battery, or is causing the patient pain or difficulty in handling secretions. If it is not possible to remove the object endoscopically and it is less than 2.5 cm, the object can be gently maneuvered into the stomach, from which spontaneous passage usually occurs.[48] Unsuccessful removal or obstruction requires surgical evaluation.

Esophageal narrowing is a common reason for recurrent food impaction. Narrowing may occur from benign conditions, such as peptic strictures, Schatzki rings, eosinophilic esophagitis, or malignancy affecting luminal diameter. Endoscopic dilation can be performed on anatomic narrowings of the esophagus, pylorus, and anastomotic strictures. Four types of dilators are currently available: tip-weighted push bougies (Maloney or Hurst), wire-guided dilators (Savary-Gilliard or American), through-the-scope dilating balloons, and clear optical dilators that allow direct endoscopic visualization. Dilation is indicated in patients with achalasia, although recurrence is common, and clinical efficacy is decreased with subsequent dilations.[49] In general, endoscopic dilation increases the risk of perforation, with reported rates between 0.1% and 0.4%.[50]

Endoscopic stenting with endoprosthesis can be performed in a wide variety of clinical scenarios. Stenting is performed for fistula closure, anastomotic leaks,[51] malignant and nonmalignant perforations.[52,53] In addition, malignant obstructive lesions of the esophagus, stomach, duodenum, and colon can be stented for palliation or preoperative dilation. Stents vary in size, material (plastic or metal mesh), and by the presence or absence of a covering. Complications include increased reflux if the gastroesophageal junction is involved, bleeding, perforation, and stent migration.

Radiofrequency ablation of the distal esophagus has been developed as a treatment for low- and high-grade dysplasia in Barrett esophagus. The HALO system (Barrx Medical, Inc., Sunnyvale, CA) consists of a balloon that contains 60 separate 250-μm electrodes circumferentially oriented on its outer surface, with electrodes separated by a distance of 250 μm. Immediately adjacent electrodes function as bipolar devices that deliver heat to the mucosa at a controlled depth. Radiofrequency energy is delivered through the electrodes, which causes superficial tissue destruction circumferentially over a length of 3 cm. If focal ablation is needed, 60-degree, 90-degree, and ultralong focal ablation catheters are available.[54]

Percutaneous endoscopic gastrostomy (PEG) tube placement is a common procedure for endoscopists. The purpose of PEG tube placement is to improve quality of life, shorten hospitalization, prevent aspiration, improve nutritional and functional status, and prolong survival.[55] Controversy exists as to whether PEG tube placement is beneficial in patients with terminal anorexia-cachexia syndromes or in permanent vegetative states.[56,57] In addition to providing nutritional support, PEG placement has been used for long-term gastric decompression and recurrent gastric volvulus management. Placement is contraindicated if the anterior abdominal wall cannot be brought into contact with the anterior gastric wall, such as in morbid obesity and significant ascites. Complications,

although infrequent, include wound infection, necrotizing fasciitis, peritonitis, septicemia, peristomal leakage, device dislodgment, bowel perforation, and fistula formation.[57] Antibiotic prophylaxis is recommended for patients undergoing percutaneous feeding tube placement. Possible implantation metastasis in patients with head and neck cancer has been reported.[58] Pneumoperitoneum is seen in 40% of cases, but is usually asymptomatic and eventually resolves spontaneously.[59]

Wireless Capsule Endoscopy

Wireless video capsule endoscopy (VCE) is a safe, noninvasive method for visualizing the entire small bowel. The capsule examination typically is performed in an ambulatory setting. Preparation involves an overnight fast. Although data are conflicting, a bowel preparation has been shown to improve visualization and results in a higher rate of capsules reaching the small intestine.[60,61] Metoclopramide also may be beneficial in ensuring a complete small bowel evaluation before expiration of the battery life.[62] After swallowing the pill, the patient can leave the outpatient office, resume nonstrenuous daily activity, and eat 4 hours later. The data recorder is returned after 8 hours.

Common indications for VCE are evaluating obscure GI bleeding, suspected Crohn disease, small intestinal tumors and polyps, chronic diarrhea, malabsorption disorders, and abdominal pain.[63,64] VCE has been shown to be superior to push enteroscopy and small bowel barium radiography in detecting sources of obscure GI bleeding.[65] Superiority also was shown when VCE was compared with double-balloon enteroscopy.[66] A major limitation of VCE is the inability to perform therapeutic interventions.

Contraindications for VCE include swallowing disorders, known or suspected GI obstruction, stricture, fistula, pregnancy, and possibly cardiac pacemakers or implantable defibrillators. (Although listed as a contraindication by the manufacturer, more recent studies have shown no interference with cardiac pacemakers and implantable defibrillators by VCE.[67,68]) The capsule does not reach the cecum within recording time in 16% of cases. Abdominal x-ray study should be performed to evaluate for capsule retention, which occurs in 1.9% of all examinations, usually secondary to an anatomic abnormality, and may require endoscopic or surgical removal.[69,70] A patency system similar in size to a video capsule, but dissolvable if retained in the body, may be useful in screening high-risk patients for possible small bowel stenosis.[71] Patients with swallowing disorders or delayed gastric emptying may have the capsule endoscopically placed into the small bowel.

A variation of the small bowel video capsule exists to evaluate the esophagus. Although similar in design to the small bowel capsule, the esophageal video capsule incorporates a camera at each end, with each camera taking up to 35 frames per second for the first 10 minutes, followed by 18 frames per second for the final 80 minutes. Fasting time is only 2 hours, and the examination time is less than 1 hour. The patient ingests the pill in a supine position and is gradually raised to an upright position at 2-minute intervals. The esophageal video capsule can be used to evaluate for Barrett disease, esophageal varices, and complications of gastroesophageal reflux disease.

Enteroscopy

With increasing use of wireless capsule endoscopy, the need for direct visualization and therapeutic intervention in the small bowel is growing. Endoscopic techniques are emerging that improve visualization, allow for therapeutic intervention, and are less invasive than prior designs. The diagnostic yield of balloon endoscopy may reach 70% to 80% with histologic sampling and endoscopic therapy in more than 50% of patients.

Introduced in 2001, double-balloon enteroscopy (DBE) uses two balloons, one at the tip of an enteroscope, and the other at the end of an overtube backloaded onto the enteroscope. Using alternating inflation and deflation of the balloons during sequential advancement of the scope and the overtube, the double-balloon enteroscope is progressively advanced through the small bowel. Using both oral and anal intubation, evaluation of the entire small bowel is possible. Single-balloon enteroscopy (SBE) was introduced in 2007, and like DBE, incorporates a backloaded overtube with a balloon at the tip. Unlike the DBE, the tip of the scope is deflected to anchor the scope against the bowel wall and permit advancement of the overtube. After advancement, the balloon on the overtube can be inflated, the intestine pleated over the overtube, and the scope advanced once again. Severe complications from DBE are described in 1% to 1.7% of patients, with pancreatitis the most common (0.3%), followed by bleeding and perforation.[72] In one meta-analysis study, 622 SBE procedures were studied and only 2 perforations (0.032%) occurred with no episodes of pancreatitis.[73]

Spiral enteroscopy was developed with the potential advantages of decreased time and increased control in examining the small bowel. The enteroscope is advanced into the small bowel by continuous rotation of the raised helix-fitted overtube, which pleats the small bowel mucosa over the overtube. An inner sleeve allows the independent motion of the overtube during advancement and withdrawal.[74] Spiral enteroscopy has demonstrated a complication rate of 0.4% with perforation found to be the leading severe complication.[75]

Several studies have been performed comparing various combinations of each of the three modalities. A meta-analysis comparing SBE of 375 patients demonstrated that DBE offers deeper penetration into the small bowel.[76] There was no significant difference between DBE and SBE in therapeutic yield and complication rates. Spiral enteroscopy offers shorter procedure time when compared with balloon-assisted enteroscopy but no apparent difference in diagnostic yield.[77]

Colonoscopy

The colonoscope is used by general practitioners, surgeons, and gastroenterologists to evaluate the colon and distal ileum. A shorter version, the flexible sigmoidoscope, is available for rectum and sigmoid examination. Colonoscopy has replaced routine sigmoidoscopy and barium studies as the gold standard for large bowel evaluation. Indications range from colorectal screening and evaluation of anemia to therapeutic interventions such as polypectomy and palliative stenting (Box 17.4). Relative contraindications to colonoscopy are acute diverticulitis and suspected perforation.

Before colonoscopy, the patient should follow a clear liquid diet with subsequent fasting after bowel preparation. Several bowel preparations are commercially available, including polyethylene glycol, sodium-free polyethylene glycol, low-volume polyethylene glycol with bisacodyl, and tablet sodium phosphate.[78] Nausea, vomiting, and abdominal discomfort are common side effects among all bowel preparations. Sodium phosphate, owing to inducement of rapid volume changes, is contraindicated in patients with serum electrolyte abnormalities, advanced hepatic dysfunction, renal failure, recent myocardial infarction, unstable angina,

• BOX 17.4 Indications for Colonoscopy

Evaluation of abnormal imaging study
Evaluation of unexplained gastrointestinal bleeding
  Hematochezia
  Melena
  Presence of fecal occult blood
Unexplained iron deficiency anemia
Screening and surveillance for colonic neoplasia
Chronic inflammatory bowel disease
Clinically significant diarrhea of unexplained origin
Intraoperative identification of a lesion not apparent at surgery (polypectomy site, location of a bleeding site)
Treatment of bleeding from lesions such as vascular malformations, ulceration, neoplasia, and postpolypectomy site (electrocoagulation, heater probe, laser, or injection therapy)
Foreign body removal
Excision of polyp
Decompression of acute megacolon or sigmoid volvulus
Balloon dilation of stenotic lesions
Palliative treatment of stenosing or bleeding neoplasms (laser, electrocoagulation, stenting)
Marking a neoplasm for localization during surgery

Adapted from Adapted from ASGE Standards of Practice Committee, Early DS, Ben-Menahem T, et al. Appropriate use of gastrointestinal endoscopy. Gastrointest Endosc. *2012;75:1127–1131.*

• BOX 17.5 Indications for Endoscopic Retrograde Cholangiopancreatography

Treatment of choledocholithiasis
Treatment of biliary pancreatitis
Evaluation and treatment of recurrent pancreatitis
Evaluation and treatment of ascending cholangitis
Tissue sampling of suspected biliary and pancreatic malignancies
Diagnosis of ampullary tumors
Malignant and benign biliary stricture management (sphincterotomy, dilation, stent placement)
Photodynamic therapy
Diagnosis and treatment of biliary and pancreatic duct injury and leak
Pancreatic pseudocyst (stent)
Stent removal
Biliary manometry
Endoscopic sphincterotomy in type I sphincter of Oddi dysfunction
Endoscopic sphincterotomy in type II sphincter of Oddi dysfunction with manometry-confirmed pressure >40 mm Hg

Adapted from Adler DG, Baron TH, Davila RE, et al. ASGE guideline: the role of ERCP in diseases of the biliary tract and pancreas. Gastrointest Endosc. *2005;62:1–8.*

congestive heart failure, ileus, malabsorption, and ascites.[79] One meta-analysis demonstrated that the use of a split-dose polyethylene glycol for bowel preparation before colonoscopy significantly improved the number of satisfactory bowel preparations, increased patient compliance, and decreased nausea compared with the full-dose polyethylene glycol.[80] Inadequate bowel preparation has been attributed to failure to follow preparation instructions; later colonoscopy start time; inpatient status; procedural indication of constipation; use of tricyclic antidepressants; male gender; and history of cirrhosis, stroke, or dementia.[81] Patients undergoing flexible sigmoidoscopy usually do not require complete bowel purgation. An enema before the procedure can assist in clearing the distal colon if incomplete preparation is suspected.

Complete colonoscopic examination is achieved in approximately 94% of patients.[82] Advanced age, female gender, body mass index less than 25 kg/m^2, diverticular disease in women, and a history of constipation or reported laxative abuse in men are predictors of a technically difficult colonoscopy.[83] In general, complications from diagnostic colonoscopy are rare. Hemorrhage and perforation occur in 0.001% to 0.008% and 0.005% to 0.14% of patients, respectively.[84] Interventional procedures, such as polypectomy, can increase the risk of bleeding and perforation to 2% and 0.3%.[85] Polypectomy is one of the most common interventions during colonoscopy. Pedunculated or sessile polyps may be removed with biopsy forceps, snare cautery, or argon plasma coagulation. As noted earlier, complications may be reduced with submucosal injection of saline solution or epinephrine.

Common causes of colonic hemorrhage include diverticulosis, postpolypectomy bleeding, vascular malformations, and hemorrhoids. Diverticular and postpolypectomy bleeding may be controlled with epinephrine injection, heater probe, electrocautery, or metallic clips. Band ligation also may be effective in hemostasis of postpolypectomy bleeds. Vascular malformations may be ablated with heater probe, electrocautery, laser, argon plasma coagulation, and metallic clips. Hemorrhoidal bleeding is effectively controlled with elastic band ligation, either with a rigid proctoscope or with a flexible video endoscope.[86]

Anastomotic strictures may occur from inflammatory bowel disease or postsurgical resection. These strictures may be dilated with balloon dilators or managed with self-expanding metallic stents.[87] Endoluminal stenting may be used as palliation or as a bridge to surgery for near-obstructive malignant lesions.[88] Laser therapy is another option for tumor ablation.[89]

Colonic decompression and placement of temporary rectal tubes is indicated in patients with sigmoid or cecal volvulus and acute pseudo-obstruction. Foreign objects also may be removed endoscopically.

Endoscopic Retrograde Cholangiopancreatography

ERCP is used to evaluate and treat diseases of the pancreas, biliary tree, gallbladder, and liver. With the advent of highly diagnostic alternative modalities, such as magnetic resonance imaging and EUS, the role of ERCP has slowly evolved into a therapeutic rather than diagnostic tool (Box 17.5).[90] The procedure is performed with the patient under anesthesia while lying on the left side or prone. After oral intubation, the side-viewing duodenoscope is advanced into the second portion of the duodenum, where the papilla of Vater is located, and the papilla is subsequently cannulated using a variety of wires, catheters, or papillotomes. Glucagon may be beneficial to reduce peristalsis of the small bowel, facilitating cannulation of the bile duct. Secretin may be administered to assist in identification of the papilla of Vater in the setting of ulceration, scarring, or malignancy, or the minor papilla in cases of pancreas divisum. Visualization of the common bile duct or pancreatic duct is achieved with injection of contrast dye and radiographic fluoroscopy.[91]

Biliary obstruction secondary to choledocholithiasis may be managed by ERCP with successful stone extraction in 90% of cases.[91] Techniques for stone extraction involve biliary sphincterotomy or balloon sphincteroplasty, followed by stone removal using a soft balloon or wire basket. Significant coagulopathy should be

corrected if sphincterotomy is to be performed. Large stones may be fragmented before removal with mechanical, laser, or electrohydraulic lithotripsy. Inadequate bile drainage may require biliary stenting to prevent ascending cholangitis. Antibiotic prophylaxis is indicated in patients undergoing ERCP for suspected biliary obstruction where incomplete drainage is anticipated or in patients with sterile pancreatic fluid collections that communicate with the pancreatic duct.[92]

Bile duct stenting is used to alleviate obstruction caused by malignant and benign disorders and to treat bile duct injuries and leaks.[93] Pancreatic stents are used for pancreatic duct disruptions[94] and pseudocysts that communicate with the pancreatic duct.[95] Stents vary in diameter, length, material (plastic, metallic, and biodegradable), and occlusion rates.

Malignant and benign strictures may be dilated with hydrostatic balloons. ERCP also is used to obtain brush cytology, fine-needle aspiration, or biopsy specimens of a suspected malignancy. Sensitivity is typically low, ranging from 30% with brushings to 60% with all three methods combined.[96] Reports of photodynamic therapy for nonresectable cholangiocarcinoma have been described.[97] Manometry, the measurement of biliary and pancreatic sphincter pressures, may be used to evaluate sphincter of Oddi dysfunction, postcholecystectomy pain, and idiopathic pancreatitis.

Choledochoscopes and pancreatoscopes are small endoscopes that can be passed through a duodenoscope channel port into the common bile duct or pancreatic duct. This placement allows direct visualization of the duct lumen. Direct visualization of vasculature and lumen within a biliary stricture may help differentiate benign from malignant lesions.[98]

ERCP carries a substantial morbidity risk. Pancreatitis is the most common complication, occurring in 3% to 10% of cases.[99] Although the benefits of prophylactic administration of gabexate mesylate are controversial,[100,101] pancreatic stenting of high-risk patients seems to be efficacious.[102] Stenting improves pancreatic duct drainage. Several major independent risk factors for post-ERCP pancreatitis that have been identified with multivariate analysis include prior post-ERCP pancreatitis, endoscopic papillary large-balloon dilation of an intact sphincter, female sex, pancreatic sphincterotomy, and repetitive pancreatic cannulation. Other reported complications include hemorrhage, cholangitis, and perforation occurring at rates of 0.3 to 2%, 1%, and 0.08 to 0.6% respectively.[103]

Endoscopic Ultrasound

EUS, a combination of endoscopy and ultrasonography, is used for evaluation of luminal walls and structures adjacent to the GI tract. In addition, high-frequency ultrasound probes that can be passed through the channel port of standard endoscopes are commercially available.[104]

A common application of EUS is evaluation of benign and malignant mucosal and submucosal lesions. EUS is used routinely for detection and staging of esophageal, gastric, ampullary, pancreaticobiliary, colorectal, and lung neoplasms. EUS also is used to evaluate chronic pancreatitis and biliary disorders, such as calculi. In general, EUS is an extremely sensitive tool and is often superior to computed tomography or magnetic resonance imaging for diagnosis and staging of neoplasia.[105] An advantage of EUS over these noninvasive modalities is the ability to perform therapeutic interventions when needed. Fine-needle aspiration can be done with EUS, which also can be used for pseudocyst drainage, celiac plexus blocks, cholangiography, pancreatography, and tumor ablation.[106] Despite the low risk of bacteremia after EUS fine-needle aspiration, patients undergoing EUS with aspiration of a cystic lesion along the GI tract should receive antibiotic prophylaxis.[92]

Preparation of the patient is similar to that for standard endoscopy. Complications from instrumentation vary, depending on the clinical scenario. Perforation rates, usually cervical esophageal in origin, occur in 0.03%.[107] Pancreatitis, hemorrhage, and bile peritonitis also have been reported.[108]

Endoscopic management of peripancreatic fluid collections has always been technically challenging. Newer lumen-opposing metal stents provide transluminal drainage of pancreatic pseudocysts, pancreatic abscesses, or walled-off pancreatic necrosis and are deployed under EUS guidance.

Endoscopy in the Pregnant Patient

Endoscopy in the general population is commonplace and widely regarded as safe. Endoscopy during pregnancy raises the unique concern of fetal safety and poses the potential risks of teratogenesis or premature induction of labor from medications, hypoxemia, and hemodynamic fluctuations. A lack of quality research into the safety of these procedures during pregnancy adds to the uncertainty of performing endoscopic procedures in this population.[109]

In controlled studies, no differences were seen between pregnant and nonpregnant patients undergoing EGD[110] or in fetal outcomes regardless of a history of EGD during pregnancy.[111] Acute upper GI bleeding, dysphagia associated with involuntary weight loss, and suspected GI mass have all been suggested as acceptable indications for EGD in the pregnant patient. Data surrounding colonoscopy during pregnancy are less robust, limited to small studies, case series, and case reports, and therefore accurate estimation of risk is not possible. Colonoscopy should be considered for unknown colonic mass or stricture, severe uncontrolled colonic hemorrhage, as an alternative to surgery in colonic pseudo-obstruction, and when required before colonic surgery.[109]

ERCP is associated with unique risks that must be appreciated when considering performing the procedure on a pregnant patient. Procedural time is often longer, requiring increased doses of anesthetic medications compared with EGD. ERCP also places the patient at risk for postprocedural complications, including bleeding and perforation from sphincterotomy and post-ERCP pancreatitis. ERCP during pregnancy also introduces a theoretical risk from fetal radiation exposure during fluoroscopy. Despite these risks, it is felt that ERCP can safely be performed during pregnancy as the literature has consistently demonstrated a high maternal success rate, a low procedural complication rate, and generally favorable fetal outcomes.[109] Additionally, although estimates of fetal radiation exposure vary, with careful technique, doses of radiation can be limited to less than the 5-rad threshold often used to minimize risk of fetal anomalies or pregnancy loss.[112] Indications for ERCP during pregnancy include choledocholithiasis with obstructive jaundice, ascending cholangitis, or gallstone pancreatitis, or the presence of biliary or pancreatic ductal injury.[109]

When considering GI endoscopy in the pregnant patient the physician must ultimately weigh the risks of performing the procedure to the fetus against the benefits to the mother. Guidelines exist that offer suggestions to help minimize these risks, such as limiting procedures to patients with strong indications, choosing medications that are safe during pregnancy, close involvement of obstetric staff, and performance of the procedure by an experienced endoscopist. In situations in which therapeutic intervention is necessary, endoscopy may offer a safe alternative to surgery.[113]

Key Points

- Endoscopy serves a diagnostic and a therapeutic role in the management of patients.
- Informed consent must be obtained before any elective endoscopic procedure.
- Perforation and bleeding are the major complications of endoscopy. Although standard endoscopy is generally low risk, interventional procedures increase the rate of complications. A benefit versus risk analysis must be done before any procedure.
- Cardiopulmonary decompensation is a possible complication of anesthesia.
- Endoscopy is the most effective technique to identify and control GI hemorrhage.
- Endoscopy plays a crucial role in the palliative care of patients with GI tract malignancy.
- ERCP has evolved into a therapeutic tool for treating pancreaticobiliary disease.
- Endoscopy in the pregnant patient can be done safely but should be limited to patients with strong indications.

Review Questions

1. A 25-year-old female with no past medical history and two prior full-term pregnancies presents with intermittent right upper quadrant pain for the past 3 weeks. She is currently 20 weeks into her third pregnancy. Physical examination reveals mild discomfort to right upper quadrant palpation. Right upper quadrant ultrasound revealed cholelithiasis and two small filling defects in the common bile duct (CBD), with the largest measuring 0.5 cm in length. Liver function test results show the following levels: aspartate aminotransferase 62 U/L, alanine aminotransferase 82 U/L, total bilirubin 4.1 g/dL, direct bilirubin 1.2 g/dL, and alkaline phosphate 60 U/L. What would the next step in management be?

- **a.** Proceed to endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy for CBD stone extraction
- **b.** Proceed to ERCP with plastic stent placement followed by a repeat ERCP 6 weeks after delivery with sphincterotomy for CBD stone extraction
- **c.** Follow clinically and if develops worsening signs, then proceed to ERCP with sphincterotomy and CBD stone extraction.
- **d.** No further intervention as these stones will likely pass

Answer: a. Stent occlusion or migration can precipitate cholangitis and a second procedure is potentially needed during the pregnancy. If limited fluoroscopy time can be observed, a therapeutic sphincterotomy with stone extraction can facilitate stone passage and potentially limit any further complications of the pregnancy.

2. Which of the following is *not* a contraindication for video capsule endoscopy?

- **a.** Crohn disease with known stricture in small bowel
- **b.** Current pregnancy
- **c.** Known or suspected small bowel fistulas
- **d.** Rapid small bowel transit time

Answer: d. The passage time of the video capsule does not influence the ability to use this tool to help with diagnosis.

3. A 63-year-old male with hypertension, type 2 diabetes, obesity, and obstructive sleep apnea presents to the emergency department with complaints of acute sharp abdominal pain in the epigastrium with new esophageal reflux for the past 1 month. He had been taking a nonsteroidal antiinflammatory drug for back pain several times a day for the past 3 months. Upon presentation his heart rate is 110 beats/min, blood pressure is 90/60 mm Hg, and respirations are 28 breaths/min. He is slightly lethargic and diaphoretic. When you encounter the patient, he begins to vomit bright red blood. What is correct regarding intubation of this patient?

- **a.** Intubation should happen after the endoscopy if there is an active bleeding source.
- **b.** Intravenous proton pump inhibitors and octreotide should be started immediately and you should proceed directly to esophagogastroduodenoscopy without intubation.
- **c.** Intubation before endoscopy can help facilitate the passage of the endoscope and should be performed with the majority of acute upper gastrointestinal (GI) bleeding cases.
- **d.** Prophylactic intubation prior to endoscopy for upper GI bleeding can result in a higher rate of pneumonia in intubated patients.

Answer: d. A meta-analysis has evaluated intubation before endoscopy for upper GI bleeding. It found a higher rate of aspiration, pneumonia, and hospital length of stay in the electively intubated patients. It is recommended to weigh risks and benefits of intubation for each individual case.

Quality Assurance and Imaging Archival Systems

Conclusions

Ultrasonography is useful to guide the diagnosis and management of critical illness. The intensivist who uses critical care ultrasonography (CCUS) assumes all responsibility for image acquisition, image interpretation, and the immediate application of the results at the bedside of the critically ill patient. This is different from standard ultrasonography, where a technician acquires the image and a radiologist or cardiologist provides interpretation. This latter approach results in a delay in performance of the scan, delay in its interpretation, and delay in transmission of results. This is compounded by the consultant typically having incomplete knowledge of the clinical facts of the case. In performing CCUS, the intensivist integrates the imaging results into the entire clinical picture, best understood by the front-line clinician. The use of CCUS has expanded rapidly over the past 2 decades. It is increasingly part of critical care training in North America as the Accreditation Council for Graduate Medical Education (ACGME) mandates knowledge of CCUS as a part of critical care fellowship training (ACGME program requirements for graduate medical education in critical care medicine are available at https://www.acgme.org/Portals/0/PFAssets/ProgramRequirements/142_critical_care_medicine_2017-07-01.pdf?ver=2017-04-27-145212-687). Thousands of attending-level intensivists have taken courses on CCUS provided by the professional societies, and the critical care societies have issued guidelines defining best practice and

competency requirements.[1,2] The International Expert Statement on Training Standards in CCUS specifies that "basic-level critical care echocardiography and general critical care ultrasound should be a required part of the training of every ICU physician."[3]

Basic Ultrasound Terminology and Probe Characterization

Echogenicity refers to the ability of a structure to reflect or transmit ultrasound waves. Different echogenicity between structures allows specific anatomy to be identified and localized (Box 18.1). It is important for intensivists to have knowledge of probe frequency to allow the choice of the appropriate probe for best resolution. High-frequency probes provide superior resolution but less penetration. A high-frequency probe is used to image superficial structures (e.g., vascular imaging), whereas a mid-range frequency probe is used to image deeper structures (e.g., cardiac or thoracic imaging). Curvilinear probes generate a wider image than linear probes and are used to visualize deeper structures (Table 18.1).

Basic Critical Care Echocardiography

The American College of Chest Physicians and La Société de Réanimation de Langue Française statement divides competence in critical care echocardiography (CCE) into two levels: basic and advanced. The basic CCE examination includes five standard views: the parasternal long-axis (PSLAX), the parasternal short-axis (PSSAX), the apical four-chamber (AP4), the subcostal long-axis (SCLAX), and the inferior vena cava (IVC) in longitudinal axis.[1] The intensivist uses basic CCE to qualitatively examine the anatomy and function of the heart.

Basic CCE is the cornerstone for the evaluation of cardiopulmonary failure, where it is used immediately, repeatedly, and serially by the front-line intensivist to establish diagnosis and guide management at the bedside of the critically ill patient.[4] Advanced critical care echocardiography (ACCE) requires the intensivist to have competence in echocardiography at a similar level to a cardiologist.[5] The National Board of Echocardiography (NBE), in cooperation with other professional societies, is developing national-level certification in ACCE. The first NBE ACCE examination is scheduled to be given in early 2019. Intensivists interested in ACCE may consult the NBE website or their professional societies for information on the process of certification. This chapter focuses on basic CCUS.

• BOX 18.1 Ultrasound Echogenicity

Hyperechoic: appears white
Hypoechoic: appears gray
Anechoic: appears black

TABLE 18.1 Frequency Probes

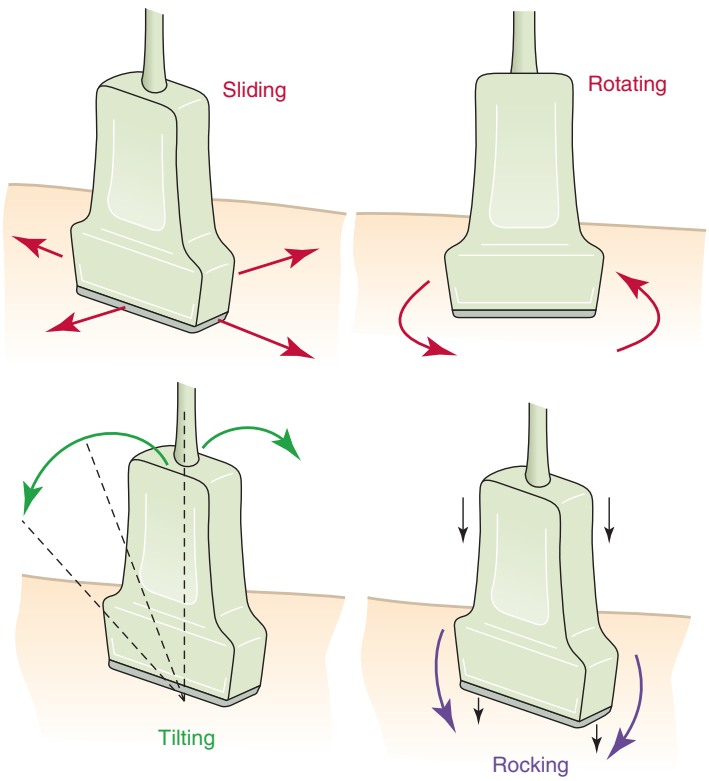
	Frequency	Optimal Structure Visualized	Probe Type
Linear	5–15 MHz	Vessels, nerves	Linear
Phased-array	0–5 MHz	Cardiac, thoracic Abdominal Imaging	Curvilinear

Performance of the CCE Examination

Basic CCE is performed with a phased-array probe (2–5 MHz). The probe is used with sufficient coupling gel (a conductive medium for sound waves generated by the transducer), and the machine is placed on the same side as the examiner to allow for easy machine control. The probe is held with part of the probe hand touching the patient to provide a stable image. The probe marker is placed on the right side of the screen, the gain (controls brightness of ultrasound image by amplifying the signal of ultrasound waves) is set to the appropriate level, and the depth is adjusted to place the target of interest in the center of the screen. The tomographic plane is a cross-sectional plane through the body. The tomographic plane of the probe is adjusted as according to the following steps[6] (Fig. 18.1):

1. Moving: The probe is moved from one place to another on the chest wall.
2. Angling: The probe is angled perpendicular along the axis of the tomographic plane.
3. Tilting: The probe is tilted along the axis of the tomographic plane.
4. Rotating: The probe is rotated without moving, angling, or tilting.

The main limitation of CCE is related to patient factors such as obesity, edema, heavy musculature, or surgical wounds/dressings



• **Fig. 18.1** Transducer movements. (From Soni NJ, Arntfield R, Kory P. *Point-of-Care Ultrasound.* Philadelphia: Elsevier; 2014.)

that may degrade image quality. The patient may be difficult to position for optimal imaging because of body size or surrounding equipment. The operator should attempt all the views; if one view fails, another may yield important information. The examination is performed in the same sequence every time to standardize scanning tactics and avoid omitting a view. The quality of the examination is influenced by the skill of the operator, so inadequate training can degrade image quality.

The Basic CCE Examination

Parasternal Long-Axis View (Fig. 18.2, Video 18.1)

The transducer is positioned to the left of sternum perpendicular to the skin surface in the left third to fifth intercostal space with the index marker of the probe pointing toward the right shoulder. The intercostal space that yields the best image is variable. The tomographic plane is adjusted so that it bisects the aortic valve (AV), the mitral valve, and the left ventricular (LV) cavity in its longest axis. The PSLAX view is used for qualitative assessment of LV function, right ventricular (RV) outflow tract size, LV wall thickness and function, septal kinetics, evaluation of AV/mitral valve anatomy, left atrial (LA) size, the descending aorta, and the pericardial space.[7]

Parasternal Short-Axis Mid-Ventricular View (Fig. 18.3, Video 18.2)

From the PSLAX view, the probe is now rotated 90 degrees clockwise without tilting or angling to obtain a cross-sectional view of the heart with the index marker of the probe pointing toward the left shoulder. By angling the probe along a right shoulder–to–left hip axis, the tomographic plane is adjusted to obtain a cross-sectional view of the left ventricle at the papillary muscle level. The PSSAX view is used for qualitative assessment of LV function, LV segmental wall function, LV/RV chamber size, RV/LV wall thickness, septal kinetics, and the pericardial space.

Apical Four-Chamber (Fig. 18.4, Video 18.4)

The transducer is positioned at the apex of the left ventricle (approximately sixth intercostal space midclavicular line) with the probe marker pointing toward the left axilla. The optimal patient position is the left lateral decubitus position, although this may not be possible in the critically ill patient. The tomographic plane is adjusted so that the intraventricular septum is oriented vertically in the center of the screen; thus it bisects the apex, the ventricles, and the atria. The AP4 view is used for qualitative assessment of LV function, RV/LV size ratio, RV/LV wall thickness, LV segmental wall function, septal kinetics, right atrium (RA)/LA chamber size, and evaluation of tricuspid valve (TV)/MV anatomy.

Subcostal Long-Axis View (Fig. 18.5, Video 18.7)

With the patient lying supine, the probe is placed immediately below the xiphoid process with the index marker pointing toward the lower lateral left chest. The tomographic plane is adjusted to yield a four-chamber view of the heart. The SCLAX view is used for qualitative assessment of LV function, RV/LV size ratio, RV/LV wall thickness, LV segmental wall function, septal kinetics, and the pericardial space.

Inferior Vena Cava Longitudinal View (Fig. 18.6, see Video 18.1)

From the SCLAX, the transducer is rotated counterclockwise so that the index marker is pointing toward the 12-o'clock position, followed by angling of the tomographic plane toward the right to obtain a long-axis view of the IVC. The tomographic plane is

• BOX 18.2 Basic Critical Care Echocardiography

Identify imminently life-threatening processes
Categorize the mechanism of shock
Develop management strategy
Look for coexisting diagnosis that will complicate management
Follow the evolution of disease

adjusted to bisect the middle of the IVC. The IVC view is used for determination of volume responsiveness.

Utility of Basic Critical Care Echocardiography

Basic CCE has the following uses:

1. Identification of an immediately life-threatening cause of shock (Box 18.2)
   Basic echocardiography may identify an immediately life-threatening cause of shock such as massive pulmonary embolism, pericardial tamponade, catastrophic valve failure, or severe reduction of LV contractility. The possibility of a life-threatening process with effective treatment is more rapidly identified by the performance of immediate basic CCE for the patient in shock.
2. Categorization of the cause for shock state and guidance of management
   The basic CCE examination permits the critical care clinician to identify the category of shock as hypovolemic, obstructive, cardiogenic, or distributive (or a combination). This guides management strategy and the search for an underlying etiology.
3. Response to therapy and evolution of disease
   Basic CCE is repeated over time to follow response to treatment and the evolution of the disease process, given that critical illness and its treatment represent a dynamic process. Owing to its ease of use, the intensivist can perform the basic ultrasound examination as often as required after the initial scan.
4. Identification of a coexisting diagnosis
   Older patients and/or patients with chronic illness may develop hemodynamic failure where the management of the acute process is complicated by coexisting disease. The basic CCE examination is useful to identify a chronic (e.g., aortic stenosis) process that complicates the management of the primary cause of the acute hemodynamic failure.

Advanced Critical Care Echocardiography

The reader is referred to the International Consensus Statement for a full discussion of ACCE.[5] Although competence in basic CCE is a core skill for the intensivist, the need for competence in ACCE is determined by individual practice requirements. The National Board of Echocardiography is to offer North American certification in ACCE. The certification process will include a high-stakes board examination and a challenging requirement for competence in image acquisition.[8]

Thoracic Ultrasonography

Thoracic ultrasonography of the lung and pleural space is simple to perform, easy to learn, and has strong clinical utility for the intensivist. It is a low-cost imaging modality without ionizing radiation that can be performed immediately, repeatedly, and in a goal-directed fashion at point of care with a portable multipurpose device.

Equipment Requirements and Scanning Technique

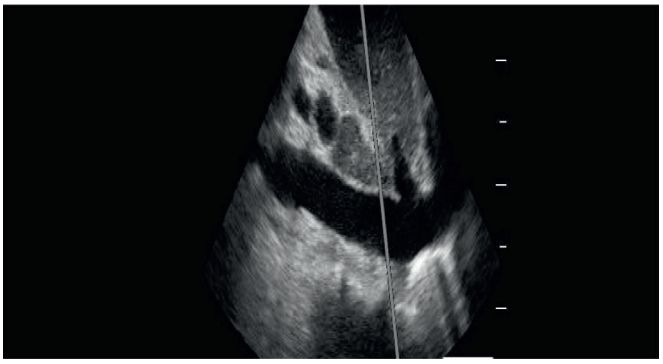
Thoracic ultrasonography is performed with a 3.5- to 5.0-MHz cardiac probe, which has a small footprint that fits well between rib interspaces. A larger curvilinear probe may also be used. The 7.5-MHz linear vascular probe is used to image pleural surface morphology, as it has better resolution than the lower frequency cardiac probe, although it lacks penetration into deeper tissues. Many portable ultrasonography machines have a lung preset that optimizes image quality for thoracic scanning. If not available, the operator may need to adjust machine settings for optimal image quality.

The probe is held perpendicular to the skin surface with the tomographic plane in the longitudinal axis and the probe indicator pointing in cephalad direction. The probe is adjusted such that the tomographic plane is directed through a rib interspace. An effective approach to examining the thorax is to move the probe across the chest wall in a series of scan lines to examine adjacent interspaces. The posterior thorax is an important area to examine, as pleural effusions and consolidations are found in the dependent thorax. To scan the posterior thoracic in the supine patient, the probe is pressed into the mattress and angled anteriorly; or the patient may be rolled to a lateral decubitus position to fully expose the posterior thorax.

Lung Sliding

The pleural line represents the apposition of the parietal and visceral pleural surfaces. Normally the two pleural surfaces move against each other in synchrony with the respiratory cycle. This results in the finding of lung sliding, which is a mobile shimmering respirophasic movement of the pleural line (Fig. 18.7, see Video 18.2).[9] Cardiac pulsation also results in cardiophasic movement of the visceral pleura against the parietal pleural, which is termed *lung pulse.*[10,11] The findings of lung sliding and lung pulse exclude the presence of a pneumothorax at the site of probe application.[11] Multiple anterior rib interspaces may be rapidly examined. This allows the operator to quickly rule out pneumothorax.

Although the presence of lung sliding effectively rules out pneumothorax, the absence of lung sliding does not necessarily indicate that the patient has a pneumothorax because the absence of lung sliding may occur in conditions other than pneumothorax. A



• **Fig. 18.6** Inferior vena cava, longitudinal view.

process that reduces air entry into the lung may cause loss of lung sliding. For example, severe pneumonia, apnea, or acute respiratory distress syndrome will result in the absence of lung sliding, as will an occlusion of a mainstem bronchus (e.g., mainstem intubation with endotracheal tube inflation blocking the contralateral mainstem bronchus, blood clot, mucous plug, foreign body, or tumor mass). Pleural symphysis (cicatricial, inflammatory, therapeutic, or neoplastic) causes loss of lung sliding. The *absence* of lung sliding indicates the possibility of pneumothorax, whereas the *presence* of lung sliding and/or lung pulse rules out a pneumothorax.

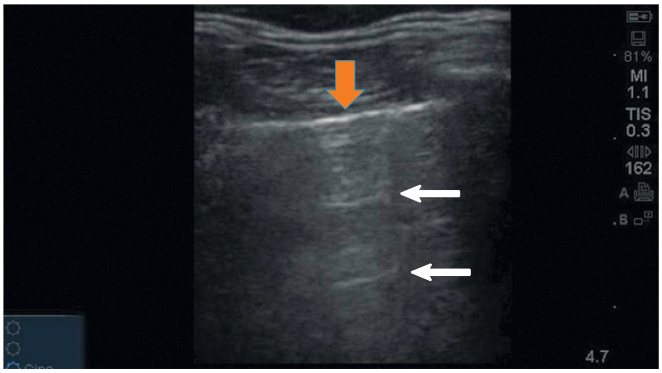
A-Lines (Fig. 18.8, Video 18.3)

Normally aerated lung is distinguished by the presence of A-lines. An "A-line" is a horizontally oriented line that is located deep to the pleural line at a depth equal or a multiplicative of the distance between the skin surface and the pleural line. A-lines can appear singly or multiply and, when multiple, are separated from one another by the same distance. In the presence of sliding lung, A-lines indicate normally aerated lung. When present without lung sliding, they suggest either air between the visceral and parietal pleura (e.g., a pneumothorax or some other cause for lack of lung sliding; see previous text). A-lines with lung sliding are strongly correlated with a normal aeration pattern on CT scan.[12]

B-Lines

Lung disease that involves the alveolar and/or interstitial compartment results in "B-lines." B-lines have several characteristics:

- They originate at the pleural interface.



• **Fig. 18.8** A-lines *(white arrows)*; *orange arrow*; visceral and parietal pleura.

- They move with the pleural interface.
- They are hyperechoic.
- They are vertical in orientation.
- They extend to the bottom of the screen.
- They erase A-lines.

B-lines are strongly correlated with alveolar or interstitial pattern abnormalities on CT scan (reticular pattern or ground-glass abnormality), and depending on their cause, they may be focal, scattered, or diffuse in distribution (Fig. 18.9, Video 18.4).[13,14]

Consolidation

On ultrasonographic examination, consolidated lung has tissue density with similar echogenicity as the liver or spleen. The finding of consolidation with lung ultrasonography is strongly correlated with the results of chest CT.[15] The distribution of the lung consolidation is readily identified with ultrasonography as being whole lung, lobar, or segmental in size with focal or multifocal distribution. If translobar in distribution, the consolidated lung may have sonographic air bronchograms within it that appear as hyperechoic foci representing small amounts of air in bronchi.

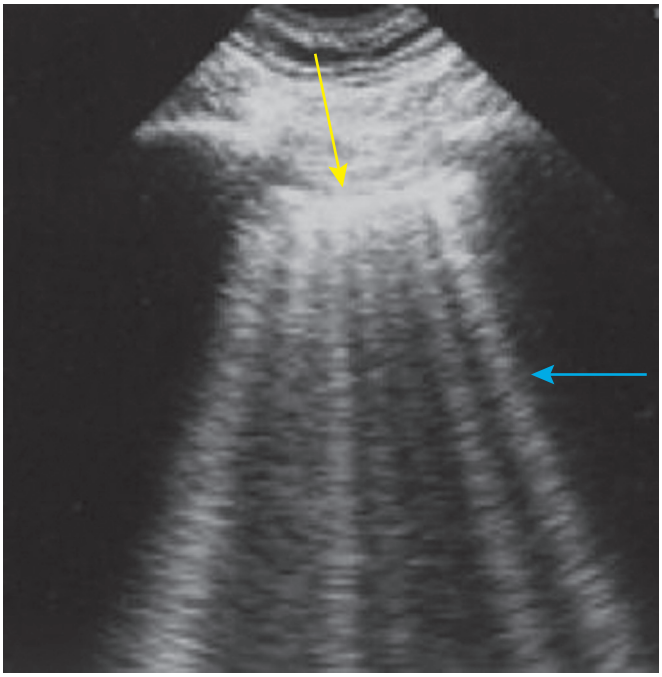
Pleural Effusion (Fig. 18.10, Video 18.5)

Pleural fluid is readily detected with thoracic ultrasonography. Unless the fluid is loculated, it assumes a dependent position within the thorax. Thus in the supine patient, the operator focuses the examination for fluid to the dependent thorax, which is posterior in location. Pleural fluid is indicated by the presence of a relatively hypoechoic space that is defined by typical anatomic boundaries (inside of chest wall, diaphragm, and surface of lung) in association with characteristic dynamic findings (diaphragmatic movement, lung movement, mobile echogenic elements within the pleural effusion). Identification of pleural fluid allows the operator to further characterize it (anechoic or containing internal echogenicity) and to identify a safe site and trajectory for device insertion.[16]

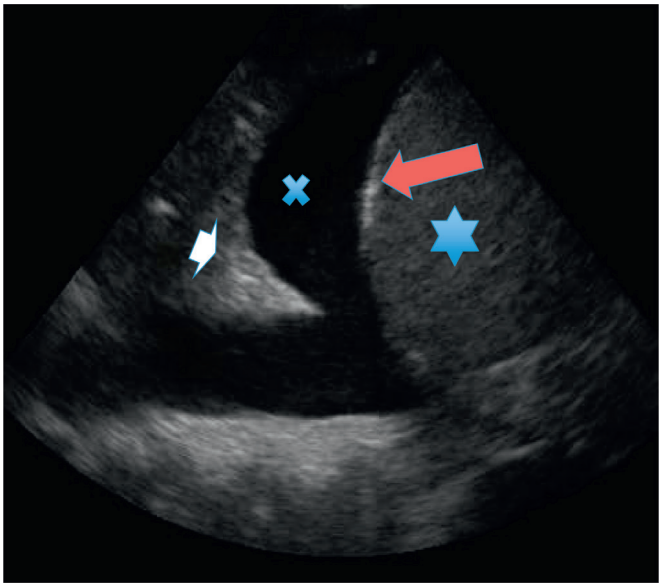
Clinical Applications of Thoracic Ultrasonography

Thoracic Ultrasonography Compared to Chest Radiography

Thoracic ultrasonography is superior to chest radiography for identification of pneumothorax, normal aeration pattern, alveolar/



• **Fig. 18.9** B-lines *(blue arrow)*; *yellow arrow* ,visceral and parietal pleura.



• **Fig. 18.10** Pleural effusion. *White arrow,* Lung; *X,* pleural fluid; *red arrow,* diaphragm; *star,* spleen.

interstitial abnormality, and pleural effusion. It also has operational characteristics that are similar to chest CT for identification of these abnormalities.[17,18] Its ease of use, portability, and cost profile favor its use over chest radiography, and whenever possible, chest CT. With this understanding, thoracic ultrasonography may be used as a primary imaging modality in the intensive care unit (ICU) instead of chest radiography.

Evaluation for Pneumothorax

In the supine patient, air within the pleural space typically collects in the anterior thorax. The intensivist can rapidly rule out a generalized (versus loculated) pneumothorax by detecting lung sliding over multiple anterior rib spaces. Thoracic ultrasonography is superior to chest radiography for detection of pneumothorax.[19–21]

Evaluation for Pneumonia

Lung ultrasonography has utility for diagnosis of pneumonia and for following its progression.[19,22,23] The effect of antibiotic treatment on ventilator-associated pneumonia can be observed with lung ultrasonography.[24] The combination of sputum analysis with lung ultrasonography has utility for the diagnosis of ventilator-associated pneumonia.[25]

Evaluation of Pneumonia Versus Atelectasis

The finding of dynamic air bronchograms with consolidated lung is a characteristic feature of pneumonia, whereas their absence increases the likelihood that the consolidation results from atelectasis (Fig. 18.11, Video 18.6).[26]

Guidance of Thoracic Procedures

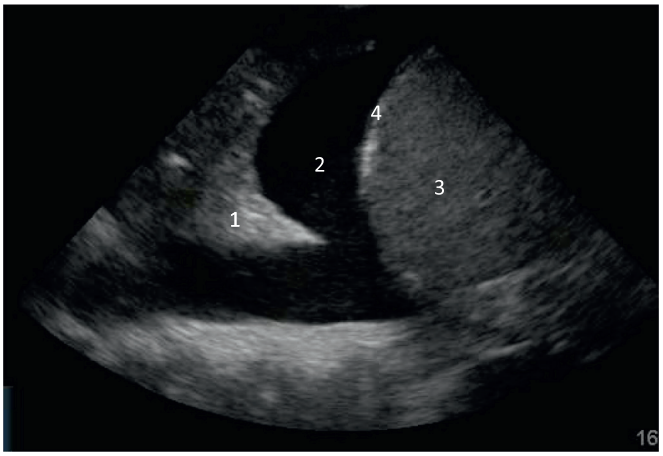
Thoracic ultrasonography increases procedure success rate and reduces the frequency of postprocedure pneumothoraces, bleeding complications, and the need for postprocedure chest radiography.[27,28] With ultrasonographic guidance, thoracentesis may be performed with a low complication rate in patients using mechanical ventilatory support.[29] Bleeding complications are reduced in patients taking clopidogrel both for thoracentesis and percutaneous chest tube insertion when guided by ultrasonography.[30] In reference to central line placement, the combination of thoracic ultrasonography and echocardiography may be used to exclude procedure-related pneumothorax and to confirm central venous catheter tip position.[31]

Evaluation for Chest Tube Removal

Galbois et al. reported the utility of thoracic ultrasonography to observe full lung expansion after pleural drainage for pneumothorax as well as the time to chest tube removal.[32] Once the lung is shown to be fully inflated with thoracic ultrasonography, the chest tube is clamped. If the lung remains fully inflated after an appropriate period of time, the chest tube is removed. Study results indicated that this method was superior to standard chest radiography.

Evaluation for Pulmonary Embolism

Nazerian et al. were able to diagnose pulmonary embolism in patients in the emergency department with 90% sensitivity and 86.2% specificity by performing a combination of vascular, lung, and cardiac ultrasonography. The investigators evaluated patients for deep venous thrombosis (DVT), alternative causes of respiratory failure, and evidence of RV dysfunction.[33] Koenig et al. similarly used a combination of vascular, lung, and cardiac ultrasonography in hospitalized patients to show that point-of-care ultrasound could eliminate the need for unnecessary CT scans of the chest.[34] Reissig et al. reported that pulmonary emboli commonly result in small areas of consolidation immediately deep to the pleural interface with preferential distribution to the lower lobes of the lung.[35] Two meta-analyses show a pooled sensitivity and specificity of 80% to 87% and 82% to 93%, respectively, for diagnosis of pulmonary embolism with thoracic ultrasonography.[36,37]



• **Fig. 18.11** Atelectasis. *1,* Atelectatic lung; *2,* pleural effusion, *3,* spleen; *4,* diaphragm.

Evaluation of Lung Recruitment With PEEP

Bouhemad et al. reported on the utility of thoracic ultrasonography to evaluate lung recruitment with positive end-expiratory pressure (PEEP) in patients with acute respiratory distress syndrome.[38] Using a standardized scoring system that reflects the degree of lung aeration, they observed the effect of varying levels of PEEP on reaeration of compromised lung at varying PEEP levels. By varying PEEP levels from 0 to 15 cm H_2O, an improvement in aeration detected by lung ultrasonography was associated with a measured increase in lung volume. Lack of improvement in lung aeration score was associated with reduced augmentation of measured lung volume.

Prediction of Extubation Failure

Using the same scoring system described for their PEEP study, Soummer et al. reported that worsening of the lung aeration score during spontaneous breathing trial was associated with weaning failure.[39]

Evaluation of Respiratory Failure

Lichtenstein and Mezière described an algorithm based on thoracic ultrasonography for the evaluation of respiratory failure.[40] With a simple three-point examination of the chest and standardized findings, the algorithm identified the cause of the respiratory failure in a high proportion of cases. The authors found that thoracic ultrasonography was as effective as standard evaluation methods for identifying the etiology of respiratory distress for a wide variety of diseases with the advantage that it reduced time to diagnosis.[40] Batialle et al. reported that the combination of thoracic ultrasonography with echocardiography for evaluation of dyspnea improved diagnostic yield when compared with thoracic ultrasonography alone.[41]

Evaluation for Cardiogenic Pulmonary Edema

Lichtenstein et al. reported that the presence of an A-line pattern with lung sliding was associated with a pulmonary occlusion pressure below 18 mm Hg and likely less than 12 mm Hg.[42] The finding of an A-line pattern in the dyspneic patient therefore rules out cardiogenic pulmonary edema. To distinguish between B-lines derived from cardiogenic pulmonary edema and those caused by primary lung injury, Copetti et al. reported that B-lines caused by cardiogenic pulmonary edema are associated with a smooth pleural surface, whereas primary lung injury B-lines are associated with an irregular pleural surface.[43] Agricola et al. reported that during cardiac stress testing, the onset of dyspnea coincident with the sudden appearance of B-lines is consistent with onset of cardiogenic pulmonary edema precipitated by cardiac ischemia under exercise load.[44]

Evaluation of Endotracheal Tube Position

Lung ultrasonography is useful to assess endotracheal tube position. Bilateral lung sliding during bag-valve-mask (BVM) ventilation indicates successful tracheal intubation.[44,45] Unilateral mainstem intubation results in ipsilateral lung sliding with BVM ventilation and with contralateral lung pulse and absent lung sliding. Withdrawal of the endotracheal tube to a position above the carina results in bilateral lung sliding with BVM ventilation.[46]

Ultrasonography for Diagnosis of DVT

Ultrasonography is useful for the diagnosis of DVT. Trained intensivists perform ultrasonography compression studies with results similar to those performed by consultative radiology without typical delay in performance of the examination.[47] The front-line intensivist who performs the DVT study accrues major advantages. The examination is done immediately at point of care, it can be repeated as often as required, and it provides important clinical information that is promptly integrated into the management plan. Proficiency in the two-dimensional compression examination for DVT is a key part of competence in basic CCUS.

Equipment Requirements and Scanning Technique

The linear vascular probe (7.5 MHz) of the type used to guide vascular access is used to perform the examination. The scanning technique is the same regardless of the vessel being examined. The selected vein is imaged in its transverse axis. The transducer is placed perpendicular to the skin surface over the targeted vein. The examiner adjusts the tomographic plane to place the vein at the center of the ultrasonography machine screen. The orientation marker is set on the right side of the screen, and the probe marker is directed to the right side of the patient when examining the leg veins. A thrombus appears as an echogenic structure within the vein (Fig. 18.12, see Video 18.7). Absent a visible thrombus, the examiner performs a compression maneuver by pressing the probe down with the force vector perpendicular to the axis of the vein sufficient to deform the adjacent artery. Normal veins are fully compressible. Occasionally the thrombus will become visible only with the compression maneuver. Although the compression maneuver is best performed with the transverse view of the vein, the longitudinal view may be used to supplement the examination. The addition of Doppler to the examination (duplex and triplex) may afford no improvement in accuracy over the two-dimensional compression ultrasonography test.[48]

• **Fig. 18.13** Deep vein thrombosus *(blue arrow)* in the internal jugular vein.

Examination for Lower Extremity DVT (Fig. 18.12, Video 18.8)

With the patient in the supine position, the leg is externally rotated. The examination is started in the inguinal region and follows an imaging sequence at defined anatomic levels of the upper leg venous system as follows:

1. Identification and compression of the proximal common femoral vein (CFV) and its paired artery (less compressible), with the CFV being medial to the common femoral artery.
2. Identification and compression of the CFV at its junction with the saphenous vein.
3. Identification and compression of the CFV at the level of the bifurcation of the common femoral artery into the femoral artery and deep femoral artery.
4. Identification and compression of the CFV at the level of the junction of the CFV and the deep femoral vein. Below this point, the CFV becomes the superficial femoral vein (SFV).
5. Identification and compression of the SFV. The SFV is deep to the femoral artery. There is debate as to how far down the thigh to continue the examination and compression of the SFV. It is uncommon for there to be a SFV thrombus in the absence of CFV or popliteal vein (PV) thrombus, so a complete examination of the entire course of the SFV may not be necessary.
6. Identification and compression of the PV. With the patient's knee flexed and leg externally rotated, the probe is positioned in the popliteal fossa to visualize and compress the PV. The PV is superficial to the popliteal artery.

Examination for Upper Extremity DVT

With the arm abducted and externally rotated, the brachial vein(s) and the adjacent brachial artery are identified in their transverse axis starting at the antecubital fossa. The brachial veins are often paired. The tomographic plane, oriented in the transverse axis to the vein, is moved proximally with examination for visible thrombus followed by compression at several points along the course of the brachial vein(s). In the proximal upper arm, the paired brachial vein(s) join to become the axillary vein. The examination continues as far into the axilla as possible.

Examination for Neck Vessel and Axillary DVT (Fig. 18.13)

Both the internal jugular vein (IJV) and SCV are imaged in their transverse axis and examined for visible thrombus followed by compression study along the length of the vessel. This is a standard part of assessment in preparation for IJV and SCV venous catheter insertion. Difficulty with compressing the SCV occurs in obese or muscular patients. Although no thrombus is present if the SCV is fully compressible along its course, absence of compression may be due to specific patient factors or the presence of an isoechoic thrombus.

Abdominal Ultrasonography

Competence in all aspects of abdominal ultrasonography is not needed by the critical care specialist. More advanced applications are under the purview of the expert-level radiologist, as they require a long training period that is unnecessary for the intensivist. Conceptually, this approach is similar to basic CCE. Implicit to competence in goal-directed abdominal ultrasonography is that the intensivist knows when to escalate to consultative radiology ultrasonography examination or abdominal CT. Goal-directed abdominal ultrasonography focuses on the evaluation of the urinary tract (kidney and bladder), identification of intraabdominal fluid, and evaluation of the aorta. A working knowledge of normal abdominal ultrasonography anatomy is required so that the intensivist can recognize abnormalities that require expert-level scanning.

Equipment Requirements and Scanning Techniques

Goal-directed abdominal ultrasonography is performed using a 3.5-Mz probe. Recent model portable ultrasonography machines in widespread use for CCUS offer the option of a curvilinear probe that is specifically designed for abdominal scanning. This probe design is not effective for cardiac scanning because of its size. Most manufacturers allow the phased-array cardiac probe to be rapidly configured for abdominal imaging. Purchase of a phased-array probe reduces equipment acquisition costs as only one probe is required to perform cardiac, thoracic, and abdominal scanning. The examination is performed using standard scanning planes that are specific to each organ system and requires knowledge of machine

controls, orthogonal views of the relevant target organs, and normal versus abnormal ultrasonography anatomy.

Kidney and Bladder Examination Technique

The evaluation of renal failure requires consideration of obstructive uropathy. Although obstructive uropathy is relatively rare, it is a potentially reversible cause that can be easily ruled out with ultrasonography. Bladder ultrasonography allows rapid evaluation of bladder volume, drainage catheter placement, and obstructive uropathy presenting as anuric renal failure that is remedied by manipulation of the drainage catheter.

The examination is performed with the patient in the supine position. The probe is positioned in the posterior axillary line over the lower lateral thorax in a longitudinal scanning axis. The tomographic plane is adjusted to obtain a coronal plane view of the right or left kidney. Once the kidney is identified, the probe is angled through the organ to fully image its anatomy. The size, cortical thickness/echogenicity, pelvicalyceal differentiation, and any pathologic findings are noted. Obstructive uropathy results in fluid collection with the collecting system. Although a primary indication for ultrasonography is identification of hydronephrosis, incidental pathology such as renal cyst, perinephric abscess, stone, or mass may be identified. The intensivist refers these findings to expert-level scanning by the radiology service.

The bladder is imaged by placing the probe immediately above the pubic bone in the midline. Using a transverse scanning plane, the tomographic plane is angled through the bladder to obtain a comprehensive view of the entire structure. Although the primary indication for ultrasonography is to identify urinary retention and to check the position of the drainage catheter, additional pathologic conditions may be identified that require referral to expert-level scanning by the radiology service.

Evaluation for Ascites

Ultrasonography allows the intensivist to identify, characterize, and access intraabdominal fluid. Identification of intraabdominal fluid has implications in urgent evaluation of the patient with abdominal trauma; thus ultrasonography for this application is now in standard use by the trauma team at the point of care. This has been codified in the focused assessment sonographic trauma (FAST) examination. In the medical patient, identification and characterization of ascites requires consideration of its etiology and management. This often requires ultrasonography-guided paracentesis.

Examination for Ascites

Whether performing a FAST examination on a trauma patient or for a less urgent indication on a medical patient, the examination technique is similar. Intraabdominal fluid is readily identified with ultrasonography. It collects in small amounts in the hepatorenal recess, the splenorenal recess, and the pelvis. It collects in larger amounts in the prehepatic and presplenic area, the subphrenic area, and the flanks bilaterally. Air-filled bowel floats on the ascites; characteristically, ultrasonography examination of the anterior abdomen detects air artifact with the fluid distributing in a dependent position.

The patient is in the supine position. The probe is placed in the right or left posterior axillary line using a longitudinal scanning axis over the lower lateral thorax, and the tomographic plane is adjusted to image the hepatorenal or splenorenal space for evidence of ascites manifested as a hypoechoic area. Prehepatic and subphrenic ascites can be identified by angling and/or tilting the probe. The FAST examination includes examination for pelvic ascites. This uses a technique similar to scanning the bladder with the depth setting adjusted to examine the area deep to the bladder. The examination for medical ascites includes the flank areas bilaterally, as this is the preferred site for performance of paracentesis.

Intraabdominal fluid has three characteristic features:

1. An anechoic or relatively hypoechoic space that is subtended by typical anatomic boundaries. This is the ascites.
2. Typical anatomic boundaries. These include bowel structures, the liver, or the spleen.
3. Dynamic changes. These include peristaltic movement of the bowel within the fluid and shape change of the fluid with application of force with the probe against the abdominal wall.

Examination of the Abdominal Aorta

Aortic pathology such as thrombus, atherosclerosis, dissection, or bleeding may be the primary cause for critical illness or may be detected as important secondary findings; therefore identification and characterization of the abdominal aorta is a component of goal-directed abdominal ultrasonography.

The patient is in the supine position. The probe is placed midline above the umbilicus in the transverse scanning plane. The tomographic plane is adjusted to obtain a transverse axis view of the abdominal aorta. The probe is then rotated in a clockwise direction to obtain a longitudinal view of the aorta with measurement of the diameter of the aorta and identification of any associated pathology. If bowel gas obscures the view, gentle downward pressure of the probe often clarifies the image.

Ultrasonography for Guidance of Critical Care Procedures

Ultrasonography can be used to guide a variety of critical care procedures, such as vascular access, pleural interventions, paracentesis, and pericardiocentesis. The widespread availability of high-quality bedside ultrasonography machines coupled with the intuitively obvious utility of the technique has resulted in widespread use of ultrasonography for guidance of procedures by critical care specialists. Independent of the literature that supports the utility of ultrasonography for this application, its widespread adoption must be predicated on a simple principle: there is an advantage to visualizing the anatomy that is relevant to the procedure rather than relying on anatomic landmarks and physical examination.

Ultrasonography for Guidance of Vascular Access

Central Venous Access

Ultrasonographic guidance of central venous access improves success rate and reduces complications at the internal jugular and femoral venous sites[49]; thus ultrasonographic guidance is now a standard of care owing to its advantages related to patient comfort, operator efficiency, safety, and ease of use.[50] Its use is supported by both national and international recommendations.[51–53]

Ultrasonography may be used in two ways to guide central venous access. In one method the operator scans the target area

to identify the appropriate site, angle, and depth for needle penetration into the vessel. The site is marked and the operator performs needle insertion with freehand technique (i.e., without real-time guidance of the needle). This "mark-and-stick" method is associated with a lower success rate and higher complication rate compared with real-time imaging throughout the needle insertion sequence, so real-time needle guidance is the preferred method.[54]

With real-time needle guidance technique, the target vessel may be imaged in either the short or long axis. Most studies describe the short-axis approach, but the long-axis approach has also been well validated. Operator preference determines which method to use. In the authors' experience, the short-axis approach seems to be in widespread use.

In using the short-axis view of the vessel, the needle tip is identified in the subcutaneous tissue well away from the vessel. It is then advanced forward under direct ultrasonographic control by moving the tomographic plane forward in tandem with the forward movement of the needle until the needle enters the vessel. The failure point with this method is that the operator may not maintain visualization of the needle tip as it is advanced toward the target vessel. This may result in adjacent organ injury. Identification and control of the needle tip are critical safety elements. We advise repeated deliberate practice on a task trainer (using a manikin to practice needle localization) before the first patient encounter.

In using the longitudinal view of the vessel, the entire needle is visualized while the operator advances it toward the target vessel. The failure point with this method is that the operator loses full visualization of the entire needle as it is advanced toward the vessel, and the barrel of the needle is misidentified as the needle tip. This may result in adjacent organ injury. Full visualization of the entire needle is a challenge to even a highly skilled operator. A solution to this problem is the use of a needle guide that attaches to the ultrasonographic probe. The needle is held by the device throughout the insertion sequence, so that it remains within the tomographic plane throughout the insertion process. As with the transverse view approach, we advise repeated deliberate practice on a task trainer before the first patient encounter.

Guidance of Internal Jugular Venous Access

Using the high-frequency linear vascular probe, the operator rules out pneumothorax bilaterally before the procedure by examining several anterior rib interspaces. The presence of lung sliding rules out pneumothorax before the start of the procedure. Before sterile skin preparation, both the right and left IJV are then examined in the transverse scanning plane along their length to check for anomalous anatomic position, small size, or a thrombus in the vessel. Although an ipsilateral IJV thrombus is a contraindication to catheter insertion, a contralateral thrombus is a relative contraindication to ipsilateral IJV access because of the possibility of formation of bilateral IJV thrombosis. Marked respiratory variation of IJV size may occur in patients with respiratory distress contraindicating an insertion attempt.

Following standard sterile preparation, the operator inserts the needle into the vessel using real-time ultrasonographic guidance of the needle. Most operators image the vessel in its transverse plane during insertion. After insertion of the guidewire, the operator documents wire position within the vessel before dilation, as the needle tip may have been deflected during wire insertion into adjacent carotid artery. Inadvertent dilation of the carotid artery is a serious complication of failed IJV access. The wire position is best identified by imaging the vessel in its longitudinal axis. After completion of the procedure, the operator examines several anterior rib interspaces to evaluate for the possibility of pneumothorax. The absence of ipsilateral lung sliding after the procedure when it was present immediately beforehand is diagnostic of a procedure-related pneumothorax.

Guidance of Subclavian Venous Access

The principles of ultrasonography guidance of IJV access (precheck and postcheck for pneumothorax, real-time needle guidance, and predilation check of wire position) apply equally to SCV access. The real-time needle guidance may be performed with the vessel visualized in either its longitudinal or transverse access according to operator preference. Because the SCV may not be easily compressible, the distinction between the SCV and the adjacent subclavian artery may be difficult. Observation of respirophasic variation of vessel size or the presence of a venous valve allows confident identification of the SCV. Flow augmentation within the vessel detected with color Doppler scanning upon squeezing the ipsilateral upper arm is characteristic of the SCV.

It often difficult to identify the wire within the SCV as the clavicle may block visualization of the lumen. Inadvertent dilation of the subclavian artery is a serious complication. An alternative method to confirm wire placement within the SCV before dilation is to image the inferior vena cava in the longitudinal axis. Identification of the wire within the IVC confirms appropriate placement within the SCV.

Whether from the IJV or SCV insertion site, correct placement of the catheter tip in the proximal superior vena cava may be confirmed with ultrasonography. Using either the subcostal long-axis view or the RV inflow view, the tip of the wire is identified and adjusted by the operator to rest at the juncture of the RA atrium and proximal superior vena cava (SVC). The catheter is then advanced over the wire until it is visible at the wire tip. After the wire is removed from the catheter lumen, the catheter tip may be further adjusted under ultrasonographic control for correct position.

Another method of confirming appropriate catheter tip position involves injection of agitated saline contrast (ASC) through the central line. Four patterns may be observed:

1. Immediate contrast opacification of the RA without laminar flow pattern. This indicates that the catheter tip position is within the RA and needs to be repositioned.
2. Immediate (<2 seconds) contrast entry into the RA with laminar flow pattern of contrast into the atrium from the SVC. This indicates appropriate catheter tip position and no need for repositioning.
3. Delayed (>2 seconds) contrast entry into right the atrium. This indicates that the catheter is above the level of the SVC and needs to be repositioned.
4. Lack of contrast entry into the RA. This indicates that the catheter tip is not within the venous circulation. Inadvertent arterial cannulation is a possibility.

The use of ASC to determine catheter position has been compared with chest radiography with strong concordance of results. Vezzani et al. reported that a laminar inflow pattern of ASC into the RA from the SVC that occurred within 2 seconds of the injection indicated appropriate catheter tip position. Right atrial placement was indicated by direct visualization of the catheter tip in the RA or by immediate opacification of the RA with use of ASC.[55] Delayed or absent entry of ACS into the RA was associated with malposition of the catheter. Weekes et al. confirmed these results in two additional studies.[56] Both investigations also included

examination for postprocedure pneumothorax using ultrasonography. Duran-Gehring et al. confirmed these findings while including adjustment of catheter position under ultrasonographic control and postprocedure check for pneumothorax.[57]

Provided the operator is able to obtain good-quality images of the cardiac chambers and pleural interface, ultrasonography can replace postprocedure chest radiography for purposes of checking catheter tip position and to rule out procedure-related pneumothorax; the limitation is that patient-specific factors such as body habitus or surgical dressings may degrade image quality to the extent that a chest radiograph is still required.

Guidance of Femoral Venous Access

The use of real-time ultrasonographic guidance for femoral venous access improves success rate and reduces complication of femoral venous access.[58] The vessel is imaged in its transverse access and the needle is guided into vessel using an out-of-plane technique. The standard needle entry point is just below the inguinal ligament where the common femoral vein lies medial to the common femoral artery. Much below this point, the femoral vein is posterior to the artery. As with the IJV and SCV, the operator checks for wire position before dilation.

Peripheral Venous Access

The use of real-time ultrasonography for guidance of difficult peripheral venous access improves the procedure success rate.[59] As the target vessel is often small, the procedure requires a high skill level of needle control. Operator preference determines whether the target vessel is imaged in its longitudinal or transverse axis.

Guidance of Arterial Access

The use of real-time ultrasonographic guidance for arterial access improves success rate and reduces complications.[60]

Ultrasonography for Guidance of Thoracentesis, Paracentesis, and Pericardiocentesis

Ultrasonography has a prime role in the performance of thoracentesis, paracentesis, and pericardiocentesis. Inadvertent injury to adjacent organs during performance of any of these may result in serious complications or death of the patient; therefore the front-line intensivist deploys ultrasonography on a routine basis to reduce the complication rate and improve success rate in these common procedures.

Although each of these procedures has different indications, contraindications, equipment requirements, and complications, the use of ultrasonography for guidance of the procedures shares a common principle: identification of a safe site, depth, and angle for needle insertion into the designated target without injury to adjacent organs. For large collections such as pleural, ascitic, or pericardial fluid, once a safe trajectory for needle insertion has been determined with ultrasonography, the procedure can be safely performed without real-time needle guidance using a mark-and-stick technique. Unlike vascular access, in which the preferred probe is a linear high-frequency probe, a lower-frequency probe is standard for body imaging because of its penetration. The phased-array cardiac probe is useful owing to its small footprint that allows easy scanning between rib spaces. Alternatively, a curvilinear probe designed for abdominal scanning may be used to guide paracentesis, although this probe design is not well suited for thoracic imaging.

Guidance of Thoracentesis

Regardless of whether ultrasonography is used to guide a simple diagnostic thoracentesis or to insert a pleural drainage device that requires wire insertion as part of the procedure, ultrasonography has a prime role in guidance of all pleural procedures. Its use is associated with a reduction of pneumothorax rate,[61] and it allows safe thoracic access in the patient using mechanical ventilatory support during which visceral pleural injury may result in tension pneumothorax.[29] Inadvertent subdiaphragmatic and cardiac injuries are rare, but potentially lethal, complications of pleural access. These can be avoided by use of ultrasonography to identify the relevant anatomy surrounding the pleural fluid collection.

Safe guidance of pleural access requires the operator to identify the pleural effusion (reviewed in the pleural ultrasonography section of this chapter) and to identify a safe site, depth, and angle for needle insertion that avoids injury to adjacent organs, such as the heart, liver, spleen, aorta, or mediastinal structures. Once identified, the site is marked and the depth required for needle penetration is measured from the frozen screen image. After equipment setup and sterile preparation are completed, the needle/syringe assembly is inserted by duplicating the angle of the probe used to identify the safe trajectory for insertion. For the operator to have a clear memory of this critical angle, a confirmatory scan is performed immediately before sterile preparation of the skin. No patient movement is permitted between the final confirmatory scan and needle insertion, as this may result in movement of the fluid within the thoracic cavity with a change in target location. It is inappropriate for the scan to be performed in the radiology suite with a skin mark applied followed by transfer of the patient to the ICU for needle insertion. The intensivist performs both the scan and the needle insertion at the bedside.

As with IJV and SCV access, the operator checks for pneumothorax both before and after thoracentesis as a routine practice. The absence of pneumothorax by ultrasonography examination obviates the need for postprocedure chest radiography. Both wire and final device position may be verified with ultrasonography according to operator preference. Kanai et al. have proposed that the trajectory for needle insertion be examined with the vascular probe to check for the rare occurrence of an aberrantly positioned intercostal vessel.[62] Although this has not been validated in a prospective study design, it can be done easily and could reduce the occurrence of a rare complication of thoracentesis.

Guidance of Paracentesis

Safe guidance of paracentesis requires the operator to identify the ascites (reviewed in the "Abdominal Ultrasonography" section) and to identify a safe site, depth, and angle for needle insertion that avoids injury to adjacent organs such as the liver, spleen, or intestine. The site is marked and the depth required for needle penetration is measured from the frozen screen image. The needle/syringe assembly is inserted by duplicating the angle of the probe used to identify the safe trajectory for insertion. No patient movement is permitted between the final confirmatory scan and needle insertion, as this may result in movement of the fluid within the thoracic cavity with a change in target location. The intensivist performs both the scan and the needle insertion at the bedside.

Guidance of Pericardiocentesis

Tsang et al. reported 1127 serial pericardiocenteses performed under ultrasonographic guidance with a very low complication rate.[63] This definitive study established that ultrasonography is the best

method to guide pericardiocentesis. The alternative—fluoroscopic guidance—is an inferior method as it does not allow a three-dimensional view of the heart, the pericardial effusion, the lung, or the liver that is obtained from the multiple tomographic planes achieved with dynamic ultrasonographic imaging at the bedside. Fluoroscopy allows identification of the position of the heart but is otherwise limited. Another outmoded technique used in conjunction with fluoroscopic guidance is the attachment of an electrocardiographic lead to the needle. Contact with the myocardium yields a current of injury on the electrocardiogram tracing indicating that the needle has been inserted too far. Rather than being preventive, this method detects the complication at the time of its occurrence. The use of ultrasonography for guidance of pericardiocentesis avoids the failure points intrinsic to fluoroscopic guidance.

As with thoracentesis and paracentesis, the operator establishes a safe site, depth, and angle for needle insertion with attention to the position of the liver and myocardium. The lung is identified by the presence of air artifact. Aerated lung blocks visualization of underlying structures, so the presence of air artifact at the site of probe placement contraindicates needle insertion. The liver is of particular concern when planning the needle trajectory from the subcostal approach because it will frequently block safe access to the pericardial effusion. When the parasternal approach is used, there is risk of injury to the internal mammary artery. The vascular probe is used to examine the planned needle trajectory to avoid this complication. When ultrasonographic control is used, the best trajectory for needle insertion is predicated on locating the greatest depth of the effusion in association with avoidance of adjacent organ injury. In the study by Tsang et al., 21% of pericardiocenteses were performed from the subcostal approach; the para-apical approach was used in the majority of cases.[63] With identification of a safe trajectory for needle insertion into the pericardial effusion, the site is marked and the depth required for needle penetration into the pericardial effusion is measured from the frozen screen image. After equipment setup and sterile preparation are completed, the needle/syringe assembly is inserted by duplicating the angle of the probe used to identify the safe trajectory for insertion. Myocardial or coronary artery laceration are lethal complications of pericardiocentesis, so the operator must precisely duplicate the angle of the probe when inserting the needle and limit the depth of insertion to that determined by measurement from the ultrasonographic image. Tsang et al. performed pericardiocentesis without real-time needle guidance with a high degree of safety. It may be useful to have a probe cover prepositioned in the sterile field—not for real-time needle guidance but in case the insertion is unsuccessful with need to adjust site, depth, and/or angle for access. After placement of the pericardial drainage device, its position is confirmed with ultrasonography by injection of ASC.

Ultrasonography can be used to guide other critical care procedures, such as lumbar puncture, transthoracic needle aspiration/biopsy, lymph node aspiration/biopsy, timing of chest tube removal, percutaneous drainage of lung abscess, pacemaker insertion, pulmonary catheter insertion, and gastric tube insertion.

Visualization of Vena Cava Diameter for Guidance of Fluid Resuscitation

The use of the IVC collapsibility index (based on respiratory cycle changes in the IVC diameter) to guide fluid resuscitation in mechanically ventilated patients gained clinical prominence over the past 10 years.[64] Recent data question the level of accuracy of the IVC collapsibility index in predicting fluid responsiveness while supporting the superior vena cava collapsibility index as more accurate and clinically useful than the IVC index.[65,66] Measurement of the SVC collapsibility index requires a transesophageal probe.

Quality Assurance and Imaging Archival Systems

As CCUS becomes a standard part of critical care fellowship training and routine practice by the front-line intensivist, quality assurance of scanning activity is a mandatory component of both training and clinical operations. This requires a well-designed imaging archival system. Review of images is needed for training purposes. Access to image files is required for clinical function, quality assurance, and billing purposes. There are several options for image archiving. One method is to interface CCUS imaging with the hospital radiology picture and archiving system (PACS). Although this method is an optimal solution, there may be impediments in achieving a CCUS-PACS connection. As an alternative solution, some CCUS programs use an ICU-based system for image archival. The typical system consists of a local hard drive that has wireless connectivity with the ICU-based machines. The system is compliant with the Health Insurance Portability and Accountability Act (HIPPA) and is relatively low cost. The system is well designed for image review, documentation purposes, quality assurance, and billing functions. Another solution, absent PACS connection or a local ICU system, is that the critical care team may simply download images from the ICU machine with a flash drive and transfer them to a hospital computer. This is a suboptimal solution associated with a high probability of data loss, difficulty in accessing the images, and risk of noncompliance with HIPPA regulations.

Conclusions

1. Ultrasonography is useful to guide the diagnosis and management of critical illness.
2. The intensivist who uses CCUS assumes all responsibility for image acquisition, image interpretation, and the immediate application of the results at the bedside of the critically ill patient.
3. Training in CCUS focuses on image acquisition, image interpretation, and the cognitive base of well-defined elements of echocardiography, thoracic ultrasonography (lung and pleura), ultrasonography for detection of DVT, screening abdominal ultrasonography, and ultrasonographic guidance of procedures.

Key Points

- The use of critical care ultrasonography is an integral part of the care of ICU patients.
- Professional societies formulated guidelines on training requirements and scope of practice intensivists.
- Basic critical care echocardiography is useful for identification, characterization, and management of the cause of shock.
- Thoracic ultrasound is based on artifacts, including A-lines, which are horizontal reflections of visceroparietal pleura with

no clinical significance, and B-lines. which are vertical lines resonating from the visceroparietal pleura that can represent pathology.
- Lung sliding consists of two pleural surfaces moving against each other in synchrony with the respiratory cycle. The absence of lung sliding may represent a pneumothorax.
- A simple three-point ultrasound examination of the chest identifies the cause of the respiratory failure in a high proportion of cases.
- Vascular ultrasonography performed by an intensivist is used to identify DVT thrombosis with high sensitivity and specificity and shortens the time to diagnosis.
- Screening abdominal ultrasonography is used to identify intraabdominal pathology.
- Ultrasonography used to guide bedside procedures, including central lines, thoracentesis, and paracentesis, decreases complications.

Review Questions

1. Which of the following statements is true?

a. The parasternal long-axis view (PSLAX) is best obtained at the sixth intercostal space in the midclavicular line.

b. In the apical four-chamber (AP4) view the tomographic plane is adjusted so the interventricular septum is oriented vertically.

c. The subcostal long axis view (SCLAX) is usually the most difficult view to obtain in mechanically ventilated patients.

d. The parasternal long axis view (PSSAX) is obtained by rotating 90 degrees from the AP4 view.

Answer: b. The AP4 view is best obtained at the midclavicular line in the sixth intercostal space. The PSLAX view is best obtained between the third and fifth intercostal spaces with the indicator on the probe facing the patient's right shoulder. The SCLAX view is often the easiest to obtain in intubated patients owing to the heart-lung interactions. The PSSAX is obtained by rotating 90 degrees from the PSLAX view. To obtain an accurate AP4 view the intraventricular septum should be vertical.

2. Which finding does not rule out a pneumothorax?

a. Lung pulse

b. A-lines

c. B-lines

d. Lung sliding

Answer: b. The pleural line represents the apposition of the parietal and visceral pleural surfaces. Lung sliding is two pleural surfaces moving against each other in synchrony and that rules out a pneumothorax. Cardiac pulsations that result in cardiophashic movement of the visceral pleural against the parietal pleura are called lung pulses and this finding rules out a pneumothorax. B-lines are vertical lines that originate at the pleural surface and extend to the bottom of the screen and their presence rules out a pneumothorax. A-lines are horizontally oriented lines that are located deep to the pleural line, but their presence does not rule out a pneumothorax.

3. Which of the following statements is true?

a. The mark-and-stick method for obtaining venous access has a success rate equal to real-time guidance of needle placement in the internal jugular vein (IJV).

b. Short-axis visualization of the IJV is associated with a higher success rate than long-axis visualization of the vein during placement of a central line.

c. The use of real-time ultrasonography does not improve the success rate for difficult peripheral venous access.

d. Ultrasound guidance decreases thoracentesis complications in mechanically ventilated patients.

Answer: d. Real-time ultrasound guidance improves the success rate and lessens complications when placing IJV central venous access. Short-axis and long-axis real-time visualization of the IJV have equivalent success rates during placement of central lines. Real-time ultrasonography improves peripheral intravenous success rates. Ultrasound guidance during thoracentesis in mechanically ventilated patients decreases complications related to the procedure.

- Anticoagulation

Complications and Troubleshooting
Multiorgan Support Technologies With CRRT
Quality Assurance and Improvement for CRRT

Acute kidney injury (AKI) occurs in 50% to 70% of all patients admitted to the intensive care unit (ICU), with approximately 20% to 30% of these patients receiving renal replacement therapy (RRT).[1] The incidence of dialysis-requiring AKI has steadily increased.[2] Among those critically ill patients with more severe AKI treated with RRT, continuous renal replacement therapy (CRRT) remains the most common modality prescribed in ICU settings worldwide.[3]

The establishment of CRRT evolved as a treatment of hemodynamically unstable patients unable to tolerate or achieve adequate therapy with conventional intermittent RRT (IRRT) or peritoneal dialysis. In general, CRRT offers many theoretical advantages over IRRT in ICU settings, including better hemodynamic tolerance, enhanced fluid balance, and enhanced uremic solute homeostasis and renal recovery; however, the superiority of CRRT relative to IRRT remains controversial. CRRT technology has undergone marked advances over time to improve efficiency, safety, and bedside simplicity.[4]

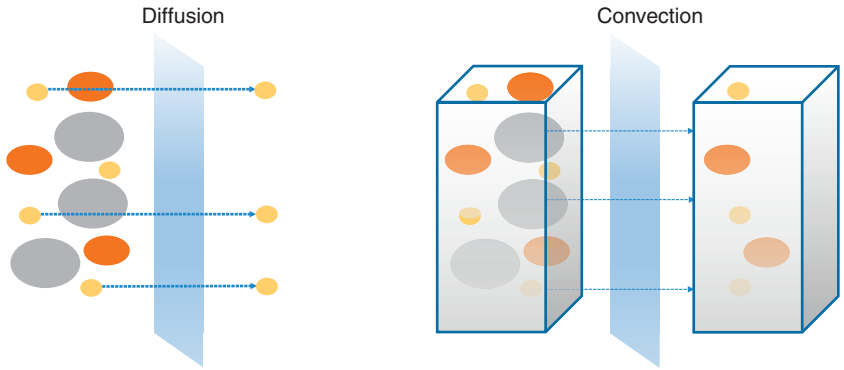
Physiologic Principles

CRRT uses a semipermeable membrane to alter the molecular composition and concentration of blood to restore the body back toward homeostatic balance. Blood flows along one side of the semipermeable membrane and a wash solution, dialysate, flows on the opposite side of the membrane. CRRT relies on two physical forces—*diffusion* and *convection*—either in isolation or in combination (Fig. 19.1).

In *diffusion*, the net movement of solute is dependent on the diffusivity of the solute and solvent, membrane permeability, membrane surface area, and concentration gradient, as governed by Fick's law. Other membrane characteristics also play a role: thickness, pore size, and electrostatic charge. To maximize the concentration gradient between the blood and dialysate, the dialysate runs countercurrent to the flow of blood. Any substance that is in higher concentration in the blood than the dialysate flows "down" its concentration gradient (e.g., creatinine, urea) and leaves the blood and flows into the dialysate. Conversely, any solute that is in higher concentration in the dialysate (e.g., bicarbonate) leaves the dialysate, crosses the semipermeable membrane, and enters the blood. Diffusion is most efficient in the clearance of low–molecular-weight (LMW) substances (<500 Da). This is particularly useful in correcting the imbalance in small molecule electrolytes (e.g., potassium [K], calcium [Ca], magnesium [Mg], phosphate [PO_4]). This form of transport occurs in continuous venovenous hemodialysis (CVVHD) and continuous venovenous hemodiafiltration (CVVHDF).

In *convection*, solutes move across a membrane in response to or following solvent flux (i.e., hydrostatic pressure is applied on the blood side of the membrane) or drag: solutes are moving along with the solvent containing them. *Solvent drag* is limited only by the pore size or electrostatic charge of any semipermeable membrane that is applied across the passage of the solution. In convection, the concentration of a solute is similar on either side of the membrane. Convection is more efficient at the clearance of high–molecular-weight substances (HMW) (500–5000 Da). Convective removal of plasma water from blood across a large-pore, semipermeable membrane results in an *ultrafiltrate* with a solute composition equivalent to plasma water. This occurs in both continuous venovenous hemofiltration (CVVH) and CVVHDF.

Fluid removal is termed *ultrafiltration* (UF). UF uses hydrostatic pressure, which is applied across a semipermeable membrane. This is a form of convective removal of solute. The clearance of molecules in UF is dependent on the volume of fluid removed.



• **Fig. 19.1** Forms of solute and water transport in continuous renal replacement therapy. Diffusion is depicted on the left. Solute is passively transported across a semipermeable membrane where molecules move from an area of higher concentration to an area of lower concentration. It is best for lower–molecular-weight solute clearance. Convection is depicted on the right. Solute is actively transported across the semipermeable membrane with the solvent (i.e., solvent drag) in response to the positive transmembrane pressure. It is best for higher–molecular-weight solute clearance.

It may be applied in isolation (in volumes usually <5 L/day) or in combination with other blood clearance techniques, such as dialysis. UF can occur in all forms of CRRT. To maintain isovolemia, each unit volume that is removed by UF is replaced with a balanced solution that is devoid of the metabolic waste and uremic solute.

Notwithstanding the mechanisms of plasma water and solute movement in CRRT, there are several parameters that can be used to characterize the performance of CRRT. *Clearance* is used to estimate the solute clearance of the blood and can be defined by the following formula:

$$K = N/C_b,$$

where K is solute clearance, N is the mass removal rate, and C_b is the blood solute concentration. In CRRT, the mass removal rate is estimated by measuring the actual amount of solute appearing in the effluent (i.e., the "waste" CRRT fluid) and is the product of effluent flow rate and the effluent concentration of the solute. This applies when diffusion occurs (i.e., CVVHD and CVVHDF). In CVVH, where no dialysate is used, clearance occurs by means of the solvent drag and is the product of the *sieving coefficient* (SC) and the UF rate. The SC represents the degree to which a membrane (i.e., filter) permits the passage of a certain solute. It can be represented by the following formula:

$$SC = C_{UF}/C_p,$$

where C_{UF} is the solute concentration in the ultrafiltrate and C_P is the concentration in the plasma. The SCs of LMW substances, such as urea and creatinine, approach 1.0 (i.e., cleared completely), whereas the SCs of HMW substances are more variable depending on the size of the substance and the membrane characteristics.

Another form of clearance of the blood is through a process called *adsorption*. This refers to molecules in the blood adhering to the semipermeable membrane. This process is dependent on the molecules contained in the blood and the composition of the semipermeable membrane. Adsorption is usually time dependent (i.e., as the semipermeable membrane is used over time, it will become saturated with a given molecule). The process begins anew when the membrane is changed (approximately every 72 hours). Selected inflammatory mediators and drugs may be cleared through this process.

CRRT is the continuous extracorporeal purification of blood (i.e., hemofiltration, dialysis, and UF) intended to support lost intrinsic kidney function. CRRT is performed through a centrally inserted double lumen-venous catheter where blood is driven by a pump through a semipermeable membrane via an extracorporeal circuit.

Principles of Ultrafiltration

Targeting fluid balance by removal is one of the most common indications for CRRT. In prescribing UF, a specific volume of fluid loss per unit of time should be determined. UF by CRRT is intended to be slow and continuous. The steady, constant loss of fluid at a rate that does not exceed the plasma-refill rate gives CRRT its superior hemodynamic stability compared with conventional intermittent hemodialysis (IHD). If extremely rapid UF in a short time frame is the therapeutic intent, intermittent forms of pump-driven UF are more efficient and therefore the treatment of choice. Common UF rates range from 50 to 400 mL/h. Larger amounts may be obtained if there is a need for rapid fluid removal. Automated continuous machines control UF through a volume-driven system, establishing a fixed loss of a determined amount of fluid from the system over a given period of time (usually on an hourly basis). The blood flow rate (QB) has a significant effect on any UF system. During UF, plasma water is removed from the blood as it moves through the dialysis filter, thereby increasing the viscosity of blood in the filter, measured by the filtration fraction. If the viscosity increases excessively, the system will clot. Therefore whenever UF is being prescribed, an appropriate QB must be prescribed to accommodate the prescribed UF. Careful attention should be given to the amount of excess recirculation. Rates greater than 15% are associated with a greater incidence of clotting. This tendency is more evident at higher UF rates (>300 mL/h), at which the returning blood tends to have a higher hematocrit, creating a more viscous, afferent blood flow.

Principles of Hemofiltration

If excessive fluid removal occurs, additional fluid may be needed as replacement to maintain intravascular volume homeostasis. This is termed *hemofiltration* or plasma water exchange. Fluid replacement

TABLE 19.1 Comparison of Predilution and Postdilution Techniques for Continuous Renal Replacement Therapy

Feature	Predilution	Postdilution
Clearance	Less clearance per milliliter	High small solute clearance per milliliter
Efficiency	Reduced efficiency by 10%–15% and reduced filtration fraction	
Ultrafiltration rate limitations	Ultrafiltration rate not limited	Ultrafiltration rate limited by blood pressure and hemoconcentration (filtration fraction)
Blood viscosity	Low viscosity of the blood	High viscosity of the blood and increased risk of clotting

can be delivered into the blood circuit either prefilter, before UF has occurred (predilutional hemofiltration), or after fluid has been removed by the filter (postdilutional hemofiltration) (Table 19.1). In predilutional hemofiltration, ultrafiltrated fluid reflects the mixture of blood and replacement solution. Because the oncotic pressure of blood is reduced within the filter, a greater rate of fluid removal is possible at the same transmembrane hydrostatic pressure. This increased rate of fluid removal is offset by dilution of plasma solute. In other words, the overall mass transfer of uremic toxins is reduced, and higher rates of fluid exchange are required to compensate. It is common to have exchange rates of 30 to 40 L/day. Predilutional hemofiltration may also be used for patients with high hematocrit levels in an effort to reduce clotting episodes. Postdilutional fluid replacement has the advantage of being easier to perform, with lower rates of fluid exchange compared with the predilutional system. One problem with this form of replacement is the increased oncotic pressures at the venous end of the filter. With high rates of exchange or high degrees of access recirculation, blood viscosity may be increased, which may predispose to clotting. Therefore fluid exchange rates may be dictated by such factors as hematocrit, blood flow, and access recirculation. The system should be kept below a filtration fraction of 15% in postdilution and 30% in predilution hemofiltration for efficient operation and a lower risk of clotting.

Principles of Hemodialysis

In hemodialysis (HD), the flow of dialysate is countercurrent to that of blood to maximize transmembrane concentration differences across all blood concentrations and at all levels of the filter. Blood flow (100–300 mL/min) is maintained well above the usual dialysate flow rates (15–30 mL/min). By contrast, in IHD, blood flow, rather than dialysate flow, is the limiting factor in diffusive clearance. Clearance of LMW substances is "flow dependent" because there is little resistance to transmembrane movement posed by the porous membrane. Substances of higher MW (e.g., β_2-microglobulin, vitamin B_{12}) are relatively slow in crossing the dialyzer membrane and are "membrane-dependent" molecules. Using the high-flux membrane characteristics generally used with continuous therapies, substances with molecular weights (masses) of 20,000 to 30,000 Da are transferred at rates that have an inverse relationship to their molecular weights. LMW substances (i.e., electrolytes, urea, creatinine) easily cross membranes at a rate that is directly proportional to membrane surface area, temperature, and concentration difference, and inversely proportional to viscosity, distance from the membrane, and molecular size. Protein-bound solutes are not subject to the concentration gradients that drive the molecular transport across the membrane. This concept is the basis for altered drug kinetics when patients are subjected to continuous supportive therapy. In CVVHD, dialysate flow rates remain the most influential factor in determining urea clearance. Dialysate usually is delivered via pumps at rates of 15 to 40 mL/min. Given adequate blood flow through the circuit, one can see why the limiting factor for flow-dependent transfer is the relatively low dialysate flow rate. Blood flow and filter membrane have limited effects on the diffusion of molecules compared with the potential of dialysate flow changes. In addition to the dialysate inflow, the dialysate outflow also must be controlled. By setting the outflow rate higher than dialysate inflow rates, one can create a negative transmembrane pressure, promoting UF across the dialysis membrane. This difference in flow is used to establish the rate of UF. An increase or decrease in this flow difference would increase or decrease the rate of fluid loss.

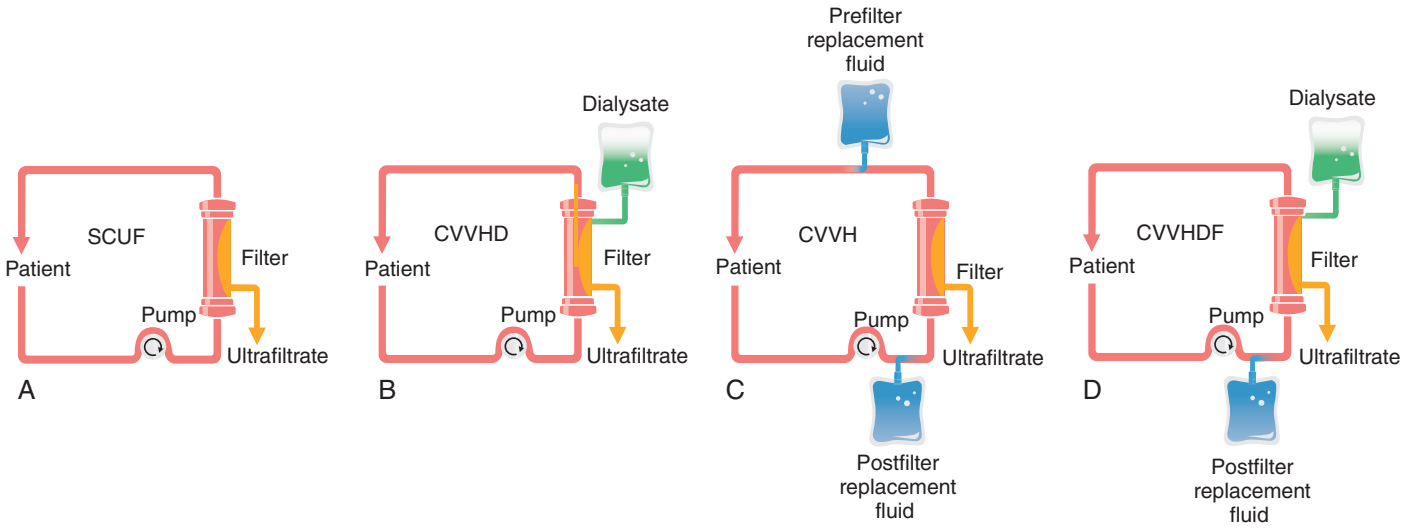
CRRT Modalities

The various modalities of CRRT are depicted in Fig. 19.2 and Table 19.2. CVVH is a form of CRRT where solute is cleared by convection and where the ultrafiltrate is either completely or partially replaced before (i.e., predilution) and/or after (i.e., postdilution) to the hemofilter (see Table 19.1). CVVHD is characterized by slow countercurrent dialysate flow into the dialysate compartment of the hemodialyzer, similar to traditional IHD. The main mechanism of solute removal is diffusion. CVVHDF combines hemofiltration and hemodialysis modalities. Solute clearance is achieved by both convective and diffusion mechanisms (Table 19.3). Slow continuous UF is based on the slow removal of plasma water (i.e., ultrafiltrate) only; there is no clearance of solutes. Table 19.2 summarizes the details of CRRT modalities.

Patient Selection and Timing of Initiation

There is no consensus on the optimal circumstances and timing for starting CRRT in critically ill patients.[5] The conventional "life-threatening" indications include volume overload, hyperkalemia, metabolic acidosis, uremia, and intoxication with a dialyzable compound (Box 19.1). Both patient-specific (i.e., reduced baseline kidney function) and provider-specific factors (i.e., perception of benefit) may influence the decision to start RRT. These may include use of CRRT to prevent AKI in patients with reduced kidney reserve (i.e., tumor lysis, myoglobinemia, nephrotoxic treatment), to prevent worsening nonrenal organ dysfunction owing to AKI, to help manage volume homeostasis (i.e., delivery nutritional support), and to compensate for respiratory acidosis in acute respiratory distress syndrome (ARDS).

Observational data and small clinical studies have suggested earlier CRRT may facilitate improved volume, acid-base, electrolyte, and uremic solute control.[6] Alternatively, an earlier start to CRRT may have disadvantages and be associated with risks, particularly for patients with marginal indications, including complications



• **Fig. 19.2** Summary of continuous renal replacement therapy (CRRT) modes showing the four primary CRRT modalities. A shows slow continuous ultrafiltration *(SCUF)* where only ultrafiltrate removal occurs. B shows continuous venovenous hemodialysis *(CVVHD).* C shows continuous venovenous hemofiltration *(CVVH)* with fluid replaced before *(Prefilter)* and after *(Postfilter)* replacement fluid. D shows continuous venovenous hemodiafiltration with fluid replaced postfilter *(CVVHDF).*

related to insertion and maintenance of vascular catheters, bloodstream infection, hemodynamic instability, and electrolyte abnormalities. Moreover, CRRT can also disrupt drug pharmacokinetics and increase bedside workload and health costs (Box 19.2).

Several recent randomized clinical trials have evaluated the optimal start for RRT in critically ill patients; however, findings have been contradictory (see Table 19.3). The ELAIN trial (Early versus Late Initiation of Renal Replacement Therapy in Critically Ill Patients With Acute Kidney Injury), a single-center study of 231 predominantly postsurgical ICU patients, found early compared with delayed start to RRT improved survival and kidney recovery in critically ill patients with AKI.[7] Alternatively, the Artificial Kidney Initiation in Kidney Injury (AKIKI) trial, a multicenter study of 620 critically ill patients without an urgent indication for RRT found no difference in survival; however, it showed only approximately 50% of those allocated to the delayed strategy received RRT.[8] These trials have highlighted the complexity of decision making for when to start RRT.[6]

Discontinuation of CRRT

Relatively few studies have focused on the optimal timing and circumstances for liberation from CRRT. Failure to successfully discontinue CRRT is associated with increased mortality.[9] Most studies have generally shown restoration of spontaneous urine output (>500 mL/24 h) to have the greatest predictive value for weaning, whereas persistent oligura (<100 mL/8 hr) predicted resumption of CRRT.[9–12] Urine biochemistry may also have value for predicting successful RRT discontinuation.[13–15] Timed 2-hour creatinine clearance (in the 12 hours preceding CRRT cessation) and greater 24-hour urine creatinine excretion have shown association for successful CRRT discontinuation. Although some urinary markers have shown more accurate prediction ability for successful RRT discontinuation than urine output, studies evaluated were small and conducted in single-center settings; thus the findings might not be generalizable. Furosemide is often administered to increase urine output and try to facilitate RRT liberation[9]; however,

a small trial failed to show furosemide improved recovery after CRRT cessation.[16] Limited data have not conclusively shown novel kidney damage and repair biomarkers provide added decision support on when to optimally attempt liberation from CRRT.[17,18]

Continuous RRT Versus Intermittent RRT

The clinical presentation and circumstances may favor either intermittent or continuous therapies (Table 19.4). There are many theoretical benefits that may favor the use of CRRT over intermittent forms of therapy, such as improved hemodynamic stability, faster resolution of fluid overload, and increased dialysis dose delivery (Table 19.5). Selected nonrenal indications favoring use of CRRT include fulminant hepatic failure, brain injury with risk of cerebral edema, and hyperammonemia (see Box 19.1).

The most important short-term advantage to CRRT over IRRT is the preservation and maintenance of hemodynamic stability. CRRT enables slower removal of solute and fluid from the intravascular space, permitting adequate time for vascular refilling from the interstitial and intracellular space, and theoretically minimizing iatrogenic episodes of hypotension. There are longer-term implications for renal recovery, with IHD-related instability potentially exacerbating or predisposing to recurrent episodes of kidney injury and disrupting repair and recovery. Data from rigorous, comparative studies, however, have shown variable conclusions.[19]

Robust data in support of the many theoretical advantages of CRRT are still lacking. In fact, Box 19.3 lists some of the limitations of CRRT. Interpretation of published data has been hampered by retrospective analysis, the use of historical control groups, incomplete randomization, incomplete descriptions of patient populations

• BOX 19.1 Indications for Renal Support

Absolute (Conventional) Indications

Pulmonary edema
Hyperkalemia
Metabolic acidosis
Uremic complications (i.e., encephalopathy, pericarditis, bleeding)
Toxin removal

Relative Indications

Medically refractory volume overload
Electrolyte imbalances
- Hyponatremia
- Hyperphosphatemia
- Hypermagnesia

Acid-base balance
- Metabolic acidosis
- Mixed acidosis/alkalosis
- Severe metabolic alkalosis

Nonrenal indications
- Lactic acidosis
- Myoglobinemia (i.e., crush injury)
- Tumor lysis syndrome
- Temperature control (i.e., hyperthermia/hypothermia)
- Hyperammonemia
- Nutritional support

Theoretical Indications

Immunomodulation

and RRT dose delivery, and study group–control group heterogeneity.

In the absence of a robust evidence base to guide clinical decision making, clinicians must adopt a patient-centric view to provide the most effective and safe RRT option for a given patient at a given point during their critical illness. The fundamental indications for delivering renal support remain unchanged (see Box 19.1) and range from the most frequent request for volume homeostasis to more esoteric indications such as immunomodulation. Common considerations in choosing to apply intermittent or continuous support are listed in Table 19.4, being mindful of numerous relative advantages and disadvantages of each (see Table 19.5). A final consideration relates to timeliness and feasibility. CRRT can often be prescribed in collaboration with ICU and nephrology, can be started any day of the week at any time of day, and can be started and managed solely by an ICU nurse, whereas this may not always be possible with IRRT. Recent data have suggested critically ill patients receiving RRT can be safely mobilized and receive physiotherapy, including those with catheters in the femoral position.[20–22]

Prescription Variables

Continuous Hemodialysis Versus Continuous Hemofiltration

Both hemodialysis and hemofiltration are equally efficient in the removal of LMW solutes; however, there is uncertainty about the incremental benefit afforded by hemofiltration. Hemofiltration may remove a wider spectrum of solutes, including inflammatory mediators and cytokines that are not removed by hemodialysis, making hemofiltration attractive, although unproven, as a potentially

TABLE 19.5 Intermittent and Continuous Forms of Renal Replacement Therapy

Feature	MODALITY		
	IHD	SLED	CRRT
Setting	Hemodynamically stable	Hemodynamically unstable	Hemodynamically unstable Increased intracranial pressure
Advantages	Rapid removal of low–molecular-weight substances and toxins Time when not receiving treatment may be used for diagnostic or therapeutic procedures Reduced anticoagulation exposure Low cost	Hemodynamic stability Time when not receiving treatment may be used for diagnostic or therapeutic procedures Decreased anticoagulation requirements	Easy control of fluid balance Hemodynamic stability Continuous removal of toxins
Disadvantages	Hypotension with rapid fluid removal Dialysis disequilibrium with risk of cerebral edema Technically complex	Slower clearance of toxins Technically complex	Slower clearance of toxins May require anticoagulation Patient immobilization Hypothermia Increased costs

adjuvant therapy for sepsis.[23] Mechanistic studies have shown the superiority of convective clearance in the removal of certain larger-sized MW solutes.[23–25] However, the effect of hemofiltration compared with hemodialysis on patient-relevant outcomes remains unclear.[26] A meta-analysis that compared hemofiltration and hemodialysis did not find any differences in patient survival or kidney recovery.[27] Pooled analysis did confirm; however, that hemofiltration was associated with greater removal of higher-MW solutes (i.e., β_2-microglobulin, vancomycin), but further found hemofilter survival may be extended by using hemodialysis, alone or in combination with hemofiltration, compared with hemofiltration alone.[27,28] Accordingly, the modality prescribed should be tailored to patient goals of therapy and institutional and provider expertise until further evidence becomes available.

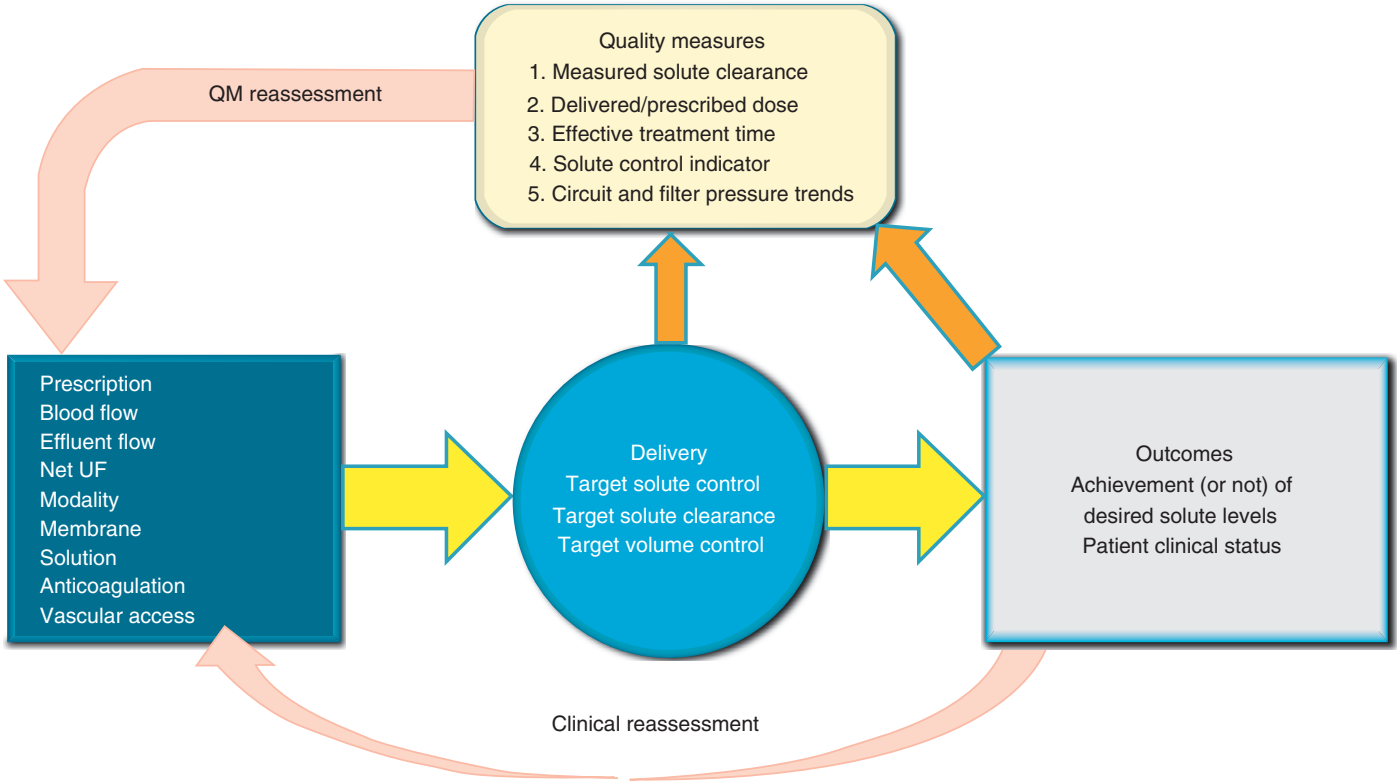
CRRT Prescribed and Delivered Dose

Dose in RRT refers to how much of a measure of the quantity of a representative marker solute is removed from a patient (i.e., reduction in serum creatinine, urea, or potassium or increase in serum bicarbonate over time during treatment with CRRT). Several trials had variably suggested that higher doses of CRRT improved outcomes in critically ill patients with AKI.[29–32] However, two large multicenter randomized clinical trials (ATN [Acute Renal Failure Trial Network] and RENAL [Randomized Evaluation of Normal versus Augmented Level Replacement Therapy]) failed to confirm these findings.[33,34] In the ATN study, CRRT was used in patients who were hemodynamically unstable while conventional IHD was used in patients who were hemodynamically stable.[33] Predilution CVVHDF was dosed to provide an effluent rate of 20 mL/kg per hour in the less intensive arm and 35 mL/kg per hour in the more intensive arm. In the RENAL study, patients were randomly assigned to postdilution CVVHDF at an effluent rate of 25 mL/kg per hour or 40 mL/kg per hour.[34] Neither study detected a survival or kidney recovery benefit from more intensive RRT, including across several subgroup analyses (e.g., sepsis). There is no evidence that high-volume hemofiltration (>35 mL/kg per hour) compared with conventional CRRT dose is beneficial in patients with septic or post-cardiac surgery vasoplegic shock.[35,36]

Accordingly, the current recommendation for a minimum dose of RRT supports the delivery of at least 20 to 25 mL/kg per hour of CVVH, CVVHD, or CVVHDF. However, patient-driven prescription should also be considered to ensure adequate metabolic, electrolyte, acid-base, and volume homeostasis.[37] Similarly, patients should receive a minimal dose of 20 to 25 mL/kg per hour with careful attention to ensuring that the target dose of therapy is actually delivered,[38] while recognizing that the prescription may need customizing to achieve these goals (Fig. 19.3). Both the RENAL and ATN trials showed that the delivered dose is often less than the prescribed dose. As such, this may practically translate into a prescribed dose of 25 to 30 mL/kg per hour if there was anticipation of treatment downtime or interruptions.

CRRT for Volume Control

The ability to control volume status is a fundamental consideration for CRRT initiation. Although studies have largely focused on timing of CRRT initiation based on serum creatinine or other metabolic thresholds,[7,8,39] a trigger based on a fluid accumulation threshold may be equally important in selected circumstances,



• **Fig. 19.3** Principles of continuous renal replacement therapy (CRRT) dose prescription. After the initial dose prescription, providers should reassess the response to the prescribed CRRT dose. This can be achieved by following select quality measures focused on dose delivery. Additionally, the patient's condition may change while undergoing CRRT, necessitating additional modifications. *QM,* quality measure; *UF,* ultrafiltration. (Reprinted with permission from Acute Dialysis Quality Initiative; www.ADQI.org.)

such as when fluid accumulation fails to respond to diuretic therapy or when their use compounds metabolic complications.[40,41] The primary therapeutic goal of CRRT in such settings is to allow for optimal nutrition, medication, and blood product administration, while concomitantly maintaining solute and volume homeostasis.[42] With respect to volume homeostasis, the decision to initiate CRRT should be based on the following four factors: (1) anticipated obligatory daily fluid requirement; (2) current and predicted output in terms of urine, chest tube, and/or other actual fluid losses; (3) likelihood of kidney function recovery in the subsequent 24 hours; and (4) the current fluid accumulation status. CRRT can prevent unavoidable fluid accumulation, maintain euvolemia, and facilitate organ support weaning (i.e., mechanical ventilation). CRRT enables hourly calculation and adjustment of UF and enables gradual fluid removal.

Technical Considerations

Access

Access for CRRT is accomplished through placement of a large (>12F) double-lumen central venous catheter. Preexisting arteriovenous fistulas or grafts in general are not used for CRRT, as this would require needles to be continuously placed in the fistula or graft, which may damage it.

Ultrasound guidance should be the reference technique for CRRT catheter placement.[4] A meta-analysis, evaluating a total of 830 catheters, showed reduced risk of catheter placement failure, higher rate of placement on the first attempt, decreased numbers of attempts, decreased time to successful placement, and a decreased rate of complications when compared with conventional anatomical landmark placement.[43]

Both the femoral and jugular venous routes are acceptable sites for catheter placement. Studies have shown similar rates of catheter-tip colonization and catheter-related bloodstream infection.[44,45] Placement of temporary catheters at the subclavian site are associated with risk of development of venous stenosis and are discouraged.[46]

Rates of catheter dysfunction were comparable between jugular and femoral locations with two notable exceptions.[47] First, catheter dysfunction and rate of recirculation may be higher with catheters in the femoral location, particularly with catheters less than 25 cm in length or with lower flow capacity.[47–49] Second, owing to anatomic differences, catheter placement in the left internal jugular vein was found to be associated with greater catheter dysfunction.[47] In patients in whom severe dysfunction develops, a catheter change is often required. Although guidewire exchange appears similar with respect to risk of catheter-tip colonization or infection compared with new site placement,[50] this strategy may be associated with a greater than threefold rate of catheter dysfunction.[51] The risk of catheter colonization and infection is strongly correlated to exposure time. Accordingly, the necessity of the RRT catheter should be reassessed daily and the catheter removed once RRT is no longer necessary.[5,52]

Tubing

Long tubing for blood transport increases exposure of blood to nonbiologic surfaces, which cools the blood and increases the risk of clotting. The presence of sampling ports, entry ports, and stopcocks may create blood turbulence. Negative preblood pump pressures can easily introduce air into the circuit from a dysfunctional afferent limb of a catheter and would carry the risk of air embolism were it not for the presence of an air trap in the efferent limb of the circuit.

Membrane

The details of membrane technology are beyond the scope of this chapter; however, the key highlights are presented here. The filter design in CRRT is hollow-fiber. The design consists of a blood compartment and a dialysate compartment, with respective inflow and outflow ports, separated by a semipermeable membrane. The hollow-fiber dialyzer consists of a tubular casing containing thousands of narrow capillary fibers through which blood flows between the arterial and venous header—two small spaces at either end of the filter where blood collects before and after running through the capillary fiber bundle. The capillaries, whose walls constitute the semipermeable membrane, are bathed in dialysate fluid, usually running in countercurrent fashion to blood flow. The hollow-fiber design allows for the maintenance of systemic blood pressure. However, if clots form at the arterial header, a large surface area of membrane for electrolyte exchange may become unavailable. Membranes may be made from (1) cellulose (e.g., cuprophane), (2) substituted cellulose (the free hydroxyl groups of cellulose, thought to activate complement, are bound to other substances, e.g., acetate in cellulose acetate membranes), (3) cellulosynthetic material (synthetic material incorporated with the cellulose polymer; e.g., Hemophan, Membrana Gmbh Solutions, Wuppertal, Germany), and (4) synthetic material (made of noncellulosic materials; e.g., polysulfone-polyacrylonitrile, polyamide, and polymethyl methacrylate). Nearly all conventional CRRT filter membranes now in use are biocompatible and synthetic.

Solutions

Replacement solutions take the form of either dialysate or replacement fluid. When hemofiltration is performed, replacement fluid composition dictates the resultant concentration of electrolytes. Similarly, knowing the composition of dialysate is important to determine to what equilibrium the electrolytes will settle. Calcium and magnesium levels should be monitored closely, and replacement should be initiated at an early stage. Because therapy is effective in removing phosphate and fluids generally do not contain phosphate, deficiencies develop, requiring supplementation. In general, these electrolytes are monitored every 12 to 24 hours.

Most fluids either contain lactate or bicarbonate as the base buffer. Other substances have also been considered, such as acetate or citrate. The use of citrate has an added advantage of being an anticoagulant. Acetate, although previously used in long-term HD, may give rise to vasodilation, myocardial depression, and increased oxygen consumption. As such, acetate should be avoided in CRRT. Lactate undergoes hepatic conversion to bicarbonate on an equimolar basis.[53] Although lactate is more stable than bicarbonate, there are theoretical disadvantages to its use in CRRT.[54] Although bicarbonate-based and lactate-based solutions can correct acidosis, bicarbonate is preferred because the metabolism of exogenous lactate may be impaired in critical illness, with accumulation giving rise to a paradoxical metabolic acidosis.[55] Hyperlactatemia carries with it potential negative hemodynamic effects and metabolic complications, including increased protein catabolism and reduced adenosine triphosphate regeneration.[56] Complications of lactate overload are more likely to develop in patients with hepatic dysfunction and organ hypoperfusion. Although lactate-based replacement dialysate solutions may be used safely in many critically ill patients, for the aforementioned reasons bicarbonate-buffered solutions may be preferable.[57]

Anticoagulation

Circuit clotting is the most frequent cause of therapy interruption in CRRT.[58] Various factors may account for the hypercoagulable state in a patient receiving CRRT. Anticoagulation during CRRT is necessary to preserve the life of the extracorporeal circuit, to maximize the CRRT dose, and to minimize blood loss caused by clotting during CRRT. Loss of the extracorporeal circuit increases bedside workload, increases costs, and may increase the risk of patient adverse events.

The ideal anticoagulant should have no effect on systemic hemostasis, no increase in hemorrhagic risk, be limited only to the extracorporeal circuit, optimize filter performance in circuit life, have a short half-life, be easily monitored, be easily reversible, and be inexpensive. Options for anticoagulation of the circuit include using no anticoagulation, unfractionated heparin, low-MW heparin, citrate, and in rare circumstances, thrombin inhibitors or prostaglandins. Box 19.4 lists current strategies to prevent circuit clotting. The most common anticoagulation used for CRRT worldwide remains unfractionated heparin.

The option of no anticoagulation is usually used in patients with intrinsic coagulopathies such as hepatic failure or thrombocytopenia. Circuits are usually primed with saline solution or heparin. Intermittent saline solution flushes may be used as well. The rates of filter clotting using this method vary widely; however, mean filter life is usually suboptimal between 12 and 48 hours.

Unfractionated heparin works by inactivating factors Xa and IIa. The half-life of unfractionated heparin is 90 minutes; however,

• BOX 19.4 Current Options to Prevent Continuous Renal Replacement Therapy Circuit Clotting

- Unfractionated heparin
  - Standard, prefilter
  - Regional
  - Low-dose, prefilter
  - Systemic
- Low–molecular-weight heparin
- Citrate
- No anticoagulation
  - Saline solution flushes
  - No intervention
- Prostacyclin
  - Epoporstenol
- Direct thrombin inhibitors
  - Hirudin
  - Argatroban
- Serine protease inhibitors
  - Nafamostat mesylate

this may be increased up to 3 hours in kidney failure. The use of protocolized unfractionated heparin involves continuous infusion at the arterial site of the circuit. Usually a bolus of 1000 to 5000 IU of heparin is used. Continuous infusion of heparin ranges between 5 and 20 units/kg per hour. In general, an activated partial thromboplastin time (aPTT) goal ranges between 1.5 and 2.0 times the normal. The reported circuit patency of this ranges between 18 and 48 hours. Advantages include the fact that it is effective, widely available, involves simple monitoring (i.e., aPTT), is easily reversed with protamine, is inexpensive, and has a relatively short half-life. Disadvantages include systemic bleeding, unpredictable kinetics, aPTT being an unreliable predictor for bleeding, heparin resistance, and heparin-induced thrombocytopenia.

Regional citrate anticoagulation works by chelating free calcium in the extracorporeal circuit and preventing activation of calcium-dependent coagulation. The anticoagulant effect of citrate is measured by ionized calcium levels. Anticoagulation is reversed by a calcium infusion. Citrate has a plasma half-life of 5 minutes and is rapidly metabolized by the liver, kidney, and muscle cells. The extracorporeal clearance of citrate is the same as that of urea (SC 0.87–1.0). In a typical circuit, blood from the patient is first infused with citrate, which chelates the free ionized calcium. This blood then enters the filter where a calcium-free dialysate is used. Postfilter ionized calcium is monitored and used to titrate the citrate rate to ensure anticoagulation. The goal is to maintain the ionized calcium at less than 0.40 mmol/L. The returning blood combines with the venous blood in the body, which normalizes the ionized calcium and prevents systemic anticoagulation. Calcium is infused through a separate central line to replace the calcium lost in the ultrafiltrate. Citrate is metabolized primarily in the liver to bicarbonate and the bound calcium is released. For CVVH, citrate may or may not be a component of the replacement fluid. Advantages of citrate are that it is regional and avoids bleeding complications. Disadvantages of citrate include metabolic complications. Metabolic consequences of citrate include metabolic alkalosis from citrate overdose or toxicity, metabolic acidosis in a setting of severe liver disease or hypoperfusion, hypernatremia from hyperosmolar citrate solutions (4% sodium citrate), and hypocalcemia and hypercalcemia from inappropriate calcium supplementation. The risk factors for citrate toxicity include fulminant hepatic failure or shock liver and nursing or pharmacy errors leading to overdose. The detection of citrate toxicity can be suspected when there is evidence of a rising anion gap, worsening metabolic acidosis, a falling systemic ionized calcium, escalating calcium infusion requirements, or a total calcium–systemic ionized calcium ratio greater than 2.5:1. Strategies to manage citrate toxicity include decreasing the citrate infusion rate, decreasing the blood pump speed, and increasing the dialysate flow rate. Another reported drawback to citrate was the necessity of complex protocols; however, recent data have reinforced that regional citrate anticoagulation is safe and more beneficial when compared with systemic heparin. Numerous trials have shown citrate yields no additional bleeding risk and leads to longer filter life compared with unfractionated heparin.[59,60]

LMW heparins have also been examined for their effect on circuit life. Prostacyclin, a potent, short-acting, endogenous inhibitor of platelet aggregation, has also been studied. Direct thrombin inhibitors such as argatroban and hirudin have been used in response to heparin-induced thrombocytopenia. Bleeding may be treated with the fresh frozen plasma transfusion. Clinical experience with various agents and strategies influence choice. Table 19.6 summarizes the advantages and disadvantages of selected anticoagulants.

Complications and Troubleshooting

CRRT is complex and complications can occur (see Box 19.2). CRRT machines have built-in alarms and sensors that can identify selected complications as they occur so that they may be promptly recognized and appropriate action taken (Table 19.7). Perhaps the most frequent problems encountered are electrolyte derangements. With the use of hemofiltration, as noted earlier, the replacement solution determines the final electrolyte outcome. The replacement solution must reflect the desired sodium, chloride, and bicarbonate concentrations in the patient's serum and the relative loss via the hemofilter. There are selected substances readily cleared but not routinely included in replacement solutions, including selected amino acids, trace elements, minerals, and phosphate.[61] These require monitoring and supplementation. In selected circumstances,

TABLE 19.6 Anticoagulation Options for Continuous Renal Replacement Therapy

Feature	None	Heparin (Unfractionated)	Low–Molecular-Weight Heparin	Citrate
Advantages	1. Reduced risk of bleeding	1. Widely available 2. Commonly used 3. Short half-life 4. Available reversal agent 5. Monitoring accomplished with routine tests (aPTT) 6. Low cost	1. Reduced risk of HIT 2. Predictable kinetics (weight-based dosing) 3. Monitoring not required	1. Strict regional anticoagulation—reduced risk of bleeding 2. Improved hemofilter lifespan
Disadvantages	1. Risk of blood loss and clotting of system 2. Microthrombi in filter may decrease efficiency	1. Narrow therapeutic index—risk of bleeding 2. Heparin resistance 3. HIT	1. Risk of accumulation in kidney failure 2. If monitoring required, then a nonroutine test is necessary (anti-factor Xa) 3. Incomplete reversal by protamine 4. May be more expensive UH	1. Citrate may accumulate in patients with hepatic dysfunction and shock 2. Metabolic complications (acidosis, alkalosis, hypernatremia, hypocalcemia, hypercalcemia) 3. Increased complexity requires a strict protocol

aPTT, Activated partial thromboplastin time; *HIT,* heparin-induced thrombocytopenia; *UH,* unfractionated heparin.

TABLE 19.7 Summary of Potential Complications During Continuous Renal Replacement Therapy

Alarm	Possible Causes	Actions
High transmembrane pressure	1. Clogging filter 2. Kinked catheter	1. Check filter for clots 2. Check catheter position
High venous pressure	1. Kinked catheter 2. Clotted line	1. Check catheter position 2. Declot vascular access
Low arterial pressure	1. Kinked catheter 2. Clotted line 3. Hypovolemia	1. Check catheter position 2. Declot vascular access 3. Stop ultrafiltration and decrease blood flow rate
Line disconnection	1. Line disconnected from patient 2. Circuit kinked before pressure sensor 3. Clotted line excluding pressure sensor	1. Check circuit and patient for disconnection 2. Evaluate circuit for change

the composition of the replacement and dialysate solutions may need to be altered to achieve target electrolyte concentrations.

Multiorgan Support Technologies With CRRT

CRRT may be used with other organ-supporting technologies. These include specific therapies for sepsis, ARDS, and liver failure.

Endotoxin is a lipopolysaccharide and an outer membrane molecule essential for all gram-negative bacteria. It is the causative agent in gram-negative bacteria believed to mediate septic shock. Sorbents composed of polymyxin B–immobilized fibers have been used to adsorb endotoxin in sepsis. CRRT therapy with polymyxin B–immobilized fibers has shown improvements in hemodynamic profile and organ dysfunction; however, it has not been shown to improve patient outcomes. Several additional sorbent and novel high-flux hemofilters have been developed and shown to clear inflammatory mediators; however, their impact on patient outcomes is uncertain.[62,63]

Albumin dialysis, through the Molecular Adsorbent Recirculating System (MARS, Gambro/Baxter International, Deerfield, IL), may be integrated into a conventional CRRT circuit for patients with advanced liver failure or in selected overdoses (i.e., calcium-channel blockers).[64] MARS uses albumin as a dialysate and contains charcoal and anion-exchange cartridges to clear protein-bound toxins. Data from small trials have shown MARS clears drugs and toxins (i.e., phenytoin, digoxin), bilirubin and bile acids, and reduces hepatic encephalopathy and hepatorenal syndrome; however, it has not been proven to improve transplant-free survival.

CRRT can be configured to deliver therapeutic plasmapheresis (TPE). TPE is the removal of plasma and is usually exchanged with albumin or fresh frozen plasma. TPE may be indicated for microangiopathies in which antibodies, immune complexes, or cryoglobulins are contributing to multiorgan dysfunction. A small clinical trial has shown improved survival in patients with septic shock with use of TPE[65]; however, further corroborative studies are needed. Recently TPE was also shown to improve survival in fulminant hepatic failure with multiorgan dysfunction.[66]

In ARDS, lung-protective mechanical ventilation targets low tidal volumes; however, it may be limited by significant hypercapnia and respiratory acidosis. A low-flow extracorporeal carbon dioxide removal circuit may be integrated in parallel with a conventional CRRT circuit to remove excess carbon dioxide and enable delivery of lung-protective ventilation.[67]

Quality Assurance and Improvement for CRRT

To ensure effective, safe, and timely CRRT, programs must measure and review their own CRRT data. Selected quality indicators should be routinely captured for all patients receiving CRRT to monitor and benchmark performance and identify areas for improvement (Table 19.8).[68] Programs should establish regional committees to review data and engage in quality improvement initiatives to continuously aim to provide high-quality CRRT care.

Key Points

- CRRT has many theoretical advantages over IHD, particularly maintenance of hemodynamic stability, enhanced fluid removal, and increased dose delivery. However, evidence has not shown patient outcome advantage.
- CRRT modality (diffusion vs. convection) has not shown an advantage in patient outcome. However, hemofiltration (CVVH/CVVHDF) is associated with greater clearance of larger MW solute and shorter filter survival compared with hemodialysis (CVVHD).
- CRRT prescription would typically include the following: a blood flow rate 150 to 350 mL/min; a cumulative replacement and/or dialysate flow rate 20 to 25 mL/kg per hour (effluent); and an UF rate determined by the daily fluid balance goal of the patient. Considering treatment downtime is common, the delivered dose may be less than the prescribed dose and the prescribed dose increased accordingly.
- Many strategies are available for anticoagulation of the extracorporeal circuit. Heparin, citrate, and no anticoagulation are the most commonly used. Education and standardized protocols should be used to prevent adverse events and complications.
- There is no consensus on the best strategy for when to initiate CRRT in the absence of absolute (or life-threatening or medically refractory) complications of AKI. Both patient- and provider-specific factors should be used to individualize the decision to start CRRT.
- There is no consensus on the optimal time to discontinue CRRT; however, the most reliable measure for successful discontinuation is spontaneous urine output.

TABLE 19.8 Summary of Suggested Core Quality Indicators for a Continuous Renal Replacement Therapy Program

Quality Indicator	Donabedian Framework[a]	Definition	Proposed Benchmark
Education and training	Structure	CRRT programs have formal processes for training and certification of bedside staff	Annual
CRRT order and anticoagulation set protocols	Structure	CRRT programs have standardized order sets for CRRT prescription and anticoagulation monitoring	Present
Filter life span	Structure	The proportion of filters that last 72 hours before being changed, censored for planned circuit disruption. Filter change is dictated by elevated TMPs <250 mm Hg for greater than 5 min	>60% of filters
LMW solute clearance	Process	Change or relative stability in small solutes (SCr, urea) over time	Stable or increase of <10% over 24 h
Delivered dose	Process	The percentage of the prescribed dose that is delivered to the patient	>80%
Downtime	Process	The amount of time CRRT was not operating per 24-h period	<20%
Fluid management	Process	The percentage of prescribed ultrafiltrate removed from the patient daily	>80%
Time prescription to Initiation	Process	The time gap from the time of CRRT prescription to CRRT initiation	<4 h
Bleeding	Outcome	Any bleeding that requires the transfusion of PRBCs during the delivery of CRRT	No events

[a]The Donabedian Framework promotes the evaluation and classification of quality indicators across structure, process and outcome measures.
CRRT, Continuous renal replacement therapy; *SCr,* serum creatinine; *TMPs,* transmembrane pressure.

Review Questions

1. A 70-kg 63-year-old male presents to the emergency department with community-acquired pneumonia and decreased level of consciousness. He is intubated and becomes markedly hemodynamically unstable. He is given 10 L of intravenous crystalloid before left internal jugular central venous catheter insertion and initiation of high-dose vasopressor therapy. He is immediately transferred to the intensive care unit (ICU) for ongoing management. Following ICU admission, the patient remains anuric despite ongoing fluid therapy with a total fluid intake of 250 mL/h. Blood work reveals a potassium level of 5.6 mmol/L, creatinine 1.8 mg/dL, and carbon dioxide 20 mmol/L. The decision to initiate renal replacement therapy (RRT) is made. Which of the following statements is correct?

a. The primary indication for RRT is for ongoing fluid management.

b. A right subclavian dialysis catheter should be inserted for RRT.

c. Intermittent renal replacement therapy should be initiated as this is the patient's first dialysis treatment.

d. Ultrasound guidance for catheter insertion is unnecessary as the priority is rapid initiation of RRT.

Answer: a. Ultrasound guidance is the reference technique for catheter placement. This decreases the risk of catheter placement failure and complications. Additionally, while theoretically decreasing the risk of infection, placement of temporary catheters at the subclavian site should be avoided owing to the risk of venous stenosis; either femoral or jugular sites are more preferable. Although smaller catheters convey a smaller puncture site, large catheters (>12F) are necessary to ensure sufficient blood flow. Continuous RRT (CRRT) would be preferential initial therapy over intermittent RRT in this clinical situation as the patient is receiving high-dose vasopressors. Traditional indications for RRT include volume overload, hyperkalemia, metabolic acidosis, uremia, and intoxication with a dialyzable compound. In this case, the patient has received a large fluid challenge (<20–30 mL/kg) and has ongoing large fluid requirements (~250 mL/h). As he is anuric, unable to manage his fluid status on his own, and not likely to imminently recover kidney function, RRT is necessary for ongoing volume management.

2. On day 2 of ICU admission, blood culture reveals gram-negative bacilli. Additionally, although the patient's vasopressor requirements are improving, the patient has worsening hypoxemia with a PaO_2/FIO_2 (partial pressure of oxygen–fraction of inspired oxygen) ratio of 105. Which one of the following statements is most correct?

a. High volume continuous hemofiltration should be initiated to clear inflammatory mediators and improve the patient's septic shock.

b. A prescribed dose of 35 mL/kg per hour should be initiated in anticipation of treatment downtime or interruptions.

c. Unfractionated heparin anticoagulation should be used as it is the most common form of anticoagulation used and leads to longer filter life compared with regional citrate anticoagulation.

d. Ultrafiltration should be initiated at 25 mL/h to initiate fluid removal to improve oxygenation while not exceeding the plasma-refill rate.

Answer: d. Although endotoxins and other inflammatory mediators can be cleared with high-volume hemofiltration, there is no evidence for improved patient outcomes. Furthermore, the evidence would support a minimal delivered CRRT dose of 20 to 25 mL/kg per hour. To ensure the target dose of therapy is actually delivered, this often translates into a prescribed dose of 25 to 30 mL/kg per hour. The choice of anticoagulation in RRT is important; unfractionated heparin has been shown to have shorter filter life compared with regional citrate. Hence, although it is the most common anticoagulation used for CRRT, regional citrate anticoagulation is preferable to extend filter life span and circuit survival. Finally, fluid management remains an important principle for CRRT. Initial ultrafiltration should occur at a low rate (e.g., 25 mL/h), which may be increased according to the patient's clinical status. This slow continuous initial rate of ultrafiltration optimizes hemodynamic stability by not exceeding the plasma-refill rate.

3. By ICU day 5, the patient is hemodynamically stable, is producing 30 mL/h of clear urine, and his gas exchange is improving. He is still currently receiving CRRT with an ultrafiltration rate of −100 mL/h. Which of the following is most correct?

a. The patient is likely recovering kidney function based on his urine output.

b. The patient should continue CRRT until he has recovered sufficient kidney function to be discharged from the ICU.

c. The patient should be subject to a furosemide challenge to increase urine output and facilitate CRRT liberation.

d. Blood and urine should be screened for kidney damage and repair biomarkers to provide additional decision support on timing for liberation from CRRT.

Answer: a. It is important to continuously screen patients for kidney recovery, and RRT should be discontinued as soon as clinically appropriate. There is evidence to support several parameters that may predict successful discontinuation of CRRT. These include restoration of urine output (>500 mL/24 h) (without diuretic exposure), an increased 2-hour creatinine clearance, and an increase in 24-hour urine creatinine excretion. There is no evidence that a furosemide challenge or continuous infusion can predict or facilitate CRRT liberation. There is also limited evidence for use of kidney damage and repair biomarkers to guide CRRT discontinuation.

Summary and Conclusions

Considerations in Managing Sedation, Analgesia, and NMB in the ICU

Critically ill patients often experience unpleasant sensations, including pain, anxiety, dyspnea, and other forms of distress.[1–3] This is particularly true for mechanically ventilated patients who make up a significant proportion of patients in intensive care units (ICUs). The ICU environment, and ICU care in general, is widely regarded as not ideally suited to patient comfort. For example, most patients have a variety of indwelling tubes and vascular catheters and some have surgical incisions. Further, sleep disruption is common, sound and light levels are often excessive, and patient communication and mobility is impaired. Core principles of ICU care are to provide comfort to our patients and to relieve their suffering.[4–7] Although nonpharmacologic interventions can improve patient comfort,[8] clinicians have relied on administration of analgesic and sedative medications to reduce the sensation of pain and anxiety, to control agitation, and to enhance tolerance of the ICU environment.[9–11] However, clinical experience and research has demonstrated the hazards associated with excessive or unnecessarily prolonged sedation and the importance of accurately achieving targeted analgesia and sedation.[12–15] Clinical practice guidelines from the Society of Critical Care Medicine (SCCM)[4] and other guidelines and reviews on sedation and analgesia[16–21] highlight the importance of adopting a management approach that is patient-focused and strives to use the lowest effective dose of medications, maintaining light levels of sedation in ICU patients as clinically feasible. The past decade has also brought a greater appreciation of the importance of development of delirium in the ICU on long-term outcomes including downstream cognitive dysfunction.[4,22–27] The topic of ICU delirium is reviewed in detail elsewhere in this textbook (see Chapter 69). Finally, the use of neuromuscular blocking agents (NMBAs) to achieve therapeutic paralysis is undergoing reevaluation, particularly for optimizing management of acute respiratory distress syndrome (ARDS).[28–31] The use of sedatives, analgesics, and NMBAs in managing critically ill patients is reviewed in this chapter.

Surveys and clinical reports indicate that the majority of ICU patients experience pain, dyspnea, or other forms of distress and receive sedative and/or analgesic medications.[9–11,32] Some key terms and definitions related to patient distress and neurobehavioral abnormalities in ICU patients are presented in Box 20.1. Much of the discomfort is related to various stressors. In one case series, pain, inability to sleep, and the presence of tubes in the nose or mouth were the most prominent stressors reported by recovering ICU patients.[3] Clearly, providing relief from these and other issues is an important goal of analgesic and sedative therapy. Consequences of suboptimal analgesia and sedative therapy can include problems related to inadequately controlled pain and anxiety or excessive sedation.

Agitation, regarded as excessive motor activity associated with internal tension, is perhaps the most widely recognized manifestation of uncontrolled anxiety or pain, because it can result in dramatic events, such as self-removal of important tubes and catheters, or even violence directed toward care providers. Overt agitation is a common occurrence among critically ill patients with rates as high as 20% of patient-shifts and nearly three-quarters of patients during ICU stay.[33–36] Self-removal of critical indwelling tubes and vascular catheters is the most common manifestation of overt agitation, placing the patient in peril from loss of an artificial airway and positive-pressure ventilation, abrupt cessation of infusion of critical medications such vasopressors, and/or the risk and discomfort associated with reinsertion of tubes and lines.[37] In prospective studies, device removal rates range widely from 22 to 157 events per 1000 patient-days[38,39] and have an associated added cost.[40] Documentation of patient agitation has become commonplace with the broad use of scales that address both sedation and agitation.[41] In addition to device removal and care provider assault, agitation is often accompanied by an intense stress response with catecholamine surge, resulting in tachycardia, hypertension, and tachypnea.[42,43]

• BOX 20.1 Terms for Patient Distress and Neurobehavioral Abnormalities in the Critically Ill

Agitation: Excessive motor activity associated with internal tension. The motor activity usually is nonpurposeful but may be irrationally purposeful and counterproductive.
Anxiety: A sustained state of apprehension with accompanying autonomic arousal in response to a real or perceived threat.
Apprehension: The subjective experience of dread and foreboding.
Autonomic arousal: Stimulation of the sympathetic and parasympathetic nervous systems and the autonomically controlled humoral axes. Autonomic arousal is manifested physically by tachycardia, systolic hypertension, hyperventilation, and diaphoresis.
Cognitive dysfunction: Reduced memory and analytical skills, confusion, and impaired judgment.
Coma: A state of unarousable unresponsiveness.
Defensive withdrawal: A physical and psychological reaction to an unpleasant situation manifested by avoidance, reduced responsiveness, and hypervigilance.
Delirium: An acute, potentially reversible impairment of consciousness and cognitive function that fluctuates in severity. Manifestations include apprehension, agitation, cognitive distortion, abnormal thought processes (including hallucinations), and impairments of short-term memory, arousal, and attention.
Distress: A global term for suffering, strain, or misery affecting the body or the mind.
Dyspnea: The experience of difficulty or distress in breathing.
Obtundation: Pathologic drowsiness, often accompanied during wakefulness by reduced attention and interest in the environment.
Pain: An unpleasant sensory or emotional experience associated with either actual or potential tissue damage that typically leads to evasive action.
Patient-ventilator asynchrony: An erratic breathing pattern in mechanically ventilated patients characterized by suboptimal matching of patient respiratory drive and mechanics with ventilator function.
Stress response: Reactions of the body and the mind to threats or forces of a deleterious nature that tend to upset physiologic homeostasis.
Stupor: A sustained state of spontaneous unarousability interruptible only by vigorous, direct external stimulation.

Withdrawal of continuous infusion sedative and analgesic medications to promote awakening is associated with a twofold to fourfold increase in circulating catecholamines,[44] and can produce evidence of withdrawal that peaks within 6 hours.[45] Adrenergic stress response has been linked to hypercoagulability, glucose intolerance, increased catabolism, immunosuppression, sleep disturbance, and delirium. Furthermore, this can precipitate adverse events such as myocardial ischemia, increased intracranial pressure (ICP), tachyarrhythmias, and complications of uncontrolled hypertension in susceptible individuals.[46] Finally, it is also worth considering that overt agitation can be a marker for extreme distress that has a cause which may be life-threatening and/or rapidly resolves upon recognition and management.[19,33,34] Endotracheal tube malposition or obstruction, severe chest pain from myocardial ischemia, and tension pneumothorax are examples of conditions for which severe agitation in the nonverbal patient may be an important clue to an urgent dangerous situation. In fact, agitation was a common clinical antecedent before cardiopulmonary arrest in one study.[47]

Although the primary effects of analgesic and sedative medications are the relief of pain, anxiety, agitation, and related problems, such relief is usually accompanied by a reduced level of consciousness. Excessive and/or unnecessarily prolonged impaired sensorium is associated with additional complications—as a result of excessively deep sedation (i.e., pressure sores or nerve compression from reduced movement) or as a result of sedation-related delayed recovery from critical illness and mechanical ventilation with higher rates of complications and interventions related to longer ICU length of stay (LOS). In addition, long-term neuropsychological consequences of ICU sedation are increasingly recognized.[27] Accordingly, it is critical to take a structured approach to managing analgesia and sedation that includes carefully examining the specific patient-focused goals of therapy, using validated tools for evaluation and monitoring, and implementing management that explicitly targets using the lowest effective dose of the best analgesic and sedative medications for the specific patient. Some important components for analgesia and sedation management gleaned from prior reviews and current clinical practice guidelines are listed in Box 20.2.[4,16–21]

Analgesia and sedation are most effective when they are patient-focused because each patient and circumstances have unique features that may influence the response to therapy. Some of the predisposing and precipitating conditions that can contribute to the development of anxiety, pain, and delirium are noted in Fig. 20.1.[16,33] For example, a variety of underlying medical conditions—such as alcohol or substance abuse,[48] psychiatric disorders, and chronic pain—can influence the likelihood of developing anxiety, pain, or delirium and can affect the response to therapy.[35] Further, inadvertent discontinuation of home medications, such as opioids, benzodiazepines, or antipsychotic medications, because of lack of awareness of their prior use is not uncommon with unscheduled ICU admissions and is an important reason to perform detailed medication reconciliation with patients and their family members. Although the notion that "ICU psychosis" is actually caused by the ICU is misleading, it is clear that excessive noise, light, and repeated patient awakening to check vital signs or perform tests at night is common, contributes to fragmented sleep, and can provoke anxiety and delirium.[49–52] Sleep hygiene is clearly important and simple interventions such as patient use of earplugs and periods of "quiet time" can decrease the incidence of delirium and sedative drug requirements.[53,54] Acute medical illness, surgical interventions; mechanical ventilation and the related interface (i.e., tracheostomy tube, endotracheal tube, oronasal mask); and nursing interventions such as suctioning and turning can contribute to pain and discomfort.[3,55] A variety of conditions and medications have been associated with development of delirium and/or agitation, as displayed in Box 20.3.[33]

Pain Management in the Intensive Care Unit

Pain is widely experienced in the ICU setting and can result from invasive procedures, surgery, and monitoring devices, as well as more direct stimuli from injury, inflammation, and immobility.[56] Treating pain is a core component of caregivers' responsibility to relieve suffering, but it also has physiologic benefits of relieving pain-induced altered glucose control, myocardial ischemia, immune system dysfunction, hypercoagulability, ventilator asynchrony, impaired ventilation, and disrupted sleep.[56] Mechanisms for these downstream effects include neurohormonal derangements, catecholamine release, and stress response.[56,57]

Effective treatment of pain begins with the assumption that pain is widely present and that caregivers should systematically evaluate each patient for the presence of pain and its intensity and characteristics on a repetitive basis.[4,6,8,56] Caregivers tend to

• BOX 20.2 Key Concepts for Management of Sedation and Analgesia

1. Develop a multiprofessional, structured approach for managing analgesia and sedation in your ICU. Use key user buy-in, education, protocols, order sets, ICU rounding checklists, and other tools such as implementation of the ABCDEF bundles to promote durable integration into patient care.
2. Perform patient assessment and optimize ICU environment:
   a. Identify predisposing and precipitating factors; manage correctable factors.
   b. Optimize patient comfort and tolerance of the ICU environment, including controlling light and noise, and promoting sleep.
   c. Optimize mechanical ventilation settings for patient-ventilator synchrony.
   d. Perform preemptive analgesia to alleviate pain associated with painful procedures.
3. Regularly perform and document structured patient evaluation and monitoring:
   a. Establish and communicate treatment goals.
   b. Assess presence and severity of pain, as well as response to therapy using self-report and/or a validated pain assessment tool.
   c. Assess level of sedation using a validated sedation scale, as well as response to therapy.
   d. Assess presence and severity of agitation using a validated agitation scale.
   e. Identify delirium using a validated delirium assessment instrument.
4. Implement a structured patient-focused management strategy:
   a. Select analgesic and sedative drugs based on patient needs and unique characteristics (such as alcohol or substance abuse), drug allergies, organ dysfunction (particularly renal or hepatic dysfunction), need for rapid onset and/or offset of action, anticipated duration of therapy, prior response to therapy, and published evidence.
   b. Focus first on analgesia, then sedation. Use opioids as primary analgesics but consider adding adjunctive agents or interventions.
   c. Evaluate and manage severe agitation, including search for causative factors, and rapidly intervene.
   d. Identify delirium, correct precipitating factors, and administer appropriate interventions and medications to reduce the intensity and duration of delirium.
   e. Titrate analgesic and sedative drugs to a defined target, using the lowest effective dose and aiming for light level of sedation.
   f. Implement a structured strategy to avoid accumulation of medications/metabolites: use scheduled interruption of medications, or intermittent dosing, of analgesic and sedative drugs. Perform daily SAT safety screen to select proper candidates for interruption of sedation.
   g. Link reductions in analgesic and sedative drugs to spontaneous breathing trials and to early mobilization, implementing the ABCDEF bundles.
   h. Avoid potential adverse effects of analgesic and sedative drugs; quickly identify and manage adverse effects that occur.
5. Recognize and take steps to ameliorate analgesic and sedative drug withdrawal during de-escalation of therapy.
6. De-escalate and discontinue sedative, opioid, and neuroleptic medications during recovery to reduce the likelihood of unnecessary long-term administration.

• BOX 20.3 Conditions and Medications Associated With Agitation and Delirium

Conditions

Central nervous system disorders—stroke
Infections—sepsis, encephalitis
Withdrawal from sedative agent (alcohol, benzodiazepine, opioid, nicotine)
Medication intoxication (central nervous system stimulants)
Metabolic disorders (hypoglycemia, thyrotoxicosis)
Electrolyte disorders (hyponatremia, hypermagnesemia)
Poisoning
Hypoxia
Endotracheal tube or tracheostomy tube malposition or occlusion
Patient-ventilator asynchrony
Pneumothorax
Pain: cardiac/vascular/gut ischemia, headache, distended viscus (i.e., bladder, bowel, indwelling tubes/catheters/devices, poor body/limb position)
Sleep deprivation

Medications

Antibiotics
Anticholinergics,
Anticonvulsants
Antihistamines
Benzodiazepines
Cardiovascular medications
Corticosteroids
Opioids
Nonsteroidal antiinflammatory agents

underrecognize pain and often fail to preemptively treat pain.[58] Accordingly, clinicians should err on the side of presuming pain is present—particularly when considering that it is far more effective to prevent and manage pain at an early stage than after it has become severe. Ideally, pain should be described in regard to location, duration, type, exacerbating and relieving factors, and intensity. Pain is sometimes conceptualized by subtypes, including somatic, visceral, and neuropathic, because manifestations and management can differ.[59] For example, somatic pain is typically dull and aching, often localized, and responds well to opioids and nonsteroidal antiinflammatory agents. In contrast, visceral pain is often cramping and colicky and may respond to anticholinergic therapy, whereas the burning and shooting neuropathic pain is often best treated with antidepressant and anticonvulsant agents.

Because pain is a subjective interpretation by an individual, the ability of that individual to convey the presence and magnitude of pain is of great value in guiding evaluation and management.[59] Detailed verbal communication by ICU patients is often limited; however, use of simple tools such as the numerical rating scale or a series of cartoon faces ranging from smiling to crying can facilitate communication by pointing or nodding in the nonverbal but cognitively intact patient.[60] A simple horizontal 0 to 10 numerical scale with an enlarged font was judged to be most feasible and valid in one study of pain intensity rating scales.[61] Other techniques to enhance the use of self-reporting of pain include adding descriptive words to the numerical scale, carefully explaining the tool and correct use with each encounter, providing glasses and hearing aids if necessary, allowing adequate time for instructions and patient response.[59] Use of a scale that incorporates descriptive pictures, such as the FACES scale, can facilitate self-reporting of pain intensity regardless of potential language barriers.

Many ICU patients are cognitively impaired and self-reporting pain intensity is not feasible. Accordingly, clinicians must rely on observed behaviors that correlate with self-reported pain or are associated with noxious stimuli.[55,58,62–64] Investigators have combined behaviors into structured assessment tools, often including facial expressions and body position and movement. Contraction of facial muscles associated with grimacing correlate particularly well with noxious stimuli.[65] Interestingly, much of the early work in pain assessment for noncommunicative ICU patients was in infants and young children, resulting in the development of the COMFORT Behavior scale,[66] the FLACC Observation (face, legs, activity, crying, and consolability) tool,[67] and others. Subsequently, a variety of pain assessment tools for nonverbal critically ill adults have been developed, validated, and critically reviewed.[59,68,69] In the 2013 SCCM guidelines,[4] published pain observation tools for adults in the ICU care were identified as the Critical-Care Pain Observation Tool (CPOT),[70] the Behavioral Pain Scale (BPS),[71] the Behavioral Pain Scale-Non-intubated (BPS-NI),[72] the Nonverbal Pain Scale (NVPS),[73] the Pain Behavioral Assessment Tool (PBAT),[74] and the Pain Assessment, Intervention, and Notation (PAIN) tool.[75] Extensive psychometric testing was performed, including examination of scale development, testing of reliability, testing of validity, feasibility, and scale relevance or impact of implementation on ICU patient outcomes yielding a maximum score of 25 and weighted score of 0 to 20. The CPOT had the highest weighted score of 14.7, followed by the BPS with 12.0,[4] and these two scales are recommended in the 2013 guidelines as the most valid and reliable behavioral pain scales for monitoring pain in adult medical, postoperative, or trauma ICU patients who are unable to self-report and in whom motor function is intact and behaviors are observable.[4] The CPOT and BPS are displayed in Tables 20.1 and 20.2.

Pain is often accompanied by changes in vital signs, with tachycardia, hypertension, and tachypnea being most common. However, changes in vital signs are inconsistently associated with pain, with many confounding factors that can mask anticipated changes, such as administration of β blockers, as well as lack of specificity with many other causes of tachycardia, hypertension, and tachypnea.[76] Accordingly, the 2013 guidelines recommend against the use of vital signs (or observational pain scales that include vital signs) alone for pain assessment in adult ICU patients.[4] However, it is acknowledged that vital signs may be an important cue to prompt further pain assessment.[4] Other potentially useful approaches include evaluating pain risk profile, use of surrogate (such as family members) report,[77] or performance of an analgesic trial.[56,59]

There are several important tenets for managing pain in the ICU. The first is that when initiating sedative treatment for mechanically ventilated ICU patients, analgesia should be the first step, followed by addition of a sedative-anxiolytic agent. This "analgesia-first" approach is suggested in the 2013 SCCM guidelines.[4,8,54] Second, the use of preemptive analgesia should be administered before performance of interventions, such as chest tube removal, that are associated with a high likelihood of producing pain.[4] It is more effective to prevent pain or manage it at an earlier and/or more mild stage than after pain has become severe.

Successful pain management in the ICU incorporates pharmacologic and nonpharmacologic treatment.[8] Parenteral opioids are the primary agents used to treat pain in the ICU setting, but use of selected nonopioid and atypical agents can enhance pain relief and may reduce adverse effects (AEs). The major parenteral opioids for continuous infusion in ICU patients, fentanyl, morphine, hydromorphone, and remifentanil (Table 20.3) are generally

TABLE 20.1 Critical Care Pain Observation Tool

Indicator	Description	Score	
Facial expression	No muscular tension observed	Relaxed, neutral	0
	Presence of frowning, brow lowering, orbit tightening, and levator contraction	Tense	1
	All of the above facial movements plus eyelid tightly closed	Grimacing	2
Body movements	Does not move at all (does not necessarily mean absence of pain)	Absence of movements	0
	Slow, cautious movements, touching or rubbing the pain site, seeking attention through movements	Protection	1
	Pulling tube, attempting to sit up, moving limbs/thrashing, not following commands, striking at staff, trying to climb out of bed	Restlessness	2
Muscle tension	No resistance to passive movements	Relaxed	0
	Resistance to passive movements	Tense, rigid	1
	Strong resistance to passive movements, inability to complete them	Very tense or rigid	2
Compliance with the ventilator	Alarms not activated, easy ventilation	Tolerating ventilator or movement	0
	Alarms stop spontaneously	Coughing but tolerating	1
	Asynchrony: blocking ventilation, alarms frequently activated	Fighting ventilator	2
OR			
Vocalization (extubated patients)	Talking in normal tone or no sound	Talking in normal tone or no sound	0
	Sighing, moaning	Sighing, moaning	1
	Crying out, sobbing	Crying out, sobbing	2
Total, range			0–8

TABLE 20.2 Behavioral Pain Scale

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering)	2
	Fully tightened (e.g., eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with ventilation	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

From Payen JF, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. *Crit Care Med.* 2001;29:2258–2263.

considered equivalent in regard to analgesic potential as well as class-based AEs such as respiratory depression or reduced level of consciousness. There are important differences among agents in regard to lipid solubility, volume of distribution (Vd), half-life, clearance, metabolism, and active metabolites that have important effects on onset, peak, and offset of action, potency, and the influence of renal or hepatic dysfunction.[8] Some of the medication features that can influence opioid selection for a particular patient are noted in Table 20.4. For example, morphine sulfate is metabolized to several active metabolites, including morphine-6-glucuronide that is as active as the parent compound and accumulates in renal failure, resulting in prolonged effects including not only analgesia but also somnolence and respiratory depression.[78] The rapid equilibration of fentanyl from plasma to lipid-rich brain tissue is responsible for its rapid onset of action but its high lipophilicity also contributes to a large Vd and delayed offset of action after prolonged infusion. Remifentanil has a small Vd and rapid clearance with metabolism by esterases yielding a short half-life and rapid offset of action that is independent of renal and hepatic function.[79,80] Several opioids not listed deserve mention. Meperidine has potential for neuroexcitatory AEs such as seizures[81] and is not recommended for ICU use.[4] Methadone can slow the development of tolerance to other opioid agents when coadministered but has unpredictable pharmacokinetics and is not administered by continuous infusion.[4] Methadone is also a potent precipitating agent for prolonging the rate-corrected QT interval.[82,83] Although opioids are most effective for pain management in the ICU patient, these agents have a well-documented propensity to produce AEs that are reviewed, along with comments for each AE, in Table 20.3.[8,56] Opioid-induced constipation is particularly common and can be ameliorated by using a stool softener, osmotic agent, stimulant laxative, and either enteral naloxone or subcutaneous injected methylnaltrexone.[84] Comprehensive pain management should include awareness of the likely AEs and how best to avoid them and/or to recognize and manage them.

It is often advantageous to use the lowest effective dose of an opioid analgesic, particularly when intolerable side effects are present. Additionally, there are clinical settings in which a nontraditional approach may be more effective, safer, and/or better tolerated. Use of alternative or complementary approaches such as adding nonopioid or atypical analgesic agents, use of epidural or other neuraxial alternatives to parenteral opioid, and use of complementary, nonpharmacologic interventions should be considered in selected cases.[8,56]

TABLE 20.3 Common Opioid Medications

Drug	Metabolism	Onset/Duration	Dosing	Titration	Advantages	Disadvantages
Fentanyl	Cytochrome P450 3A4	1–2 min/2–4 h (longer in liver failure)	Bolus: 25–50 μg IV push MD: 12.5–200 μg/h continuous infusion	Increase/decrease in increments of 25–50 μg every 5–30 min as needed; may be used to attain goal RASS or goal pain score	Less hypotension than morphine, short-acting, less accumulation with organ dysfunction than with other opiates	CYP 3A4 inhibitors may increase fentanyl effect; tolerance develops over time
Hydromorphone	Hepatic	5–10 min/2–4 h (longer in liver failure)	Bolus: 1–4 mg IV push MD: 0.25–50 mg/h (no real maximum dose)	Increase/decrease in increments of 1–4 mg every 15–30 min as needed; may be used to attain goal RASS or goal pain score	May be preferred in patients with tachyphylaxis to fentanyl, does not accumulate with renal dysfunction like morphine	Long-acting and very potent
Morphine	Conjugation; active metabolites that undergo renal excretion	5–10 min/2–4 h (longer in liver failure and ESRD)	Bolus: 2–4 mg IV push MD: 0.5–49 mg/h	Increase/decrease in increments of 1–4 mg every 15–30 min as needed; may be used to attain goal RASS or goal pain score	May be preferred in patients with tachyphylaxis to fentanyl	Accumulates with renal and hepatic dysfunction, hypotension owing to histamine release
Remifentanil	Plasma esterase	1–3 min/10–20 min	Bolus: 1 μg/kg over 1 minute IV push MD: 0.6–15 μg/kg per hour (use ideal body weight if >30% over ideal body weight)	Increase/decrease in increments of 1–2 μg/kg every 5–10 min as needed; may be used to attain goal RASS or goal pain score	No accumulation in hepatic or renal dysfunction	Can cause bradycardia, hypotension, and may increase intracranial pressure

TABLE 20.4 Common Opioid Adverse Effects

Potential Adverse Effect	Comment
Allergy	Rare. Most common with morphine
Arrhythmias	QTc prolongation with methadone
CNS depression	Accumulation of active morphine metabolite in renal failure
Constipation	Start bowel regimen early if sustained opioid administration is likely. Enteral naloxone sometimes effective, but reverse analgesia; consider methylnaltrexone
Cough	Most common with fentanyl and similar agents
Dry mouth	Use oral lubricants
Histamine release	Uncommon with fentanyl and similar agents. Slow infusion rate. Treat with combination of H_1 and H_2 agonists
Hyperalgesia	Paradoxical increase in pain sensitivity, more common with short-acting opioids
Myoclonus	Consider reduced opioid dose or switch agent. Hydrate
Nausea/vomiting	Administer antiemetic until tolerance develops
Neurotoxicity	Avoid meperidine as has highest incidence. Can occur with morphine or hydromorphone, particularly at higher doses or in renal failure
Opioid dependency	Withdrawal symptoms can develop—usually coincides with clearance. Prevent by tapering, reinstitute agent if withdrawal occurs
Pruritus	Consider naloxone, serotonic antagonists such as ondansetron
Rigidity	Most common with fentanyl and similar agents, but can occur with any agent at high dose
Serotonin syndrome	Reported with meperidine and methadone. Avoid concomitant serotonic reuptake inhibitor

Nonopioid and Atypical Agents

The use of nonopioid medications is best approached from the perspective of differentiating neuropathic pain for which anticonvulsants, antidepressants, and other agents play a primary role versus nonneuropathic pain for which opioids are the first-line therapy and other agents are used to reduce opioid dosage and reduce side effects. There is compelling evidence that the addition of oral gabapentin or carbamazepine to opioids provides superior pain relief for neuropathic pain in ICU patients compared with opioids alone,[85,86] and this is strongly recommended in this setting in the 2013 SCCM guidelines.[4] Pharmacotherapy for neuropathic pain has been extensively studied in randomized controlled trials (RCTs) in non-ICU patients, and medications including tricyclic antidepressants, selective serotonin receptor inhibitors, serotonin and norepinephrine reuptake inhibitors, anticonvulsants, tramadol, dextromethorphan, ketamine, topic capsaicin, lidocaine patch or gel, cannabinoids, and other agents have shown efficacy, albeit often in trials with small sample size and with associated side effects.[87]

Nonopioid adjuvant therapy in nonneuropathic pain can help reduce the quantity of opioids administered and potentially decrease the incidence and severity of opioid-related side effects. Such agents have been extensively studied in various noncritically ill populations—primarily postoperative patients—with efficacy demonstrated in meta-analyses of RCTs for corticosteroids, nonsteroidal antiinflammatory agents, acetaminophen, ketamine, and others.[88–91] There is relatively limited research in ICU patients and most of the RCTs performed with ICU patients have been in the postoperative setting. The drugs most studied in the ICU population are intravenous (IV) acetaminophen, cyclooxygenase inhibitors, and ketamine.[92–94] As a result of the limited evidence base in ICU patients, the 2013 SCCM guidelines generally support this approach as a weak recommendation for the addition of nonopiods for nonneuropathic pain.[4] The potential benefits as well as risks of no-opioids for ICU use are further discussed in recent reviews.[8,56]

Regional Anesthesia and Analgesia

Although systemic administration of opioids for pain management in the ICU is typically by the IV route, regional approaches can offer advantages in selected cases.[8] These options include continuous epidural analgesia and/or anesthesia (central neuraxial techniques) and continuous peripheral nerve or plexus block. With medication delivery in close proximity to the spinal cord or nerves, these techniques can promote parenteral opioid sparing, which is associated with less respiratory depression and gastrointestinal hypomotility and other benefits. However, these techniques introduce new issues related to needle and catheter placement and maintenance, as well as physiologic alterations related to local anesthetic block and/or epidural drug delivery. Critically ill patients are often at higher risk for complications owing to coagulopathy, thrombocytopenia, sepsis, and hemodynamic instability. Peripheral nerve blocks are particularly useful for anatomically localized pain such as limb injury or operation. However, of all the various regional anesthesia and analgesia (RAA) techniques, the greatest experience in ICU patients is with continuous epidural analgesia.

Similar to other pain management issues, there is more published research to support the use of RAA in noncritical care settings, and most ICU studies focus on postoperative patients or those who have sustained injury. The recent evidence-based review undertaken to develop the 2013 SCCM guidelines provides the most relevant and current basis for use of RAA in ICU patients.[4] Specific patient populations were examined, and only thoracic epidural anesthesia/analgesia for postoperative analgesia in patients undergoing abdominal aortic surgery received a strong recommendation as a superior alternative to IV opioids.[95] Interestingly, high-level evidence was also available to compare lumbar epidural analgesia to IV opioids in the same population and no benefit was demonstrated.[96] Patients with traumatic rib fractures are the other population for whom benefit from RAA was demonstrated for ICU patients. Specifically, use of thoracic epidural analgesia was associated with superior pain control and reduced incidence of pneumonia—but more hypotension—compared with parenteral opioids,[97,98] and its use is supported as a weak recommendation in this setting.[4] The evidence was insufficient to recommend thoracic

epidural analgesia for intrathoracic or nonvascular abdominal surgical procedures.[4] Similarly, the lack of high-quality research prevented a recommendation regarding the use of RAA for medical ICU patients.[4]

Complementary Techniques

Nonpharmacologic interventions such as music, relaxation, and provision of information can provide complementary pain relief and can be considered.[8,56,99–101] However, although these measures are low cost, easy to provide, and safe, they have a relatively weak body of evidence to support their routine use and they are not "high impact," providing only limited opioid-sparing or pain intensity reduction capability.[8,56,99]

Sedation Management

Sedative drugs have formed the cornerstone for patient comfort and tolerance of the ICU environment for decades by calming anxiety, providing amnesia, and controlling agitation. There have been changing paradigms from preferential use of moderate- to long-acting benzodiazepines and acceptance of prolonged deep sedation a decade ago, to patient-focused sedation with careful monitoring, analgesia first, and more recently to emphasis on use of nonbenzodiazepine sedative agents and using the lightest level of sedation possible.[4] Management of sedation should be preceded by examining individual patient characteristics and effective pain control. It incorporates establishing the goals of sedative therapy, monitoring of the depth of sedation, selecting and administrating the best agent(s) for the particular patient, and using protocolized management of sedation that includes structured elements to ensure use of the lowest effective dose and lightest level of sedation. Common goals of therapy include relief of anxiety, control of frank agitation, promotion of patient-ventilator synchrony, and elimination of awareness when NMBAs are used. Monitoring of the depth of sedation is now routinely performed in most ICUs and is applied to titrate medications to a targeted level of consciousness and to avoid excessive or prolonged sedation.

Monitoring the depth of sedation is most commonly performed by observing patient behaviors, often after varying levels of stimulation, using a structured sedation scale.[4,41,67,102] The domain being tested is that of arousal or level of consciousness and typically ranges from alert to comatose. Ramsay and coworkers developed the first widely used sedation scale for ICU patients: a six-level scale based on response to the assessor's voice and to physical stimulation.[103] Subsequent scale development has introduced assessment of agitation, ranging from calm to combative. Useful features of sedation-agitation scales include multidisciplinary development; ease of administration, recall, and interpretation; well-defined discrete criteria for each level; sufficient sedation levels for effective drug titration; assessment of agitation; demonstration of good interrater reliability for relevant patient populations; and evidence of validity.[41] Recently the SCCM guideline task force performed a careful analysis of the sedation scales that have undergone validation analysis in ICU patients, including the Ramsay Sedation Scale (RSS),[103] the New Sheffield Sedation Scale,[104] the Observer's Assessment of Alertness/Sedation Scale (OAA/S),[105] the Sedation Intensive Care Score (SEDIC),[106] the Motor Activity Assessment Scale (MAAS),[107] the Adaptation to the Intensive Care Environment (ATICE) tool,[108] the Minnesota Sedation Assessment Tool (MSAT),[109] the Vancouver Interaction and Calmness Scale (VICS),[110] the Sedation-Agitation Scale (SAS),[111] and the Richmond Agitation-Sedation Scale (RASS).[112] Of these, the RASS had the highest total weighted psychometric score (19 of 20 possible points), followed by the SAS (16.5 points), and these two instruments are recommended in the 2013 SCCM guidelines as the most valid and reliable sedation assessment tools for measuring quality and depth of sedation in adult ICU patients.[4] The RASS, developed by a multidisciplinary group led by Sessler, is displayed in Table 20.5.[112] The RASS incorporates assessment of arousal in response to two levels of stimulation (voice, physical), presence or absence of cognition, sustainability of response, and the presence and

TABLE 20.5 Richmond Agitation-Sedation Scale

Score	Term	Description
+4	Combative	Overtly combative or violent, immediate danger to staff
+3	Very agitated	Pulls on or removes tube(s) or catheter(s) or has aggressive behavior toward staff
+2	Agitated	Frequent nonpurposeful movement or patient-ventilator dyssynchrony
+1	Restless	Anxious or apprehensive but movements not aggressive or vigorous
0	Alert and calm	
–1	Drowsy	Not fully alert, but has sustained (>10 s) awakening, with eye contact, to voice
–2	Light sedation	Briefly (<10 s) awakens with eye contact to voice
–3	Moderate sedation	Any movement (but no eye contact) to voice
–4	Deep sedation	No response to voice, but any movement to physical stimulation
–5	Unarousable	No response to voice or physical stimulation

Performed using a series of steps: observation of behaviors (score +4 to 0), followed (if necessary) by assessment of response to voice (score –1 to –3), followed (if necessary) by assessment of response to physical stimulation, such as shaking shoulder and then rubbing sternum if no response to shaking shoulder (score –4 to –5).

TABLE 20.6 Sedation-Agitation Scale

Score	Term	Description
7	Dangerous agitation	Pulling at endotracheal tube, trying to remove catheters, climbing over bedrail, striking at staff, thrashing side to side
6	Very agitated	Does not calm despite frequent verbal reminding of limits, requires physical restraints, biting ETT
5	Agitated	Anxious or mildly agitated, attempts to sit up, calms down to verbal instructions
4	Calm and cooperative	Calm, awakens easily, follows commands
3	Sedated	Difficult to arouse, awakens to verbal stimuli or gentle shaking but drifts off again, follows simple commands
2	Very sedated	Arouses to physical stimuli but does not communicate or follow commands, may move spontaneously
1	Unarousable	Minimal or no response to noxious stimuli, does not communicate or follow commands

ETT, Endotracheal tube.

intensity of agitated behavior into a 10-level scale subcategorized with positive (agitation) and negative (sedation) values.[112] The SAS, developed by Riker and colleagues, is displayed in Table 20.6.[111] Both the RASS and SAS have been extensively tested for interrater reliability and validity in a cross section of ICU populations, correlated with subjective and objective measures of sedation, and evaluated for ease of use in clinical settings.[4,67,111–115] The introduction of a sedation scale into clinical practice has been demonstrated to result in higher quality sedation with fewer hours of oversedation, as well as reduced use of sedative and analgesic drug doses, shorter duration of mechanical ventilation, and reduced use of vasopressors.[116,117] Structured assessment and management of agitation and pain was similarly associated with less agitation, quicker extubation, and fewer nosocomial infections.[118]

Objective measures of cerebral function have been developed to quantify the level of consciousness as reflected by the cortical electrical activity based on processed electroencephalographic (EEG) signals.[67,119] Raw EEG signals are difficult to interpret, but proprietary mathematical algorithms have been developed and incorporated into commercially available devices to simplify interpretation of the power and frequency of the signal by converting this into a numerical display ranging from 0 (flat EEG) to 100 (fully alert). The Bispectral Index (BIS), Narcotrend Index (NI), Patient State Index (PSI), and State Entropy (SE) are examples of processed EEG monitors that have been used to assess level of consciousness in ICU patients.[4] The addition of assessing the "evoked potential" to an auditory signal (i.e., auditory evoked potentials)—displayed as the auditory evoked responses index (AAI)—incorporates measurement of latency and amplitude of the evoked electrical potential.[120] Collectively, these devices offer the advantage of continuous display of data—which can be used to rapidly detect unanticipated changes in level of conscious—such as accidental cessation of propofol infusion.[67] However, validation studies of these objective tools against sedation scales and other parameters has yielded inconsistent results.[4,67,121] A particularly challenging problem has been filtering out electromyographic signals generated by activity of muscles of the head that lie between the brain and the EEG electrodes.[122] Additionally, demonstration of added value to justify widespread use of this expensive monitoring technology when compared to routine sedation scale monitoring has been lacking in RCTs of ICU patients. Accordingly, the use of objective measures of brain function to assess the depth of sedation in noncomatose adult ICU patients who are not receiving NMBA is not recommended in the 2013 SCCM guidelines.[4] There are unique clinical circumstances for which objective monitoring may be superior to routine clinical monitoring, including patients who are receiving NMBAs and to guide titration of anticonvulsant medications to achieve burst suppression.[4]

Sedative Drug Therapy

Sedative medications are widely used in the ICU setting and although various agents can be administered by other routes, most are given by the IV route—either by continuous infusion or intermittent bolus. Inhalational agents, such as sevoflurane, can provide effective sedation and can improve oxygenation, but have significant logistical barriers for widespread use.[123] Historically, benzodiazepines formed the cornerstone of ICU sedation; however, clinical trial results and meta-analyses suggest that nonbenzodiazepines such as propofol and dexmedetomidine are associated with better results such as reduced delirium and shorter ventilator time.[4]

Propofol is perhaps the most widely used agent administered for continuous IV sedation in the United States.[124] Propofol binds to gamma-aminobutyric acid (GABA) A receptors as well glycine, nicotinic, and muscarinic receptors, producing effects similar to benzodiazepines.[4,125] Like benzodiazepines, propofol has no analgesic effects. Propofol is highly lipid soluble, quickly crosses the blood-brain barrier, and rapidly redistributes into peripheral tissues. These features result in rapid onset and offset of action (Table 20.7). However, prolonged administration can result in tissue saturation that can ultimately produce delayed offset of action. Similar to benzodiazepines, propofol commonly causes respiratory depression as well as systemic hypotension. Because propofol is dissolved in a lipid emulsion, higher rates of propofol infusion can produce hypertriglyceridemia and acute pancreatitis. Each milliliter of propofol solution contains 1.1 kcal of nutrition; thus an infusion rate of about 40 mL/h results in more than 1000 kcal of nutrition in 24 hours. Propofol infusion syndrome is an uncommon complication that is typically associated with prolonged infusion of high dose propofol (i.e., >70 μg/kg per minute), although cases are reported at lower infusion rates or more brief administration. Propofol infusion syndrome is characterized by metabolic acidosis, hypotension, cardiac arrhythmias, hypertriglyceridemia, and less commonly, with acute kidney injury, rhabdomyolysis, liver

TABLE 20.7 Common Sedative Medications

Drug	Metabolism	Onset/Duration	Dosing	Titration	Advantages	Disadvantages
Lorazepam	Conjugation to inactive metabolite	5–20 min/6–8 h (duration prolonged in elderly/cirrhosis/ESRD to 48–72 h)	Bolus: 2–4 mg IV push MD: 2–6 mg IV/PO every 4–6 h (preferred); infusion 0.25–20 mg/h	Infusion: Increase/decrease in increments of 0.5–2 mg every 10–60 min to attain goal RASS	Long half-life allows for intermittent dosing, less accumulation with renal/hepatic dysfunction	Propylene glycol toxicity in patients with renal failure; accumulation common with continuous infusion
Midazolam	Cytochrome P450 3A4; active metabolite renally excreted	5–10 min/1–4 h (accumulates in ESRD/CHF/liver failure)	Bolus: 2–4 g IV push MD: 0.5–25 mg/h	Increase/decrease in increments of 1–2 mg every 5–60 min to attain goal RASS	Short-acting if preserved organ function or with bolus dosing; fast onset	CYP 3A4 inhibitors may increase effect; accumulates with both renal and hepatic dysfunction; distributes to adipose tissue
Propofol	Conjugation	30–50 sec/3–10 min	MD: 2.5–105 μg/kg per minute	Increase/decrease in increments of 2.5–15 μg/kg per minute every 1–15 min to attain goal RASS	Short-acting; less delirium than with benzodiazepines	Hypotension; increased triglycerides; pancreatitis; propofol-related infusion syndrome; zinc depletion (brand name only)
Dexmedetomidine	Hepatic via cytochrome P450 and glucuronidation	Immediate onset only when bolus is given; ~3 h to see full effect if bolus omitted/6 min (longer in liver failure)	Bolus: 0.5–1 μg/kg, *rarely given* owing to hypotension/bradycardia MD: 0.2–1.5 μg/kg per hour	Increase by 0.1 μg/kg per hour no more often than every 30 min. May titrate to effect (goal RASS) OR until HR decreases by 10–20 bpm. Full effect will take ~3 h to see. If patient becomes hypotensive or bradycardic (HR <55 bpm), contact MD and stop infusion	Associated with less delirium than other agents; short-acting; little to no respiratory depression	Hypotension (especially with bolus dose and in under–fluid-resuscitated patients); bradycardia

bpm, Beats/min; *CHF*, congestive heart failure; *CYP*, cytochrome P450; *ESRD*, end-stage renal disease; *HR*, heart rate; *IV*, intravenous; *MD*, physician; *PO*, oral; *RASS*, Richmond Agitation-Sedation Scale.

dysfunction, and hyperkalemia.[4,126,127] In a meta-analysis of 16 RCTs that compared propofol with alternative agents for moderate- to long-duration sedation (i.e., >2 days), propofol was associated with shorter duration of mechanical ventilation and shorter ICU LOS.[128]

Dexmedetomidine is a selective α_2-receptor agonist with sedative properties similar to benzodiazepines and propofol, but has a number of unique features. In contrast to other sedatives, dexmedetomidine has analgesic properties and can be opioid-sparing; is sympatholytic, potentially producing prominent bradycardia as well as hypotension at higher doses; is associated with a more alert state relative to anxiolytic properties; and has minimal effect on respiratory drive.[129,130] It does not bind GABA receptors. Selected pharmacokinetic and clinical characteristics are displayed in Table 20.7. The most common AEs are hypotension and bradycardia. Hypotension can be particularly prominent when a loading dose is used—although hypertension can also occur. In a meta-analysis of 24 RCTs comparing dexmedetomidine with alternative agents, ICU LOS was shorter with dexmedetomidine, whereas duration of mechanical ventilation was not significantly different.[131] Clinical trial results suggest that when compared directly with midazolam, dexmedetomidine may be associated with lower prevalence of delirium.[132] The 2013 SCCM guidelines suggest that dexmedetomidine may be preferred over benzodiazepines in mechanically ventilated patients who have delirium and require continuous IV infusion of sedative medications.[4]

Benzodiazepines activate GABA A receptors, producing anxiolytic, amnestic, sedating, and hypnotic effects.[4,133] Benzodiazepines cause respiratory depression and systemic hypotension—problems that are particularly prominent in the elderly. Although diazepam, midazolam, and lorazepam have been used for ICU sedation over the years, diazepam is now used infrequently. Key pharmacokinetic and clinical features of midazolam and lorazepam are displayed in Table 20.7. Delayed offset of action is relatively common with these drugs for a variety of reasons, including tissue saturation after prolonged administration, impaired metabolism owing to hepatic dysfunction, and in the case of midazolam, accumulation of active renally cleared metabolities.[6,133,134] Continuous infusion of lorazepam can lead to accumulation of the diluent vehicle, propylene glycol, causing toxicity that is characterized by metabolic acidosis and acute kidney injury, and accompanied by development of an increased osmolal gap.[135,136]

Management of Sedation

Sedative drug therapy is an important component of sedation and analgesia management as discussed earlier and outlined in Box 20.2. Careful selection and titration of sedative drugs is critical to achieve optimal patient comfort while avoiding the adverse impact of excessive or unnecessarily prolonged sedation. The use of structured approaches to sedation and analgesia via algorithms and protocols has achieved a prominent place in ICU practice. There are several common themes. One theme is to tailor the sedation to the specific patient, including medication selection based on sedation goals (such as rapid arousal), avoidance of side effects (such as hypotension), and consideration of elimination issues (such as avoiding midazolam in a patient with impaired renal function).

Although all of the sedative drugs listed in Table 20.7 have a role in ICU sedation management, emerging evidence appears to favor using propofol or dexmedetomidine in preference to benzodiazepines in patients for whom continuous infusion sedation is needed—as suggested in the 2013 guidelines.[4] A meta-analysis limited to moderate- or high-quality RCTs demonstrated slightly longer ICU LOS with benzodiazepines compared with propofol or dexmedetomidine.[4] Several studies deserve additional comment. A multicenter RCT comparing dexmedetomidine to midazolam by Riker and colleagues demonstrated that dexmedetomidine was associated with a shorter time to extubation, lower prevalence of delirium, and fewer infections but no difference in ICU LOS, mortality, or sedation quality.[132] Dexmedetomidine was less potent than midazolam and was associated with more bradycardia but less hypertension.[132] Jakob and coworkers subsequently reported two phase III multicenter RCTs that compared dexmedetomidine with midazolam and propofol.[137] Patients randomly assigned to receive dexmedetomidine had a shorter duration of mechanical ventilation than those who received midazolam, but not those who received propofol. Patient interaction (communication, arousability, cooperation) was better with dexmedetomidine than with either other agent, but hypotension and bradycardia were more common.

Prospective studies have identified additional unique patient circumstances in which dexmedetomidine may be advantageous. For example, use of dexmedetomidine in patients with alcohol withdrawal syndrome is associated with reduced benzodiazepine and haloperidol administration as well as better sedation quality and patient communication, although bradycardia was common.[138,139] Similarly, adding dexmedetomidine to the management of patients with agitated delirium can enhance the quality of sedation and reduce the duration of mechanical ventilation and ICU stay.[140,141] Finally, compared with propofol, dexmedetomidine has been linked to reduced delirium and reduced likelihood of development of atrial fibrillation after cardiac surgery.[142,143]

A second major theme is to focus first on analgesia, as discussed. The 2013 guidelines suggest that analgesia-first sedation be used in mechanically ventilated adult ICU patients.[4] Asking first about pain, before the patient has been sedated and cognitively impaired, is advantageous. Additionally, several RCTs have demonstrated analgesia-based sedation to be associated with shorter duration of mechanical ventilation compared with hypnotic-based sedation.[144–146] Finally, Strom et al. randomized assigned mechanically ventilated adult ICU patients to bolus morphine (analgesia-based, limited sedation) versus morphine plus propofol for the first 48 hours, then midazolam (sedation + analgesia) and found shorter duration of mechanical ventilation and ICU LOS but threefold more agitation when sedative drugs were minimized.[15]

A third major theme is to strive for a light level of consciousness and to avoid accumulation of medications and their active metabolites, thus reducing the likelihood of delayed awakening. This approach is strongly recommended in the 2013 guidelines,[4] based in part on studies like those of Strom et al.[15] The underlying rationale for this approach arises from the observation by Kollef and colleagues that use of continuous IV sedation and analgesia is associated with delayed recovery from respiratory failure and longer LOS.[12] Although a variety of sedation management strategies have been demonstrated to shorten the duration of mechanical ventilation, the most robust data support the use of a sedation protocol or the implementation of daily interruption of sedation.[4,17] In an early RCT, Brook et al. found the use of a nurse-implemented protocol that emphasized intermittent therapy to be associated with shorter duration of mechanical ventilation, reduced ICU and hospital LOS, and fewer tracheostomies compared with usual management.[13]

The following year, Kress and colleagues showed in an RCT that daily interruption of IV sedation (DIS) or a spontaneous

awakening trial until the patient was alert or agitated then restarting the medications at 50% of the original dose was accompanied by more rapid recovery from respiratory failure, as well as performance of fewer tests for unexplained altered mental status.[14] Interestingly, not all of the benefit could be attributable to reduced accumulation of medications or active metabolites because the total propofol dosage was similar between groups although significantly less midazolam was used with daily interruption.[14] This prompted speculation that the DIS might also permit earlier identification of sufficient respiratory reserve for ventilator weaning (i.e., "wake up and breathe").[148] Girard and colleagues subsequently demonstrated that the strategy of combining DIS with performance of a spontaneous breathing trial (SBT) led to faster recovery from respiratory failure as well as reduced all-cause 1-year mortality compared with SBT alone.[149] Abrupt withdrawal of sedative (and sometimes analgesic) medications is accompanied by severalfold increases in circulating catecholamines as well as tachycardia and hypertension.[44] Experts have expressed concern that this unmasked stress response might be associated with cardiac ischemia.[150] In a prospective study, DIS was not accompanied by electrocardiographic or cardiac enzyme evidence of myocardial ischemia in at-risk patients.[44] Questions have also been raised as to the potential impact of this abrupt withdrawal of medications designed to provide comfort on downstream neuropsychological disturbances such as posttraumatic stress disorder (PTSD).[150] An additional study by Kress and colleagues demonstrated no increase in subsequent posttraumatic stress disorder and, actually, trends for better neuropsychological health months after daily interruption[151]—perhaps as a result of the added opportunities to establish concrete memories during awakening.[152]

There are populations for whom complete cessation of IV sedatives and analgesics is probably unwise. Girard et al. incorporated a safety screen into their protocol and avoid performing DIS in patients (1) receiving sedative infusion for active seizures or alcohol withdrawal, (2) receiving escalating doses for ongoing agitation, (3) receiving NMBAs, (4) having evidence of myocardial ischemia within the past 24 hours, or (5) having elevated ICP.[138] It may be that patients with alcoholism are at particular risk for poor tolerance of daily interruption because patients randomly assigned to this intervention had worse outcomes compared with a protocol approach in an RCT conducted in an ICU with a high prevalence of patients with alcohol use disorders.[153] In a multicenter RCT major outcomes were identical for patients randomly assigned to protocolized sedation versus protocolized sedation plus DIS.[154] Patients randomly assigned to DIS had more doses and higher total amount of midazolam and fentanyl and corresponding greater nursing workload.

A variety of other structured approaches have been examined in prospective trials, although many have used a less robust two-phase approach. Protocols that use an evidence-based nurse-implemented algorithm that seeks to minimize medication doses have been linked to shorter duration of mechanical ventilation,[155–160] shorter ICU and hospital LOS,[156,159,160] lower direct drug costs,[156,158] less opioid medication,[160] less medication-induced coma,[160] and lower 30-day morality.[160] These interventions appear to be less effective in Australian ICUs, perhaps as a result of higher nurse:patient ratios.[161,162] Other algorithms apply active pharmacist input[163] or focus on pain and agitation.[118] Carson and colleagues found continuous infusion propofol with DIS to be superior to intermittent lorazepam.[164]

In summary, a variety of structured approaches to sedation management are effective for speeding recovery from respiratory failure and critical illness. Practical considerations for establishing a sedation protocol include multidisciplinary development, integrating published algorithms into the local environment, and sustaining a durable approach despite the challenges of insufficient time and resources.[17] Finally, emphasis on protocolized light sedation brings additional opportunities such as linking to SBTs[149] and to early mobilization,[165] with the importance of using safety screens to identify appropriate clinical scenarios in which lightening of sedation is appropriate and considering that unplanned extubation is more common with lighter sedation.[165a] Sedative and opioid dosing should be scrutinized as they tend to be higher at night and such excessive dosing is associated with delayed extubation.[166]

• BOX 20.4 ABCDEF Bundle

- **A** Assess, prevent, and manage pain
- **B** Both spontaneous awakening trials and spontaneous breathing trials
- **C** Choice of analgesia and sedation
- **D** Delirium: assess, prevent, and manage
- **E** Early mobility and exercise
- **F** Family engagement and empowerment

The 2013 SCCM guidelines recommend using a multidisciplinary ICU team approach with provider education, preprinted protocols and order sets, and ICU rounds checklist to facilitate pain, agitation, and delirium management guidelines and protocols.[4] Much work has been done to adapt the recommendation from the 2013 guidelines into tools to promote implementation of pain, agitation, and delirium guidelines. A robust approach is the "ABCDEF bundle."[167] This bundle embraces the concept of fully integrating management of pain, agitation, and delirium into the comprehensive care of the patient and family with each letter representing to one component of best practice in critical care as displayed in Box 20.4. As discussed earlier, this strategy begins with (A) managing pain, (B) stressing linkage of the awakening the patient to providing the opportunity for the patient to demonstrate readiness to breath independently, (C) emphasizing optimal selection of medications for analgesia and sedation, (D) promoting effective prevention and/or management of delirium, (E) highlighting mobility and exercise for the patient, and (F) circling back to family support for the patient. Application of the ABCDEF bundle can speed recovery from critical illness and respiratory failure, reduce incidence of delirium, shorten LOS, and enhance quality of life.[167] Some approaches that can enhance the successful implementation of sedation-focused bundles include proactive pharmacist involvement, use of daily rounds checklists, high-quality order sets, and process control methodology.[168–172]

Neuromuscular Blocking Agents

In contrast to analgesic and sedative medications, NMBAs are administered relatively infrequently in the management of mechanically ventilated ICU patients. In an international study of mechanically ventilated patients with ARDS, 22% of patients received NMBAs, although the rate was higher at 38% of patients with severe ARDS.[173] The most common indication for NMBA is to facilitate mechanical ventilation in particularly challenging scenarios such as ARDS or refractory status asthmaticus. NMBAs can enhance oxygenation, reduce the risk of barotrauma, and improve synchronization of the patient and ventilator.[28,174] There are additional data that pulmonary and systemic inflammation may be reduced, although the mechanism(s) are not established.[175] Indications for

use of NMBAs include facilitation of mechanical ventilation, control of ICP, management of status epilepticus, reduction of oxygen consumption from muscle rigidity or shivering, prevention of lactic acidosis in conditions such as tetanus or neuroleptic malignant syndrome, and empirically in patients with severe ARDS.

Generally lacking robust RCTs, it is noteworthy that the most recent published guidelines assigned either a weak recommendation (ARDS) or make no recommendation for most of the indications just mentioned.[28] Most use of NMBAs is driven by improving control of a particular problem such as patient-ventilator asynchrony or elevated ICP that persists despite use of less invasive measures.[28,29] To date, the results of three RCTs and meta-analyses of these studies support the use of cisatracurium for patients with ARDS with a partial pressure of arterial oxygen:fraction of inspired oxygen (PaO_2/FIO_2) ratio less than 150 mm Hg, as there is an association of neuromuscular blockade infusion for 48 hours with lower 90-day, 28-day, and ICU mortality and barotrauma with no difference in ICU-acquired weakness.[28,30,174–176] Post hoc analysis of the largest study revealed that the benefit appeared to be confined to patients with PaO_2/FIO_2 less than 120 mm Hg.[30] A confirmatory multicenter study of North American patients is under way.

Comparison of Neuromuscular Blocking Agents (Table 20.8)

The neuromuscular junction consists of a prejunctional motor nerve ending separated from a postjunctional membrane—or motor end plate—of skeletal muscle by a synaptic cleft.[177] Acetylcholine (ACh) is released from vesicles in the prejunctional motor ending and bind nicotinic cholinergic receptors of the motor end plate, producing a change in membrane potential as a result of influx of sodium and efflux of potassium. Calcium is released from the sarcoplasmic reticulum, producing muscle action potential. Depolarizing NMBAs such as succinylcholine bind the receptors and cause the ion channel to remain open, producing depolarization and potentially causing sufficient potassium efflux to produce hyperkalemia. Additional depolarizations cannot occur until the agent diffuses from the receptors. Succinylcholine is the prototypical paralytic for rapid-sequence intubation owing to its rapid onset and short duration of action.[178] However, it can precipitate malignant hypertension and can cause hyperkalemia, which can lead to fatal arrhythmias.[179] The cause of this adverse event is thought to be upregulation of ACh receptors along the skeletal muscle membrane. Stimulation of these additional receptors by succinylcholine results in potassium efflux, leading to hyperkalemia. Hence, caution should be used when succinylcholine is considered for patients at risk for upregulation of ACh receptors such as upper or lower motor denervation, chemical denervation (by muscle relaxants, drugs, or toxins), immobilization, infection, direct muscle trauma, muscle tumor, muscle inflammation, and/or burn injury. Furthermore, succinylcholine should be avoided in patients with renal dysfunction, as hyperkalemia is potentiated in this population. Additionally, succinylcholine has been associated with increases in intracranial and intraocular pressure and should be used with caution in patients with acute ocular or traumatic brain injury.[180]

The nondepolarizing agents are bulky molecules with ACh-like moieties that bind the ACh receptors without ion flow or depolarization. Broadly, the nondepolarizing NMBAs are divided into two structural classes: aminosteroidal and benzylisoquinolinium agents. The aminosteroidal NMBAs incorporate an ACh-like structure onto a steroid backbone.[181] Much like other steroidal drugs, elimination of the aminosteroidal agents is organ dependent. Pancuronium, the first aminosteroidal NMBA, antagonizes not only nicotinic ACh receptors, but also muscarinic receptors.[182] This results in vagal blockade and tachycardia, making it less ideal for patients with significant cardiac disease.[28,29] Compared with other aminosteroidal NMBAs, pancuronium has a long half-life, which allows for sustained neuromuscular blockade to be achieved with intermittent bolus dosing.[28] Because of its long half-life, organ-dependent metabolism, and production of active metabolites, pancuronium has a high propensity to accumulate in critically ill patients. Newer aminosteroidal NMBAs, such as vecuronium and rocuronium, offer advantages over pancuronium as they do not antagonize muscarinic receptors. Vecuronium is an intermediate-acting aminosteroidal NMBA with both renal and hepatic elimination. It offers utility both for procedural and sustained paralysis, but like pancuronium, can accumulate in patients with organ dysfunction. Rocuronium has the fastest onset and shortest duration of action of the aminosteroidal NMBAs, making it ideal for rapid-sequence intubation in circumstances when succinylcholine is contraindicated. Like all aminosteroidal NMBAs, it exhibits organ-dependent clearance; however, when used as intermittently for procedural paralysis, this is rarely of clinical significance.

In contrast to the aminosteroidal NMBAs, benzylisoquinolinium agents are nonsteroidal agents that are degraded by plasma esterase and Hofmann degradation.[181–182] Atracurium was the first benzylisoquinolinium NMBA and was advantageous in that it was an intermediate-acting paralytic with organ-independent clearance. However, atracurium causes significant histamine release and thus must be used with caution in patients with hypotension and/or shock. Additionally, patients with organ dysfunction are at increased risk of seizures when atracurium is used for sustained paralysis owing to accumulation of a toxic metabolite, laudanosine.[29] Cisatracurium is the cis-cis isomer of atracurium and represents approximately 15% of the atracurium conformation.[181] Like atracurium, cisatracurium undergoes clearance via plasma esterase and Hofmann degradation but is devoid of histamine release and toxic metabolites.

Monitoring

Monitoring of the patient during chemical paralysis is performed to ensure safety and effectiveness of the intervention. Goals of monitoring include achieving the targeted depth of paralysis to accomplish therapeutic goals while reducing the likelihood of undesired prolonged paralysis or acute quadriplegic myopathy (AQM), and also avoiding other potential complications. Different targets for neuromuscular blockade may vary from merely reduced spontaneous movement or better synchronization of spontaneous breathing with mechanical ventilation, to apnea for fully passive ventilation or complete cessation of all skeletal muscle activity. Accordingly, observation of limb and respiratory muscle activity as well as review of graphic display of ventilator data should be performed to confirm the therapeutic target is reached. Testing of deep tendon reflexes may be helpful as they disappear as 100% blockade is reached. Monitoring the depth and duration of paralysis is important to optimize neuromuscular blockade for each individual patient and to avoid complications of therapy.[28,29,177,183] Such monitoring typically includes clinical evaluation as well as an objective measure of the extent of blockade using peripheral nerve stimulation (PNS) testing by evaluating the response to "train-of-four" (TOF) stimulation. In TOF testing, four equal brief electrical charges are delivered every 0.5 seconds from a nerve stimulator device attached to leads placed on the skin overlying a superficial

TABLE 20.8 Properties of Neuromuscular Blocking Agents

Property	Atracurium	Cisatracurium	Pancuronium	Rocuronium	Succinylcholine	Vecuronium
Mechanism of action	Nondepolarizing	Nondepolarizing	Nondepolarizing	Nondepolarizing	Depolarizing	Nondepolarizing
Class	Benzylisoquinolinium agent	Benzylisoquinolinium agent	Aminosteroidal agent	Aminosteroidal agent	Acetylcholine-like	Aminosteroidal agent
Onset	3–5 min	2–3 min	2–3 min	1–2 min	1–1.5 min	3–4 min
Duration	25–35 min	45–60 min	90–100 min	30 min	5–10 min	35–45 min
Renal elimination	<5%	<20% by renal and hepatic pathways combined	60%–80%	30%	<10%	10%–20%
Hepatic elimination	—	<20% by renal and hepatic pathways combined	15%–40%	—	—	20%–30%
Biliary excretion	—	—	5%–10%	50%	—	40%–75%
Hofmann elimination and ester hydrolysis	Yes	Yes	No	No	—	No
Plasma cholinesterase	No	No	No	No	Yes	No
Active metabolites	None (toxic metabolite laudanosine)	None	3–OH and 17–OH pancuronium	None	Succinylmonocholine (clinically insignificant depolarizing muscle relaxant properties)	3-Desacetylvecuronium
Bolus dosing	0.4–0.5 mg/kg	0.1–0.2 mg/kg	0.02–0.1 mg/kg	0.6–1 mg/kg	0.3–1.5 mg/kg	0.08–0.1 mg/kg
Continuous dosing	5–20 μg/kg/min	3 μg/kg per minute (initial: titrated to effect) vs. 37.5 mg/h (fixed dose in ARDS)	0.8–1.7 μg/kg per minute	8–12 μg/kg per minute	0.6–6 mg/kg per hour (not routinely recommended)	0.8–1.7 μg/kg per minute
Histamine release	Yes (dose-dependent)	No	No	No	Yes	No
Vagal blockade tachycardia	No	No	Yes	At higher doses	None (actually can cause bradycardia from vagal stimulation)	No
Prolonged blockade	Rare	Rare	Yes	No	Yes (in patients with reduced plasma cholinesterase activity)	Yes

ARDS, Acute respiratory distress syndrome.
For continuous dosing, use consistent weight such as ideal or adjusted body weight for dosing paralytic in obese patients.

nerve that innervates an easily observed muscle. The most common placement is over the ulnar nerve with observation of contraction of the adductor pollicis muscle, or over the facial nerve with observation of contraction of the orbicularis occuli muscle. It is estimated that if less than 75% of receptors are blocked, the four muscular contractions are equal in intensity and that once more than 90% of receptors are blocked no contractions occur. A common safety goal is for titration of NMBA so that one to three muscle contractions are present, thus potentially avoiding excessive dosing. It is worth considering, however, that clinical effectiveness (such as patient-ventilator synchrony) is sometimes achieved while TOF reveals all four contractions. In contrast, to achieve apnea or complete cessation of muscular activity, TOF of zero may be necessary. In this circumstance, periodically decreasing the NMBA infusion rate until TOF is 1 or above may be necessary to avoid excessive dosing.

Despite the intuitive value of monitoring the depth of NMB, clinical trials that compare PNS monitoring to clinical monitoring alone have not consistently demonstrated added value. In one RCT, Rudis and coworkers demonstrated more rapid recovery to 4/4 TOF contractions and to spontaneous breathing as well as fewer episodes of delayed recovery when vecuronium infusion was titrated to achieve 1/4 TOF contractions compared to patients with clinical monitoring alone.[184] Patients with impaired renal function had the slowest recovery. In contrast, PNS monitoring did not lead to better outcomes in prospective trials of patients who received atracurium [185] or cisatracurium.[186] Further, intentional dosing of cisatracurium to achieve TOF of zero only marginally prolonged the recovery time.[187] Finally, no PNS monitoring was performed in the 2010 placebo-controlled RCT in which 178 patients received a 48-hr cisatracurium infusion and there was no difference in the rate of ICU paresis compared to the placebo group.[30] Unfortunately, maintenance of TOF in excess of 0 does not guarantee AQM will not occur. Most reported cases developed despite documented appropriate TOF results. Accordingly, the 2016 guidelines state that PNS monitoring with TOF may be useful for monitoring the depth of NMB, but only if it is incorporated with a clinical patient assessment (weak recommendation, very low–quality of evidence).[28] Monitoring of patients who are receiving NMBAs should also address prevention and/or early detection of VTE, pressure ulcers, corneal ulcers, patient awareness, and inadequately controlled pain and anxiety.[28]

Complications of Neuromuscular Blocking Agents

The primary safety concerns with NMBAs relate to prolonged paralysis owing to persistent drug effect or from AQM. Both circumstances result in significant weakness and are considerations in the broad differential diagnosis of weakness in the ICU patient. Causes of weakness range widely from severe electrolyte disturbances like hypermagnesemia or hypophosphatemia to critical illness polyneuropathy, steroid myopathy, or Guillain-Barré syndrome. A variety of factors can increase the risk for prolonged recovery from NMBA, including organ dysfunction and resulting impaired clearance of the parent compound, accumulation of active metabolites, drug-drug interactions, and other medical conditions. Drugs that potentiate or antagonize the actions of nondepolarizing NMBAs are listed in Box 20.5. There is also considerable variability in duration of effect among NMBAs. The aminosteroids are eliminated by a combination of renal clearance and hepatic metabolism to a number of compounds, some of which are active and are eliminated in the urine. Accordingly, dysfunction of liver and/or kidneys is associated with prolonged paralysis.[29,188] Resolution of paralysis is not predictable with vecuronium, particularly with prolonged infusion.[188,189] This contrasts sharply with the benzylisoquinoliniums with recovery times of about 1 hour, even despite prolonged infusion and with higher doses.[187] Perhaps most instructive is a prospective head-to-head comparison of vecuronium and cisatracurium in ICU patients in which average recovery time was fivefold longer with vecuronium.[190] Close monitoring of depth of sedation using TOF PNS appears to reduce the incidence of prolonged paralysis with vecuronium[184] but is of less certain value with atracurium or cisatracurium[185,186]

AQM is a potentially devastating form of NMBA-related weakness because the muscle weakness can be severe and quite protracted.[28] AQM is characterized by weakness of the limb and trunk muscles with sparing of the extraocular muscles as well as preserved sensory function and cognition. Understanding of the mechanisms underlying AQM has evolved from suspicion that myonecrosis alone was responsible to that of altered muscle membrane properties with loss of motor protein myosin and myosin-associated thick filament proteins. Work by Larsson and associates has demonstrated that a combination of myofibrillar protein degradation plus downregulation of protein synthesis at the transcriptional level is prominent.[191] Key predisposing factors for intensive care–acquired weakness appear to be functional denervation—such as from NMBAs and corticosteroids. The argument has been made that prolonged deep sedation may be another source of immobilization. Additional risk factors for

• BOX 20.5 Drugs That Potentiate or Antagonize the Actions of Nondepolarizing Neuromuscular Blocking Agents

Drugs That Potentiate the Action of Nondepolarizing NMBAs

Local anesthetics
Lidocaine
Antimicrobials (aminoglycosides, polymyxin B, clindamycin, tetracycline, vancomycin, amphotericin B, colistin)
Antiarrhythmics (procainamide, quinidine)
Magnesium
Calcium channel blockers
β-Adrenergic blockers
Immunosuppressive agents (cyclophosphamide, cyclosporine)
Dantrolene
Diuretics (furosemide, bumetanide, ethacrynic acid)
Lithium carbonate
Corticosteroids
Inhaled anesthetics (enflurane, halothane, isoflurane, methoxyflurane, nitrous oxide)
Acetylcholinesterase inhibitors

Drugs That Antagonize the Actions of Nondepolarizing NMBAs

Phenytoin
Carbamazepine
Theophylline
Ranitidine

ICU-acquired polyneuropathy and myopathy include sepsis and other forms of systemic inflammation, hyperglycemia, malnutrition, and prolonged immobility. Although both aminosteroid and benzylisoquinolinium agents have been linked to AQM in case reports, it is noteworthy that in the relatively limited prospective clinical trial literature of NMBs in ICU patients, AQM is described in about 5% of patients who received vecuronium but none of the more than 200 patients who received atracurium or cisatracurium infusions.[183] Further, in the largest multicenter RCT of cisatracurium versus placebo, there was no difference in the incidence of ICU-acquired weakness.[30] Finally, some experts consider the causality of NMBAs—particularly short-duration NMBAs—for producing ICU-acquired weakness to be far from certain.[31] Standard precautions to reduce the likelihood of NMBA-associated weakness include a preference for use of cisatracurium, limiting duration of NMBA infusion to less than 48 hours if possible, performing periodic interruption of infusion, and ongoing clinical evaluation.[28,192,193]

Summary and Conclusions

The use of analgesic and sedative medications is the ICU setting is widespread and although often viewed as a component of "supportive care" of critically ill patients, clearly can affect major outcomes. Accordingly, adopting a thoughtful, structured, and multidisciplinary approach to managing analgesia and sedation is important and centers around reasoned medication selection, close monitoring, and applying strategies to use the lowest effective dose. Similarly, NMBA administration can be of critical importance in managing selected clinical situations and should be guided by monitoring and limiting use to the shortest duration possible.

Key Points

- A combination of nonpharmacologic and pharmacologic interventions can be useful to enhance patient comfort and reduce the distress associated with invasive procedures, mechanical ventilation, postoperative pain, and sleep deprivation common to the ICU experience.
- Adopting a patient-focused approach to managing sedation and analgesia that strives to minimize the depth and duration of reduced consciousness is associated with better outcomes.
- Development of delirium in the ICU is associated with worse outcomes, including impaired cognitive function after discharge.
- Agitated behavior is a common occurrence associated with adverse consequences, including self-removal of critical tubes and lines and excessive adrenergic stress response.
- Identification of delirium or agitation should prompt a search for predisposing and precipitating medical conditions and medications.
- Self-reporting using standardized tools is the best method to detect and quantify pain; however, observation of characteristic behaviors can be helpful in the patient who is unable to self-report.
- Routine use of a validated sedation-agitation scale such as the RASS or SAS promotes better communication, more precise sedative drug titration, and timely detection and grading of agitation.
- Use of nonbenzodiazepines is preferred to benzodiazepines when continuous infusion sedation is required.
- Targeting a more alert state for mechanically ventilated ICU patients is associated with better outcomes, including shorter duration of mechanical ventilation, fewer tests, and shorter ICU LOS.
- Linking management of sedation and analgesia, including interruption of sedation, with SBTs on mechanical ventilation, delirium prevention, and early mobility improves patient outcomes.
- NMBAs, particularly cis-atracurium, can be of value to facilitate mechanical ventilation in severe ARDS or status asthmaticus.
- Safe and effective use of NMBAs requires prevention of undetected pain and awareness in the paralyzed patient, prevention of adverse consequences of paralysis such as corneal damage or nerve injury from inappropriate positioning, prophylaxis against deep venous thrombosis, and clinical monitoring.

Review Questions

1. Dexmedetomedine is associated with which one of the following adverse effects?
a. Hypertriglyceridemia
b. Bradycardia
c. Metabolic acidosis
d. Prolonged drug effect in patients with renal failure
Answer: b. Dexmedetomidine is an α_1-agonist sedative with unique characteristics of limited suppression of respiratory drive, reduced rates of delirium, and modest analgesia. The most common adverse effect is bradycardia and it can produce hypotension. Propofol is formulated in a lipid vehicle for administration and can be associated with hypertriglyceridemia when given at higher doses. The vehicle for delivery of lorazepam includes several glycols, which can lead to metabolic acidosis, impaired renal function, and increased osmolar gap. Midazolam has active metabolites that can accumulate in patients with impaired renal function, resulting in prolonged drug effect.

2. Which of the following opioid analgesics is associated with the uncommon complication of chest wall rigidity?
a. Fentanyl
b. Morphine sulfate
c. Meperidine
d. Hydromorphone
Answer: a. Fentanyl has been associated with chest wall rigidity—an uncommon adverse effect that can produce impaired ventilation. Morphine sulfate is associated with histamine release, which can produce hypotension or bronchospasm and delayed recovery as active metabolites can accumulate in patients with renal failure. Meperidine has been linked to neuroexcitatory complications including seizures and its use in critically ill patients is discouraged. Hydromorphone is a potent opioid analgesic not associated with chest wall rigidity.

3. Which of the following statements regarding train-of-four (TOF) peripheral nerve testing during neuromuscular blockade is true?
a. Responses differ for steroid nucleus agents (i.e., vecuronium) versus benzoquinolinium agents (i.e., cisatracurium).
b. Absence of TOF response always means there is an overdose of the neuromuscular blocking agent.
c. Presence of two of four muscle twitches during TOF testing signifies blockade of about 50% of receptors.
d. TOF testing should be paired with clinical evaluation.
Answer: d. TOF peripheral nerve stimulation is used to gauge the depth of paralysis with neuromuscular blocking agents (NMBAs) of all classes administered by continuous infusion to mechanically ventilated patients. A series of four brief electrical stimuli is applied to a peripheral nerve (typically ulnar or facial nerve) and the contractile response of the innervated muscle is observed. Presence of one to four muscle twitches indicates blockade of more than 75% of receptors. Although the absence of all twitches may signify an excessive dose of NMBA, it may also be the result of inadequate stimulation of the nerve owing to development of tissue edema or faulty positioning of the nerve stimulator leads. In all cases, TOF testing should be paired with clinical evaluation, including assessment of breathing or other movement.

4. What does the C of the ABCDEF bundle stand for?
a. Circulatory assessment
b. Comfort
c. Choice of analgesia and sedation
d. Confusion rating scale
Answer: c. The ABCDEF bundle provides a structure for managing pain, sedation, delirium, mechanical ventilation, exercise, and family engagement as follows: A = assess, prevent, and manage pain; B = both spontaneous awakening trials (SATs) and spontaneous breathing trials (SBTs); C = choice of analgesia and sedation; D = delirium: assess, prevent, and manage; E = early mobility and exercise; F = family engagement and empowerment.

5. Which of the following statements about cisatracurium is correct?
a. Metabolism is independent of end-organ function.
b. It is associated with a higher incidence of prolonged residual paralysis compared with vecuronium.
c. It may be associated with clinically significant histamine release.
d. Onset of action after injection occurs in 20 to 30 seconds.
Answer: a. Cisatracurium is a benzoquinolinium neuromuscular blocking agent that is metabolized by Hofmann degradation—an enzymatic process that is not dependent on hepatic metabolism or renal clearance. Onset of action is within 2 to 3 minutes. In contrast to its related compound atracurium, cisatracurium it is not associated with histamine release. When compared with vecuronium it has a shorter and more reliable duration of residual effect, particularly in patients with renal or liver disease.

The Effect of Critical Illness on Pharmacokinetics and Pharmacodynamics

JUDITH JACOBI AND QUINN A. CZOSNOWSKI

CHAPTER OUTLINE

Physiologic Changes in Critical Illness
General Pharmacokinetic Principles
- Absorption
- Distribution
- Clearance
- Half-Life

Pharmacodynamics
- β-Lactams
- Aminoglycosides
- Vancomycin

Dosing Considerations in Select Critical Care Patients
- Renal Disease
- Hepatic Disease
- Obese Patients
- Pregnancy
- Burn Injury
- Hypothermia

Pharmacogenetics
Principles of Therapeutic Drug Monitoring
Conclusion

Critically ill patients are closely monitored and procedures are performed, but supportive care and treatment is primarily with medications. To maximize effectiveness and minimize adverse effects, dosing must be optimized for each patient, which requires an understanding of typical pharmacokinetic changes. Individualized dosing regimens, based on expected concentrations and potential changes over time, are needed. The science of pharmacokinetics (PK) describes what the body does to drugs: absorption, distribution, metabolism, and excretion. However, understanding PK alone is not sufficient to design optimal dosing regimens. Other important questions remain: What concentration is needed to produce the desired effect? What concentration has the potential to produce toxicity? These questions are answered by the science of pharmacodynamics (PD), the study of what drugs do to the body, ideally at a receptor level. Understanding PD allows the clinician to relate specific serum concentrations to pharmacologic effects. The use of both pharmacokinetic and pharmacodynamic principles enables the clinician to maximize therapeutic efficacy while minimizing toxicity.

Complexity around drug dosing is typical for critically ill patients. The majority of pharmacokinetic and pharmacodynamic information available has been obtained from studies in healthy volunteers and other non–critically ill populations. Critically ill patients differ from those often studied because they frequently experience hepatic and renal dysfunction, receive aggressive fluid resuscitation, and require vasoactive medications to maintain adequate organ perfusion. These physiologic alterations can dramatically alter dose response and vary greatly from patient to patient and even from day to day in the same patient. In addition, patients also frequently have significant comorbid conditions, such as chronic kidney disease, cirrhosis, and heart failure, that affect dose response. Interventions such as renal replacement therapies and extracorporeal circulation can further influence drug effect and behavior.

Physiologic Changes in Critical Illness

The third international consensus conference on definitions of sepsis recommended the de-emphasis of the systemic inflammatory response syndrome (SIRS) and the abandonment of a special characterization of the group of infected patients with SIRS but no organ dysfunction.[1] However, we believe the use of SIRS to describe the systemic perturbation that often occurs in the presence of acute body insult is important to the understanding of how drug therapy is influenced in conditions associated with SIRS, especially when it is profound. SIRS is present to some degree in nearly all critically ill patients. Common insults, such as sepsis, trauma, surgery, the acute respiratory distress syndrome (ARDS), and pancreatitis, all produce SIRS. Before adequate fluid resuscitation patients may have low intravascular volume, inadequate preload, and low cardiac output. As a result, blood flow to organs such as the liver and kidneys can be compromised, leading to decreased drug clearance with associated serum and tissue drug accumulation. This physiology is commonly seen in patients admitted with sepsis when adequate resuscitation has not yet occurred. Fluid resuscitation restores preload and increases cardiac output. Because of increased

heart rate and low systemic vascular resistance, patients with resuscitated SIRS or sepsis frequently have hyperdynamic physiology in which organ blood flow can be higher than normal.[2] Sepsis also frequently leads to organ dysfunction including acute liver and kidney injury. Careful assessment of renal and hepatic clearance is required and must be combined with prudent judgment of the risk-benefit ratio of each individual drug. Clinicians may err on the aggressive side of dosing decisions for drugs with a wide therapeutic index such as the β-lactam antibiotics. Conversely, the risk-benefit ratio may support more conservative dosing decisions for drugs that have serious dose-related toxicity such as antiarrhythmic agents and anticoagulants.

The amount of fluid resuscitation required to maintain intravascular volume in patients with SIRS can be significant. Positive fluid balance may also occur in postsurgical patients, trauma patients, and patients with ARDS, among others. These changes in fluid balance combined with the capillary leak produced by SIRS can have significant effects on the distribution and dilution of hydrophilic drugs. In addition to changes in organ blood flow and volume status, critically ill patients also have altered serum protein concentrations, which can have important effects on drugs that are highly protein bound. The two most important serum proteins that contribute to drug binding are albumin, which binds mostly to acidic drugs, and α_1-acid glycoprotein (AGP), which binds mostly to basic drugs. A variety of factors contribute to altered serum protein concentration, including malnutrition, hemodilution, and the acute-phase response. Interestingly, the acute-phase response has a discordant effect on these proteins: albumin decreases whereas AGP increases.[3]

General Pharmacokinetic Principles

The PK profile of a drug is a mathematical model that describes the determinants of drug exposure. A complete model provides quantitative estimates of drug absorption, distribution, metabolism, and excretion after single doses, in addition to the extent of serum and tissue accumulation after multiple doses. The definition of common PK terms can be found in Table 21.1. The illustration in Fig. 21.1 depicts the concentration-time curve for a single intravenous (IV) dose of tobramycin. The curve allows for estimation of the maximum concentration achieved and the time course of drug elimination. If dosing is repeated before elimination is complete, accumulation occurs and will continue until the system reaches "steady state," at which time the rate of administration is in equilibrium with the rate of elimination (Fig. 21.2). Understanding the basic concepts of PK and PD is essential to providing safe and effective drug therapy. However, the physiologic derangements found in critically ill patients can significantly alter PK/PD relationships, which can lead to both exaggerated and diminished pharmacologic response with standard dosing regimens. Consequently, the intensive care unit clinician must integrate a thorough understanding of critical illness physiology with PK/PD principles to provide appropriate drug therapy. A summary of these changes can be found in Table 21.2.

Absorption

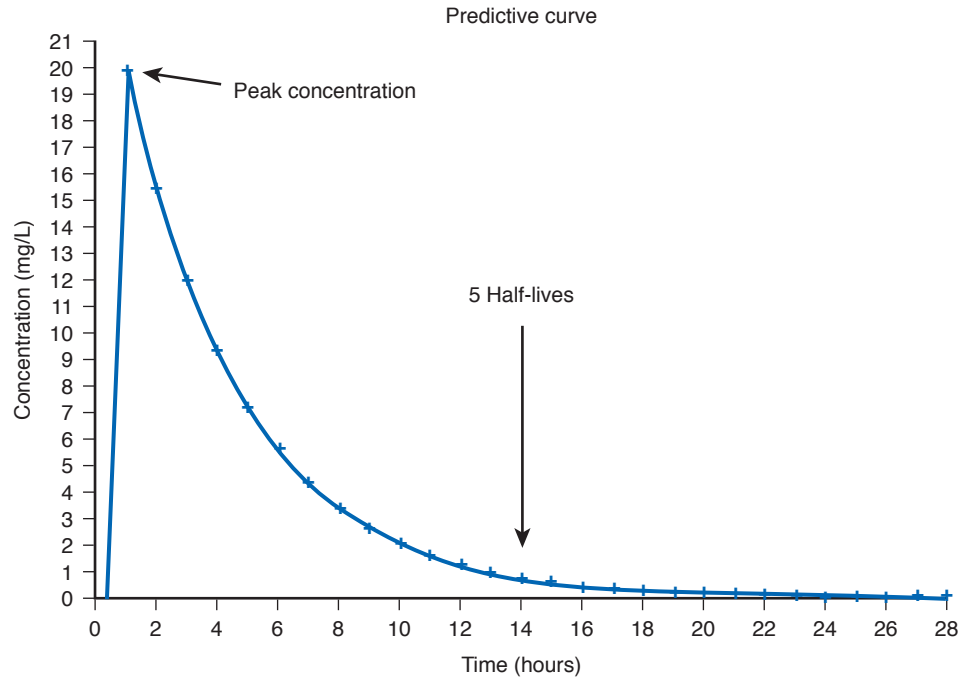
The first step in modeling exposure is to quantify the relationship between drug dosage administered and the amount of drug that reaches the systemic circulation. This relationship is known as the drug's bioavailability. IV administration provides 100% bioavailability, whereas this value can be considerably less for other routes. The oral route is the most common for the general population and remains useful in many critically ill patients. Bioavailability through oral administration is usually less than 100% and is a function of two main factors: (1) absorption, which is the intrinsic ability of the drug to cross the gastrointestinal (GI) tract, and (2) presystemic metabolism, also known as the first-pass effect, which

TABLE 21.1 Basic Pharmacokinetic Parameters

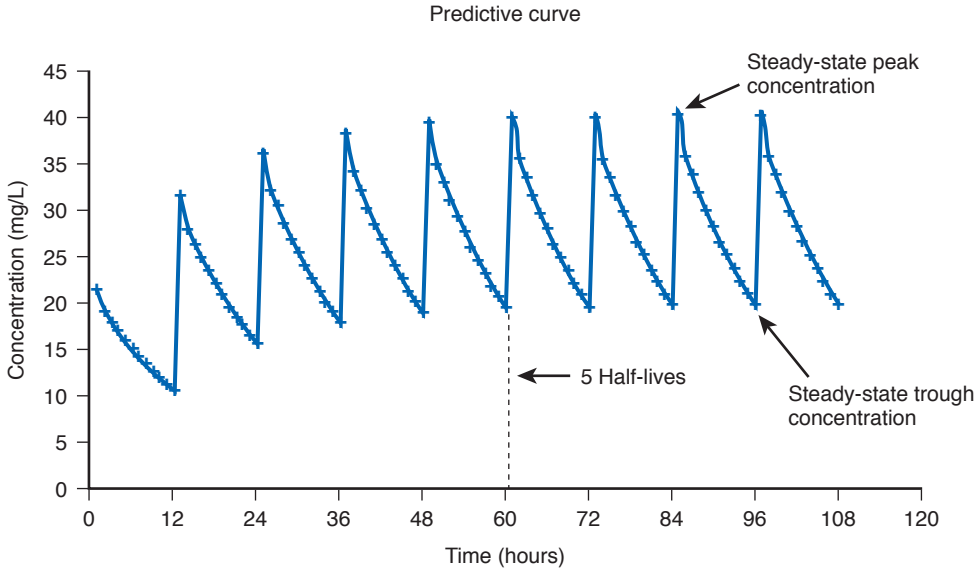
Parameter	Definition	Notes
Volume of distribution (Vd)	$Vd = \frac{\text{Dose (mg)}}{\text{Peak concentration (mg/L)}}$	Size of distribution compartment Quantifies the degree to which drug distributes into tissue
Area under the concentration time curve (AUC)	$AUC = \frac{\text{Dose (mg/h)}}{\text{Cl (L/h)}}$	Total drug exposure produced by administered dose
Clearance (Cl)	$Cl = \frac{\text{Dose (mg/h)}}{\text{AUC (mg/L per hour)}}$	Volume of blood cleared of drug per unit time
Elimination rate constant (Ke)	$Ke = \frac{Cl\ (L/h)}{Vd\ (L)}$	The rate of drug elimination from the body per unit of time. Relates clearance (liters cleared/hour) and Vd (volume to be cleared). This value is inversely related to drug half-life.

Bioavailability (F)	$F = \frac{AUC_{po}/dose_{po}}{AUC_{IV}/dose_{IV}}$	Percentage of dose that reaches systemic circulation
		Varies by route:
		• Intravenous (100%)
		• Variable (0%–100%)
		  • Oral
		  • Subcutaneous
		  • Transdermal
		Value expressed as a percentage of exposure relative to IV administration

Cl, Clearance; *IV*, intravenous; *po*, oral.



• **Fig. 21.1** Concentration versus time curve following a single 200-mg intravenous dose of tobramcyin in a 50-kg female. Note: Peak concentration determined by volume of distribution (Vd) and the size of dose given. The time course of elimination is determined by clearance and Vd. Approximately 90% of dose is eliminated after 5 half-lives.



• **Fig. 21.2** Concentration versus time curve demonstrating accumulation after repeated dosing of 750 mg vancomycin every 12 hours in a 50-kg patient. Note: Dosing regimens are based on steady-state concentrations. Therapeutic drug monitoring should be conducted when regimens have reached steady state, which occurs after 5 to 7 half-lives.

occurs primarily in the liver, and to a lesser extent in the intestinal lumen. Drugs that undergo extensive hepatic metabolism may have large first-pass effects and thus low bioavailability compared with IV administration. Similarly, drugs that are poorly absorbed will have low bioavailability.

Factors that determine absorption from the GI tract include drug characteristics, such as lipid solubility, ionization, and molecular size, in addition to physiologic factors, such as gastric emptying rate, intestinal blood flow, motility, gastric and intestinal pH, gut wall permeability, and whether the dose is administered during the fasted or fed state. Most drugs are orally absorbed through passive diffusion, although carrier-mediated absorption can also be important. The most important sites of absorption are the upper and lower segments of the small intestine.[4] The stomach regulates absorption through gastric emptying but is not an important site for absorption. Similarly, little drug absorption occurs in the colon,

TABLE 21.2 Pharmacokinetic Changes During Critical Illness

Parameter	Relevant Critical Illness Physiology	Effect on Pharmacokinetics
Absorption	Reduced mesenteric and subcutaneous blood flow during shock Delayed gastric emptying Reduced GI motility	Reduced peak concentration and AUC Delayed onset of effect Variable
Distribution	Capillary leak and fluid resuscitation Reduced albumin concentration Increased AGP concentration Decreased tissue binding	Increased Vd for hydrophilic drugs Increased Vd for drugs highly bound to albumin Decreased Vd for drugs highly bound to AGP Decreased Vd
Clearance	SIRS response increases blood flow to liver and kidneys Acute kidney injury and acute liver injury Reduced albumin concentration Increased AGP concentration	Increased drug clearance Decreased drug clearance Increased drug clearance for acidic drugs highly bound to albumin Decreased clearance for basic drugs highly bound to AGP

AGP, α_1-Acid glycoprotein; *AUC*, area under the concentration-time curve; *GI*, gastrointestinal; *SIRS*, systemic inflammatory response syndrome; *Vd*, volume of distribution.

with the exception of extended-release products. Drugs with low oral bioavailability will require larger doses administered orally to produce equivalent exposure to that obtained from IV administration. Some drugs (e.g., vancomycin) have such poor bioavailability after oral administration that they cannot be used to treat the same disease processes as the IV formulations. Bioavailability is an important consideration when converting between oral and IV routes. For example, converting amiodarone IV at 0.5 mg/min (720 mg/24 h) to an equivalent oral dose would require approximately 1440 mg/24 h, considering the average 50% (35%–65%) bioavailability.[5] Other routes of administration include subcutaneous or intramuscular injection, transdermal or buccal absorption, and inhalation. Many drugs available as IV preparations are amenable to subcutaneous and intramuscular administration. Drugs with adequate lipid solubility may be available for transdermal or buccal administration, including nitroglycerin, fentanyl, and tacrolimus.

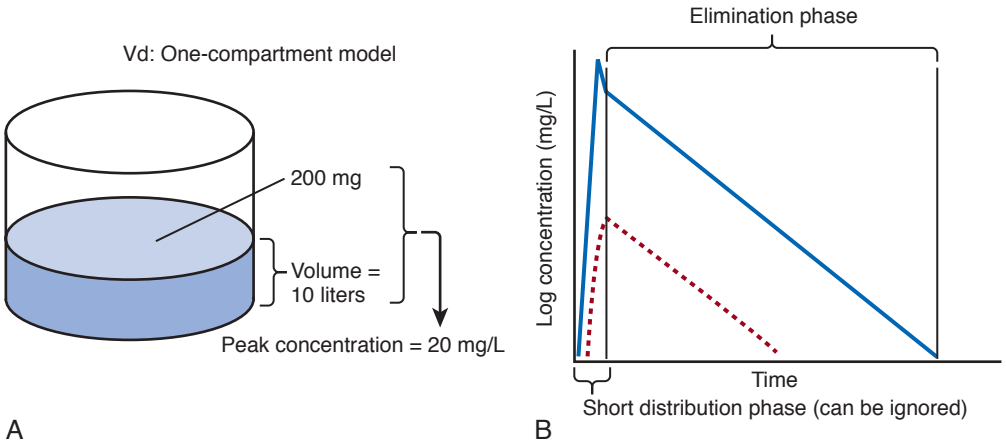
Although oral administration is useful in critically ill patients, the route may not always be appropriate. Physiologic changes, such as decreased mesenteric blood flow, altered intestinal motility, gastric acid suppression, and gut wall edema, can alter the rate and extent of absorption.[6] The hemodynamic response to hypotension involves shunting blood flow away from mesenteric circulation, substantially limiting a drug's access to the systemic circulation.[7] Hepatic blood flow may be preserved in the short term owing to the "hepatic buffer" response but is often decreased with prolonged states of low systemic perfusion.[8] Low hepatic blood flow will limit hepatic metabolism and result in increased bioavailability of drugs with a large first-pass effect. The net effect of these derangements can be highly unpredictable but often leads to diminished bioavailability. Slow gastric emptying, which occurs in 50% to 60% of critically ill patients, delays the onset of absorption and often results in lower peak serum concentrations.[9–11] Impaired small intestine motility also slows the rate of absorption. However, because residence time in the GI tract will be longer, bioavailability may actually increase for poorly absorbable drugs such as furosemide and ampicillin.[12] Carrier-mediated absorption may be limited independent of changes in motility or blood flow as a result of dysfunctional membrane transporters.

There are limited data describing the effectiveness of oral administration in critically ill patients. Some studies, conducted in patients tolerating enteral feeding, show absorption to be adequate for drugs with normally high bioavailability such as fluconazole and ciprofloxacin.[13,14] However, other studies show unpredictable and sometimes inadequate absorption.[15] Given this variability and the absence of a useful parameter to monitor GI function at the bedside, the IV route is preferred in patients with hemodynamic instability. The oral route should be reserved for patients who are clinically stable and tolerating enteral feeding. When transitioning medications from IV to oral, it is helpful to begin with agents that have easily measurable effects, such as cardiovascular agents. Very little research has been done on the absorption of medications after delivery via jejunal feeding tubes. Although sustained-release products cannot be crushed, others with special coatings may be successfully delivered beyond gastric acid. Some medications, such as rivaroxaban, may not be well absorbed if delivered beyond the stomach, with a 29% decrease in area under the concentration-time curve and 56% decrease in the maximum concentration when delivered to the proximal small intestine, and may be lower if delivered to the distal small intestine.[16]

Subcutaneous absorption is dependent on the characteristics of the drug, volume administered, and perfusion of the tissue. Special formulations like glargine insulin are delivered as soluble microcrystals in acid solution that covert into aggregates of insulin hexamers at physiologic pH. These hexamers slowly dissociate into monomers that are then physiologically active and are slowly absorbed. However, patients receiving vasopressors or those with subcutaneous edema may not absorb drugs well from the subcutaneous space, as demonstrated with low–molecular-weight heparins.[17,18] Peak anti–factor Xa levels of these agents are significantly reduced in patients receiving vasopressors.[17,19] Although these data are provocative, the clinical importance of low anti–factor Xa levels is unclear regarding the risk of thrombosis.[20,21]

Distribution

After reaching the systemic circulation an administered dose then distributes throughout the body to produce a peak concentration. The relationship between the dose administered and the peak concentration observed is termed the *volume of distribution* (Vd). The Vd estimates the size of the compartment into which the drug distributes. Although it is not a measurable space, it



• **Fig. 21.3** One-compartment model of drug distribution when drug rapidly distributes between plasma and tissue. A, Volume of distribution *(Vd)* defines the relationship between dose and peak concentration. B, Concentration versus time curve for one-compartment model on a logarithmic scale. The *solid line* represents serum concentration. The *dashed line* represents tissue concentration. Note that tissue concentrations increase during the distribution phase. Because target receptors are frequently within tissues, the time course of the dashed line determines the onset and duration of effect.

rather mathematically reflects the net effect of multiple fluid and tissue spaces. Total plasma volume in the average adult is 3 to 4 L but may be larger in critically ill patients, although the Vd for most drugs is much greater than this value. The discrepancy between plasma volume and a drug's Vd depends on the extent that drugs concentrate in various tissues. The main determinants of Vd are the lipid solubility, degree of protein binding, and extent of tissue binding. High lipid solubility increases Vd through improved passage across cell membranes. Avid tissue binding also increases Vd as this concentrates drug outside the vascular space. Conversely, because only unbound drug can cross cell membranes and bind to tissue, high serum protein binding decreases Vd, concentrating drug in the vascular space.

The simplest conceptualization of Vd is to view the body as a bucket—one large compartment where drug rapidly equilibrates between plasma and tissue and has uniform distribution (Fig. 21.3A). The one-compartment assumption is useful for drugs with small to intermediate Vd, such as aminoglycoside or many cephalosporin antibiotics, because these hydrophilic drugs have a short distribution phase owing to their limited tissue penetration. Drugs with large Vds, such as fentanyl and amiodarone, require longer periods of time to achieve equilibrium between serum and tissue and thus have a prolonged distribution phase. As a result, the one-compartment assumption fails to accurately describe Vd drugs with large Vds. An alternative is to view the body as multiple compartments: a central compartment composed of blood, extracellular fluid, and highly perfused tissues; and one or more peripheral compartments composed of tissue beds with lower perfusion and higher drug binding affinity (Fig. 21.4A). The number of peripheral compartments is determined by the differential distribution rate in each tissue. Two-compartment models adequately describe most drugs with large Vds; however, a three-compartment model can be useful for agents that act in the central nervous system because of slower distribution as a result of the blood-brain barrier.

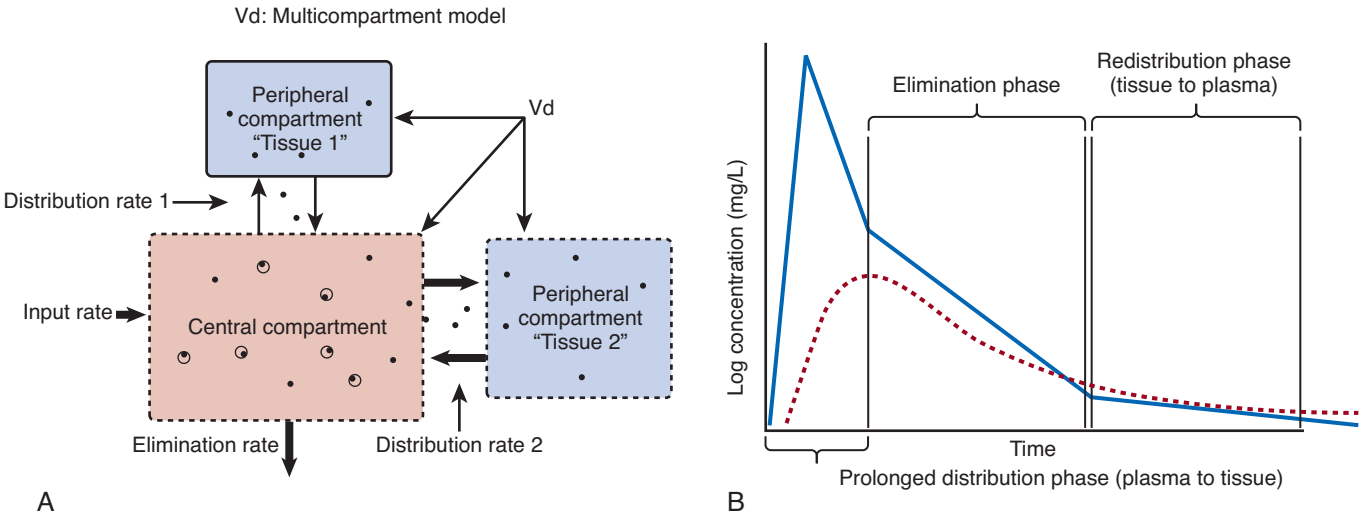
An increase in the Vd of hydrophilic drugs is predictable in critically ill patients with expanded body water, proportionately reducing the peak concentration of the initial dose. Loading doses of most antimicrobials should be considered during and after volume resuscitation to compensate for this dilutional effect.

As previously discussed, changes in protein concentrations—such as reduced albumin and elevated AGP—may affect the degree of drug binding. The levels of AGP are not static after an acute injury or illness, making assessment of free (non–protein-bound) drug more challenging.[22] Lidocaine is the primary agent studied for the impact of AGP changes, but phenytoin is also slightly bound to this protein, and changes in AGP may alter total protein binding, although formulas to predict free phenytoin levels typically consider only albumin concentration; thus direct measurement of the free level is recommended when possible.[23]

Other physiologic changes such as the extremes of weight also make prediction of Vd difficult, as obese patients have varying ratios of muscle and fat, as discussed later.

Clearance

Drug elimination begins immediately upon entry into the body and can be divided into two main components: metabolism and excretion. Metabolism occurs mainly in the liver via enzymatic degradation, although it occurs to lesser extents in other tissues, such as the kidney, lung, small intestine, and skin. Enzymes found in the serum also metabolize drugs, such as remifentanil elimination via nonspecific plasma and tissue esterases. Nonenzymatic metabolism also occurs in the serum, as is the case for cisatracurium, which undergoes spontaneous degradation in the serum through ester hydrolysis. Excretion occurs primarily in the kidney, bile, and feces. Some drugs are eliminated predominantly by a single mechanism. For example, more than 95% of elimination for the aminoglycoside antibiotics occurs through excretion in the kidneys. Other drugs, such as ceftriaxone, are removed through multiple pathways (renal and biliary elimination). Regardless of pathway, the degree of protein binding exhibited by a drug is an important determinant of elimination rate, as only unbound drug can be eliminated from the serum. A reduction in albumin binding is expected to increase the percentage of unbound drug or free fraction, although the free concentration may not increase to the extent predicted if more unbound drug is eliminated. Ceftriaxone is normally 85% to 95% protein bound, but as protein concentrations fall in critical illness, the Vd may increase by 90% and clearance



• **Fig. 21.4** Multicompartment model of drug distribution when drug requires a longer period of time to achieve equilibrium between plasma and tissue. A, Depiction of a multicompartment model of volume of distribution *(Vd)*. Drug enters the central compartment (serum) and then distributes into peripheral compartments (tissues). Total drug Vd is the sum of the individual compartments. Drug must then distribute back into serum to be eliminated. *Open circles* represent serum protein molecules. *Solid circles* represent drug molecules. B, Concentration versus time curve for one-compartment model on a logarithmic scale. The *solid line* represents serum concentration. The *dashed line* represents tissue concentration. Note that tissue concentrations increase during the distribution phase. Drugs with large Vds require prolonged distribution phases to saturate the peripheral compartments. The large Vd also results in a prolonged redistribution phase, which prolongs drug half-life.

by 100%, leading to suggestions of more frequent dosing or continuous infusion to maintain effective concentrations.[24,25]

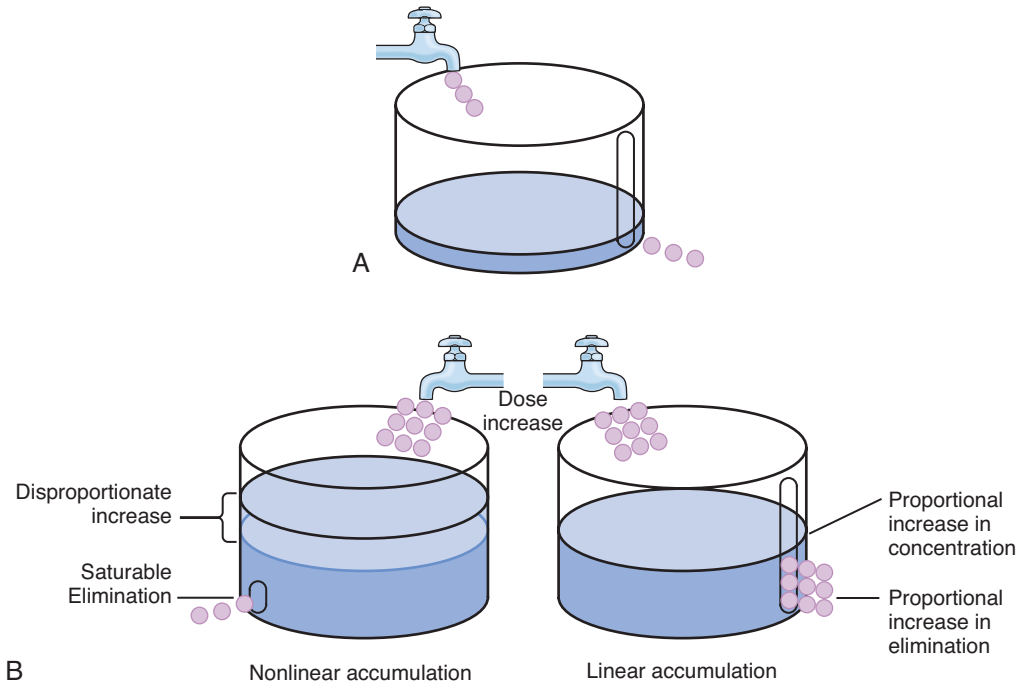
The rate of drug removal via all routes is termed clearance (Cl), which is expressed as the volume of plasma cleared per unit of time. This value is assumed to be constant for most drugs when organ function is stable. If the *volume cleared per unit of time is constant,* it then holds that the *amount of drug cleared per unit of time* must change in proportion to serum concentration. Rapid administration and a high concentration increase the amount of drug removed. The amount of drug removed per unit of time is called the elimination rate (ke). In contrast, a reduction in serum concentration, owing to expansion of the Vd, reduces the amount of drug removed and reduces the ke. Mathematically, ke is inversely related to the half-life. Serum and tissue concentrations accumulate until the ke is in equilibrium with the rate of administration, at which time the system is said to be at "steady state" (Figs. 21.2 and 21.5). Accumulation follows a linear pattern for most drugs, meaning that increases in dose are always matched by proportional increases in elimination, thus producing proportional changes in serum concentration (Fig. 21.5). Drugs that follow this pattern of accumulation are said to have first-order kinetics.

However, some drugs exhibit saturable elimination. These drugs follow linear accumulation until a saturation point is reached. Once elimination is saturated, small changes in dose can produce substantial increases in concentration (see Fig. 21.5). Drugs that follow this pattern of accumulation have zero-order kinetics. Examples of drugs with saturable elimination are phenytoin, high-dose heparin, propranolol, and verapamil.

Renal elimination of drugs is an important clearance mechanism. Glomerular filtration rate (GFR) is measured or estimated to predict elimination of drugs undergoing filtration, but is less accurate for drugs with substantial tubular secretion. Methods to estimate or measure GFR are discussed in detail later. Although most of the research has focused on reduced renal function, it is now recognized that a subset of critically ill patients may experience augmented renal clearance (ARC), exceeding what may have been taught as the "maximum" Cl through higher GFR and renal tubular anion secretion.[26,27] This ARC is defined as creatinine clearance (CrCl) greater than 130 mL/min (range >120 to >150 mL/min) and has been described in patients younger than 50 years of age, male sex, higher diastolic blood pressure, and fewer acute comorbidities over the first week of care.[28] Populations at risk include those with major trauma, traumatic brain injury (TBI) or subarachnoid hemorrhage, or central nervous system infection. Patients with ARC are at risk for treatment failure if doses are not increased. Urine collection for measured CrCl is needed to identify these patients and should be considered for younger patients and those with Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI)-estimated CrCl >108 mL/min.[29]

The liver serves as the primary site for drug metabolism, and therefore drug dosing is an important consideration in any patient with hepatic disease. Hepatic drug clearance (CL_H) is an extremely complex process, dependent on hepatic blood flow and the hepatic extraction ratio. The hepatic extraction ratio depends on hepatic flow, intrinsic clearance of unbound drug (CL_{int}), and the fraction of unbound drug in blood.[30]

Drugs can be categorized as either high– or low–extraction ratio drugs. Elimination of high–extraction ratio drugs is dictated by hepatic blood flow and is less sensitive to changes in drug protein binding or enzyme activity. With oral administration, high–extraction ratio drugs (>70% extracted) undergo extensive presystemic metabolism, commonly referred to as the hepatic first-pass effect. This results in significantly lower bioavailability and serum drug concentrations. Patients with reduced hepatic



• **Fig. 21.5** Pharmacokinetic principle of linear and nonlinear drug elimination. A, Faucet and bucket representation of drug elimination. The faucet represents drug input rate. The channel in the side of the bucket represents drug elimination pathways. At steady state drug input is in equilibrium with drug elimination. B, The effect of a dose increase. On the right is an example of first-order kinetics. The channel allows for elimination to increase in proportion to the dose increase, producing proportional changes in drug level. On the left is an example of zero-order kinetics, in which elimination is constant after the saturation point. Here the elimination channel is saturated at low input rates, producing a disproportionate increase in drug level.

blood flow have less first-pass effect, leading to higher serum concentrations. This effect is most pronounced in drugs that normally have low bioavailability after oral administration. Agents such as lidocaine, morphine, verapamil, propranolol, propofol, and nitroglycerin illustrate flow dependence, and poor cardiac output will contribute to rapid accumulation of serum concentrations unless doses are adjusted. Hyperdynamic flow rates in sepsis or stimulated by catecholamines could increase the rate of drug elimination of high–extraction ratio drugs.

Low–extraction ratio drugs are more sensitive to changes in drug protein binding and enzyme activity and are affected to a lesser degree by changes in blood flow. Plasma protein binding of drugs is lower in critically ill patients and those with hepatic disease owing to decreased albumin production and accumulation of endogenous compounds that inhibit protein binding (e.g., uremia or hyperbilirubinemia). As discussed previously, this decrease in protein binding can increase free/unbound drug levels and may increase the risk of adverse effects.

Intrinsic hepatic clearance is the ability of the liver to clear unbound drug from the blood. It is highly dependent on the activity of metabolic enzymes and hepatic transporters. The two phases of hepatic metabolism are phase I (i.e., hydrolysis, oxidation, reduction) and phase II (i.e., acetylation, glucuronidation, sulfation). The cytochrome P450 (CYP) family of enzymes is responsible for approximately 75% of drug metabolism and the phase I reactions.[31] Drugs are converted to a more soluble salt form and in some cases to the active moiety or active metabolites. For example, midazolam oxidative metabolism produces several metabolites, including α_1-hydroxymidazolam, a renally eliminated active, sedating moiety.[32]

The activity of phase I enzymes is dependent on genetic predisposition, drug interactions (inhibition or induction), body temperature, and hepatic injury. Phase I metabolism is very dependent on oxygen and is sensitive to reduced oxygen delivery, such as shunting, sinusoidal capillarization, and reduced liver perfusion.[33] The changes are not homogenous across CYP 450 isoenzymes after a hypoxemic insult.

Phase II metabolism converts the parent drug to an inactive salt form that is renally eliminated (e.g., lorazepam, valproic acid). These conjugation reactions were historically thought to be spared in patients with liver disease, but recent data suggest that impairment in patients with advanced cirrhosis as well.[30] A unique interaction involving phase II metabolism is the most plausible explanation of the dramatic reduction in valproic acid concentrations with concurrent carbapenem (doripenem, ertapenem, imipenem, meropenem) administration.[34,35] The interaction occurs without regard to route of valproic acid administration and cannot be easily overcome with an increase in valproate dose, resulting in seizures or loss of control of mania. This combination should be avoided. Demonstration that meropenem accelerates the glucuronidation of valproic acid glucuronide and further inhibits the hydrolysis or deconjugation back to the parent compound is the leading explanation for this interaction.[35] The valproic acid glucuronide is rapidly eliminated via renal routes. It is unknown if other interactions can alter phase II homeostasis in a similar manner.

Half-Life

Once clearance is known the clinician can estimate the time needed for a given dose to be eliminated. Elimination time is commonly

expressed in terms of half-life ($t_{1/2}$), the time required for the amount of drug to decrease by 50%. Half-life is calculated from the elimination rate constant:

$$\text{ke (per hour)} = \frac{\text{Cl (L/h)}}{\text{Vd (L)}};$$

ke can be further transformed into half-life:

$$t_{1/2}\text{(hours)} = \frac{0.693}{\text{ke}}$$

For any system that follows exponential decay, half-life can be used to estimate the amount of elimination that has occurred; after 5 half-lives more than 90% is eliminated. Elimination approaches 100% after 7 half-lives. The time required for a dosing regimen to reach steady state is also an exponential function and thus can be estimated using half-life. This same "5-7" rule of thumb is useful at the bedside. Dosing regimens approach maximal effects after 5 to 7 half-lives. Similarly, drug effects are usually completely dissipated after 5 to 7 half-lives. Using this rule, it can be predicted that drugs with long half-lives may take several days to produce target effects. Lorazepam via continuous infusion is a classic example owing to its prolonged half-life.[36] This is less than ideal in the critically ill population when effective treatment is needed rapidly. As a result, loading doses are frequently used to hasten the time to achieve the goal concentration.

It is important to note that the time needed to eliminate a given dose is dependent not only on the clearance rate, but also on the drug's Vd. It is intuitive that half-life is affected by changes in elimination pathways (e.g., renal failure). However, changes in Vd can have equally important effects on half-life. For example, expanded Vd after resuscitation prolongs the half-life of aminoglycosides, without a change in clearance, as illustrated in the previous equations. Failure to account for Vd expansion can lead to drug accumulation independent of changes in drug clearance.

Modeling the Concentration-Time Curve

When estimations of bioavailability, Vd, and clearance are available, the concentration-time curve can be modeled. As discussed earlier, the one-compartment model is useful for hydrophilic drugs with small Vd, such as aminoglycosides. Fig. 21.3B depicts the serum concentration-time curve of a one-compartment model drug after intermittent IV administration plotted on a logarithmic scale. The initial peak concentration can be estimated from dose and Vd. The peak is followed by a short distribution (α) phase, during which time drug is removed from the plasma through distribution to tissue in addition to clearance. After distribution is complete, the curve is defined by a second phase (β) when drug is removed from plasma via clearance. The time course of this phase can be estimated using half-life. The transition from distribution to elimination phase occurs at an inflection in the slope of the concentration curve. This is known as a biexponential pattern of decay. Because the distribution phase is often short (usually 15–30 minutes) it can usually be ignored when performing calculations.

Conversely, drugs with large Vds are more accurately represented using a two-compartment model (see Fig. 21.4B). The important difference between one-compartment and two-compartment models is the significance of the distribution phase, which is much longer for drugs following a two-compartment model. Concentration sampling before completion of the distribution phase can lead to dosing errors through calculation of an inappropriately rapid ke. A third phase is also evident near the end of the curve (γ), at the end of therapy, or with a long dosing interval. This redistribution phase is a result of slow release of drug from the tissues back into the serum. This slow tissue release, known as the "context-sensitive half-life," is responsible for the prolonged duration of pharmacologic effect seen after continuous infusions of highly lipophilic drugs such as fentanyl, midazolam, and propofol.

Pharmacodynamics

PD parameters provide an additional perspective on drug dosing by focusing on important clinical endpoints, such as bactericidal efficiency or ability to achieve the desired clinical response to a sedative. Although PD concepts are important for all dosing decisions, PD parameters have been best defined for antibiotics in part because the effect of interest (bacterial killing) can be readily measured through in vitro and in vivo studies. Therefore the PD portion of this chapter focuses on antibiotics. However, the basic concepts can be applied to all drugs. Minimum inhibitory concentration (MIC) was the first PD parameter to show utility in predicting the effectiveness of antibiotic regimens. The MIC of an antibiotic is the lowest tested concentration needed to inhibit bacterial growth in vitro. There are at least three patterns relating drug effect to MIC: concentration-dependent or time-dependent killing, and a combined endpoint relating area under the concentration-time curve (AUC) to the MIC. In concentration-dependent killing, the ability to achieve a peak concentration many times greater than the MIC determines effectiveness. Aminglycosides achieve maximal bacterial killing with a peak concentration at or above 8 to 10 times the MIC and quinolones similarly exhibit concentration dependence (peak:MIC). High peak concentrations may also increase tissue penetration of intracellular-active agents. However, the maximal dose is often limited by potential adverse effects. In contrast, the time-dependent agents, such as β-lactams, are most effective when the concentration exceeds the MIC for a large portion of the dosing interval (time [T] > MIC). These antibiotics reduce the formation of bacterial cell walls via inhibition of penicillin-binding protein. This protein is located on the bacterial cell surface, and effective drug binding occurs at low drug concentrations. In fact, in vitro analyses have shown that nearly all available penicillin-binding protein targets become saturated at concentrations that are four to five times the bacteria's MIC.[37] Effectiveness of the third group of antimicrobials, including vancomycin, requires consideration of total antibiotic exposure, measured as a ratio of AUC to the MIC (AUC:MIC). Effectiveness measures for antimicrobials are illustrated in Fig. 21.6.

It is important to note that most PD analysis is based on total drug concentrations in the serum. However, only free drug concentrations reach the site of action and cause bacterial killing. High protein binding or a large Vd predicts poor tissue penetration and potential treatment failure, despite high serum concentrations, such as daptomycin for pneumonia. Tissue level analysis may offer better prediction of effectiveness but availability is limited in clinical practice.

Dosing regimens should be designed to optimize achievement of the desired PD endpoint for the majority of patients, accounting for inherent PK differences. This is termed the target attainment. Dosing regimens for optimal target attainment in critically ill patients are often different from those listed in approved drug labeling, obligating clinicians to individualize drug dosing.

β-Lactams

The T > MIC endpoint for target attainment varies within the β-lactam class. Cephalosporins require the highest T > MIC (50%–70%), followed by the penicillins (30%–50%) and the carbapenems (20%–40%) to effect optimal bacterial killing.[38,39] The importance of T > MIC has gained significant attention with increasing bacterial resistance (higher MIC). Resistant bacteria have higher MICs, making it more difficult to achieve adequate T > MIC (Fig. 21.7). Studies conducted in critically ill patients have shown that using standard β-lactam dosing regimens, developed for non–critically ill patients, may produce unacceptably low serum concentrations, resulting in inadequate T > MIC.[40,41] Various strategies may address these deficiencies by increasing time above MIC, including loading doses, larger or more frequent maintenance doses, prolonged infusions, or continuous infusion.[42] Continuous-infusion β-lactam regimens may be the most appealing in theory, but they are less practical when considering limited stability in solution, need for dedicated IV sites owing to incompatibility, and less clinical outcome data.[43,44]

There is also a theoretical concern for selection of resistant subpopulations. Mathematical modeling of bacterial growth dynamics suggests that a constant rate of bacterial killing creates more opportunity for generating resistant mutants than does a fluctuating kill rate.[41,45] A concentration above the inhibitory threshold but below the bactericidal concentration of these strains has been coined the mutant selective window.[45] A concentration that kills these bacteria has been coined the mutant protection concentration. An in vitro model of ceftazidime via continuous infusion, with maintenance of steady-state serum concentrations slightly above the bacteria's MIC resulted in the emergence of resistant bacteria subpopulations.[46]

The use of prolonged infusions of β-lactam antimicrobials over 3 to 4 hours has become common as a mechanism to maximize T > MIC with the same or lower total daily dose, while minimizing some of the challenges with continuous infusions. Extending the infusion duration, without a dose increase changes the shape of the concentration-time curve to promote longer T > MIC, as seen in Fig. 21.7. Effectiveness of this strategy has been demonstrated with improved target attainment and improved clinical outcomes, including reduced mortality in critically ill patients.[43,44,47,48] With either continuous or prolonged infusions, loading doses are advocated for critically ill patients with an expanded Vd to achieve target concentrations more rapidly.[49]

Larger doses at a typical interval or high total daily doses may improve target attainment, but they also increase the risk of adverse effects, illustrated by the reports of seizures and neurotoxicity when doses of cefepime or meropenem are not appropriately adjusted for reduced CrCl.[50,51]

The *red dashed line* represents continuous infusion. *MIC,* Minimum inhibitory concentration.

Aminoglycosides

Aminoglycosides are broad-spectrum gram-negative antimicrobial agents that have been in clinical use since the 1960s, but they are increasingly used for resistant pathogens and as a potentially synergistic agent with other broad-spectrum agents for patients with septic shock.[52] Historical dosing strategies used low doses given every 8 hours and proved to be suboptimal with high rates of nephrotoxicity and inadequate clinical response compared with other antimicrobials. The importance of achieving an adequate peak:MIC was first described in patients by Moore and colleagues, who found that the likelihood of having a positive clinical response was greater than 90% when peak concentrations were 8 to 10 times the MIC.[53] Individualized dosing strategies were used to achieve peak concentrations of ~8 mg/L for critically ill patients with expanded Vd, such as those with abdominal infections. Longer intervals were gradually used to ensure that trough concentrations were less than 1 to 2 mg/L. A later study found that time to defervescence and normalization of leukocytosis was greater than 90% when peak:MIC was 10 or greater.[54] Achieving high peak aminoglycoside concentrations (10 × MIC) is fundamental to successful treatment and is now the standard of practice. These doses dictate the need for an extended dosing interval to allow sufficient time to eliminate the drug, ideally achieving a drug-free period to reduce tissue accumulation (especially renal and cochlear/vestibular) and potential toxicity. Critically ill patients with a high Vd often need more than 24 hours between doses to achieve a drug-free interval, even with good renal function, as a result of expanded Vd and reduced ke.

A wide variety of doses have been used in extended interval dosing (EID) strategies. Typical doses are 5 to 7 mg/kg for gentamicin and tobramycin.[55] These doses were chosen to achieve peak concentrations 10 times the MIC for typical gram-negative bacteria in patients with a normal Vd, approximately 0.3 L/kg. Dosing nomograms (such as the Hartford nomogram) using a single concentration to define the frequency of repeated doses have been designed for patients with normal Vd, but they should not be used in critical care patients with expanded Vd or for doses that differ from the original dosing model.[56] Critical care patients exhibit substantial interpatient and intrapatient variability in PK owing to changes in Vd, clearance, and ke. The use of standard doses of amikacin (15–20 mg/kg) was shown inadequate to achieve a peak more than 8 times the MIC breakpoints owing to larger Vd values of 0.41 (0.29–0.51) L/kg. A dose of at least 28 mg/kg (dosing weight) or 25 mg/kg of actual weight is suggested for patients with sepsis.[57–59]

Individualized dosing is needed for patients who are not expected to have a normal Vd or who have unpredictable CrCl, especially if treatment is continued for more than one dose. Two post-dose concentrations should be drawn after the first dose (e.g., 2 and 12 hours after) to calculate Vd and ke. When designing an ongoing regimen, a patient-specific dose based on the MIC of the organism should be considered. A dose to achieve 10 times the MIC using the calculated Vd may be different from the standard 5 to 7 mg/kg for tobramycin or 25 mg/kg for amikacin, A dosing interval should be chosen that is sufficient to achieve near-complete elimination. Computer programs are available to facilitate the calculation of patient-specific PK parameters. Volume resuscitation or renal function changes during this monitoring interval may alter the accuracy of these parameters to predict ongoing dosing needs, and a concentration should be rechecked 4 hours before a subsequent dose to confirm near-complete elimination.

As mentioned, the use of aminoglycosides is limited by their potential to induce nephrotoxicity. Nephrotoxicity is the result of accumulation in the epithelial cells of the proximal renal tubule. Of great importance is the fact that the rate of accumulation is saturable at relatively low concentrations in the tubule lumen of the rat.[60] This means that toxicity is not concentration dependent but rather time dependent. Once saturated, the rate-limiting step of tissue accumulation becomes the duration of exposure. Because EID regimens should be designed to produce a drug-free period near the end of the dosing interval, it reduces drug accumulation, potentially reducing toxicity. In vivo studies have confirmed that EID reduces renal accumulation and enzymatic markers of nephrotoxicty.[61,62] There is no standard to define the optimal drug-free interval, but extensive patient experience suggested safety when targeting a 4-hour drug-free interval (e.g., tobramycin concentration <0.5 mg/L).[56] It has been shown that a threshold of accumulation is needed before nephrotoxicity is produced and that this threshold is typically reached after 5 to 7 days of therapy.[63] The risk of ototoxicity also appears related to duration of therapy but other undefined factors may also contribute. Although often not recognized acutely, dizziness, vertigo, tinnitus, and hearing loss may be permanent.[64]

Vancomycin

Methicillin-resistant *Staphylococcus aureus* (MRSA) remains one of the most important pathogens causing infection in critically ill patients.[65] Vancomycin has been a drug of choice for nearly 50 years. It inhibits cell wall formation in gram-positive bacteria in a fashion similar to the action of β-lactams. However, vancomycin binds a different receptor and produces a slower bactericidal effect. This slow rate of killing may explain the slower symptom resolution and higher failure rates with vancomycin compared with β-lactams in the treatment of methicillin-susceptible *S. aureus* infections.[66] The current breakpoint for vancomycin susceptibility against *Staphylococcus* species is an MIC of 2 mg/L, but recognition of heteroresistant strains with intermediate susceptibility (MIC 1-2 mg/L) has heightened concern over inadequate dosing.[67,68] In recent years, studies have identified AUC:MIC > 400 as the preferred PK parameter associated with clinical success.[69] In clinical practice, however, monitoring a predose level during intermittent infusion therapy has been used as a practical surrogate for AUC:MIC, with a target trough of 15 to 20 mg/L in complicated infections such as endocarditis, osteomyelitis, bacteremia, meningitis, and pneumonia (MIC ≤1 mg/L).[70] Use of the trough level as a surrogate is based on PK models that assume a predictable peak concentration for any given dose, although this may not be an accurate assumption in critically ill patients. Physiologic and PK differences in individual patients may alter the relationship between trough level and AUC:MIC target attainment.

A standard Vd of approximately 0.7 to 0.8 L/kg is used in many vancomycin dosing protocols. In reality, a broad range of Vd values is reported for adults, 0.5 to 1.7 L/kg of total body weight (TBW), depending on the population.[71] Estimates in obese patients range from 0.26 to 1.7 L/kg in obese and morbidly obese individuals.[72] Some reported small Vd values could be the result of incomplete distribution at the time of the postdose measurement—sampling earlier than 1 to 2 hours after the end of the infusion—leading to a factitiously high peak. Some large Vd values, as reported in critically ill patients, may be the result of vigorous volume resuscitation and low plasma protein concentrations. In reality, if the peak value for a given dose is significantly different from the

model used to extrapolate a single trough level, clinicians may not achieve the target AUC:MIC.

Further complicating the use of population parameters for estimation of initial doses or Vd is the conflicting data on optimal weight to use. The American Society of Health-System Pharmacists guideline recommends TBW based on a single trial; however, data in obese patients (>120% above ideal body weight) have suggested that adjusted body weight (ABW) is more accurate for the prediction of vancomycin clearance (Table 21.3).[70,73,74] Additional testing is needed to determine the most appropriate weight parameters in various populations. See the obesity section for more discussion.

Patient-specific dosing of vancomycin with more than a single trough level is advocated to ensure target attainment.[75,76] Serum concentration monitoring with extensive sampling indicates that vancomycin is best characterized with at least a two-compartment model (see Fig. 21.4). A prolonged distribution phase, up to 3 hours after the infusion has been demonstrated, indicates that a postdose level should be delayed several hours if attempting to characterize the elimination rate in an individual patient.[77] Individualized dosing of vancomycin has been studied using the techniques that are widely accepted for individualized aminoglycoside dosing. One group has published a series of articles on the use of intensive serum concentration monitoring after steady state to individualize later doses. Both a Bayesian and an equation-based methodology have been developed, but only the equation-based method was reported in obese patients.[77–79] At steady-state, predose and postdose (1–2 hours after dose) concentrations were measured and the first-order elimination rate constant (ke) calculated. This ke is used to back extrapolate from the postdose level to a mathematical value at the time of infusion initiation (*Csoi'*) and to forward calculate from the predose level to the actual level at the start of the next infusion (C*t*). The AUC for the dosing interval (int) is then estimated as follows:

$$\text{AUC}_{\text{int}} = \frac{Csoi' - Ct}{\text{ke}}$$

To determine a 24-hour AUC, multiply AUC_{int} by the number of intervals in 24 hours. If the AUC target is not achieved, an individualized dose can be calculated. Delayed dose optimization is a disadvantage of this method, occurring 2 to 3 days into therapy, but this technique can be directed toward patients with documented *Staphylococcus* spp. infections. Levels drawn after a loading dose helped to establish dosing needs more rapidly in a small number of patients with CrCl less than 60 mL/min and SIRS/sepsis.[80] Patients received a fixed vancomycin dose of 25 mg/kg and were then randomly assigned to individualized monitoring with levels after the loading dose. Use of a one-compartment model for a two-compartment drug like vancomycin risks drug accumulation, so steady-state trough monitoring is still needed. Validation of the benefit of these methods is needed in larger populations to be widely recommended. Although it is not incorrect to monitor vancomycin with a single trough level at steady state, clinicians can use more detailed methods to improve vancomycin dosing and target attainment in serious staphylococcal infections or for patients with abnormal drug clearance, Vd, or at extremes of weight.

The targeted AUC:MIC greater than the 400 endpoint is not achievable with conventional dosing methods when MIC is elevated. A meta-analysis found a 64% relative increase in mortality risk comparing high-MIC (>1.5 mg/L) isolates to low-MIC (<1.5 mg/L) isolates.[69] Balancing effectiveness and safety is a consideration if vancomycin is used instead of potentially more effective agents. Higher doses of vancomycin could be used to treat staphylococcal isolates with a high MIC to achieve higher trough levels of 25 to 30 mg/L and thus the target AUC:MIC, but nephrotoxicity risk may increase with doses above 4000 mg/day.[70] A meta-analysis of studies where vancomycin trough levels were maintained between 15 and 20 mg/L showed an odds ratio of 2.67 (95% confidence interval 1.50–3.65) for the risk of nephrotoxicity compared with levels below 15 mg/L, so the incremental risk of higher troughs may be substantial.[81] An alternate strategy may be to combine other antimicrobials such as a β-lactam agent with vancomycin for increased bactericidal effect. A retrospective study of vancomycin versus vancomycin plus various β-lactams was associated with higher microbial eradication compared with vancomycin alone.[82] However, the combination of vancomycin with piperacillin/tazobactam has been associated with a greater risk of nephrotoxicity compared with vancomycin alone or in combination with cefepime or meropenem in some reports.[83,84] An adequately powered prospective randomized trial is needed to address safety and efficacy of this combination.

Continuous infusion of vancomycin has been evaluated to maintain an optimal AUC:MIC; however, significant differences in effectiveness have not been demonstrated. A meta-analysis found a high degree of heterogeneity between studies and concluded that continuous infusion was associated with a significantly lower risk of nephrotoxity but that prospective, randomized trials were needed to evaluate mortality rate or other outcomes.[85] Thus a continuous infusion may be considered for patients at high risk of nephrotoxicity.

The vancomycin infusion dose should be patient-specific, with a loading dose of 35 mg/kg TBW and a daily dose adjusted for renal function and supported by serum concentration monitoring.[86] A dosing model to achieve a concentration of 20 to 30 mg/L in ICU patients was developed and tested in a small number of

patients with measured CrCl (8-hour clearance × 1.73/body surface area [BSA]).[87] After a loading dose of ~20 mg/kg, the daily vancomycin dose (in grams/day) was calculated as = [(0.021 × 8-hour CrCl) + 2.3] × 0.6 and achieved the goal in 84% of patients. The potential benefit of an infusion must be weighed against the challenge of limited compatibility data with other agents and the use of one infusion site for a single therapy.

Dosing Considerations in Select Critical Care Patients

Renal Disease

Acute kidney injury (AKI) is a common occurrence in the ICU. Using a consensus definition, rates of AKI range from 10% to 30% in the general ICU population and 40% to 60% in patients with severe sepsis and septic shock.[88] In addition, approximately 5% will require some form of hemodialysis. Therefore it is important for ICU practitioners to understand the basic approach to drug dosing in renal failure and insufficiency.

Assessing Renal Function

Accurate assessment of renal function is imperative to make appropriate dosing decisions. This assessment may include a measurement or estimate of the GFR. Inulin is the gold standard for the assessment of renal function.[89] However, with limited availability and high cost, it is rarely used outside a research setting. Laboratories routinely report estimated GFR using the Modification of Diet in Renal Disease (MDRD) equation as a screening tool for GFR below 60 mL/min per 1.73 m^2, although this formula lacks validation in critical care patients, at extremes of weight, or abnormal creatinine production.[90] In 2009 the National Kidney Disease Education Program suggested that either the Cockcroft-Gault (CG) formula with serum creatinine or MDRD equation could be used for drug dosing purposes[91] (Table 21.4). For very large or very small people, adjustment of the MDRD equation to account for BSA is recommended. However, in critical care patients with early AKI, both have unacceptably high errors and poor precision compared with infusion clearance of chromium 51 complexed with ethylene diamine tetraacetic acid (^{51}Cr-EDTA), a gold standard method.[92] Significant between-patient variability exists with overpredicted and underpredicted CrCl.

The clinical reference standard method is via a carefully collected, timed urine creatinine collection. The traditional 24-hour collection period has multiple opportunities for error and is often impractical because a practitioner must wait longer than 24 hours for data that influences drug dosing. The ideal duration of collection is unclear, but shorter collections have been studied. A 2-hour collection was similar to a 24-hour collection in a mixed medical-surgical ICU population and an 8-hour collection in a critical care population.[93,94] Direct measurement of urine creatinine should be considered when making dosing decisions in patients who are receiving narrow therapeutic index drugs, may have ARC, or are at the extremes of age or weight or in early AKI.

Predictive equations using creatinine concentrations are used more routinely to estimate GFR.[95] Formulas to predict GFR based on serum creatinine concentrations in critically ill patients exhibit low accuracy and precision with a tendency to overestimate GFR.

TABLE 21.4 Equations Commonly Used to Estimate Renal Clearance[96,97,101,105,109]

Equation	Measure	Equation	Considerations
Cockcroft-Gault	CrCl (mL/min)	(140 − age) BW/(SCr × 72) (0.85 if female)	• Inaccurate in patients with acutely changing renal function • Optimal weight parameter is controversial in obese patients
Reexpressed MDRD (4 variable)	GFR (ml/min/1.73 m^2)	$175 \times SCr^{-1.154} \times age^{-0.203} \times$ (0.742 if female) × (1.21 if AA)	• Inaccurate in patients with acutely changing renal function • Must be individualized for BSA by multiplying estimated GFR × (estimated BSA/1.73 m^2) • Little information available in obese, elderly, or hepatic disease patients
Obesity 1 (Winter et al.[97])	CrCl (mL/min)	(140 − age) BW/(S_{Cr} × 72) × (0.85 if female) Use various weights	• Underweight use actual weight • Normal weight use ideal weight • If BMI 26–50, use adjusted weight using 40% factor = [(actual − ideal weight) × 0.40] + ideal weight
Obesity 2 (Demirovic et al.[109])	CrCl (mL/min)	(140 − age) LBW/(S_{Cr} × 72) × (0.85 if female)	• For BMI >40 kg/m^2 • LBW_{male} = (9270 × TBW)/(6680 + 216 × BMI) • LBW_{female} = (9270 × TBW)/(8780 + 244 × BMI)
Cystatin C	eGFR (mL/min)	$135 \times \min(S_{Cr}/\kappa, 1)^{\alpha} \times \max(S_{Cr}/\kappa, 1)^{-0.601} \times \min(S_{cys}/0.8, 1)^{-0.375} \times \max(S_{cys}/0.8, 1)^{-0.711} \times 0.995^{Age}$ × 0.969 [if female] × 1.08 [if AA] κ = –0.7 (if female), 0.9 (if male) α = –0.248 (if female)], 0.207 (if male) $\min(S_{Cr}/\kappa$ or 1) = minimum of S_{Cr}/κ or 1 $\max(S_{Cr}/\kappa$ or 1) = maximum of S_{Cr}/κ or 1 $\min(S_{cys}/0.8, 1)$ = minimum of $S_{cys}/0.8$ or 1 $\max(S_{cys}/0.8, 1)$ = maximum of $S_{cys}/0.8$ or 1	

AA, African American; *BMI,* body mass index; *BSA,* body surface area; *BW,* body weight in kg; *CrCl,* creatinine clearance; *eGFR,* estimated glomerular filtration rate; *LBW,* lean body weight; *GFR,* glomerular filtration rate; *MDRD,* Modification of Diet in Renal Disease equation; S_{Cr}, serum creatinine; S_{cys}, serum cystatin C.
Ideal weight = (height in inches – 60) × 2.3 + 50 kg for males or 45.5 kg for females.

Creatinine secretion is dependent on muscle mass and not body mass. Creatinine production does not increase in proportion to TBW, which also represents fat weight. Use of TBW to estimate CrCl in obese patients creates potential for significant error. The CG formula is widely used for drug dosing, although it was developed for outpatients with stable renal function, using actual body weight.[96] Use of the CG formula with early AKI, unstable creatinine, oliguria, extremes of weight, or patients with reduced muscle mass (amputation, prolonged bedrest, plegia, malnourishment, and so on) adds the potential for inaccuracy. Manipulation of the parameters (weight, creatinine) to arbitrary values for abnormal patients has been widely used by clinicians, but routinely rounding creatinine to an arbitrary minimum value reduces the accuracy of CrCl prediction and should not be a standard of practice.[97,98] In the search for better tools in clinical care, cystatin C has been evaluated as a marker of GFR.[95] It is a serum protein that is filtered by the kidney and concentrations are less dependent on age, sex, race, and muscle mass compared with creatinine.[99–102] Laboratories may not routinely assay cystatin C (cystC) and other factors such as malignancy may alter its accuracy. Although a formula that considered both creatinine and cystatin C (CKD-EPI$_{creat\text{-}cystC}$) performed better than either marker alone in a non-ICU study, a clear role for this approach has not been delineated.[101] Although cystatin C formulas may prove to be more accurate than creatinine-based approaches for selected patients, the data do not support routine use at this time.[102,103] Nevertheless, preliminary work with cystatin C has been studied as part of a vancomycin dosing quality improvement project and suggested to improve achievement of goal concentrations.[104] Table 21.5 lists the commonly used equations and considerations for their use.[96,105,106] Several other less frequently used equations to estimate CrCl or GFR can be found in more detailed reviews on estimating renal clearance.[89]

Other patient populations that require specific considerations are patients at the extremes of weight and elderly patients. Both CG and MDRD equations have varied results in patients older than 65 years of age. The MDRD equation has been shown to overestimate kidney function in elderly patients, and the CG equation may either overestimate or underestimate renal clearance.[90,107] Obese patients also present problems when determining renal clearance for the purposes of drug dosing. The MDRD equation has been shown to underestimate renal clearance in obese patients, and the CG equation overestimates renal clearance in obese patients when the TBW is used.[108] Formulas to predict CrCl have used TBW, ABW, and lean body weight (LBW) in various ways; no consensus has emerged for all weight ranges, and none are specific to critical care. With the CG formula, it is reasonable to use TBW for underweight and normal weight patients (body mass index [BMI] <25 kg/m^2) and for overweight patients (BMI 25–30 kg/m^2) use either TBW or ABW, for obese patients (BMI 30–40 kg/m^2) use ABW, and for morbidly obese patients (BMI >40 kg/m^2) use LBW.[96,97,109,110] Regardless of which approach to renal function assessment is used, it is important to remember that all have limitations relative to the population studied and accuracy of height and weight of an individual patient. Because changes in serum creatinine are delayed compared with changes in actual renal function, calculations based on this marker are unreliable in rapidly changing renal function.

With the inherent limitations of renal function assessment in critically ill patients, many renal dose adjustment decisions are done with a fair deal of uncertainty. Accordingly, it is essential for the clinician to have a clear understanding of the risks of toxicity associated with excessive dosing as well as the consequences of therapeutic failure associated with underdosing. As discussed, patients with septic shock may benefit from loading doses and early aggressive dosing of antimicrobials owing to their relative safety. However, drugs with a narrow therapeutic index (i.e., digoxin, lidocaine) may not allow as much latitude because of potential dose-related adverse effects and the need for close monitoring.

TABLE 21.5 Child-Pugh Classification of Liver Disease

Indicator	1 Points	2 Points	3 Points
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time (seconds > control)	<4	4–6	>6
Total bilirubin (mg/dL)	<2	2–3	>3
Encephalopathy (grade)	None	1 or 2	3 or 4
Ascites	None	Slight	Moderate

Total score: 5–6 points (mild/group A); 7–9 points (moderate/group B); 10–15 points (severe/group C).

Dosing in Renal Replacement Therapy

Several factors contribute to drug clearance in patients receiving renal replacement therapy (RRT). They can generally be broken down into dialysis mode/device, drug, and patient factors. The two methods by which dialysis can remove drugs are diffusion and convection. Diffusion is a passive process during which substances move over a concentration gradient across a hemodialysis (HD) filter and into the dialysate. Convection/hemofiltration is an active process during which drugs are cleared across a pressure gradient if their size and protein binding permit passage. Hemofiltration removes a smaller percentage of drug and is more dependent on effluent rates and the sieving coefficient of the drug. However, sieving coefficients are not readily available for most drugs, and therefore the fraction of unbound drug is often used to assess the likelihood of drug clearance. Additional loss may occur by adsorption to the dialysis filter, although this is less well quantified.

The three main drug factors that affect clearance are molecular weight, protein binding, and Vd. The clearance of drugs relative to their molecular weight is determined by the efficiency of the filter. Synthetic membrane filters (e.g., polysulfone, polycarbonate, polyamide, or polymethylmethacrylate) are used for acute HD because of their efficiency and are referred to as high-flux membranes. These have greater permeability for large molecules, including drugs up to 20,000 Da.[111] Most research done on drug removal with HD is done with a single filter and may not be applicable to other membranes. Similar to endogenous clearance mechanisms, clearance by RRT is inversely related to the degree of protein binding and Vd. Because large Vd (>1.5 L/kg) drugs distribute well into tissue, the low serum levels make less drug available for elimination. Small Vd drugs (<0.7 L/kg) reside primarily in the serum, increasing the efficiency of extracorporeal removal.

Either continuous or intermittent modes of RRT may be used in critically ill patients. Although intermittent hemodialysis (IHD) is the most common form of chronic dialysis, and drug clearance data are readily available, it may not apply to critically ill patients with AKI. Most intermittent hemodialysis drug dosing data are

derived from patients with end-stage renal disease with adaptive changes in nonrenal clearance mechanisms—such as reduced hepatic metabolic activity. Patients with AKI may not require the same degree of dose alteration in the acute phase of injury. End-stage renal disease dosing recommendations should be used only as an initial guide to therapy in patients with AKI and individualized with close monitoring when possible.[111]

Continuous renal replacement therapy (CRRT) can be done with hemofiltration (continuous venovenous hemofiltration [CVVH]), continuous venovenous hemodiafiltration, or just as dialysis (continuous venovenous hemodialysis). A target effluent rate of 20 to 25 mL/kg per hour is recommended, but a higher prescribed dose of 25 to 30 mL/kg per hour may be required to achieve that target considering potential interruptions in treatment.[112,113] Drug dosing data with CRRT often differ from study to study and depends on mode (diffusion, convection, or both), site of replacement fluid (prefiltesr vs. postfilter), filter composition, and most importantly, the dialysis dose (effluent rate and dialysate rate).[111,114] Patients may also have preserved endogenous renal elimination. Therefore it is important that practitioners evaluate how published doses were derived before applying them broadly. Concern with potential underdosing of drugs during CVVH is becoming widespread.[115] An in-depth review of the types of RRT and degree of drug removal is beyond the scope of this chapter, but several references are available that provide this information.[113,116,117] A simplified assessment of the impact of RRT has been proposed using piperacillin as an example. It has an 81% free fraction, thus continuous venovenous hemodialysis clearance using 25 mL/kg per hour in a 100-kg patient could be estimated as 0.81 ×100 kg × 25 mL/(kilograms/hours) × 1 hour/60 min or about 35 mL/min. Dosing would be compatible with that level of GFR using typical dosing references, piperacillin/tazobactam 3.375 g every 8 hours.[118] Use of high-flow RRT (rates 4–6 L/h) for selected patients makes dosing more difficult, as many early studies were done for patients receiving replacement rates ~2 L/h. A meropenem dose of 1 g every 8 hours (via 30-minute infusion) was suggested for high-flow continuous hemofiltration for target attainment with susceptible organisms (MIC = 4 mg/L); this is a more frequent dose than suggested in common drug references.[119] Extended infusions (3–4 hours) or continuous infusion may reduce the amount of drug eliminated with high-volume RRT, as demonstrated with piperacillin/tazobactam.[120]

Thus although the general degree of drug removal is generally as follows: continuous venovenous hemodiafiltration > continuous venovenous hemodialysis > continuous venovenous hemofiltration > slow extended daily dialysis > intermittent hemodialysis, the use of high-volume effluent rates may alter this sconvention.

Once a dosing recommendation has been made in patients receiving CRRT it is important to continue monitoring patients for changes in their dialysis prescription and residual renal function. Dialysis flow rates and ultrafiltration rates often change. Although CRRT implies that a patient is receiving treatment for 24 hours per day, this is frequently not the case. In fact, the reported mean daily stop times for CRRT range from 3 to 8 hr/day owing to filter clotting, procedures done while off the filter, catheter exchange, patient mobilization, and surgery.[121]

Hepatic Disease

Assessing Hepatic Function

Hepatic dysfunction is caused by infection associated with cholestasis or hepatocellular injury, ischemic hepatitis (shock liver through hypoperfusion), hemolysis, or direct damage from hepatotoxic pharmaceuticals or prior alcohol use. Hepatic dysfunction is reflected by elevated liver enzymes, bilirubin, and ammonia or reduced synthesis of coagulant factors. A reduction of at least 90% of the metabolic capacity of the liver is needed to substantially affect drug clearance. Most data regarding changes in drug clearance are in patients with cirrhosis and therefore do not necessarily apply to acute changes in liver perfusion. Few data are available in patients with acute hepatic dysfunction, making assessments and recommendations in this patient population difficult.

Unfortunately, owing to the complexity of hepatic elimination there are few data to guide drug dosing recommendations, and a simple method to quantify liver function does not exist. Elevated liver transaminases (i.e., aspartate aminotransferase, alanine aminotransferase) indicate hepatocellular injury and do not reflect synthetic function. Although international normalized ratio and albumin reflect synthetic capacity, they do not adequately capture the complex process of drug metabolism, and are altered by volume status and critical illness such as sepsis. Scoring systems have been developed to assess severity of liver disease, but no score has been developed for the sole purpose of drug dosing. The Pugh modification of the Child-Turcotte scoring system (see Table 21.5) has been shown to predict changes in drug clearance that occur in hepatic disease.[122] The utility of this score has led to the U.S. Food and Drug Administration (FDA) recommendation that it be used to categorize degree of liver impairment in patients enrolled in hepatic PK studies completed during drug development.[123] There are several limitations to use in the ICU setting, including dynamic changes in perfusion and inability to quantify the degree of change in metabolism. The Child-Pugh score may be used to guide dosage adjustment of caspofungin, clindamycin, esomeprazole, metronidazole, tigecycline, verapamil, and voriconazole (to name a few) in clinical practice, despite not being validated in critically ill patients (with depressed albumin synthesis) or those with acute hepatic dysfunction.[124–126] Despite these limitations, it is still the most useful tool to assess hepatic function at the bedside. Another scoring system, primarily used for prognostication and prioritizing liver transplantation recipients, is the Model for End-Stage Liver Disease (MELD) score. It has not been adequately studied for drug dosing, and therefore recommendations should not be made based on the score.

Dosing in Hepatic Disease

The Child-Pugh score uses five clinical features to assess prognosis of cirrhosis and chronic liver disease.[126] It was originally developed to predict surgical outcomes in patients presenting with bleeding esophageal varices. Because drug dosing recommendations based on the Child-Pugh score are lacking, a decision must be made based on clinical judgment. Some general considerations include avoiding drugs metabolized by the CYP 450 system in favor of drugs that undergo phase 2 metabolism (i.e., glucuronidation) or renal elimination. If all available choices undergo phase 1 metabolism, then consider the agent with the shortest duration of action. The doses of many drugs with hepatic elimination may need reduction, particularly those with a high extraction ratio (large first-pass effect) as bioavailability may be increased. Patients with a prior transjugular intrahepatic portosystemic shunt may also have improved bioavailability owing to bypass of a first-pass effect and risk an exaggerated response to drugs with high extraction.[127] Reduced plasma protein levels in chronic hepatic disease may lead to alteration in unbound fraction of drugs, and accumulation of endogenous compounds such as bilirubin may alter protein binding.

Expanded Vd in ascites may reduce peak serum concentrations and prolong the half-life of hydrophilic drugs. Further adding to the complexity is that changes in drug metabolism and activity of specific CYP 450 enzymes may not be uniform. A model suggests that CYP 2C19 activity decreases quickly in hepatic dysfunction but reductions in CYP 1A2, CYP 2D6, and CYP 2E1 may occur later or only in more severe disease.[128]

As mentioned earlier, use of drugs with phase 2 clearance mechanisms such as glucuronidation may be preferred, as cirrhotic patients may have compensatory upregulation of uridine diphosphate (UDP)–glucuronosyltransferase enzymes or increased extrahepatic glucuronidation. Nevertheless, use caution with agents such as morphine, oxazepam, lamotrigine, zidovudine, or mycophenolate in advanced cirrhosis.[128] Biliary clearance of drugs such as ceftriaxone, clindamycin, and ciprofloxacin may be reduced with biliary obstruction. Although there are few data to support a specific dose reduction with most medications, a reduction of at least 50% is probably warranted in patients with severe disease. Selected references provide more detailed dosing recommendations on a number of medications, and they should be consulted before making dosing decisions in these patients.[124,125,129–131]

The PD of drugs may be altered in liver disease, in particular β blockers owing to a reduction in receptor density, or increased as in the case of opioid analgesics and sedatives, whether owing to an altered blood-brain barrier, increased gamma-aminobutyric acid tone or receptors, but patients are typically more sensitive to their sedating effects.

Obese Patients

More than 36.5% of adults in the United States are considered obese (BMI >30 kg/m^2).[132] Available data suggest more than 25% of all patients admitted to ICUs can be categorized as obese, with 6% to 7% of patients morbidly obese.[133,134] These alterations in body weight present potential pharmacokinetic challenges with many drugs that have not been adequately studied in this population.

Pharmacokinetic Alterations in Obesity

The two primary pharmacokinetic parameters, Vd and clearance, may be altered in obese patients, but prediction is difficult as body composition is quite variable within the same BMI values. Further, gender and ethnic differences in body composition warrant careful assessment when making dosing decisions. The increase in adipose tissue seen in obesity may lead to a higher Vd for highly lipophilic drugs. This can result in two important changes: a decrease in peak concentration and a longer half-life compared with nonobese patients. In addition, adipose tissue has less water per unit of weight, but obese patients have higher extracellular water than normal weight persons.

The effects of obesity on clearance are less clear. Some studies have shown higher renal and hepatic blood flow in obese individuals, which could lead to increased clearance. In addition, there is evidence of glomerular hyperfiltration in obese patients, but less information on tubular secretion or reabsorption. Less clear is how clearance changes relative to increasing degrees of obesity, although it is proposed that LBW is correlated with drug clearance.[135]

Dosing Considerations in Obesity

The first step in determining a drug dosage for an obese patient is deciding what weight to use. This presents a significant challenge as the ideal weight parameter to use for drug dosing varies among agents. Drugs may be dosed based on ideal body weight (IBW), ABW, TBW, LBW, or BSA (see Table 21.3).[135–139] TBW may be appropriate for very lipophilic drugs, as Vd increases in a nearly linear fashion with body weight. Hydrophilic drugs do not distribute completely into adipose tissue and TBW-based recommendations may lead to overdosing.

LBW can be a useful predictor of pharmacokinetic behavior of drugs that are highly water soluble as it accounts for nonfat cell mass and intercellular connective tissue. The term IBW was based on historical data that compared the relative mortality rate of people of different height-weight combinations. It has frequently been used as a surrogate for LBW in many pharmacokinetic studies owing to ease of calculation.[137,138] Hydrophilic drugs may also be dosed based on ABW. Different correction factors have been used to calculate ABW, but the most common factor is 0.4. The equations to calculate these values are listed in Table 21.3.[136–138]

As with renal and hepatic disease, it is imperative to assess the risk/benefit ratio with each drug before making any dosing decisions in obese patients. Some drugs have been studied using different weight parameters and it is always beneficial to know this information before deciding on a drug dose. Lists of drugs and dosing strategies in obese patients are frequently updated in the literature.[140–142] Awareness of the literature for individual agents is essential. Use of standardized dosing was economically favorable in one hospital after they developed detailed dosing guidelines for obese patients.[141]

Antimicrobial Dosing in Obesity

Using the appropriate weight to dose antimicrobial drugs is extremely important as underdosing may lead to therapeutic failures and overdosing (use of standard milligram/kilogram doses and TBW) may lead to toxicity (i.e., nephrotoxicity with aminoglycosides or acyclovir).[141–144] Infection-related mortality is higher in obese patients, possibly because of underdosing or poor drug penetration into adipose tissue.[145] Antimicrobial dosing is discussed extensively in the Pharmacodynamics section. Several antibiotic classes are not normally dosed based on weight, including penicillins, cephalosporins, carbapenems, linezolid, and fluoroquinolones. There is relatively limited pharmacodynamic data in obese patients for these classes.[145,146] However, these drugs are generally well tolerated and therefore it is probably reasonable to use aggressive dosing strategies such as maximal studied doses. This approach may not be prudent in patients at increased risk of adverse effects such as seizures with imipenem or cefepime or rate-corrected QT interval prolongation with fluoroquinolones. A prospective linezolid study and case reports show high interpatient PK variability and lower concentrations in patients with higher BMI (up to 32 kg/m^2).[146] Despite this, a clear relationship between concentration and treatment failure has not been demonstrated, and increasing the dose to 600 mg every 8 hours may produce greater hematologic toxicity.

Sedative Dosing in Obesity

Benzodiazepines, dexmedetomidine, and propofol are the most commonly used sedatives in the ICU. The benzodiazepines are highly lipophilic compounds that have significantly higher Vd and clearance in obese patients.[147] The use of TBW has been suggested for bolus doses of benzodiazepines. However, the risk of respiratory depression in patients without an advanced airway is an important consideration. Because parenteral benzodiazepines have relatively rapid onset, the use of smaller doses based on IBW repeated every 5 to 15 minutes is a reasonable approach in patients without an

advanced airway. In one study midazolam half-life was increased nearly threefold in obese patients.[147] This effect increases the risk of accumulation, oversedation, and delirium in obese patients, especially with continuous infusions.

Although propofol is a highly lipophilic compound, available data do not demonstrate changes in Vd or clearance in obese patients. This information would suggest that TBW should be used for maintenance doses in this patient population.[148,149] However, propofol is associated with several significant adverse effects, including hypotension with bolus dosing and the life-threatening propofol-related infusion syndrome (PRIS) with high doses or extended durations of infusion.[150] Owing to the hemodynamic complications associated with propofol an initial bolus based on IBW followed by additional small doses might be reasonable. Because propofol is a short half-life drug it can be rapidly titrated to effect. High doses and the risk of PRIS represent a more complicated therapeutic dilemma. One of the recognized risk factors is a dose of propofol exceeding 83 mcg/kg per minute, but total dose has also been suggested as a risk.[150,151] It is not known how dosing based on TBW versus IBW would affect the development of PRIS. Therefore these patients should be closely monitored for symptoms of PRIS, including significant creatine kinase elevation, metabolic acidosis, lactate elevation, hyperkalemia, rhabdomyolysis, or cardiac failure. Pharmacokinetic data for dexmedetomidine in critically ill patients is not readily available. However, dexmedetomidine has been studied in patients up to 285 kg using TBW and the manufacturer provides dosing recommendations based on TBW for patients weighing up to 185 kg.[152] If TBW is used, then it is important that the dose be titrated to effect with monitoring for hypotension and bradycardia.

Anticoagulant Dosing in Obesity

Anticoagulant dosing in obesity presents challenges because overdosing may result in bleeding complications but underdosing can result in worsening of thrombosis. Weight has been reported to be the single best predictor of unfractionated heparin (UFH) requirements and a weight-based nomogram should be used for dosing.[153,154] TBW is frequently used for UFH dosing in nonobese patients because the Vd of UFH approximates total blood volume. However, the exact weight parameter that should be used in obesity (BMI 30–40 kg/m^2) and morbid obesity (BMI >40 kg/m^2) is unclear. When TBW is used in morbid obesity, there is a higher rate of high activated partial thromboplastin time (aPTT) and anti–factor Xa measurements.[155,156] Despite the potential for higher than anticipated aPTTs or factor Xa levels, there was no difference in major bleeding events or rates of primary event recurrence when UFH was dosed on TBW, although obese patients required lower weight-based infusion rates to achieve the target compared with nonobese patients.[155,156] Individualized heparin dosing based on either TBW or ABW has been suggested without a standard upper limit but data are inadequate.[157,158] The decision regarding which weight to use may be influenced by the indication and risk for bleeding, with practitioners using a more aggressive approach in the treatment of venous thromboembolism (VTE) and a less aggressive dosing approach for atrial fibrillation or acute coronary syndrome.[159,160] Regardless of what weight is used for the bolus dose, the subsequent infusion should be titrated based on aPTT or anti-Xa heparin level.

Unlike UFH there has been more research on the ideal weight parameter for low–molecular-weight heparins (LMWHs) with TBW being identified as the best predictor of LMWH requirements.[161] Pharmacodynamic data for enoxaparin and dalteparin are available in patients weighing up to 159 and 190 kg and demonstrate little to no accumulation.[161–164] Retrospective data suggest similar rates of values at goal and elevated anti-Xa results in patients weighing more than 150 kg versus those weighing less than 150 kg.[161,163] Because of the limited data in patients weighing more than 190 kg, some practitioners use a maximum dose limit at this weight. There are no data to suggest this will limit bleeding risk and it may in fact increase the risk of VTE. The use of anti–factor Xa monitoring in patients weighing more than 190 kg has been advocated to avoid excessive exposure.[165] An anti–factor Xa level should be checked 4 hours after the third dose of a LMWH, although data are insufficient to establish if this improves safety or efficacy. The use of trough monitoring to assess for accumulation has been suggested as a method to assess for increased risk of bleeding, and may be especially important with renal insufficiency.[164]

When used for VTE prophylaxis both UFH and LMWH are commonly given as fixed-dose regimens irrespective of weight. However, when used in obese patients, standard fixed doses of enoxaparin (30 mg twice daily or 40 mg daily) result in low rates of goal anti–factor Xa achievement.[165] Current guidelines for the prevention of VTE suggest that bariatric surgery and other obese patients may require higher doses without providing dose recommendations.[166] Although various high-dose prophylactic regimens of both enoxaparin and UFH have been evaluated, there is not a consensus on the optimal drug, dose, or even patient population that would benefit.[167,168] The largest retrospective study suggests that patients with a BMI of 40 kg/m^2 or higher are less likely to develop VTE with a high-dose prophylactic regimen (enoxaparin 40 mg twice daily or UFH 7500 units three times daily) rather than a standard dose regimen.[168] However, it should be noted that there are currently no prospective trials to support a reduced risk of VTE in obese patients with higher doses of chemical VTE prophylaxis. If higher doses of enoxaparin or UFH are used, practitioners must monitor patients closely for bleeding.

Pregnancy

Pregnancy is a dynamic state with physiologic changes occurring throughout gestation. These changes include alterations in cardiovascular, pulmonary, GI, renal, and hepatic function that may result in clinically significant changes in drug PK.[169] Pregnant patients are frequently excluded from PK trials, limiting data that describe PK/PD and fetal adverse effect profiles for many drugs commonly used in critically ill pregnant patients. An in-depth discussion of all drug classes in pregnancy is beyond the scope of this chapter.[170,171]

Pharmacokinetic Changes in Pregnancy

Pregnancy results in multiple physiologic changes that affect absorption, distribution, metabolism, and elimination of various drugs.[169,170] Absorption may be decreased owing to a reduction in GI motility and an increased gastric pH. However, these changes are minimal and therefore are unlikely to significantly alter outcomes. Distribution is potentially increased owing to changes in volume (up to 50% increase in blood volume) and decreases in protein binding (up to 30% decrease in albumin). These changes may lead to either lower or higher concentrations of free drug in the serum depending on the properties of the agent administered. Pregnancy increases hepatic blood flow and has variable effects on CYP enzymes.[169] Available data suggest an increased activity of CYP 2D6 (metoprolol, selective serotonin reuptake inhibitors, citalopram), CYP 2C9 (nonsteroidal antiinflammatory drug,

phenytoin), CYP 2A6, UDP-glucuronosyltransferase, and CYP 3A4 (midazolam) and a decrease in the activity of CYP 1A2 (theophylline, olanzapine, ondansetron) and CYP 2C19 (diazepam, omeprazole, pantoprazole, propranolol) in the second and third trimesters.[169–171] Transporters also increase activity in the third trimester, including P-glycoprotein. The interplay between enzyme and transporter changes in different tissues makes interpretation of animal models more difficult. After delivery, some of these revert to normal as soon as 3 to 14 days, requiring dose adjustment to prepregnancy doses. Renal elimination increases throughout gestation with an 80% increase in renal plasma flow during the second trimester, leading to a 50% increase in GFR. Consequently, pregnant women often require higher doses of drugs with renal elimination; however, this requirement changes throughout pregnancy.[172]

Medical emergencies occur in pregnant women, including trauma, hemorrhage, sepsis, and thrombosis.[173–175] Awareness of the changes in maternal body composition and consideration of the effects on fetal development are important. The FDA label requirements for pregnancy and lactation have changed from a lettering system to a system that includes more detail regarding risk summary, clinical considerations—whether disease-associated maternal/fetal risk, dose adjustments in pregnancy, maternal adverse reactions, and labor/delivery concerns.[176] Drug labels should include available human and animal data. The new lactation section provides information to inform prescribers on minimizing exposure and monitoring for adverse effects, with applicable data. However, data remain inadequate for many critical care medications and the risk to the fetus, as pregnant patients are not included in clinical drug trials. Clinicians must balance the need to care for the mother, their primary patient, but also with care of the baby.

Burn Injury

The two distinct physiologic phases of burn injury have significant effects on PK and PD. The first 48 hours after injury are characterized by hypovolemia, edema, hypoalbuminemia, and decreases in GFR. During this initial resuscitative phase prolonged drug distribution, reduced maximum serum concentrations, and lower drug clearance are likely. The second phase occurs beyond 48 hours and is a hyperdynamic state characterized by increased renal and hepatic blood flow, altered serum protein production, and insensible drug losses through exudate leakage.[177] During this phase, faster drug distribution, increased maximum serum concentrations, increased renal drug clearance, decreased oxidative (CYP 450) metabolism, and altered volumes of distribution may occur.[177] These changes vary from patient to patient and may be affected by a number of factors, including burn-related factors (i.e., total body surface area burn, fluid resuscitation) and nonburn-related factors (preexisting comorbidity, age, and presence of sepsis). Further complicating matters, some patients may experience alterations in drug pharmacokinetics and dynamics that last up to 1 to 3 years after burn injury.[178]

The potential PK/PD changes along with interpatient variability complicate drug dosing. Data assessing drug dosing in burn injury are limited to small PK/PD analysis and Monte Carlo simulation (a broad class of computational algorithms that rely on repeated random sampling to arrive at numerical results). In addition to small sample sizes, these studies are limited by significant interpatient and intrapatient variation along with model design.[179] Despite these variations, available data indicate that, for most antimicrobials, the doses recommended in package labeling result in suboptimal target attainment in patients with burn injuries greater than 20% total BSA.[180]

Burn patients are at risk for ARC and initial doses should be maximized. Specific dosing recommendations for agents commonly used in burn injury have been published.[177,180] Given the significant interpatient and intrapatient variability, these recommended doses should function as a starting point, with therapeutic drug monitoring (TDM) used to optimize therapy. Because significant changes in serum proteins are common, the use of levels that detect free drug concentrations is preferred. If free levels are not available, clinicians must be aware that a total level in the therapeutic range does not necessarily reflect an appropriate drug dose. In these situations, physical and laboratory assessment to evaluate therapeutic efficacy and adverse effects is warranted. If TDM is not available and the agent is a drug with a wide therapeutic index, then using maximal drug dosing is acceptable to ensure therapeutic effect.

Hypothermia

The process of cooling patients to mild hypothermia (32°C–35°C) has been studied to minimize neurologic injury in several conditions, including TBI, spinal cord injury, stroke, cardiac surgery, and cardiac arrest.[181] Hypothermia is a recommended treatment in comatose adult patients after ventricular fibrillation cardiac arrest. In addition, the guidelines from the American Heart Association suggest it may be beneficial for other cardiac arrest patients including in-patients and those with nonshockable rhythms.[182] With the increasing prevalence of hypothermia for cardiac arrest and the potential for use in other indications it is important to understand the impact hypothermia has on drug PK.

Therapeutic hypothermia has been studied for the impact on the PK and PD of various drugs.[183] Although the PK of drugs has been reported in small trials and series, the PD effects are more difficult to study owing to the confounding effect of the hypothermia itself. Significant interindividual variation in PK parameters has been reported and is not surprising considering concurrent changes in hemodynamics and organ function that may accompany cardiac arrest or TBI and resuscitation. Most PK studies have been done with target cooling to 32°C to 34°C.

Hypothermia has been shown to reduce the activity of metabolic processes, including metabolic enzymatic reactions and active transport mechanisms, including drug absorption and excretion.[184] Selected drugs illustrate the changes that have been reported, but likely reflect a more global issue in medication management. Enteral absorption appears to be delayed after gastric drug administration and as a result, clopidogrel has been shown ineffective in the inhibition of platelet aggregation during hypothermia. There may also be diminished conversion of this prodrug to its active moiety.[185,186] Crushing clopidogrel tablets for nasogastric tube administration may also affect bioavailability owing to incomplete dose administration and loss of the acid-resistant coating. Prasugrel and ticagrelor absorption is also delayed, but the impact of hypothermia on platelet aggregation appears to be less significant.[187–190] The impact on patient outcome and stent thrombosis has not been adequately studied.

During hypothermia, hepatic drug metabolism of drugs is altered. Midazolam is a substrate of CYP 3A4 and is also an important marker of activity of this enzyme. Animal studies suggest that cardiac arrest reduces midazolam clearance and in human volunteers, cooling produces an 11% decrease in midazolam clearance per each 1°C reduction.[191,192] It is difficult to interpret the data for midazolam metabolism during hypothermia as steady state is not achieved, even with multiple days of cooling. The midazolam half-life approached 7000 hours in patients with TBI with body

temperature below 35°C, although the observation period was too short to validate this value, so accumulation may continue almost indefinitely while cooled.[192] Post–cardiac arrest studies with 12 to 24 hours of cooling have not demonstrated significant midazolam accumulation because of the short observation periods.[193,194] Initiation of rewarming appears to accelerate clearance of midazolam once core temp is above 35°C.[192,193] Altering midazolam doses to prevent accumulation during therapeutic hypothermia does not appear to be necessary unless the duration of cooling is prolonged.

Propofol, morphine, and remifentanil exhibit a similar biphasic pattern of metabolism, dependent on temperature (slow when cool and faster when rewarmed despite their different clearance mechanisms) remifentanil by blood and tissue esterases, whereas propofol and fentanyl are high extraction drugs dependent on hepatic blood flow and morphine is metabolized by glucuronidation.[195,196] Doses of these agents may not require adjustment during short periods of hypothermia. Fentanyl clearance is also reduced during hypothermia, but unlike other sedatives, does not increase rapidly with rewarming.[193,195]

Reduced hepatic metabolism via CYP 3A4 also affects the neuromuscular blocking agents, vecuronium and rocuronium, during hypothermia.[197,198] Atracurium is cleared by ester hydrolysis and Hoffman degradation, and has reduced clearance during cooling of surgical patients, leading to potential delay in recovery of neuromuscular function.[196]

Morphine is an example of hypothermia affecting phase 2 metabolism with glucuronidation catalyzed by UDP-glucuronosyltransferase. It also appears to display biphasic changes in clearance with cooling and rewarming, similar to midazolam.[193] This enzyme also metabolizes phenobarbital, propranolol, aspirin, and acetaminophen.

The effect of hypothermia on plasma protein binding is poorly studied, although cooling to 34°C did not change phenytoin binding to albumin.[199] Hepatic metabolism of phenytoin is via CYP 2C9 and CYP 2C19, and the metabolic rate slows during cooling.[200] Close monitoring of serum concentrations is warranted during hypothermia and after rewarming to minimize the risk of seizures. Changes in phenytoin binding to albumin should also be monitored. Drugs that are basic bind to AGP, an acute-phase reactant that would be expected to increase after cardiac arrest or TBI, but data on specific changes during hypothermia are not available.

Heparin is a drug that is partially cleared by renal mechanisms, especially at high doses. At low concentrations, a saturable clearance mechanism that includes reticuloendothelial macrophage and endothelial cell-bound heparinase and desulfatase enzymes plays a more significant role. The use of standard weight-based heparin doses may produce an exaggerated aPTT response in hypothermic patients, but the exact PK mechanism (enzyme activity, protein binding, or filtration) has not been defined.[201,202]

Pharmacogenetics

Pharmacogenetics (PG) is the study of genetic polymorphisms between patients, and pharmacogenomics takes a genome-wide approach in the study of drug response polymorphisms. The first reports of genetic polymorphisms affecting drug response were published in the 1950s. One of these early reports involved prolonged apnea after succinylcholine administration in patients with a variant of the enzyme responsible for succinylcholine metabolism.[203] It has become an area of increasing interest with variants identified that cause alterations in metabolism, transport, and drug interactions. Most of the data on the impact of polymorphisms on drug therapy relate to the risk of adverse drug effects. A review of pharmacogenomics and adverse drug reactions includes discussions of some critical care drugs, but the majority are not ICU specific.[204] However, patients with drug-induced liver injury, adverse cardiac effects, or severe skin reactions are often in the ICU. Ideally, information on genomic risk factors could minimize the risk of some of those reactions. Data on important polymorphisms are growing rapidly in the areas of antiplatelet and anticoagulant drugs and pain management. A 2010 review discusses some of the genetic polymorphisms that are most likely to affect drug therapy in the ICU.[205] Serious adverse events with the use of vasopressin and norepinephrine in septic shock have been associated with poor patient outcome. A genetic polymorphism located near the vasopressin receptor 1b gene is associated with serious adverse events in patients with sepsis receiving vasopressin and norepinephrine, and also in a validation cohort.[206] If further research confirms this risk and if the PG data could be obtained early in treatment, this type of information could benefit patients. However, the challenge in complex patients is great as many different drugs are administered to ICU patients, each is metabolized by various enzymes, transported by numerous proteins, and may interact with multiple receptor targets. Each step in the sequence may be affected by genetic variation, and that compounds the difficulty of identifying specific risks based on genetic testing.[207] Genomics also affects the response to critical illness, potentially affecting the regulation of inflammatory response and sepsis-related complications or mortality, although patient heterogeneity and inadequate study populations have led to inconsistent research findings.[207]

Genetic variations in drug metabolism are some of the best understood genetic polymorphisms. Variations have been described for both phase 1 and phase 2 reactions. These variations may result in patients becoming extensive or poor metabolizers and may result in increased toxicity or decreased efficacy. Research has focused on the CYP 450 family because it is responsible for approximately 75% of all drug metabolism. Within the CYP family most research has focused on 2D6, 2C19, and 2C9. The most studied of these enzymes is 2D6, with variants associated with increased serum concentrations of carvedilol, metoprolol, and flecainide, although decreased response is observed with codeine and tramadol. Other drugs metabolized by CYP 2D6 and potentially affected by polymorphisms include neuroleptics, diltiazem, hydrocortisone, oxycodone, and propafenone. Variants in CYP 2C9 metabolism may affect amiodarone, metronidazole, pantoprazole, valproic acid, and variants in CYP 2C19 are associated with decreased efficacy of clopidogrel, diazepam, phenobarbital, phenytoin, propranolol, voriconazole, and the proton pump inhibitors.[205] Slow acetylators of hydralazine, procainamide, and sulfamethoxazole are at an increased risk of immune-related toxic conditions such as systemic lupus erythematosus. On the other hand, slow acetylators of isoniazid are at increased risk of neurotoxicity and rapid acetylators have an increased risk of hepatitis.

Even though a number of commonly used ICU drugs are metabolized by these enzymes, prescribing based on pharmacogenetics and phenotyping is still uncommon, although several drugs have the potential to model this scenario. For example, 20% of patients using clopidogrel may be nonresponders, as demonstrated by failure to adequately inhibit platelet aggregation.[208] Prospective recognition of patients who are poor or intermediate metabolizers of this prodrug, owing to CYP 2C19 genetic polymorphism, could reduce the risk of thrombosis in this subset of patients.[209] The Clinical Pharmacogenetics Implementation Consortium provides guidelines for the avoidance of clopidogrel in at-risk patients with

acute coronary syndrome and similar guidance for a growing number of drug products.[210] Guidelines from the American College of Cardiology now suggest consideration of genetic testing for clopidogrel response.[211] Although not as well developed, it is known that voriconazole serum concentration monitoring improves efficacy and reduces adverse effects. Thus there is potential for prior knowledge of CYP 2C19 polymorphisms in voriconazole metabolism to improve initial dosing. The most well-developed example is with warfarin in which CYP 2C9, VKORC1, and CYP 4F2 are known to affect metabolism and influence at least half of dosing requirements, although most dosing is done through iterative monitoring and adjustment over weeks. Use of genotype-guided warfarin therapy may shorten the time to achieve the goal level of anticoagulation, but data on clinical benefits such as improved efficacy or reduced bleeding have been lacking until recently.[212] Despite these examples, based on current studies there is not much of a role for routine pharmacogenetic testing in critically ill patients.

Principles of Therapeutic Drug Monitoring

Several factors must be assessed before TDM can be performed in any medication. A reliable assay with a reasonably rapid turnaround is needed, the relationship between concentration and effect or toxicity has been defined, and understanding of the proper dosing model is available for interpretation of the result. Intermittent doses should be given on a predictable schedule and sampling should be done at a uniform time, relative to the dose, and both documented accurately. Predose levels are often more consistent than peak levels because of unpredictable absorption or delayed distribution after an IV dose. There must be a relationship between the sampling site—typically serum—and the site of drug effect. Although total drug concentrations are typically measured, the free (unbound) level may be more relevant to drug action. Unfortunately, availability of free levels and insight into interpretation are often limited. Finally, the clinical effect of the drug may be more important than concentration, so concentration interpretation must be relative to the desired effect and clinical assessment.

Dosing decisions based on limited sampling requires an understanding of the disease state tangent (improvement or worsening), the pharmacokinetics of the drug (measure levels at steady state), and often requires some prediction of patient needs or status on subsequent days. Clinicians need to reevaluate dosing relative to changes in clinical status, but to weigh that with the need to avoid excessive or burdensome sampling.

Conclusion

To maximize the efficacy and minimize toxicities associated with medications it is important for practitioners to understand the basic principles of PK and PD and the emerging role of PG. This knowledge becomes even more important in critically ill patients who undergo significant physiologic changes and have disease states that result in altered drug responses. All medication regimens in critically ill patients should be individualized based on knowledge of a drug's kinetics and dynamics along with an understanding of the impact the patient's comorbid conditions will have on these parameters. In addition, TDM and dose individualization should be used if available, particularly with drugs with narrow therapeutic indices. Through the vigilant use of this knowledge practitioners can maximize therapeutic outcomes in their patients while minimizing toxicity.

Key Points

- Most drug dosing recommendations are based on studies in healthy volunteers and often do not account for the pharmacokinetic and pharmacodynamic alterations seen in critically ill patients.
- Alterations in drug absorption, distribution, metabolism, and clearance are common in critically ill patients, and failure to modify drug dosages based on these changes may result in increased drug toxicity or treatment failure.
- The pharmacodynamic parameter that determines efficacy varies among drug classes as demonstrated by the different targets to maximize bacterial kill among aminoglycosides (concentration dependent, peak:MIC ratio), β-lactams (time-dependent, T > MIC), and vancomycin (time- and concentration-dependent, AUC/MIC).
- Physiologic changes seen with critical illness may alter the rate and extent of medication absorption from the GI tract or subcutaneous sites, making IV administration the preferred route in patients with hemodynamic instability or therapeutic hypothermia.
- Commonly encountered factors in critically ill patients that affect drug PK and PD include augmented renal clearance, renal dysfunction, hepatic disease, obesity, advanced age, pregnancy, thermal injury, and hypothermia.
- Current data do not support routine pharmacogenetic testing for critically ill patients; however, as more data become available it may become a standard of care for some medications.
- When available, patient-specific PK based on appropriately timed serum concentrations (i.e., therapeutic drug monitoring) and measured creatinine clearance should be used to minimize toxicity and maximize the efficacy of drug therapy.

Acknowledgment

The authors thank Todd Miano, PharmD, MSCE, for his contributions to this chapter.

Review Questions

1. What statement best describes augmented renal clearance (ARC)?
- **a.** Readily identified with the Cockcroft-Gault formula.
- **b.** Not a significant concern in 24-year-old trauma patient.
- **c.** Can quantify with a 4-hour urine creatinine clearance.
- **d.** The high creatinine clearance persists for several weeks.

Answer: c. ARC, with values exceeding the traditional value of 125 mL/min, has been described in young, hyperdynamic patients admitted with trauma, subarachnoid hemorrhage, or other acute illnesses/injuries. The time course is not well defined but appears to subside in about a week. Recognition of patients who are at risk and measured urine for creatinine clearance is recommended to quantify the degree of change.

2. What is the best strategy to increase the likelihood of target attainment with an antimicrobial against a more resistant organism?
- **a.** Continuous infusion of cefepime
- **b.** Continuous infusion of tobramycin
- **c.** Extended infusion of ceftriaxone over 2 hours
- **d.** Increase ciprofloxacin to 800 mg every 12 hours

Answer: a. Rationale: Each antimicrobial and therapeutic class has a defined treatment goal in terms of concentration. Agents that are concentration dependent should achieve a peak:minimum inhibitory concentration (MIC) ratio for optimal effectiveness. Time-dependent agents rely on achieving an adequate time above the MIC but may be limited by the risk of adverse reactions with high peak serum concentrations. Ciprofloxacin doses above 600 mg may not be well tolerated, and tobramycin should be dosed intermittently with adequate time for near-complete elimination to minimize renal injury. Methods to achieve an optimal time above the MIC include continuous infusion of β-lactam agents such as cefepime or prolonged infusions (3–4 hours) for β-lactam agents with a short half-life.

3. What is the best therapeutic option to maintain anticonvulsant effect in a patient with a polymicrobial infection who is receiving chronic valproic acid therapy?
- **a.** Initiate meropenem and double the dose of valproic acid.
- **b.** Initiate piperacillin/tazobactam and maintain the current valproic acid dose.
- **c.** Initiate cefepime and metronidazole and double the dose of valproic acid.
- **d.** Initiate meropenem and maintain the dose of valproic acid.

Answer: b. Monobactam antimicrobial agents contribute to profoundly low valproic acid concentrations that occur very rapidly after initiation of the antimicrobial. Increasing the dose of valproate products is not effective to counteract this interaction; thus it is best to avoid the combination. If unavoidable, however, the clinician would add an additional antiepileptic agent.

4. After vigorous volume resuscitation for septic shock, what change in hydrophilic cephalosporin dosing is needed?
- **a.** Start continuous-infusion antibiotic.
- **b.** Give intermittent intravenous push antibiotic doses.
- **c.** Give a loading dose and then use prolonged infusion doses.
- **d.** Give intermittent doses with each infused over 1 hour.

Answer: c. Expansion of the body water through volume resuscitation will dilute the concentration of water-soluble drugs and, over time, will prolong the half-life. A loading dose of hydrophilic drugs will achieve the desired concentration and a prolonged infusion will facilitate target attainment. A continuous infusion would be acceptable but would ideally be initiated after a loading dose. Rapid administration of β-lactam agents makes target attainment (time > MIC) more difficult to achieve.

5. What approach to sedation should be considered for a patient cooled to 32°C–34°C for 24 hours?
- **a.** Use propofol infusion because it does not accumulate during cooling.
- **b.** Use a reduced dose of midazolam infusion to avoid accumulation.
- **c.** A continuous sedative is not needed while cooled owing to central nervous system depression.
- **d.** Use standard midazolam dose via infusion because accumulation is not an issue.

Answer: d. The pharmacokinetics of hepatically metabolized drugs such as midazolam is affected during moderate hypothermia below 35°C. Hepatic metabolism is dramatically reduced, and although an agent such as midazolam will accumulate over the usual short cooling periods, the serum concentrations fall rapidly with rewarming, minimizing a clinical impact. Propofol is an option for sedation but may cause undesirable cardiac effects, such as bradycardia. Although the need for sedation has not been clearly defined during cooling, the use has been endorsed for patient comfort.

Shock: Classification, Pathophysiology, and Approach to Management

ANAND KUMAR, VICTOR TREMBLAY, GLORIA VAZQUEZ-GRANDE, AND JOSEPH E. PARRILLO

CHAPTER OUTLINE

History

Definitions and Categorization of Shock

Classification
- Hypovolemic Shock
- Cardiogenic Shock
- Obstructive Shock
- Distributive Shock

Pathogenesis and Pathophysiology of Shock
- Hemodynamic Basis of Shock
- Microvascular Function in Shock
- Mechanisms of Cellular Injury in Shock
- Compensatory Responses to Shock

Organ System Dysfunction Owing to Shock

Diagnostic Approach and Evaluation
- Clinical Evaluation
- Laboratory Studies
- Imaging
- Invasive Hemodynamic Monitoring
- Ancillary Monitoring Techniques

Management and Therapy
- Aims
- Resuscitation

Conclusion

The syndrome of shock in humans is often the final pathway through which a variety of pathologic processes lead to cardiovascular failure and death. As such, it is perhaps the most common and important problem with which critical care physicians contend. The importance of shock as a medical problem can be appreciated by the prominence of its three dominant forms. Cardiogenic shock, related to pump failure, is a major component of the mortality associated with cardiovascular disease, the leading cause of death in the United States with almost 800,000 deaths annually.[1] Similarly, hypovolemic shock remains a major contributor to early mortality from trauma, the most common cause of death in those between the ages of 1 and 45 years (approximately 200,000 cases annually).[1,2] Finally, despite improving medical and surgical therapy, the ranking of septicemia as a cause of death has increased over the past two decades from the 13th to the 11th most frequent cause of death in the United States.[1,3,4] Most current estimates suggest more than 100,000 cases of septic shock annually in the United States alone.[5,6] In addition, all forms of shock increase the probability of other major comorbidities, such as serious infection, adult respiratory distress syndrome (ARDS), and multiple organ dysfunction syndrome (MODS).

This chapter provides an overview of circulatory shock with an emphasis on the common elements and important differences in the pathophysiology and pathogenesis of the various forms of the syndrome. This focus on common elements of different forms of shock continues through sections on systemic shock hemodynamics, microvascular dysfunction, mechanisms of cellular injury, oxygen supply dependency, compensatory responses, diagnostic approach/evaluation, and management/therapy.

History

Despite recognition of a posttraumatic syndrome by Greek physicians such as Hippocrates and Galen, the origin of the term *shock* is generally credited to the French surgeon Henri François Le Dran, who in his 1737 *A Treatise of Reflections Drawn from Experience with Gunshot Wounds,* coined the term *choc* to indicate a severe impact or jolt.[7] An inappropriate translation by the English physician Clarke, in 1743, led to the introduction of the word *shock* to the English language to indicate the sudden deterioration of a patient's condition with major trauma.[7] It was Edwin A. Moses,[8] however, who began to popularize the term, using it in his 1867 *A Practical Treatise on Shock After Operations and Injuries.* He defined it as "a peculiar effect on the animal system, produced by violent injuries from any cause, or from violent mental emotions." Before this definition, the rarely used term *shock* referred in a nonspecific sense to the immediate and devastating effects of trauma, not a specific posttrauma syndrome. Although not entirely accurate by today's standards, his definition was one of the first to separate the syndrome involving the body's response to massive trauma from the immediate, direct manifestations of trauma itself.

By the late 1800s, two theories of traumatic shock physiology dominated. The first, based on observations by Bernard, Charcot, Goltz, and others, was proposed by Fischer in 1870.[9–11] He suggested that traumatic shock was caused by generalized "vasomotor paralysis"

resulting in splanchnic blood pooling. The corollary was that total circulating blood volume is preserved in shock. The second dominant theory, articulated by Mapother in 1879, suggested that decreased cardiac output (CO) in traumatic shock is caused by intravascular volume loss owing to extrusion of plasma through the vessel wall from the intravascular space to the interstitium.[12] He proposed that this was a consequence of the failure of "vasodilator nerves" in traumatic shock and subsequent generalized arteriolar vasoconstriction. With the 1899 publication of *An Experimental Research into Surgical Shock* (perhaps the first experimental studies of shock), George W. Crile provided scientific data supporting a variation of the vasomotor paralysis theory.[13] After documenting the importance of decreased central venous pressure (CVP) and venous return in experimental shock as the result of hemorrhage and demonstrating the potential for intravascular volume replacement as therapy, he proposed that traumatic shock was caused by exhaustion of the overstimulated "vasomotor center" and subsequent generalized relaxation of large vessels (veins), leading to decreased ventricular filling and CO.

Further advances in shock research were substantially driven by military concerns. During World War I, Walter B. Cannon and other physiologists/physicians studied the early clinical response to battlefield trauma. Their work eventually led to the publication of the classic monograph *Traumatic Shock* in 1923.[14] Cannon and his colleagues were the first to relate trauma-associated hypotension in a large group of patients to a fall in blood volume, loss of bicarbonate, and accumulation of organic acids. Others, using dye dilution techniques, demonstrated that severity of shock was directly related to the decrease in intravascular volume.[15] Clinical data from war casualties also suggested the importance of reduced blood flow (independent of blood pressure) in shock.[16] The observation that blood in the capillaries of victims of massive trauma was hemoconcentrated compared to venous blood was to lead to the practice of resuscitating trauma patients with dried pooled plasma rather than whole blood in the early part of World War II.[17]

Although work originating from the battlefields of World War I clearly linked traumatic shock associated with substantial, obvious bleeding to a loss of circulating blood volume, the origin of traumatic shock in the absence of defined hemorrhage was unclear. The accepted explanation for this phenomenon remained a variation of the vasomotor paralysis theory of shock. It was postulated that nonhemorrhagic, posttraumatic shock ("wound shock") was caused by the liberation of "wound toxins" (histamine and/or other substances), which resulted in "neurogenic" vasodilation and peripheral blood pooling. However, after the war, Blalock and others demonstrated in animal models that nonhemorrhagic traumatic shock was due to the loss of blood and fluids into injured tissue rather than circulating toxins resulting in stasis of blood within the circulation.[18]

Additional advances occurred during World War II. Using injured subjects from the European front, Henry Beecher confirmed that hemorrhage and fluid loss leading to metabolic acidosis was a major cause of shock.[19] In the first use of indicator dye techniques in humans for studying blood flow, Cournand and Riely, in 1943, demonstrated that CO was typically reduced in shock.[20] They also reinforced Blalock's findings regarding non-hemorrhagic "wound shock" in trauma patients by demonstrating that circulating blood volume was reduced in such patients through loss of fluid into damaged tissues. The importance of maintaining intravascular volume in traumatic and hemorrhagic shock was supported by the well-known cardiovascular physiologist, Carl J. Wiggers, who published a landmark series of studies[21] in the 1940s using a standardized animal model which showed that prolonged hypovolemic shock resulted in a resuscitation-resistant state that he termed *irreversible shock.* He defined it as condition resulting from "a depression of many functions but in which reduction of the effective circulating blood volume is of basic importance and in which impairment of the circulation steadily progresses until it eventuates in a state of irreversible circulatory failure." Aggressive fluid support became the standard of resuscitation for trauma and shock.

Subsequently, the Korean War fueled the research demonstrating the relationship of acute tubular necrosis (ATN) and acute renal failure (ARF) to circulatory shock.[22] In addition, studies of battlefield casualties clearly demonstrated the relationship between early resuscitation and survival.[22] During the Vietnamese conflict, with the widespread use of ventilator technology, the dominant research concern became postshock infection and "shock lung" (ARDS), a concern that has evolved to the present interest in shock-related MODS.

Definitions and Categorization of Shock

The definition of shock has evolved in parallel with our understanding of the phenomenon. As noted, until the late 1800s, the term *shock* was used to indicate the immediate response to massive trauma, without regard to a specific posttrauma syndrome. The definition consisted of descriptions of its obvious clinical signs. In 1895, John Collins Warren[23] referred to shock as "a momentary pause in the act of death" that was characterized by an "imperceptible" or "weak, thread-like" peripheral pulse and a "cold, clammy sweat."

Subsequently, with the introduction of noninvasive blood pressure monitoring devices, most clinical definitions of shock added the requirement for arterial hypotension. In 1930 Blalock[9] included arterial hypotension as one of the required manifestations of shock when he defined it as "peripheral circulatory failure resulting from a discrepancy in the size of the vascular bed and the volume of the intravascular fluid." Simeone,[24] as recently as 1964, suggested that shock exists when "the cardiac output is insufficient to fill the arterial tree with blood under sufficient pressure to provide organs and tissues with adequate blood flow."

Current technology, which allows assessment of perfusion independent of arterial pressure, has shown that hypotension does not define shock. The emphasis in defining shock is now on tissue perfusion in relation to cellular function. According to Fink,[25] shock is "a syndrome precipitated by a systemic derangement of perfusion leading to widespread cellular dysoxia and vital organ dysfunction." Cerra[26] has emphasized supply/demand mismatch in his definition: "a disordered response of organisms to an inappropriate balance of substrate supply and demand at a cellular level."

The appropriate definition of shock varies with the context of its use. For paramedical personnel, a definition that incorporates the typical clinical signs of shock (arterial hypotension, tachypnea, tachycardia, altered mental status, and decreased urine output) may suffice. For the physiologist, shock may be defined by specific hemodynamic criteria involving alterations of ventricular filling pressures, venous pressures, arterial pressures, CO, and systemic vascular resistance (SVR). Similarly, in the appropriate context, shock could also be defined by alterations of biochemical/bioenergetic pathways or intracellular gene expression. For the physician, however, we find the most appropriate definition to be "the state in which profound and widespread reduction of effective

• BOX 22.1 Determinants of Effective Tissue Perfusion in Shock

1. Cardiovascular performance (total systemic perfusion/cardiac output)
   - Cardiac function
     - Preload
     - Afterload
     - Contractility
     - Heart rate
   - Venous return
     - Right atrial pressure (dependent on cardiac function)
     - Mean circulatory pressure
     - Stressed vascular volume
     - Mean vascular compliance
     - Venous vascular resistance
     - Distribution of blood flow
2. Distribution of cardiac output
   - Intrinsic regulatory systems (local tissue factors)
   - Extrinsic regulatory systems (sympathetic/adrenal activity)
   - Anatomic vascular disease
   - Exogenous vasoactive agents (inotropes, vasopressors, vasodilators)
3. Microvascular function
   - Precapillary and postcapillary sphincter function
   - Capillary endothelial integrity
   - Microvascular obstruction (fibrin, platelets, WBC, RBC)
4. Local oxygen unloading and diffusion
   - Oxyhemoglobin affinity
   - RBC 2,3-DPG
   - Blood pH
   - Temperature
5. Cellular energy generation/utilization capability
   - Citric acid (Kreb) cycle
   - Oxidative phosphorylation pathway
   - Other energy metabolism pathways (e.g., ATP utilization)

2,3-DPG, *2,3-diphosphoglycerate;* ATP, *adenosine triphosphate;* RBC, *red blood cell;* WBC, *white blood cell.*

tissue perfusion leads first to reversible, and then, if prolonged, to irreversible cellular injury."

"Effective" tissue perfusion, as opposed to tissue perfusion per se, is an important issue. Effective tissue perfusion may be reduced by either a global reduction of systemic perfusion (CO) or by increased ineffective tissue perfusion owing to a maldistribution of blood flow or a defect of substrate utilization at the subcellular level (see Box 22.1).

Classification

Although hypovolemic shock associated with trauma was the first form of shock to be recognized and studied, by the early 1900s it became broadly recognized that other clinical conditions could result in a similar constellation of signs and symptoms. Sepsis as a distinct cause of shock was initially proposed by Laennec in 1831 and subsequently supported by Boise in 1897.[27,28] In 1934, Fishberg and colleagues introduced the concept of primary cardiogenic shock caused by myocardial infarction (MI).[29] Later the same year, Blalock developed the precursor of the most commonly used classification systems of the present.[30] He subdivided shock into four etiologic categories: hematogenic or oligemic (hypovolemic), cardiogenic, neurogenic (e.g., shock after spinal injury), and vasogenic (primarily septic shock). Shubin and Weil, in 1967, proposed the additional etiologic categories of hypersensitivity (i.e., anaphylactic), bacteremic (i.e., septic), obstructive, and endocrinologic shock.[31] However, as the hemodynamic profiles of the different forms of shock were uncovered, a classification based on cardiovascular characteristics (initially proposed in 1972 by Hinshaw and Cox[32]) came to be accepted by most clinicians. The categories include the following:

1. Hypovolemic shock, caused by a decreased circulating blood volume in relation to the total vascular capacity and characterized by a reduction of diastolic filling pressures and volumes;
2. Cardiogenic shock related to cardiac pump failure as the result of loss of myocardial contractility/functional myocardium or structural/mechanical failure of the cardiac anatomy and characterized by elevations of diastolic filling pressures and volumes;
3. Extracardiac obstructive shock involving obstruction to flow in the cardiovascular circuit and characterized by either impairment of diastolic filling or excessive afterload;
4. Distributive shock caused by loss of vasomotor control resulting in arteriolar and venular dilation and (after resuscitation with fluids) characterized by increased CO with decreased SVR.

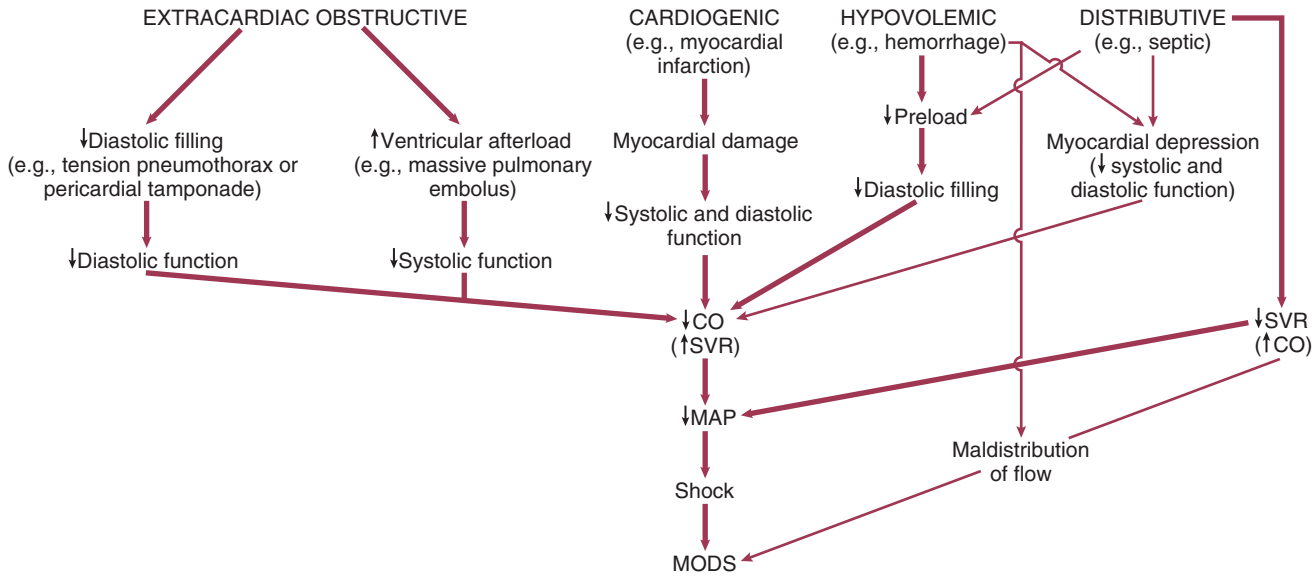
We have adapted these categories into an etiologic/physiologic classification of shock that is summarized in Fig. 22.1 and Box 22.2. This figure and table represent our current understanding of the causes and typical hemodynamic features of different forms of shock.

Despite this hemodynamic-based categorization system, it is important to note the mixed nature of most forms of clinical shock. Septic shock is nominally considered a form of distributive shock. However, before resuscitation with fluids, a substantial hypovolemic component may exist as the result of venodilatation and third spacing. In addition, depression of the myocardium in human septic shock is well documented (see Fig. 22.1).[33–35] Similarly, hemorrhagic shock in experimental models has been linked to both myocardial depression[36,37] and vascular dysfunction (Fig. 22.1).[38,39] Cardiogenic shock typically presents with increased ventricular filling pressures. However, many patients have undergone aggressive diuresis before the onset of shock and may have a relative hypovolemic component. In addition, SVR is only inconsistently increased in cardiogenic shock, suggesting that an inflammatory element may exist under some circumstances. Finally, shock from any cause may cause a deterioration of the coronary perfusion pressure, the difference between mean arterial pressure (MAP) and the higher of left ventricular diastolic pressure or the right atrial pressure, resulting in some degree of myocardial ischemia and myocardial dysfunction.[40] Although four categories of shock exist based on hemodynamic profile, clinical shock states tend to combine components of each (Fig. 22.1).[33–40]

Hypovolemic Shock

Hypovolemic may be related to dehydration, internal or external hemorrhage, gastrointestinal fluid losses (diarrhea or vomiting), urinary losses resulting from either diuretics or kidney dysfunction, or loss of intravascular volume to the interstitium owing to increased vascular permeability (in response to sepsis or trauma). Alternately, venodilation secondary to sepsis, spinal injury, various drugs, and toxins can result in a relative hypovolemic condition that contributes to shock (Box 22.2, see Fig. 22.1).

Hemodynamically, hypovolemic shock is characterized by a fall in ventricular preload resulting in decreased ventricular diastolic pressures and volumes (Table 22.1). Cardiac index (CI) and stroke volume index (SVI) are typically reduced. In addition to hypotension, a decreased pulse pressure may be noted. Because of a decreased output and unchanged or increased metabolic demand, mixed



• **Fig. 22.1** The interrelationships between different forms of shock. For cardiogenic, hypovolemic, and obstructive shock, hypotension is primarily due to decreased cardiac output with systemic vascular resistance rising secondarily. With distributive (and particularly, septic) shock, hypotension is primarily due to a decrease in systemic vascular resistance with a secondary increase of cardiac output. In many forms of shock, the hemodynamic characteristics are influenced by elements of hypovolemia, myocardial depression (ischemic or otherwise), and vascular dysfunction (which may affect afterload). Dominant pathophysiologic pathways are denoted by *heavier lines*. *CO,* Cardiac output; *MAP,* mean arterial blood pressure; *MODS,* multiple organ dysfunction syndrome; *SVR,* systemic vascular resistance.

venous oxygen saturation (Mv_{O_2}) may be decreased and the arteriovenous oxygen content difference widened. Clinical characteristics include pale, cool, clammy skin (often mottled); tachycardia (or if severe shock, bradycardia[8,41]); tachypnea; flat, nondistended peripheral veins; decreased jugular venous pulse; decreased urine output; and altered mental status.

Several factors can influence the development and hemodynamic characteristics of hypovolemic shock in humans. Studies in animals and humans have demonstrated a clear relationship between the degree of circulating blood volume loss and clinical response.[42–45] Acute loss of 10% of the circulating blood volume is well tolerated and compensated by tachycardia. CI may be minimally decreased despite a compensatory increase in myocardial contractility. SVR typically increases slightly, particularly if sympathetic stimulation augments MAP. Compensatory mechanisms begin to fail with a 20% to 25% volume loss. Mild to moderate hypotension and decreased CI may be present. Orthostasis (with a blood pressure decrease of 10 mm Hg and increased heart rate [HR] of 20 to 30 beats/min) may become apparent. There is a marked increase in SVR and serum lactate may begin to rise. With decreases of the circulating volume of 40% or more, marked hypotension with clinical signs of shock is noted. CI and tissue perfusion may fall to less than half normal. Lactic acidosis is usually present at this stage and predicts a poor outcome.[46,47] The case fatality rate can exceed 50% in hemorrhagic shock associated with trauma.[48]

The rate of loss of intravascular volume and the preexisting cardiac reserve is of substantial importance in the development of hypovolemic shock. As an example, although an acute blood loss of 1 L in a healthy adult may result in mild to moderate hypotension with a reduced pulmonary artery occlusion pressure (PAOP) and CVP,[43] the same loss over a longer period may be well tolerated owing to compensatory responses, such as tachycardia, increased myocardial contractility, increased red blood cell 2,3-diphosphoglycerate (2,3-DPG), and increased fluid retention. On the other hand, a similar slow loss may lead to substantial hemodynamic compromise in a person with a limited cardiac reserve even while their PAOP and CVP remain elevated.

Hypovolemic shock represents more than a simple mechanical response to loss of circulating volume. It is a dynamic process involving competing adaptive (compensatory) and maladaptive responses at each stage of development. Thus although intravascular volume replacement is always a necessary component of resuscitation from hypovolemia or hypovolemic shock, the biologic responses to the insult may progress to the point where such resuscitation is insufficient to reverse the progression of the shock syndrome. Patients who have sustained a greater than 40% loss of blood volume for 2 hours or more may be unable to be effectively resuscitated.[38,42,45] A series of inflammatory mediator, cardiovascular, and organ responses to shock are initiated that supersede the importance of the initial insult in driving further injury.

Cardiogenic Shock

Cardiogenic shock results from the failure of the heart as a pump (see Box 22.2 and Fig. 22.1). It is the most common cause of in-hospital mortality in patients with Q-wave MI.[49,50] Hemodynamically, cardiogenic shock is characterized by increased ventricular preload (increased ventricular volumes, pulmonary wedge pressure and CVP) (see Table 22.1). Otherwise hemodynamic characteristics are similar to those for hypovolemic shock (see Table 22.1). In particular, both involve reduced CI, SVI, and ventricular stroke work indices with increased SVR. As the result of inadequate tissue perfusion, the Mv_{O_2} is substantially reduced and the arteriovenous oxygen content difference increased. The degree of lactic acidosis may predict mortality.[51] Clinically, the specific signs of shock are similar. However, signs of congestive heart failure (CHF, volume

• BOX 22.2 Classification of Shock

1. Hypovolemic (Oligemic)
   - Hemorrhagic
     - Trauma
     - Gastrointestinal
     - Retroperitoneal
   - Intravascular fluid depletion (nonhemorrhagic)
     - External fluid loss
       - Dehydration
       - Vomiting
       - Diarrhea
       - Polyurea
     - Interstitial fluid redistribution
       - Thermal injury
       - Trauma
       - Anaphylaxis
   - Increased vascular capacitance (venodilatation)
     - Sepsis
     - Anaphylaxis
     - Toxins/Drugs
2. Cardiogenic
   - Myopathic
     - Myocardial infarction
       - Left ventricle
       - Right ventricle
     - Myocardial contusion (trauma)
     - Myocarditis
     - Cardiomyopathy
     - Post-ischemic myocardial stunning
     - Septic myocardial depression
     - Drug toxicity
       - Anthracycline cardiotoxicity
       - Calcium channel blockers
   - Mechanical
     - Valvular failure (stenotic or regurgitant)
     - Hypertropic cardiomyopathy
     - Ventricular septal defect
   - Arrhythmic
     - Bradycardia
     - Sinus (e.g., vagal syncope)
     - Atrioventricular blocks
     - Tachycardia
     - Supraventricular
     - Ventricular
3. Extracardiac Obstructive
   - Impaired diastolic filling (decreased ventricular preload)
     - Direct venous obstruction (vena cava)
       - Intrathoracic obstructive tumors
     - Increased intrathoracic pressure (decreased transmural pressure gradient)
       - Tension pneumothorax
       - Mechanical ventilation (with positive end-expiratory pressure [PEEP] or volume depletion)
     - Decreased cardiac compliance
       - Constrictive pericarditis
       - Cardiac tamponade
         - Acute
           - Post MI free wall rupture
           - Traumatic
           - Hemorrhagic (anticoagulation)
         - Chronic
           - Malignant
           - Uremic
           - Idiopathic
   - Impaired systolic contraction (increased ventricular afterload)
     - Right ventricle
       - Pulmonary embolus (massive)
       - Acute pulmonary hypertension
     - Left ventricle
       - Saddle embolus
       - Aortic dissection
4. Distributive
   - Septic (bacterial, fungal, viral, rickettsial)
   - Toxic shock syndrome
   - Anaphylactic, anaphylactoid
   - Neurogenic (spinal shock)
   - Endocrinologic
     - Adrenal crisis
     - Thyroid storm
   - Toxic (e.g., nitroprusside, bretyllium)

overload) are typically present in cardiogenic shock. The jugular and peripheral veins may be distended. An S_3 and evidence of pulmonary edema are usually found.
