Focal aware (previously "simple partial") seizures arise focally in the cerebral cortex, without taking over either the limbic system or subcortical nuclei. The patient remains aware of the environment during the ictus, and except for the seizure itself appears unchanged. Bilateral limbic system dysfunction results in a *focal seizure with impaired awareness* (previously "complex partial seizure"); the patient's awareness and ability to interact with the environment are diminished (but not always completely abolished). *Automatisms* are movements that the patient seems to make without being aware of them; typical automatisms include swallowing, masticatory movements, and fumbling with nearby items. *Focal to bilateral tonic-clonic* seizures (previously "secondary generalized") imply invasion of either the other hemisphere (with loss of consciousness) or, more commonly, subcortical structures, with the development of a generalized convulsion.

Generalized seizures seem to arise from the entire cerebral cortex and the diencephalon at the same time. Consciousness is lost from

the start of the seizure. True *absence* seizures are usually confined to childhood; they consist of the abrupt onset of a blank stare usually lasting 5 to 15 seconds, without lateralizing phenomena, from which the patient abruptly returns to normal. *Generalized myoclonic* seizures begin with brief, bilaterally synchronous jerks without an initial change in consciousness, followed by a generalized convulsion. They occur in several of the genetic epilepsies, but in the ICU are more commonly the consequences of anoxia or metabolic disturbances such as renal failure.[27] *Clonic* seizures involve repetitive movements; they may be generalized (synchronous movements of all extremities and both sides of the face) or focal (e.g., one side of the face and the arm of the same side). *Tonic* seizures are episodes of tonic extension of the arms, legs, and trunk; they must be distinguished from extensor posturing and from tetanic spasms.[28] *Tonic-clonic* seizures begin with tonic extension, followed by a brief phase of rapid vibration of the extremities, evolving into bilaterally synchronous clonus, and concluding with a postictal phase in which incontinence is common and brief apnea is occasionally noted. They may start as generalized or, more commonly, occur as the manifestation of spread of a focal seizure (*focal to bilateral tonic-clonic*).

SE is defined by the Neurocritical Care Society as "five or more minutes of continuous seizure activity or seizure activity without return to baseline."[29] SE is classified by a somewhat similar system as seizures, with alterations to match the observable clinical phenomena (Box 62.2).[30,31] SE has most recently been divided based on whether there are prominent motor symptoms present or not. *Generalized convulsive SE* (GCSE) is the type most commonly encountered in ICUs and poses the greatest risk to the patient. As with generalized convulsive seizures, GCSE may be either primarily generalized or may start as *focal SE evolving into bilateral generalized convulsions*. *Epilepsia partialis continua* is a special form of *focal motor SE* in which a small area of the body makes repetitive movements, sometimes for months or years after a CNS insult. This type of SE is most commonly associated with nonketotic hyperosmolar hyperglycemia and does not tend to respond to conventional antiseizure drug treatment.[32] *Focal nonmotor SE with impaired awareness* (previously "*complex partial SE*") presents with a state of diminished awareness, although frank loss of consciousness is rarely noted. The patient may exhibit automatisms, but commonly the diagnosis comes as a surprise when an EEG is obtained.

Nonconvulsive SE (NCSE) in the ICU is most commonly the consequence of partially treated GCSE and is defined by the International League Against Epilepsy as SE "without prominent motor symptoms."[31] As a means of simplifying the categorization of convulsive SE and NCSE, terms such as *complex partial SE* have been removed from the classifications. Most notably, NCSE can exist with or without coma, an example of which is *focal aphasic NCSE*, during which patients lack language abilities yet remain aware of their surroundings.

Up to 40% of SE patients may continue to have seizures, meeting criteria for *refractory SE* (RSE), which has been defined as ongoing seizure activity for more than 60 minutes despite administration of both a first-line benzodiazepine and a second-line antiseizure drug.[29,33] *Superrefractory SE* (SRSE) occurs once seizures continue in patients for more than 24 hours despite third-line anesthetic agent administration.

Pathogenesis

The reported "causes" of SE can be separated, if imperfectly, into predispositions and precipitants. *Predispositions* are relatively fixed conditions that increase the likelihood of SE, such as a brain tumor, in the presence of a precipitant. *Precipitants*, in contrast, are transient conditions that can produce SE in most, if not all, people but tend to affect those with predispositions at lesser degrees of severity (e.g., barbiturate withdrawal).

• BOX 62.2 Clinical Classification of Status Epilepticus

I. With prominent motor symptoms
  A. Convulsive SE (CSE, synonym: tonic-clonic SE)
    1. Generalized convulsive
    2. Focal onset evolving into bilateral convulsive SE
    3. Unknown whether focal or generalized
  B. Myoclonic SE (prominent epileptic myoclonic jerks)
    1. With coma
    2. Without coma
  C. Focal motor
    1. Repeated focal motor seizures (Jacksonian)
    2. Epilepsia partialis continua
    3. Adversive status
    4. Oculoclonic status
    5. Ictal paresis (i.e., focal inhibitory SE)
  D. Tonic status
  E. Hyperkinetic SE

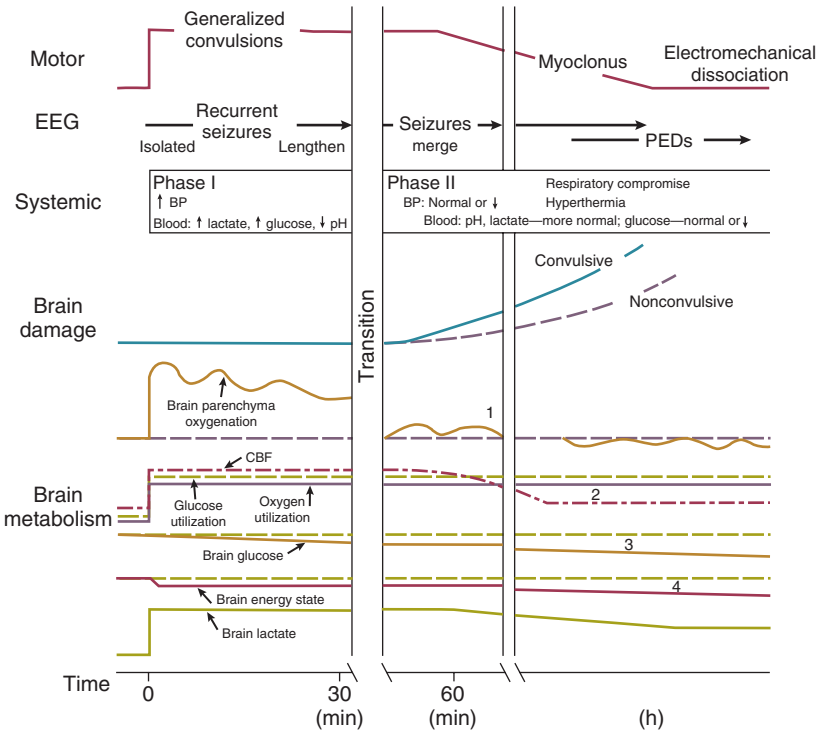
II. Without prominent motor symptoms (i.e., nonconvulsive SE)
  A. NCSE with coma (including so-called "subtle" SE)
  B. NCSE without coma
    1. Generalized
      a. Typical absence status
      b. Atypical absence status
      c. Myoclonic absence status
    2. Focal
      a. Without impairment of consciousness (aura continua, with autonomic, sensory, visual, olfactory, gustatory, emotional/psychic/experiential, or auditory symptoms)
      b. Aphasic status
      c. With impaired consciousness
    3. Unknown whether focal or generalized
      a. Autonomic SE

CSE, *Convulsive status epilepticus;* NCSE, *nonconvulsive status epilepticus;* SE, *status epilepticus. From Trinka E, Cock H, Hesdorffer D, et al. A definition and classification of status epilepticus—report of the ILAE Task Force on Classification of Status Epilepticus.* Epilepsia. *2015;56: 1515–1523.*

Pathophysiology

The causes and effects of SE at the cellular, brain, and systemic levels are interrelated, but their individual analysis is useful for understanding them and their therapeutic implications. One must first understand the consequences of a single seizure and then contrast this information with the effects of prolonged or frequent seizures merging into SE. Longer durations of SE produce more profound alterations with an increasing likelihood of permanence and of becoming refractory to treatment. Fig. 62.1 illustrates the variety of processes involved in a single seizure and in the transition to SE.[34]

The ionic events of a seizure follow the opening of ion channels coupled to excitatory amino acid (EAA) receptors. Although the endogenous ligands of these channels are glutamate and aspartate, the channels are named for synthetic compounds that potently activate them. From the standpoint of the intensivist concerned



• **Fig. 62.1** Pathophysiology of status epilepticus (SE). Summary of pathophysiologic events during experimental SE. Note that the abscissa is discontinuous. Numerals in the figure indicate the following events: *1*, loss of cortical responsiveness to changes in oxygen tension; *2*, a fall in cerebral blood flow *(CBF)*; *3*, depletion of brain glucose; and *4*, a decline in the total brain energy state. *BP,* Blood pressure; *CBF,* cerebral blood flow; *EEG,* electroencephalogram; *PEDs,* periodic epileptiform discharges. (Adapted from Lothman EW, Bertram EH. Epileptogenic effects of status epilepticus. *Epilepsia.* 1993;34[suppl 1]: S59–S70.)

with SE, three channels are particularly important because their activation may raise intracellular free calcium to toxic concentrations. The first channels primarily conduct sodium ions (the AMPA [amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid] channels). The second are the N-methyl-D-aspartate (NMDA) channels, which admit sodium and calcium when the cell has been depolarized (which relieves the resting blockade of the ionophore by magnesium). The third channels, the metabotropic or ACPD (aminocyclopentane-trans-1,3-dicarboxylic acid) channels, mobilize calcium from intracellular stores via coupling to G-protein–linked second messengers. These EAA systems are normally crucial for learning and memory.

The cellular consequences of the excessive EAA channel activation include (1) accumulation of toxic concentrations of free intracellular calcium; (2) activation of autolytic enzyme systems; (3) production of oxygen-derived free radicals; (4) generation of nitric oxide, which both enhances subsequent excitation and serves as a toxin; (5) phosphorylation of several enzyme and receptor systems, making seizures likely; and (6) increasing intracellular osmolality, thereby producing neuronal swelling. If adenosine triphosphate production should fail (because the substrate becomes inadequate or is diverted into EAA-related events), membrane ion exchange systems stop functioning, and the neuron swells further. These events are responsible for the neuronal damage associated with SE.

Many other important biophysical and biochemical alterations occur during and after SE. The intense neuronal activity activates immediate-early genes and produces heat shock proteins, providing strong indications of the deleterious effects of SE and insight into the mechanisms by which neurons protect themselves.[35] Wasterlain and colleagues summarized the many mechanisms through which SE damages the nervous system.[36]

Absence SE is an exception among these conditions. It appears to consist of rhythmically increased inhibition and does not produce clinical sequelae or neuropathologic abnormalities.

The mechanisms that terminate seizure activity are uncertain. Counterregulatory ionic events are also triggered by the epileptiform discharge; the most important is activation of inhibitory interneurons, which feed back to the bursting cells via γ-aminobutyric acid (GABA) ionotropic receptor family A ($GABA_A$) synapses. Given the relative rarity of SE in a population in which at least 1 in 50 patients has had a seizure, one must infer that these mechanisms are generally effective. The leading candidates for seizure-terminating systems are inhibitory mechanisms, primarily GABAergic neuronal aggregates. This hypothesis receives strong support from the clinical observation that human SE frequently follows withdrawal from GABA agonists (e.g., benzodiazepines).

Multiple neurobiochemical changes occur that contribute to the refractoriness of seizures. There is evidence of internalization of GABA receptors, lowering the responsiveness of seizure activity to GABAergic drugs such as benzodiazepines, as well as an increase in NMDA receptors at the synaptic membrane, further increasing excitatory glutamatergic activity.[37,38] The repetitive firing that characterizes SE alters the extracellular microenvironment. The most important change is probably the elevation of the extracellular potassium concentration. Although extruding potassium is an effective strategy to maintain normal electronegativity, the excessive amounts of potassium ejected during SE overcome the ability of astrocytes to buffer it. Patients with cerebral edema, glial scarring,

or alien tissue lesions have extracellular space abnormalities that impair the potassium buffering ability of glial cells. Raising extracellular potassium is a potent epileptogenic stimulus.

The tremendously increased cellular activity of SE elevates tissue demand for oxygen and glucose. To meet this demand, cerebral blood flow initially increases threefold or greater. However, after about 20 minutes, energy supplies become exhausted. This accentuates the demand for local catabolism to support ion pumps (in a vain attempt to restore the internal milieu during the flood of sodium and calcium). Many researchers believe that this is the major cause of epileptic brain damage in GCSE. Other forms of SE may not be subject to such severe hypercatabolism but still pose a risk.

When focal seizures generalize, subcortical structures begin to play an active role in the clinical phenomena observed. Spread of the electrical activity into the substantia nigra and other subcortical regions appears to be necessary before a tonic-clonic convulsion occurs.

At the anatomic level, SE can produce cerebral edema, which follows ictal damage to the blood-brain barrier. Prolonged SE produces chronic neuropathologic changes. Before the 1970s, these changes were often attributed to the systemic effects of SE (e.g., hypoxia and hyperthermia). However, SE itself produces these changes even in patients who are paralyzed, supported by mechanical ventilation, and maintained at normal temperature and blood pressure. The hippocampus, which is one of the most important areas for memory function, contains the most susceptible neurons, but the cerebral cortex is also vulnerable. These regions express high densities of EAA receptors and may be relatively deficient in systems for handling unusual elevations of free intracellular calcium. Cells that contain nitric oxide synthase seem relatively protected.

In addition to damaging the CNS, GCSE produces serious, often life-threatening, systemic effects.[39] Pressures in the systemic arterial system (under sympathetic control) and in the pulmonary arterial system (raised via efferents from pontine and medullary centers) are dramatically elevated from the moment of seizure onset. Epinephrine and cortisol release prompts further elevations of systemic arterial pressure and also produces hyperglycemia. Increased muscular work raises the circulating lactate concentration. Respiration becomes ineffective; both airway obstruction and diaphragmatic contraction impede air movement. The consequent hypoxia further elevates lactate levels. Ventilatory failure impairs carbon dioxide excretion while carbon dioxide production increases markedly, adding a respiratory component to the acidosis. In GCSE, the arterial blood pH frequently falls below 7.0. The muscular work accelerates heat production; when coupled with decreased dermal blood flow (produced by sympathetic stimulation), GCSE can quickly raise the core temperature to 40°C or higher.

If GCSE is not completely controlled within the first 20 minutes, motor activity begins to diminish in intensity, and ventilation usually improves. Therefore even without treatment, the metabolic acidosis improves. Core temperature may continue to climb, however, probably reflecting hypothalamic dysfunction. The initial hyperglycemia diminishes; after an hour or more, hepatic gluconeogenesis may fail, and hypoglycemia develops.

Patients with GCSE frequently have secondary complications as well. Aspiration of oral or gastric contents commonly produces chemical pneumonitis, with bacterial pneumonia often following. Rhabdomyolysis is common and is occasionally followed by acute renal failure. Compression fractures, joint dislocations, and tendon avulsions are other common sequelae of GCSE.

Clinical Manifestations

Recognition of Seizures in the ICU

Because of the close observation patients receive in the critical care setting, most seizures are witnessed. Three problems occur in ICU seizure recognition: (1) NCSE in patients with already impaired awareness, (2) seizures in patients receiving neuromuscular junction blockade, and (3) the misinterpretation of movement disorders and psychiatric disturbances as seizures. (In any ICU patient in whom abnormal movements or unexplained changes in awareness develop, thiamine deficiency [Wernicke encephalopathy] should be excluded immediately by giving high-dose thiamine.)

ICU patients often have altered awareness in the absence of seizures, reflecting their underlying condition, complications of those conditions (such as septic encephalopathy[40]), and drugs that depress alertness (intentionally or not). Although clonic motor activity in these patients remains visible, it may be difficult to determine whether a subsequent further decline in alertness reflects a seizure or some other process.

Patients receiving neuromuscular junction blocking agents do not manifest any of the usual signs of seizures. As long as such patients receive concomitant sedation with GABA agonists (e.g., benzodiazepines, propofol), the likelihood of seizures is small. The autonomic signs of seizures (hypertension, tachycardia, pupillary dilation) are not readily distinguished from the effects of pain or the patient's response to inadequate sedation. Thus any patient who manifests these findings and who has a potential reason for seizures (e.g., intracranial disease) should have an EEG to exclude this possibility.

Many sorts of abnormal movements occur in patients with severe metabolic disturbances or anoxic brain damage. Some of them can be distinguished from seizures by observation; such movements are frequently evoked or exacerbated by sensory stimuli and can sometimes be suppressed by changing the patient's posture. However, Hirsch and colleagues have demonstrated that seizures in ICU patients may be induced by external stimuli[41]; if any doubt about the nature of such movements persists, an EEG should be performed.

During therapeutic cooling for patients in a coma after cardiac arrest, seizures may be difficult to detect clinically, especially when neuromuscular junction blockade is used.[42] Because up to 30% of cardiac arrest patients may experience seizures, EEG monitoring should be performed as soon as possible in all cardiac arrest patients who remain comatose.[43]

Manifestations of Status Epilepticus

GCSE usually begins as tonic extension of the trunk and extremities with no preceding focal ictal activity. Consciousness is immediately lost, and after several seconds the tonic phase gives way to clonic (rhythmic) extension of the extremities, with flexion occurring during each brief relaxation. Usually this clonic phase wanes in intensity over 1 to 3 minutes. The patient developing SE may then repeat the cycle of tonic activity followed by clonic movements, or may continue to have intermittent bursts of clonic activity without recovery between. Less commonly encountered forms of GCSE are *myoclonic SE,* in which bursts of brief myoclonic jerks increase in intensity until a convulsion occurs.

Focal evolving to bilateral convulsive SE in the ICU begins with a focal seizure that progresses to a tonic-clonic convulsion. Even under the watchful eye of the ICU staff, the initial focal clinical activity may be overlooked.

Tonic SE is almost always confined to patients (usually children) with serious preexisting cerebral disorders. Its importance in critical care practice follows from the observation that benzodiazepines may *precipitate* tonic SE; paradoxically, these agents are also used to treat it.

There are several forms of *generalized NCSE*. Of greatest importance to intensivists is NCSE as a sequela of inadequately treated GCSE. In this circumstance, a patient with GCSE is treated with one or more antiseizure drugs, often in inadequate doses, after which visible convulsive activity stops. However, the patient does not awaken (or otherwise return to baseline), and SE is actually continuing. As a rule, patients who have not begun to awaken after 20 minutes should be assumed to have entered NCSE. This form of SE is sometimes termed *subtle SE,* and careful observation sometimes reveals low-amplitude clonic activity in some part of the body (most commonly, the face or the hands). Most investigators view NCSE as an extremely dangerous problem, because the neuronally destructive effects of SE continue unabated, often for several hours. This condition requires emergent treatment under EEG monitoring to prevent further cortical damage.

The usual form of *focal SE* in the ICU follows a stroke or is seen in patients with rapidly expanding cerebral masses (e.g., abscesses). Although clonic motor activity is the most easily recognized form, the seizure will take on the functional characteristics of the adjacent functional tissue. Thus somatosensory or special sensory manifestations may occur; the ICU patient who is already neurologically impaired may not be able to report these symptoms. *Aphasic SE* may occur if the seizure begins in a language area; this must be distinguished from a stroke. Physical examination usually reveals at least some mild lateralizing findings.

Diagnostic Approach

The Intensive Care Unit Patient With New-Onset Seizures

When a patient already in an ICU has a seizure, the staff has a natural tendency to somehow stop the ictus. This may, unfortunately, lead to both diagnostic obscuration and iatrogenic complications. Beyond trying to protect the patient from harm, very little can be done with sufficient rapidity to influence the course of the seizure. In particular, padded tongue blades (or similar items) should not be placed in the mouth, because they are more likely to obstruct the airway than to preserve it. Similarly, seizures in most patients have stopped before any medication, even administered into a preexisting intravenous (IV) line, can reach the brain in an effective concentration. A common scenario is the administration of IV diazepam, which begins to take effect after the seizure is over; the patient is now both postictal and pharmacologically sedated and becomes apneic.

The most important "intervention" during a single seizure is careful observation. This is the best time to collect evidence of a focal onset, which implies structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized convulsion should also be viewed as evidence of focal disease.

In addition to the standard historical information to be requested from patients and family members after a seizure, the ICU patient has several special predispositions that must be investigated. As previously noted, certain medications are an important cause of ICU seizures, especially in patients with diminished renal or hepatic function, or in those with damage to the blood-brain barrier. A complete list of potentially epileptogenic drugs is beyond the scope of this chapter; the medications of any patient who has a seizures should be reviewed with this possibility in mind.

Drug withdrawal is another common problem. Although ethanol withdrawal is the most common offender, discontinuing any hypnosedative agent (e.g., barbiturates, benzodiazepines, baclofen, gabapentin) may prompt convulsions 24 to 96 hours later. This may be a particular problem in the ICU, where such agents may be withheld from patients because the staff is afraid that the drug's effects will obscure the neurologic examination.

The physical examination should be conducted with special emphasis on the points mentioned earlier for the postictal examination. In addition, evidence of cardiovascular disease (as a source for cerebral emboli) and systemic infection should be sought. Careful examination of the skin and fundi are sometimes revealing. The presence of papilledema is obviously important, but its absence does not exclude increased intracranial pressure.

In addition to routine biochemical studies, screening for drugs of abuse should be performed on patients with unexplained seizures. Cocaine has emerged as a prominent cause of seizures in many urban hospitals[44] and newer proconvulsant synthetic substances should still be suspected in the presence of negative results of a toxicology screen. Hypocalcemia is rarely a cause of seizures beyond the neonatal period, and its discovery should not be the end of the diagnostic workup. Hyperparathyroidism has been linked anecdotally to seizures, with the inference that parathormone is neurotoxic. Similarly, hypomagnesemia has an unwarranted reputation as a cause of seizures, especially in the malnourished alcoholic patient.

In our prospective study of neurologic complications in medical ICU patients, 38 of 61 patients (62%) with seizures had a vascular, infectious, or neoplastic explanation for their fits.[1] Computed tomography (CT) scanning should be performed on all ICU patients with new seizures once their condition is stable enough for transport. The decision whether to administer contrast agent for a CT or perform magnetic resonance imaging scan depends on the clinical setting and on the appearance of the plain scan. In patients at risk for cerebrovascular events who present with "seizure activity" more suggestive of extensor posturing, it is imperative to obtain intracranial vessel imaging without delay to rule out a basilar artery thrombosis.

The EEG is the most vital diagnostic tool for the seizure patient. Continuous EEG monitoring is recommended in any ICU patient with the following conditions: persistent encephalopathy after seizures; patients with fluctuating mental status of unknown etiology; periodic epileptiform discharges on routine EEG; requirement for pharmacologic paralysis and risk for seizures; and clinical paroxysmal events suspected to be seizures.[45] Although the detailed interpretation of EEGs is beyond the scope of this chapter, the intensivist can easily learn to recognize basic seizure types and other important EEG abnormalities in critically ill patients.[46]

The need for a lumbar puncture depends on the clinical situation. In view of the common causes of seizures in the critical care setting, those who need cerebrospinal fluid (CSF) analysis will usually require a CT scan before the lumbar puncture. If a CNS infection is suspected in such patients, empiric antibiotic treatment should be strongly considered while these studies are being performed, rather than waiting for the scan to be performed and cerebrospinal fluid results to be obtained.

The Patient Presenting With or Developing Status Epilepticus

In contrast to the ICU patient with a single seizure, the patient with SE requires concomitant diagnostic and therapeutic efforts.

TABLE 62.2 Electrographic-Clinical Correlations in Generalized Convulsive Status Epilepticus

Stage	Typical Clinical Manifestations[a]	Electroencephalographic Features
1	Tonic-clonic convulsions; hypertension and hyperglycemia common	Discrete seizures with interictal slowing
2	Low- or medium-amplitude clonic activity, with rare convulsions	Waxing and waning of ictal discharges
3	Slight, but frequent, clonic activity, often confined to the eyes, face, or hands	Continuous ictal discharges
4	Rare episodes of slight clonic activity; hypotension and hypoglycemia become manifest	Continuous ictal discharges punctuated by flat periods
5	Coma without other manifestations of seizure activity	Periodic epileptiform discharges on a flat background

[a]The clinical manifestations may vary considerably, depending on the underlying neuropathophysiologic process (and its anatomy), systemic diseases, and medications. In particular, stages of the electrographic progression may be sufficiently brief to be overlooked. Partially treating status epilepticus may dissociate the clinical and electrographic features.

The first issue is to make a diagnosis of SE. Because most seizures stop within 5 to 7 minutes,[47] it is reasonable to begin treatment after 5 minutes of continuous seizure activity or after the second or third seizure occurs without recovery between the spells.

Continuous EEG monitoring is frequently useful in SE,[48] but treatment should not be delayed to obtain it when the diagnosis is apparent. A variety of EEG findings may be present, depending on the type of SE and its duration (Table 62.2). The electrical phenomena of SE at the whole brain level, as seen in the scalp EEG, reflect the seizure type that initiates SE (Fig. 62.2). Thus, absence SE begins with a generalized 3-Hz wave-and-spike EEG pattern. During the course of SE, there is usually some slowing of this rhythm, but the wave-and-spike characteristic persists. In contrast, GCSE goes through the sequence of EEG changes outlined in Table 62.2. The initial high-frequency discharge becomes progressively less well formed over minutes; this pattern implies that neuronal activity is less synchronous. Whether this indicates that inhibitory systems are attempting to terminate SE, a progressive decay in the ability of synaptic mechanisms to maintain synchrony, or global deterioration in neuronal function remains to be determined. The most typical pattern early in SE is that of rhythmic, high-frequency (>12 Hz) activity that increases in amplitude and decreases in frequency, finally terminating abruptly and leaving postictal low-amplitude slowing in its wake.

Management Approach

The Intensive Care Unit Patient With New-Onset Seizures

Deciding whether to administer antiseizure drugs to an ICU patient who experiences a single seizure or a few seizures requires a provisional etiologic diagnosis, an estimate of the likelihood of seizure recurrence, and an understanding of the utility and limitations of available antiseizure drugs. For example, the patient who has seizures during ethanol withdrawal will probably not benefit from chronic antiseizure drug treatment, and the administration of phenytoin (PHT) will not prevent more withdrawal convulsions during the same episode. Such a patient may need prophylaxis against delirium tremens with benzodiazepines, but the seizures themselves seldom require treatment. The patient who has seizures during barbiturate or benzodiazepine withdrawal, in contrast, should usually receive short-term treatment (usually with lorazepam [LRZ]) to prevent the development of SE. Seizures caused by drug intoxications or metabolic disturbances should similarly be treated for a brief period but do not indicate chronic antiseizure drug therapy.

The ICU patient with CNS disease who has even a single seizure should usually start a chronic antiseizure drug regimen, with the decision to continue medication reviewed before hospital discharge. It is now apparent that initiating antiseizure drug therapy after the first *unprovoked* (e.g., not drug-related or withdrawal-related) seizure helps delay the onset of subsequent seizures, but it does not change their eventual incidence.[49] Starting treatment after the first seizure in a critically ill patient who has a condition predictive of seizure recurrence may be even more important if the patient's problems include coagulopathies, myocardial ischemia, or other conditions that would be seriously complicated by a convulsion.

The Neurocritical Care Society recently published extensive guidelines for the treatment of SE,[29] which should be consulted for detailed information about the drugs discussed briefly here.

In the ICU setting, PHT (20-mg/kg loading dose, no faster than 50 mg/min, followed by an initial maintenance dose of 5 mg/kg per day) is often chosen to prevent subsequent seizures because of its relative ease of administration. Slowing the infusion rate to less than 25 mg/min can usually prevent hypotension and cardiac arrhythmias that may complicate its rapid IV administration. Because of the possible precipitation of third-degree atrioventricular block, an external cardiac pacemaker should be available when patients with conduction abnormalities receive IV PHT. Although fosphenytoin is safer than PHT if it extravasates, this agent does not have less cardiovascular toxicity. Fosphenytoin can also be used for intramuscular loading; PHT (pH 12) should not be administered intramuscularly because it produces myonecrosis.

The total PHT serum concentration should be kept in the "therapeutic" range of 10 to 20 μg/mL while the patient is in the ICU unless further seizures occur; the level may then be increased until signs of toxicity occur. If the patient is unable to express these signs (e.g., ataxia) because of his or her underlying condition or its treatment, failure to prevent seizures at a concentration of 25 μg/mL is usually an indication to add a second antiseizure drug (see later text). Although the usual goal of chronic antiseizure drug treatment is to administer the smallest dose of a tolerated single agent that completely controls seizures, such an approach is often impossible in the critical care environment. When the patient's condition is more stable, an attempt to decrease minor side effects or to convert to monotherapy may then be made.

PHT is normally about 90% protein-bound. Patients with renal dysfunction will have lower total PHT levels for a given dose

because the drug is displaced from its binding sites, but the "free" (unbound) level is not affected. Thus in patients with renal failure, and perhaps in others who are receiving highly protein-bound drugs (which will compete for PHT binding sites), it may be advantageous to measure free PHT levels. Because only the free fraction is significantly metabolized, the dose need not be altered with changing renal function. Calculations of the unbound concentration based on the serum albumin concentration are unreliable. The half-life for PHT clearance in patients with normal liver function varies from about 20 hours for the IV form and the oral solution to more than 24 hours for the extended-release oral capsules. Hence, a new steady-state serum concentration will take 4 to 6 days to establish. The drug need not be given more often than every 12 hours; the dosage interval for the enteral forms depends on the preparation but may be even longer. Hepatic dysfunction will mandate a decrease in the maintenance dose; if the serum albumin is very low, the loading dose can be reduced as well.

Hypersensitivity to PHT is the major adverse effect of concern to the intensivist. This allergy may be manifested solely as fever, but more commonly it includes a rash and eosinophilia. Febrile reactions appear to be more common with IV than with enteral loading. The Stevens-Johnson syndrome occurs rarely. The diagnosis and management of adverse reactions to PHT and other antiseizure drugs have been reviewed.[50] PHT is associated with a number of long-term adverse effects, and prophylactic administration in the

• **Fig. 62.2, cont'd**

setting of intracerebral hemorrhage, subarachnoid hemorrhage, or traumatic brain injury is not advised because of its association with worsening outcomes.[51–53] In these settings, levetiracetam may serve as a better choice. Valproate should be avoided in settings in which liver disease or hyperammonemia may be problematic but is otherwise a useful drug available both orally and intravenously. A loading dose of 30 mg/kg is reasonable, followed by a maintenance dose of 30 to 60 mg/kg per day.

The place of the newer antiseizure drugs in critical care is not well established. Levetiracetam has gained substantial popularity because of its limited drug interactions as well as benign side effect profile; it is predominantly excreted by the kidney, so the dose must be adjusted in renal insufficiency. The usual dose for seizure prevention is between 500 and 1500 mg/day, although doses up to 6 g/day have been used. The role of serum concentrations for assessment of efficacy or toxicity is not yet established. Lacosamide is also available intravenously and is started at a dose of 200 mg twice daily.

Phenobarbital (PB) (10- to 20-mg/kg loading dose, followed by an initial maintenance dose of 1.5 mg/kg per day) remains useful as an antiseizure drug for patients who cannot tolerate other antiseizure drugs, or for those who have breakthrough seizures after *adequate* PHT loading. The target level for PB in ICU patients should be 20 to 40 µg/mL. Either hepatic or renal dysfunction may affect PB metabolism. The half-life for PB clearance is about 96 hours. Thus maintenance doses of this agent need be given only once a day, and a steady-state level will take about 3 weeks to be established. Sedation is the major adverse effect; allergy is rare.

Carbamazepine, one of the most useful chronic antiseizure drugs, is seldom introduced to critically ill patients because its insolubility

has precluded a parenteral formulation. Oral loading with carbamazepine in conscious patients may produce coma lasting several days. It should be recalled as a cause of hyponatremia in patients receiving it chronically.

Status Epilepticus

The patient in GCSE has an obvious medical emergency; unfortunately, the NCSE patient also requires emergent treatment but is less straightforward to recognize. In a patient with any of these conditions, the clinician must move quickly to stop seizures to prevent further brain destruction.[54] A suggested management protocol for these conditions is presented in Box 62.3, and Fig. 62.3 shows a management algorithm for SE. Patients with focal SE without impaired awareness appear to be at substantially less risk of developing widespread cerebral damage and also appear less likely to respond to the aggressive approach outlined in Box 62.3. In this group, correction of underlying metabolic derangements is most important. Of the available antiseizure drugs, PB and benzodiazepines seem most likely to be efficacious.

Some frequent errors in the use of medications to terminate SE include (1) use of inadequate doses of potentially effective agents and, conversely, (2) continued administration of drugs that are ineffective in the patient being treated. The first point most frequently applies to PHT; the proverbial "gram of Dilantin" is not adequate for patients weighing more than 50 kg.

• BOX 62.3 Suggested Therapeutic Sequence for Terminating Status Epilepticus

I. Recognize SE, which is defined as at least 5 min of persistent generalized, convulsive seizure activity or two or more seizures within 15 min, between which there is incomplete recovery of consciousness.

II. Airway, breathing, circulation
Often the most rapid way to ensure airway protection is to rapidly terminate SE. If endotracheal intubation under neuromuscular junction blockade is necessary, use a nondepolarizing agent. If increased intracranial pressure is a concern, premedicate with lidocaine (1 mg/kg). The patient should be considered to still be in SE until neuromuscular transmission is reestablished, or until an EEG demonstrates that SE is no longer present.
If the patient is hypotensive, begin volume replacement and/or vasoactive agents as clinically indicated. Hypertension should not be treated until SE is controlled, because terminating SE will usually substantially correct it, and many of the agents used to terminate SE can produce hypotension.

III. Unless the patient is known to be normoglycemic or hyperglycemic, administer dextrose (1 mg/kg) and thiamine (1 mg/kg).

IV. First-line benzodiazepine
1. Administer LRZ 0.1 mg/kg. Dose may be repeated every 5 minutes if seizures persist. Most adult patients who will respond will have done so by a total dose of 8 mg.
2. If SE persists or if the patient does not have proper intravenous access, administer MDZ 0.2 mg/kg (IV or IM; 10 mg maximum per dose).

NOTE: Be cognizant of the potential of these drugs to eliminate the visible convulsive movements of GCSE while leaving the patient in NCSE. Patients who do not begin to respond to external stimuli 15 minutes after the apparent termination of GCSE should be considered at risk for NCSE and undergo emergency EEG monitoring.

V. Second-line anti-seizure drug
Administration of a second-line agent after the initial benzodiazepine dose is recommended even if the patient's convulsions have ceased. Options include the following:
1. Fosphenytoin 20 mg/kg (150 mg/min maximum rate)
2. Phenytoin 20 mg/kg (50 mg/min maximum rate)
3. Phenobarbital 20 mg/kg
4. Valproic acid 30 mg/kg
5. Levetiracetam 15 mg/kg (add-on agent once previous options are used)
6. Lacosamide 200 mg (add-on agent once previous options used)

VI. Refractory status epilepticus is defined as ongoing seizure activity that does not terminate with a first-line benzodiazepine and second-line antiseizure agent. In these instances, intubation, ICU transfer, and continuous EEG monitoring are indicated, as well as initiation of a third-line anesthetic agent such as the following:
1. Midazolam 0.2-mg/kg loading dose followed by a maintenance infusion at a rate of 0.05–2 mg/kg per h
2. Propofol 50–250 μg/kg per min loading dose followed by a maintenance infusion at a rate of 5–60 μg/kg per min
3. Pentobarbital 12-mg/kg loading dose followed by a maintenance infusion at a rate of 0.25–2 mg/kg per h

NOTE: Initiation of a sedative drip will require mechanical ventilation if the patient has not yet been intubated. Higher doses of these sedative agents may be needed in certain clinical situations. With any breakthrough seizure requiring uptitration of sedative drips, second-line antiseizure drug therapeutic levels should be maximized or another antiseizure drug should be added. Slow sedative taper should be initiated once the patient is seizure-free for more than 24 h.

VII. Patients with ongoing electrographic seizure activity that is not terminated by a first-line benzodiazepine, a second-line antiseizure drug, and a third-line anesthetic infusion are classified as having superrefractory status epilepticus. In these rare cases, initiation of any of the following fourth line therapies is recommended:
1. Ketamine 1- to 5-mg/kg loading dose (may repeat every 5 min up to 3 times) followed by a maintenance infusion at a rate of 1.5–5.0 mg/kg per h (higher doses may be needed in certain clinical situations)
2. Addition of other nonconventional antiseizure drugs (topiramate, clonazepam, clobazam, vigabatrin)
3. Immunotherapy (methylprednisolone, IV immunoglobulin, plasma exchange)
4. Ketogenic diet (with assistance of nutrition services)

VIII. Treat complications.
1. Rhabdomyolysis should be treated with a vigorous saline solution diuresis to prevent acute renal failure; urinary alkalinization may be a useful adjunct. If definitive treatment of GCSE takes longer than expected because of hypotension or arrhythmias, neuromuscular junction blockade under EEG monitoring might be considered.
2. Hyperthermia usually remits rapidly after termination of SE. External cooling usually suffices if the core temperature remains elevated. In rare instances, cool peritoneal lavage or extracorporeal blood cooling may be required. High-dose pentobarbital generally produces poikilothermia.
3. The treatment of cerebral edema secondary to SE has not been well studied. When substantial edema is present, SE and cerebral edema are likely to be manifestations of the same underlying condition. Hyperosmolar agents may be valuable if edema is life-threatening. Edema owing to SE is vasogenic, so steroids may be useful as well.

Specific Agents

Benzodiazepines

A study in the Veterans Affairs medical system compared LRZ, diazepam followed by PHT, PHT alone, and PB as first-line agents and demonstrated that LRZ is the definitive agent of first choice for terminating SE.[55] The advantages of LRZ over PHT include (1) its longer duration of action against SE (4–14 hours as opposed to 20 minutes) and (2) a higher initial response rate.[56] One study concluded that children receiving PHT for SE were far more likely to require intubation for ventilatory failure than comparable children receiving LRZ[57]; the same was true for all ages in the San Francisco Prehospital Status Study.[58]

Recently the Rapid Anticonvulsant Medication Prior to Arrival Trial (RAMPART) showed intramuscular midazolam (MDZ; 10 mg) to be as effective as IV lorazepam in the prehospital treatment of seizures, and this agent should be highly considered in patients with seizures who do not have IV access.[59] MDZ is also exceptionally useful for RSE, but it is hampered by tachyphylaxis,[60] which occurs because the $GABA_A$ receptors bearing benzodiazepine-sensitive subunits are removed from the neuronal cell membrane and replaced with receptors bearing benzodiazepine-insensitive ones.[61] Respiratory depression is the major adverse effect of all agents in this class when administered intravenously.

Hydantoins

PHT is an effective anti-SE agent but cannot be delivered rapidly enough to be used as a first-line agent. Its major advantage is a very long duration of action once an adequate dose has been administered (the 20-mg/kg loading dose reliably produces a total serum concentration above 20 µg/mL for 24 hours). Concerns about its IV administration were discussed earlier. If the patient is no longer in SE during PHT administration, a slower rate should be used.

PHT is highly insoluble, and it must be dissolved in sodium hydroxide and propylene glycol at a pH greater than 11 to remain in solution. Therefore extravasation can produce severe necrosis. The drug can also cause thrombophlebitis, which may result in the "purple glove syndrome."[62]

Fosphenytoin is a PHT prodrug, which is converted to PHT by phosphatases with a half-life of about 7 minutes. It is prescribed in "PHT equivalents," so the loading dose remains 20 mg/kg. The maximal recommended rate of infusion is 150 mg/min, but it should be started more slowly and increased to this rate if tolerated. Because it is water-soluble, extravasation does not pose the problem of skin and soft tissue necrosis. Hydantoins should not be used in absence SE, as they may worsen the condition.

Barbiturates

PB has long been one of the major anti-SE agents. Some advocate it as a first-line drug,[63] but it is rarely used in this role. It has classically been a third-line agent for control of SE, after a benzodiazepine and PHT. Its utility in SE is diminished by the length of time required to obtain a therapeutic effect in patients for whom treatment with a benzodiazepine and PHT has failed. It remains an important agent in patients with focal motor SE and in preparing patients for withdrawal from high-dose pentobarbital. It is important to note that, although barbiturates also act on $GABA_A$ receptors, they prolong the duration of chloride channel opening, in contrast to benzodiazepines, which increase the frequency of channel opening. Thus their combination should not be discredited, as their collaborative GABAergic actions may assist in terminating seizures.

Pentobarbital and thiopental are commonly reserved for the control of refractory SE, although thiopental is not currently available in the United States. Although these agents are effective if used in large enough doses, side effects often limit their use[64] or may even be fatal.[65] They are important when other rapidly available modalities have failed (see Box 62.3).

Valproate

Intravenous VPA, given in a dose of 20 to 30 mg/kg, has gained popularity for the treatment of SE because it does not produce respiratory depression or marked sedation. It has been successful in case series[66,67] but has not been directly compared to the other available agents. Hypotension may occur with large doses.[68] This drug should be avoided if the patient has an inborn error of metabolism affecting the liver, as it may precipitate fulminant hepatic failure.[69] VPA has a number of drug interactions that limit its utility in the ICU.[70]

Propofol

Propofol has been reported effective in RSE in doses up to 250 μg/kg per minute.[71] It offers more rapid recovery of consciousness after the agent is stopped compared with MDZ therapy, regardless of the duration of infusion.[72] We use it in RSE patients in whom MDZ therapy has failed or those who become resistant to MDZ.[73] A randomized trial found propofol to have the same efficacy as barbiturate therapy for RSE and significantly shorter length of mechanical ventilator days.[74] One should observe for evidence of the propofol infusion syndrome and stop the drug should a metabolic acidosis, hypertriglyceridemia, or evidence of muscle injury develop.

Levetiracetam

Although there are no randomized trials evaluating its efficacy, levetiracetam is frequently used as a second-line agent in seizure control. It is available for IV use, but its role in SE remains to be established. Although some retrospective studies have found it to have a higher failure rate than traditional drugs such as VPA for the treatment of RSE, its lower risk of side effects and drug interactions at times makes it a more desirable medication.[75] Levetiracetam exerts its antiseizure actions via binding of the synaptic vesicle protein 2, decreasing the rate of synaptic vesicle exocytosis in the CNS.[76,77] The effective dose in adults is reported to be between 1 and 6 g/day.[78] Oral administration may be useful for maintenance.[79]

Lacosamide

Lacosamide, which is available for both IV and oral use, is typically started at 200 mg twice daily and may be increased to 400 mg twice daily if needed.[80] Although prior studies with small sample sizes have provided mixed results regarding the benefits of adding IV lacosamide as a fourth-line agent in the treatment of RSE, larger prospective studies have shown a seizure termination rate of up to 76%.[81,82] It should be avoided in patients with atrioventricular block, and electrocardiogram studies should be checked before and after administration to evaluate for PR interval prolongation.

Ketamine

Although only anecdotes and small case series are available, ketamine appears to be a useful agent for the termination of RSE and SRSE.[83] Its NMDA blocking effect distinguishes it from the other agents discussed here, and it carries theoretical advantages in terms of brain protection.[84] Its antagonistic actions on NMDA receptors should be highly considered for the treatment of RSE or SRSE when other GABAergic medications are failing. Its intrinsic sympathomimetic effect makes it a useful choice in hypotensive patients, and it does not markedly impair ventilation. The appropriate dose in SE has not been established; we use a loading dose of 1 to 5 mg/kg, with an infusion rate of 1.5 to 5 mg/kg per hour.

Isoflurane and Desflurane

The inhalational anesthetics isoflurane and desflurane are effective in controlling RSE, but the difficulties involved in delivering the gases (such as the requirement for an anesthesia machine) and the need for a gas scavenging system have essentially confined their use to the operating suite or the recovery area.[85] Advances in delivery systems may make their use in the ICU more reasonable, but long-term use is potentially hepatotoxic.

Immunosuppressants

No etiology for RSE can be found in up to half of patients, for whom the term "new-onset RSE of unknown etiology" has been coined. Up to 37% of these patients are now recognized to have an autoimmune or paraneoplastic cause for their condition.[86,87] Early immunotherapy, unless contraindicated, should thus be considered in patients with new-onset RSE of unknown etiology and should not be delayed pending autoimmune antibody results if the suspicion exists. Although these situations of patients sometimes seem hopeless, it is important to remember that 35% will return to their premorbid level of function.[88]

Hypothermia

The recent HYBERNATUS (Hypothermia for Brain Enhancement Recovery by Neuroprotective and Anticonvulsant Action after Convulsive Status Epilepticus) study showed that addition of hypothermia to 33°C for 24 hours for the treatment of SE did not improve outcomes when compared to standard of care in French hospitals.[89] However, some experts advise a trial of mild hypothermia (32°C to 36°C) on a case-by-case basis as a therapeutic option for RSE.[90]

Controversial Management Issues

Controversy remains regarding the long-term neurologic consequences of periodic lateralized epileptiform discharges (PLEDs). PLEDs are an EEG phenomenon usually seen in the setting of large acute strokes or rapidly expanding mass lesions (e.g., tumors or abscesses). Less commonly, acute metabolic or toxic disorders will "reactivate" PLEDs in the vicinity of an old lesion. The EEG activity signifies the repetitive, synchronous firing of large numbers of neurons near the lesion; there is occasionally contralateral myoclonic jerking of the hand or face. Expert opinion is divided regarding the possibly epileptic nature of these phenomena. Patients who have clinical seizures (i.e., other than the myoclonic jerks) should receive antiseizure drugs. The myoclonic movements associated with PLEDs are difficult to suppress without resorting to high-dose barbiturates or benzodiazepines.

Another area of contention concerns the epileptiform discharges frequently seen after respiratory or cardiac arrests. Although certain EEG findings can assist with prognostication, multiple studies have now shown that SE (including myoclonus) is not a definite sign of poor prognosis in patients treated with hypothermia and experts recommend that it be treated aggressively when encountered.[91–94]

Prognosis

Wijdicks and Sharbrough reported that 34% of patients experiencing a seizure in any ICU at the Mayo Clinic died during that hospitalization.[20] In our prospective study of neurologic complications in

medical ICU patients,[1] having even one seizure while in the unit for a nonneurologic reason doubled the patient's in-hospital mortality rate. This effect on prognosis appeared to be due to the effect of the cause of the ictus, rather than the seizure itself.

Three major factors determine the outcome of SE: the type of SE, its cause, and its duration. In general, GCSE carries the worst prognosis for neurologic recovery as a consequence of SE itself. Focal nonmotor SE produces some risk of limbic system damage, usually manifested by memory dysfunction. Focal motor SE may produce neuronal damage, but this is difficult to discern from the effect of the lesion that commonly produces this form of SE. At the far end of the spectrum, absence SE does not seem to carry a risk of neurologic deterioration.

Most studies of SE outcome have concentrated on mortality rates in GCSE. Hauser[17] summarized the data available in 1990, showing mortality rates for SE to vary from 1% to 53%. The few studies that attempted to distinguish the mortality rate caused by SE from that of the underlying disease attributed rates of 1% to 7% to SE and 2% to 25% to its cause. The Virginia Commonwealth University population-based studies have analyzed the mortality risks for various aspects of GCSE.[25] SE lasting longer than 1 hour was associated with a 10-fold increase in mortality rate compared with SE lasting less than 1 hour. Other causes associated with marked increases in mortality rate were anoxia, intracranial hemorrhages, tumors, infections, and trauma. Independent factors associated with poor outcome in RSE include age older than 60 years, coma on presentation, and longer duration of anesthetic-induced coma,[95,96] whereas early seizure termination is associated with good outcomes.[97]

Very few findings are available regarding the functional status of GCSE survivors, and none reliably allows a distinction between the effects of SE and its causes. A review of intellectual impairment as an outcome of SE concluded intellectual abilities probably did decline as a consequence of SE.[98] Survivors of SE frequently have memory and behavioral disorders out of proportion to any structural damage produced by the cause of their seizures. This observation is supported by a wealth of experimental data and argues strongly for the rapid and effective control of SE.

The effect of the treatment of SE on the risk of subsequent epilepsy is uncertain. Experimental studies suggest that SE does lower the threshold for subsequent seizures.[99]

Key Points

- Primary generalized seizures arise from the entire cerebral cortex without evidence of focal point.
- SE is defined as 5 or more minutes of continuous seizure activity or seizure activity without return to baseline.
- NCSE should be suspected in any patient with GCSE who does not begin to awaken within 20 minutes.
- In addition to damaging the CNS, GCSE produces serious, often life-threatening, systemic effects that include cardiovascular, respiratory, and muscular systems.
- LRZ is the definitive agent of first choice for terminating SE.
- Hypersensitivity to PHT is the major adverse effect of concern to the intensivist. This allergy may be manifested solely as fever but more commonly includes a rash and eosinophilia. Rarely Stevens-Johnson syndrome occurs.
- Patients who have seizures during ethanol withdrawal will probably not benefit from chronic antiseizure drug treatment, and the administration of PHT will not prevent more withdrawal convulsions during the same episode.
- Errors in the use of medications to terminate SE include (1) use of inadequate doses of potentially effective agents and, conversely, (2) continued administration of drugs that are ineffective in the patient being treated.
- Seizures lasting longer than 1 hour markedly increase mortality risk compared with seizures lasting less than 1 hour.
- Myoclonic SE in the era of postarrest therapeutic hypothermia no longer carries a definite poor prognosis and SE in this setting should be treated aggressively.

Review Questions

1. A 69-year-old man presents to the emergency department after three witnessed generalized tonic-clonic seizures that began 1 hour before arrival. Although he is no longer having convulsions, the patient has not yet returned to his baseline level of mentation. Which of the following medications should be the first-line therapy for this patient?

a. Diazepam 5 mg IV
b. Levetiracetam 1500 mg IV
c. Lorazepam 0.1 mg/kg IV
d. Phenytoin 20 mg/kg IV

Answer: c. The patient has had three seizures with no improvement in his mentation, meeting criteria for status epilepticus. The Veterans Affairs Status Epilepticus Cooperative Study confirmed lorazepam to be the most effective agent in terminating seizures compared with diazepam or phenytoin. Levetiracetam has not yet been shown as an effective first-line agent in terminating status epilepticus (SE).

2. An 82-year-old female nursing home resident with a history of chronic renal insufficiency, hypertension, and atrial fibrillation has been admitted to the intensive care unit (ICU) for treatment of pneumonia. The patient required intubation on presentation for hypoxemic respiratory failure. She has received 3 days of antibiotics with resolution of fevers, leukocytosis, and she has now been successfully weaned from vasopressor support. On hospital day 3 she has not yet awakened after sedatives have been discontinued for more than 24 hours. Which of the following most significantly increases her risk of nonconvulsive SE?

a. Chronic renal insufficiency
b. Elderly age
c. Administration of vancomycin
d. Septic shock

Answer: d. Although Oddo and colleagues[12] found chronic renal failure to be a risk factor for subclinical seizures in medical ICU patients, multivariate analyses revealed septic shock to be the only independent predictor, with up to 32% of these patients having abnormal continuous electroencephalograms (cEEGs). Antibiotics associated with lowering of seizure threshold include penicillins, carbapenems, and cefepime.

3. A 25-year-old woman has been admitted to the ICU for management of refractory SE. She is otherwise healthy, but she began experiencing personality changes 2 weeks before presentation. She experienced her first generalized tonic-clonic seizure 2 days ago and has progressed to nonconvulsive status epilepticus on cEEG refractory to benzodiazepines, phenytoin, phenobarbital, levetiracetam, and a propofol infusion. Her head computed tomography (CT) scan on admission showed no acute or chronic abnormalities and results of toxicology screens were negative. Which of the following studies should be performed next?

a. Cerebral spinal fluid (CSF)
b. Magnetic resonance imaging (MRI) of the brain
c. CT chest/abdomen/pelvis
d. Psychiatry evaluation

Answer: a. This patient is experiencing new-onset refractory SE of unknown etiology. The preceding psychiatric symptoms suggest a limbic phenomenon. Although an MRI brain scan could show medial temporal abnormalities suggestive of autoimmune limbic encephalitis, it is important to rule out any infectious etiology such as herpes encephalitis before initiating immunosuppressive therapies such as steroids. An autoimmune encephalitis antibody panel should also be sent from the CSF as well as serum, but immunotherapy should not be delayed pending these studies, which can take up to 3 weeks for results.

Head Injury

ALAN R. TURTZ AND JAMES C. BARRESE

CHAPTER OUTLINE

Incidence

Diagnostic Approach
- Glasgow Coma Scale
- Computed Tomography

Primary Head Injury
- Skull Fractures
- Epidural Hematoma
- Subdural Hematoma
- Traumatic Subarachnoid Hemorrhage
- Intraparenchymal Contusions and Hematomas
- Hypothalamic-Pituitary Injury
- Diffuse Axonal Injury
- Penetrating Brain Injury

Secondary Head Injury
- Basic Concepts
- Cerebral Blood Volume
- Brain Compartment
- Cerebrospinal Fluid Compartment

Specific Treatment Considerations
- Decompressive Craniectomy
- Management of Intracranial Hypertension
- Anticoagulation
- Seizure Prophylaxis
- Nutritional Support
- Role of Steroid Therapy

Conclusions

In the context of critical care medicine, the management of severe head injuries remains the Achilles' heel of neurosurgery, as borne out by our observations over 25 years of practice in academic Level I trauma centers. The search for neuroprotective and neuroregenerative treatments that can consistently prevent or reverse the devastating cascade of events that leads to irreparable brain damage remains for future investigators as of this writing.

Key to optimizing clinical outcomes has been the recognition that the time from injury to surgery must be as short as possible to minimize the secondary manifestations of serious brain trauma in patients with surgical lesions. The operating room is where patients with significant mass effect and shift are initially managed. The critical care unit is where all patients with severe traumatic brain injury (TBI) are managed, with or without surgery, in an effort to optimize cerebral blood flow (CBF), oxygenation, and metabolism.

The management of serious brain trauma requires specialty teams consisting of experienced neurosurgeons, traumatologists, intensivists, and neurointensivists working together in a dedicated unit equipped and staffed to optimally care for these patients. In the absence of such facilities, outcomes suffer.[1–3]

Throughout this chapter, the 2016 updated guidelines from the Brain Trauma Foundation (BTF) are noted at the time of this writing. These BTF guidelines are intentionally based on the limited studies with relatively high levels of scientific evidence. This approach results in focused conclusions that can be limited by study design and are, therefore, carefully worded to reflect the specific methodology of the study used to support a specific recommendation. Conversely, and equally important, is that the absence of a recommendation is based on the absence of sufficient evidence, so it is important to remember the maxim: absence of proof is not necessarily proof of absence.

Incidence

The Centers for Disease Control and Prevention report the number of patients sustaining a TBI to be at least 2.5 million per year in the United States.[4] Approximately 80% of patients are released from the emergency department, 275,000 are admitted, and 52,000 die. Nearly a third of all traumatic deaths in the United States involve a head injury. The ages most likely to sustain a TBI are children up to 4 years old and adults older than 64 years of age, with adults older than 74 years having the highest rates of hospitalization and death associated with head injury.[5] Teenagers and young adults continue to be at high risk for sustaining TBI, but the age range has decreased over time from between 15 and 24 years to between 15 and 19 years of age.[5,6] The incidence of head injury has been shown to be inversely proportional to economic status[7] and has remained up to three times more common in males in every age group over time.[5,8,9] In the United States, falls are the most common cause of TBI and are responsible for half of children up to 14 years of age who sustain head injuries and 60% of the adults older than 64 years.[5] Although the frequency of head injury related to motor vehicle crashes has decreased over the years to a little less than 20%, these crashes are the second leading cause of head injury in all age groups and result in the largest percentage of TBI-related deaths.[5,10] The incidence of TBI worldwide is difficult to quantify but is estimated to be at least 10 million people a year, with traffic accidents accounting for more than half and falls being the second leading cause[11]; this is the opposite of the distribution seen in the United States.[5] Violence is estimated to cause about

10% of head injuries throughout the world[11] as well as in the United States,[5] but there is significant variability in the specific mechanisms. For example, between 1997 and 2007 in the United States, firearms were related to just over a third of all violent, lethal TBIs compared with a single hospital in South Africa that reported its experience with more than 300 stab wounds to the brain.[12]

Diagnostic Approach

The presenting neurologic condition of patients with head injuries is the primary factor in determining the initial management and prognosis. When a detailed history is unavailable, it is important to keep in mind that loss of consciousness may have preceded and possibly caused the traumatic event, such as aneurysmal subarachnoid hemorrhage (SAH), hypoglycemia, intoxication, or syncope. Level of consciousness is one of the most important neurologic considerations in managing a patient with a head injury. Neurosurgical patients generally have an alteration in level of consciousness from either brainstem or bilateral cerebral hemispheric involvement. This may be secondary to poor perfusion owing to high intracranial pressure (ICP) or brainstem compression, both of which require emergent intervention either in an operating room or an intensive care unit (ICU). Therefore an accurate tool to measure level of consciousness is essential. Many clinical assessment tools are available for use in the critical care setting.[13–25]

Glasgow Coma Scale

Ideally, using the Glasgow Coma Scale (GCS), a nurse, medical student, paramedic, physician assistant, intensivist, trauma surgeon, emergency medicine physician, neurologist, and neurosurgeon all should obtain the same score when assessing a patient. The GCS system is not perfect, but it has proven itself to be, overall, a practical, straightforward grading system that can be used by health care professionals in various fields and at different levels of experience to produce reliable results.[26–31] The GCS has become the most widely used assessment tool and is considered the gold standard for the clinical evaluation of patients with head injuries.[13]

The GCS is a measure of level of consciousness and does not take into account focal deficits. It is based on eye opening (1–4 points), verbal response (1–5 points), and motor response (1–6 points) (Table 63.1). A patient with a normal level of consciousness should have the highest possible score of 15. The lowest score possible is 3, not 0 as might be expected. It is important to identify the score for each observed variable tested: E + V + M = GCS (where E denotes eye opening, V is verbal response, and M is motor response). Commonly, an intubated patient gets a 1 for verbal response and is assigned 1T (for Tube) for the verbal score. However, the American College of Surgeons (ACS) recommends that if a GCS component is untestable because of intubation, sedation, or another confounder, the reason for this should be recorded. The ACS suggests that a score of 1 should not be assigned because differentiation between a "true 1" and an untestable component is relevant.[32]

The GCS attempts to assign a numeric value to level of consciousness; a score of 15 is representative of normal. Therefore it is important to realize the shortcoming of this system in evaluating patients with dementia or aphasia. If a patient from a nursing home who has dementia presents with a normal level of consciousness after a fall but does not know what day it is, the GCS would be calculated as E4 + V4 + M6 = 14. A GCS score of 14 describes a patient with an abnormal level of consciousness but fails to accurately communicate this particular patient's condition. Likewise, clinicians must use caution when applying the GCS to patients with aphasia. Conversely, patients with profound focal deficits and a normal level of consciousness should have a GCS score of 15, illustrated by the case of a quadriplegic patient with a normal level of consciousness who is able to blink the eyes or stick out the tongue to command, thereby achieving a top score of 6 on the motor assessment.

TABLE 63.1 Glasgow Coma Scale

Component	Score
Eye Opening	
Spontaneously	4
To voice	3
To pain	2
No response	1
Verbal	
Oriented	5
Disoriented	4
Inappropriate	3
Incomprehensible sounds	2
No response	1
Motor	
Following commands	6
Localizing to pain	5
Withdrawing to pain	4
Abnormal flexion	3
Abnormal extension	2
No response	1

The GCS has been used to help predict outcome.[33] The motor score itself has predictive value as well.[34] The GCS score is best calculated after initial hemodynamic and pulmonary resuscitation and without sedatives or muscle relaxants, when clinically feasible[35] Aggressive implementation of early sedation and intubation in patients with severe head injuries compromises the ability to determine an accurate GCS score.[36]

Head injuries are typically classified as mild (GCS score 13–15), moderate (GCS score 9–12), or severe (GCS score 3–8), although there is debate that the GCS score of 13 should be in the moderate category.[37]

Computed Tomography

Computed tomography (CT) scanning is the diagnostic imaging study of choice in trauma. Plain x-ray films of the skull are rarely indicated as a screening study for patients with head injuries. Outcomes with the strategy of obtaining CT scans in all patients with head injuries are superior to those with other management strategies. The incidence of missed surgical lesions in patients with mild head injuries by CT scanning is as low as 0.028%.[38–41]

TABLE 63.2 Marshall Computed Tomography Classification

Category	Definition
Diffuse injury I (no visible pathology)	No visible intracranial pathology seen on computed tomography scan
Diffuse injury II	Cisterns are present with midline shift of 0–5 mm and/or: lesion densities present; no high or mixed-density lesion >25 cm^3; may include bone fragments and foreign bodies
Diffuse injury III (swelling)	Cisterns compressed or absent with midline shift of 0–5 mm; no high- or mixed-density lesion >25 cm^3
Diffuse injury IV (shift)	Midline shift >5 mm; no high or mixed-density lesion >25 cm^3
Evacuated mass lesion	Any lesion surgically evacuated
Nonevacuated mass lesion	High- or mixed-density lesion >25 cm^3; not surgically evacuated

From Marshall F, Marshall SB, Klauber MR, et al. A new classification of head injury based on computerized tomography. *J Neurosurg*. 1991;75:S14–S20.

TABLE 63.3 Prognostic Score Chart for Probability of Mortality in Patients With Severe or Moderate Traumatic Brain Injury by Computed Tomography Characteristics

Predictor	Score
Basal Cisterns	
Normal	0
Compressed	1
Absent	2
Midline Shift	
No shift or shift <5 mm	0
Shift >5 mm	1
Epidural Mass Lesion	
Present	0
Absent	1
Intraventricular Blood or tSAH	
Absent	0
Present	1
Sum Score[a]	+1

[a]The sum score can be used to obtain the predicted probability of mortality (see Table 63.4). The authors chose to add +1 to make the grading numerically consistent with the grading of the motor score of the Glasgow Coma Scale and with the Marshall computed tomography classification.
tSAH, Traumatic subarachnoid hemorrhage.

TABLE 63.4 Computed Tomography Classification by Prediction Score

Score	Mortality Rate (%)
1	0
2	6.8
3	16.0
4	26.0
5	53.0
6	61.0

A useful classification of brain injuries by findings on CT has been devised by Marshall and colleagues. This CT classification, presented in Table 63.2, can serve as a guide in describing scans and has strong predictive power.[36,42] Maas and associates have proposed a scoring system with better predictive power (Table 63.3), with a sum total adjusted to be consistent with the GCS.[36] Table 63.4 presents a mortality prediction chart based on this classification. This scoring system is best used as one piece of data in the overall clinical assessment in considering a patient's prognosis.[43] Severe brain injury outcomes can also be approximated using four variables: age, GCS score on admission (especially the motor score), CT characteristics, and the presence of ischemic and hemodynamic secondary insults. Using these four predictors, numerous investigators have used statistical modeling techniques to predict up to 80% or more of outcomes.[44]

Primary Head Injury

Primary head injury can be defined as the damage that occurs the moment an abrupt force affects the head and can take the form of skull fractures, contusions, lacerations, diffuse axonal injury, or vascular injury.[41] Some authors include the contusions and hematomas that blossom as a direct and immediate effect of the initial trauma as part of the primary injury as well.[45] These hemorrhages may develop significant mass effect requiring surgical intervention.

Management of a primary injury generally involves emergent neurosurgical intervention to limit secondary injury and prevent permanent damage to the central nervous system (CNS) in general and to the reticular activating system in particular. Located in the brainstem, the reticular activating system is what allows a meaningful, awake condition; if it is destroyed, the patient will be in a vegetative state.

The surgical management of patients with head injuries is typically driven by the presence of pathologic masses (hematomas) in anatomic spaces. These spaces are best described by reviewing the anatomic layers.

In most cases of head injury seen in neurosurgical practice, the pathogenic mechanism is an impact. The first layer involved is the scalp, the layers of which are best remembered by the pneumonic SCALP: S for *s*kin, C for *c*onnective tissue, A for galea *a*poneurosis, L for the *l*oose connective tissue layer, and P for *p*eriosteum. The scalp is the thickest skin in the body and absorbs some of the energy delivered to the head during impact. The scalp has a rich blood supply with relatively large blood vessels situated in the space where the connective tissue meets the galea aponeurosis. A large laceration has the potential for heavy blood loss and needs to be managed with local, direct pressure until surgical repair can be accomplished. Care must be taken in applying pressure if there is an underlying depressed skull fracture or defect, as is seen in

missile injuries. It should be noted that an unattended, serious scalp laceration does have the potential for enough blood loss to cause hemodynamic instability. This extracranial hemorrhage should be differentiated from an intracranial hemorrhage. An adult cannot lose enough blood volume from a contained intracranial hemorrhage to cause hypovolemia to the point of hemodynamic instability. Blood clots within the scalp usually are limited to the loose connective tissue layer and are referred to as subgaleal hematomas, which may be a feature of massive injuries or a sign of coagulopathy, but they rarely require treatment other than direct pressure if active bleeding is suspected. A cephalohematoma is a blood clot that expands in the potential space between the periosteum and the skull and is typically limited to neonates.

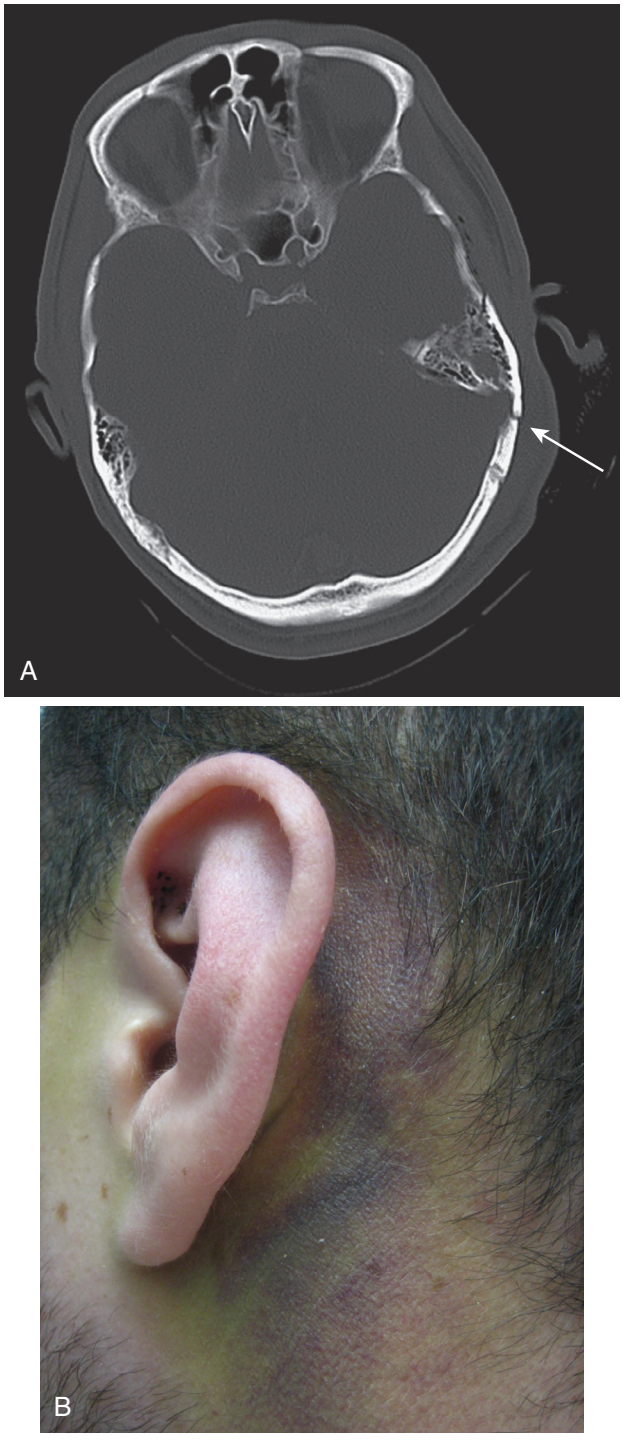
Skull Fractures

The next layer involved in trauma is the skull, composed of outer and inner tables with the intervening vascular diploic space. Skull fractures are best considered as involving the cranial vault or the skull base. Cranial vault fractures are further divided into linear or depressed, and open or closed. In general, closed linear fractures of the cranial vault do not require any specific treatment.

Basilar skull fractures are commonly linear and mostly involve the anterior cranial base and the petrous part of the temporal bone. Approximately 4% of significant head injuries include skull base fractures, with most (90%) the result of closed head trauma and the remainder involving penetrating trauma.[46] These fractures have the potential for an associated dural laceration adjacent to potentially contaminated paranasal sinuses, or the external ear canal if the tympanic membrane is disrupted. This allows the potential for a cerebrospinal fluid (CSF) fistula to develop, as well as meningitis. Clinical signs of a fracture of the petrous portion of the temporal bone include hemotympanum with or without tympanic membrane disruption, hearing loss, CSF otorrhea, and Battle sign. The cranial nerves that course through the temporal bone include the facial, acoustic, and vestibular nerves; therefore associated vestibular dysfunction or facial weakness may be noted (Fig. 63.1). Anterior cranial base fractures may be associated with "raccoon eyes," anosmia, and CSF rhinorrhea. It is important to remember that when a fracture of the floor of the anterior cranial base is suspected, a nasogastric tube should not be inserted because of the risk of intracranial penetration (Fig. 63.2).

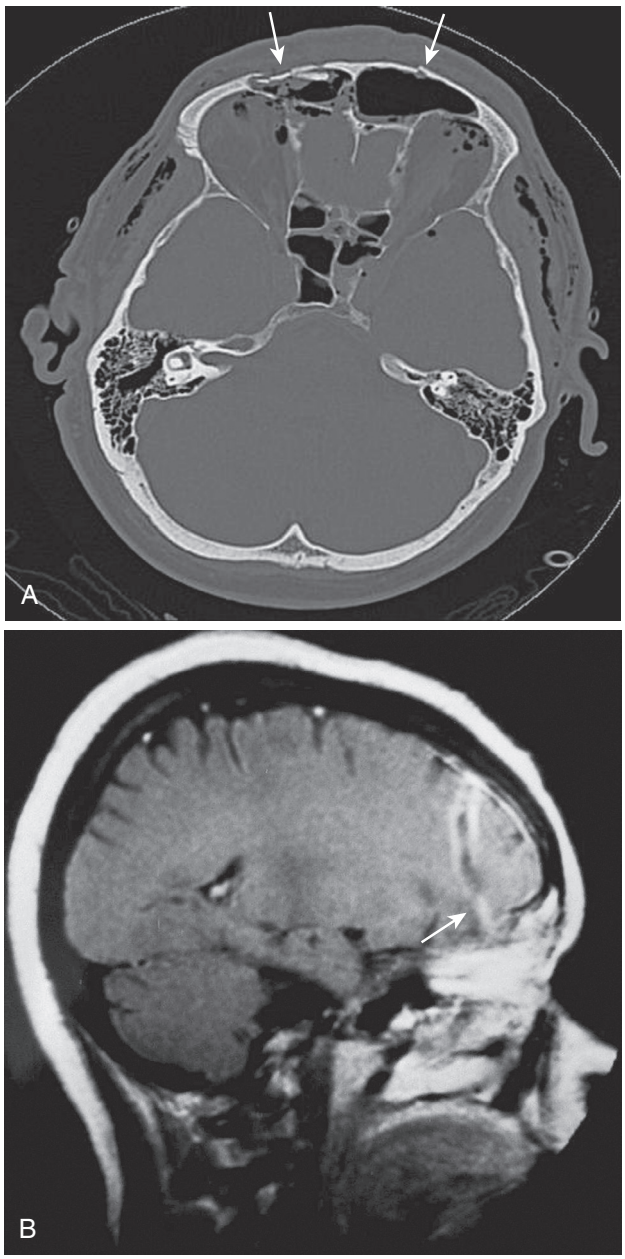
The use of prophylactic antibiotics in basilar skull fractures has been debated but generally is not recommended. A 2016 study of basilar skull base fractures observed associated CSF leaks in 15% and meningitis in less than 4% of patients. All cases of meningitis were in patients with a clinically evident CSF leak. The researchers concluded that there is no indication for prophylactic antibiotics in patients with skull base fractures.[46] When CSF leak does occur, the fistula will usually heal with conservative treatment over the course of a week, unless the defect is very large or a bony spicule is identified. Keeping the patient's head elevated and possibly using external CSF diversion after a few days are reasonable nonoperative methods; however, if the leak persists, surgical repair is indicated.[47]

Most depressed skull fractures occur in men younger than 30 years of age.[48] Despite little literature to support any particular management strategy, closed depressed skull fractures are generally operated on if the extent of depression is greater than the full thickness of the adjacent skull, with theoretical benefits of a decrease in late-onset posttraumatic epilepsy and a reduction in the incidence of persistent neurologic deficit, as well as an improved cosmetic result.[7] Many depressed skull fractures are open[48] (Fig. 63.3), meaning that a scalp laceration with galeal disruption overlying the fracture is present.



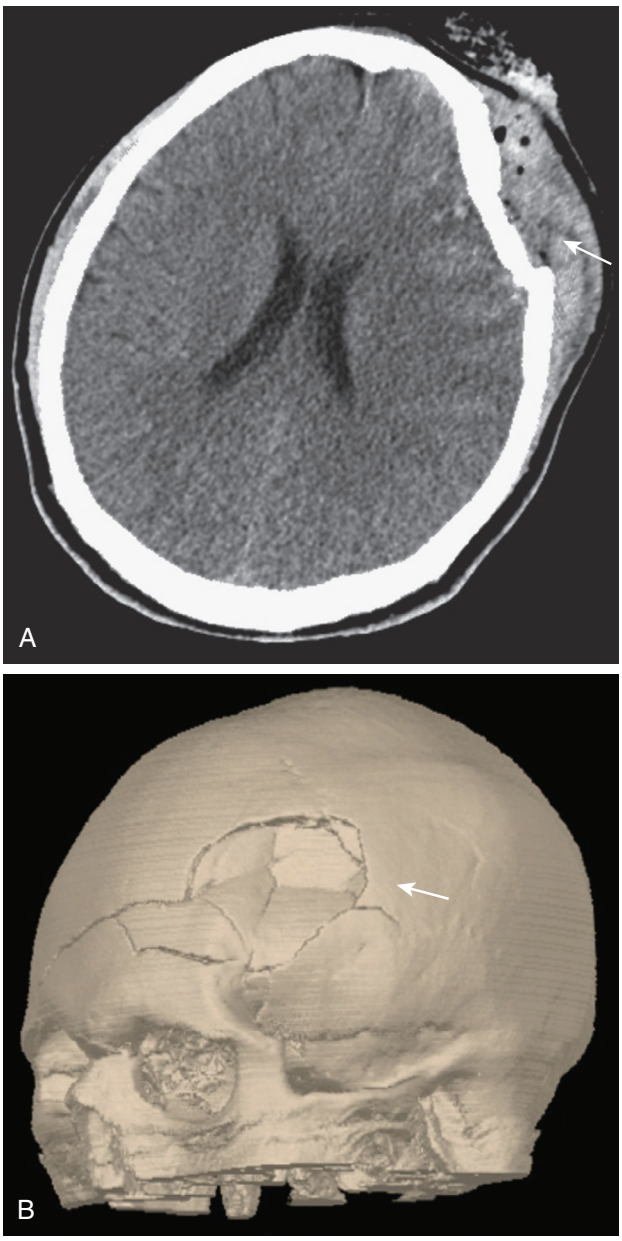
• **Fig. 63.1** A, Axial computed tomography image demonstrating skull base fracture *(arrow)* through the petrous portion of the temporal bone. B, Battle sign.

Open depressed skull fractures may be associated with significant morbidity and mortality.[48,49] Infection rates are reported to be between 1.9% and 10.6%,[49–53] with neurologic morbidity and mortality rates of approximately 11% each[50] and an incidence of late epilepsy up to 15%.[54]



• **Fig. 63.2** A, Preoperative axial computed tomography image demonstrates multiple anterior cranial base fractures involving the cribriform plate and posterior wall of the frontal sinus *(arrows)* in a 50-year-old man who fell off a ladder onto his face. The patient sustained minimal brain injury from the impact because the facial and anterior frontal sinuses absorbed much of the energy, cushioning the brain during impact, much like an air bag. B, Image from a preoperative sagittal T1 magnetic resonance imaging study without contrast demonstrates the tract of a nasogastric tube through the frontal lobe in a 42-year-old woman with an anterior cranial base defect *(arrow)*.

By convention, open depressed cranial vault fractures are treated surgically, with debridement and elevation, primarily to attempt to decrease the incidence of infection. Open depressed cranial fractures may be treated nonoperatively if clinical and radiographic examination reveals no evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination.[50]



• **Fig. 63.3** Depressed skull fracture. A, Brain window *(arrow)*. B, Computed tomography three-dimensional reconstruction also demonstrates the depressed skull fracture *(arrow)*.

A special type of depressed fracture involves the frontal sinus. Depression of the fracture may require surgery to prevent CNS infection and CSF leak (Fig. 63.4). Another special type of depressed fracture involves a major dural venous sinus (see Fig. 63.4). Under these circumstances, the risks associated with surgery are increased, and elevation of the fracture fragment generally is reserved for significant compromise of venous drainage.[47]

Epidural Hematoma

The next anatomic layer below the skull is the dura, which is the periosteum of the inner table of the skull and, as such, is tightly adherent to the bone. The potential space between the inner table of the skull and the dura is the *epidural space*. Epidural hematomas (EDHs) expand this potential space between the skull and the

• **Fig. 63.4** Depressed skull fracture requiring urgent decompressive surgery. The patient was a 32-year-old man hit on the back of the head by a metal beam at a construction site who presented with a deteriorating level of consciousness. A, Axial computed tomography scan demonstrates an open depressed skull fracture *(arrow)* at the level of the superior sagittal sinus (SSS) that extended down to the confluence of the transverse and SSS. B, Sagittal magnetic resonance venogram demonstrates occlusion of venous outflow *(arrow)* at the level of the fracture, which necessitated emergency surgical decompression and repair of the SSS.

dura. The most common mechanism for the development of an EDH is a motor vehicle crash (in 53% of the cases), followed by falls (30%) and assault (8%).[55–63] Typically bleeding results from damage to the middle meningeal artery, a dural vessel that runs half in the dura and half through a groove along the inner table of the skull. When a fracture extends across the bony groove of the artery, it can tear and bleed. An EDH also can occur from injury to the middle meningeal vein, diploic veins, or venous sinuses.[63]

EDHs generally occur in the temporal and temporoparietal regions (Fig. 63.5).[55,60,64–67] A useful way to describe the development of an EDH is to follow the clinical events that occur when a patient presents with a lucid interval following a brief loss of consciousness after head trauma. A lucid interval occurs when a patient initially is rendered unconscious from a concussive head injury that causes a linear skull fracture involving the middle meningeal artery with bleeding into the potential epidural space. Because the dura is tightly adherent to the inner table of the skull, significant force is needed to push the dura off the inner table. An arterial hemorrhage generally has enough pressure to strip the dura off the bone, converting the potential epidural space into a mass. The bony attachment of the dura becomes progressively stronger with age; therefore the dura of a younger patient requires less force to push off the bone than would be required in an older patient. Not surprisingly, the mean age of patients with an EDH is between 20 and 30 years of age,[56–58,66–73] and EDHs are unusual in patients older than 50 years.[63]

The growing epidural mass commonly compresses the anterior temporal lobe, which usually does not cause a major detectable neurologic deficit early in the course in the emergency department. During this lucid component of the lucid interval, the patient regains consciousness from the concussive injury while the EDH is expanding and compressing the clinically silent anterior temporal lobe. The medial part of the temporal lobe, the uncas, lies just lateral to the brainstem at the level of the third cranial nerve (oculomotor nerve), which runs alongside the tentorial edge. When the EDH enlarges to the point at which it pushes the uncas of the temporal lobe over the tentorial edge, rapid development of a third nerve palsy, along with brainstem compression, is possible. This may cause a contralateral hemiparesis from direct compression of the cerebral peduncle and a decrease in level of consciousness from the effect on the reticular activating system in the brainstem. The classic signs at this point are coma with a dilated pupil ipsilateral to the EDH and a contralateral hemiparesis. Occasionally, instead of directly compressing the ipsilateral cerebral peduncle, the herniating uncas can shift the brainstem itself into the contralateral tentorial edge, a relatively sharp rigid structure. This can damage the brainstem on the side opposite the EDH and cause a hemiparesis ipsilateral to the side of the hematoma. This is known as Kernohan notch phenomenon.

Taking a general view, the patient progresses from unconscious at the time of impact from a concussive injury, to awake, to unconscious again secondary to brainstem compression—hence the term *lucid interval*. The lucid interval is observed in close to half of the patients undergoing surgery for EDH.[a]

Pupillary abnormalities occur in approximately 20% to 30% of patients with surgical EDH.[55,57,62,63,70] Cranial fractures are present in between 70% and 95% of the cases.[b] Associated intracranial lesions are found in 30% to 50% of adults with surgical EDHs,[c] and subdural or parenchymal lesions in association with EDH lower the chance of a good outcome.[63]

The overall mortality rate (for all ages and GCS scores) is approximately 10%.[d] The time lapse between the onset of pupillary abnormalities and surgery determines outcome,[64,69,83] but the single most important predictor of outcome in patients who undergo

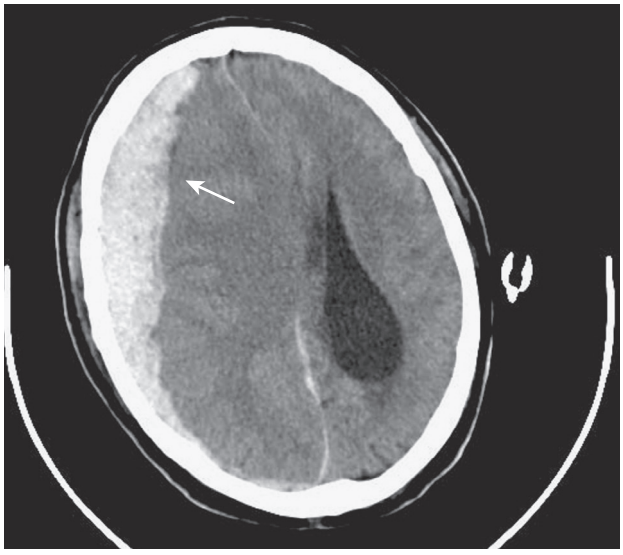
surgery for EDH is the GCS score on admission and before surgery.[55,56,58,64,84–86]

Not all EDHs, however, require surgery. No prospective randomized trials have been conducted to compare surgical treatment with nonoperative management, nor should there be. Available data describe nonsurgical management in selected cases. In one study, approximately 10% of the total number of EDHs were treated nonoperatively. All patients were conscious with a GCS score greater than 11 and a midline shift on CT scan of less than 10 mm. Not one of these nonoperative hematomas was in the temporal region.[87]

Another study reported findings in a group of 57 selected patients treated nonoperatively with an initial GCS score of 10 or higher, with maximum hematoma thickness less than 13 mm, with 5 clots located in the temporal region, but only one patient had a midline shift on CT.[56]

An interesting approach for dealing with thin, acute EDHs in an early stage has been reported in a small, isolated series of patients using endovascular techniques to occlude the middle meningeal artery.[88] Surgical decision making for an acute EDH is based on GCS score, pupillary findings, comorbid conditions, CT findings, age, and, in delayed decisions, ICP. Guidelines for the surgical management of acute EDH published in 2006 recommend surgical evacuation of an EDH greater than 30 mL in volume, regardless of GCS score. Smaller hematomas in patients with a GCS score greater than 8 and without focal deficits, clot thickness less than 15 mm, and less than 5 mm of midline shift may be considered for nonoperative management. Close neurologic monitoring and serial CT scanning are essential if a nonoperative approach is taken. Of importance, a temporal location for an EDH is associated with failure of nonoperative management and should lower the threshold for surgery.[63]

The time between neurologic deterioration and surgery is critical, and the question of whether a patient with an acute EDH should receive treatment at the nearest hospital or be transferred to a trauma center is important. The issue is whether or not a non-neurosurgeon should operate on a patient whose condition is deteriorating from an acute EDH is a true emergency. One suboptimally controlled study reported worse outcomes in a small group of patients who underwent emergency operations by non-neurosurgeons and attributed this mainly to the technical inadequacy of the operation.[62,63] Other studies have documented worse outcomes in patients transferred from outlying hospitals for surgery.[55,76] The take-home message is that EDHs are extra-axial hemorrhages located adjacent to the brainstem that can represent a true neurosurgical emergency, and that rapid, competent decompression makes a difference.



• **Fig. 63.6** Axial computed tomography scan demonstrating a typical acute subdural hematoma *(arrow)*. Note that the hematoma expands the subdural space and follows the contour of the brain as it generates severe extra-axial mass effect and shift.

Subdural Hematoma

Deep to the epidural space, below the dura, is the subdural compartment. Unlike the potential epidural space, the subdural compartment is a real space. It is a compartment that follows the contour of the brain, which is how it appears on a CT scan (Fig. 63.6). Anatomically, bridging veins course through the subdural space from the cerebral hemispheres to the superior sagittal sinus. As the brain accelerates within the skull, these veins can stretch and tear.[89] The source of bleeding can also be from a cortical artery[90,91] or vein.

These hematomas typically form over the surface or between the cerebral hemispheres, over the tentorium, or along the skull base.

Acute SDHs consist of clotted blood, which is fibrous and can be adherent to adjacent tissue. The blood remains clotted for several days. After this time, the clot gradually and progressively lyses, resulting in a mixture of clot and fluid as it transitions to the subacute phase. After several weeks, the clot is fully liquefied and becomes a chronic SDH. Chronic SDHs may manifest weeks or months after what may have been mild or insignificant trauma. Chronic SDHs occur more often in elderly patients and individuals who have more of a subdural space because of cortical atrophy. A membrane often surrounds these hematomas, and the collection of fluid may slowly grow in size because of repeated small bleeds or accumulation of fluid transudate from the membrane.[89]

The incidence of acute SDHs is approximately 20% in severe TBI,[63,92–95] and the mean patient age is between 31 and 47 years, with most patients being men.[63,96–99] The mechanism of injury differs between age groups, with patients older than 65 years more commonly presenting after a fall and younger patients more often being involved in a motor vehicle crash,[63,100–102] which, among comatose patients with acute SDH, is the most common mechanism of injury.[63,93,95,103]

Between 37% and 80% of patients with acute SDH present with a GCS score of 8 or lower,[a] and the overall mortality rate is between 40% and 60%.[b] Mortality rates among comatose patients requiring surgery are somewhat higher, with reported rates between 57% and 68%.[c] Acute subdural hematomas are frequently associated with other brain injuries,[99,104] which is one of the reasons why the mortality rate is relatively high.

A simple acute SDH is a subdural, extra-axial hematoma without any other associated brain injury (Fig. 63.7). A complex SDH is associated with parenchymal injury (Fig. 63.8).[109,110] Fewer than half of acute SDHs requiring surgery are isolated, simple lesions.[63,99,104]

One useful method to identify the presence of associated injury is to measure the thickness of the subdural clot relative to the amount of brain shift on the CT scan. If the amount of shift is directly proportional to the thickness of the extra-axial clot, the injury is likely to be simple and the brain simply compressed. However, if the amount of shift is more than expected as indicated by the size of the hematoma, then additional parenchymal brain injury probably is present under the clot, causing additive mass effect. Not surprisingly, the mortality for complex injuries is higher than that for simple SDHs.[109,110]

In addition to the obvious compressive effects that an SDH generates, the available evidence points to a direct toxic effect of the blood itself on the underlying cortex, potentially compounding the problem.[111,112]

Age is an important factor in acute SDHs. There is a significant increase in poor outcome among patients older than 60 years of age with severe head injury in general.[95,100–103,113,114] Older patients with an acute SDH and a low GCS score do especially poorly.[100–103,113,114]

The decision for immediate surgery is dependent on GCS score, age, pupillary examination, comorbidities, CT findings, and salvageability with respect to the patient's level of injury. In addition to all of these factors, decision making for delayed surgery is dependent on clinical course and ICP.[63]

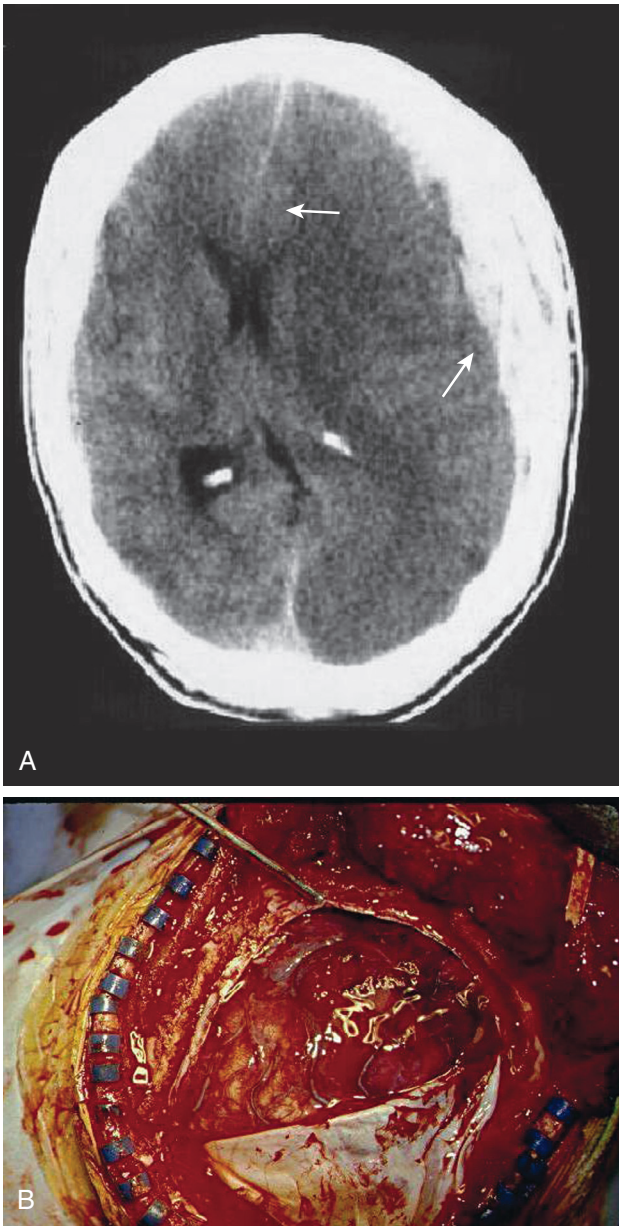
• **Fig. 63.7** A, Intraoperative view of a solid subdural hematoma *(SDH)* on the surface of the brain. B, Decompressed brain with demonstration of evacuated subdural space.

On the basis of a contemporary search of the literature, Bullock and colleagues found that CT parameters of a midline shift greater than 5 mm and/or a clot thickness greater than 10 mm were independent factors requiring surgery in salvageable patients. They also identified a select group of comatose patients with smaller SDHs who could be managed nonoperatively if the patients remained neurologically stable with normal pupils and ICP of 20 mm or less.[63]

Traumatic Subarachnoid Hemorrhage

The subarachnoid space is a CSF-filled compartment within which are the major cerebral blood vessels. The CSF within the subarachnoid space fills the basal cisterns and interdigitates into the cortical sulci. Traumatic SAH can be caused by bleeding of cortical arteries, veins, or surface cerebral contusions.[115]

In contrast with hemorrhages in other locations, SAH is not a discrete surgical clot that requires evacuation. Trauma is the most common cause of SAH, and a ruptured aneurysm is the most common cause of a spontaneous SAH. Aneurysmal SAH generally involves the suprasellar cistern, where the circle of Willis lies. Traumatic SAH can be found as small-volume hemorrhages in the sylvian fissures and interpeduncular cistern. Traumatic SAH also commonly involves the cerebral convexity and can fill cortical



• **Fig. 63.8** A, Computed tomography scan of acute, complex left-sided subdural hematoma (SDH) *(lower arrow)* with mass effect *(upper arrow)* disproportionate to the size of the clot, indicating more than just the effect of an extra-axial compressive mass—that is, intrinsic, parenchymal brain injury with edema. B, Intraoperative photograph of decompressed brain reveals hemorrhagic, inflamed, and edematous brain swelling out through the cranial defect. Compare with the intraoperative photograph of the simple SDH in Fig. 63.7.

sulci, which can sometimes mimic sulcal effacement[116] (Fig. 63.9A). Occasionally, the distribution of the hemorrhage may be hard to differentiate from an aneurysmal hemorrhage. Under this circumstance, a vascular study should be obtained (Fig. 63.9B).

Cerebral vasospasm after aneurysmal SAH is a common, well-described problem with an unclear pathogenesis. In general, traumatic SAH has not been considered a cause of clinically relevant cerebral vasospasm, but increasing evidence suggests that SAH from trauma may cause clinically significant cerebral vasospasm, which may be responsible for ischemia and infarction.[117,118] Clearly the incidence of clinically relevant cerebral vasospasm is less than what is seen in aneurysmal SAH; however, posttraumatic SAH may cause ischemia during the acute as well as the delayed phase.[117,119]

In severe nonpenetrating head injury, the degree of SAH can help predict outcome,[120,121] and although traumatic SAH can be an isolated finding, it is commonly associated with other intracranial injuries.[122] Traumatic SAH can be a marker of severe primary injury, and the amount of blood can also be an independent predictor of the development and progression of intraparenchymal contusions[115] (Fig. 63.9C).

Intraparenchymal Contusions and Hematomas

Traumatic parenchymal mass lesions are common and are reported in 13% to 35% of severe TBI.[123–129] Contusions consist of heterogeneous areas of necrosis, pulping, infarction, hemorrhage, and edema.[130–132] Hemorrhagic contusions are mixtures of blood and edematous cerebral parenchyma that also have a heterogeneous appearance on CT.[130] Contusions commonly occur in the frontal and temporal lobes at the poles and on the inferior surfaces as a result of contact with the rough, bony skull base[133] (Fig. 63.10A).

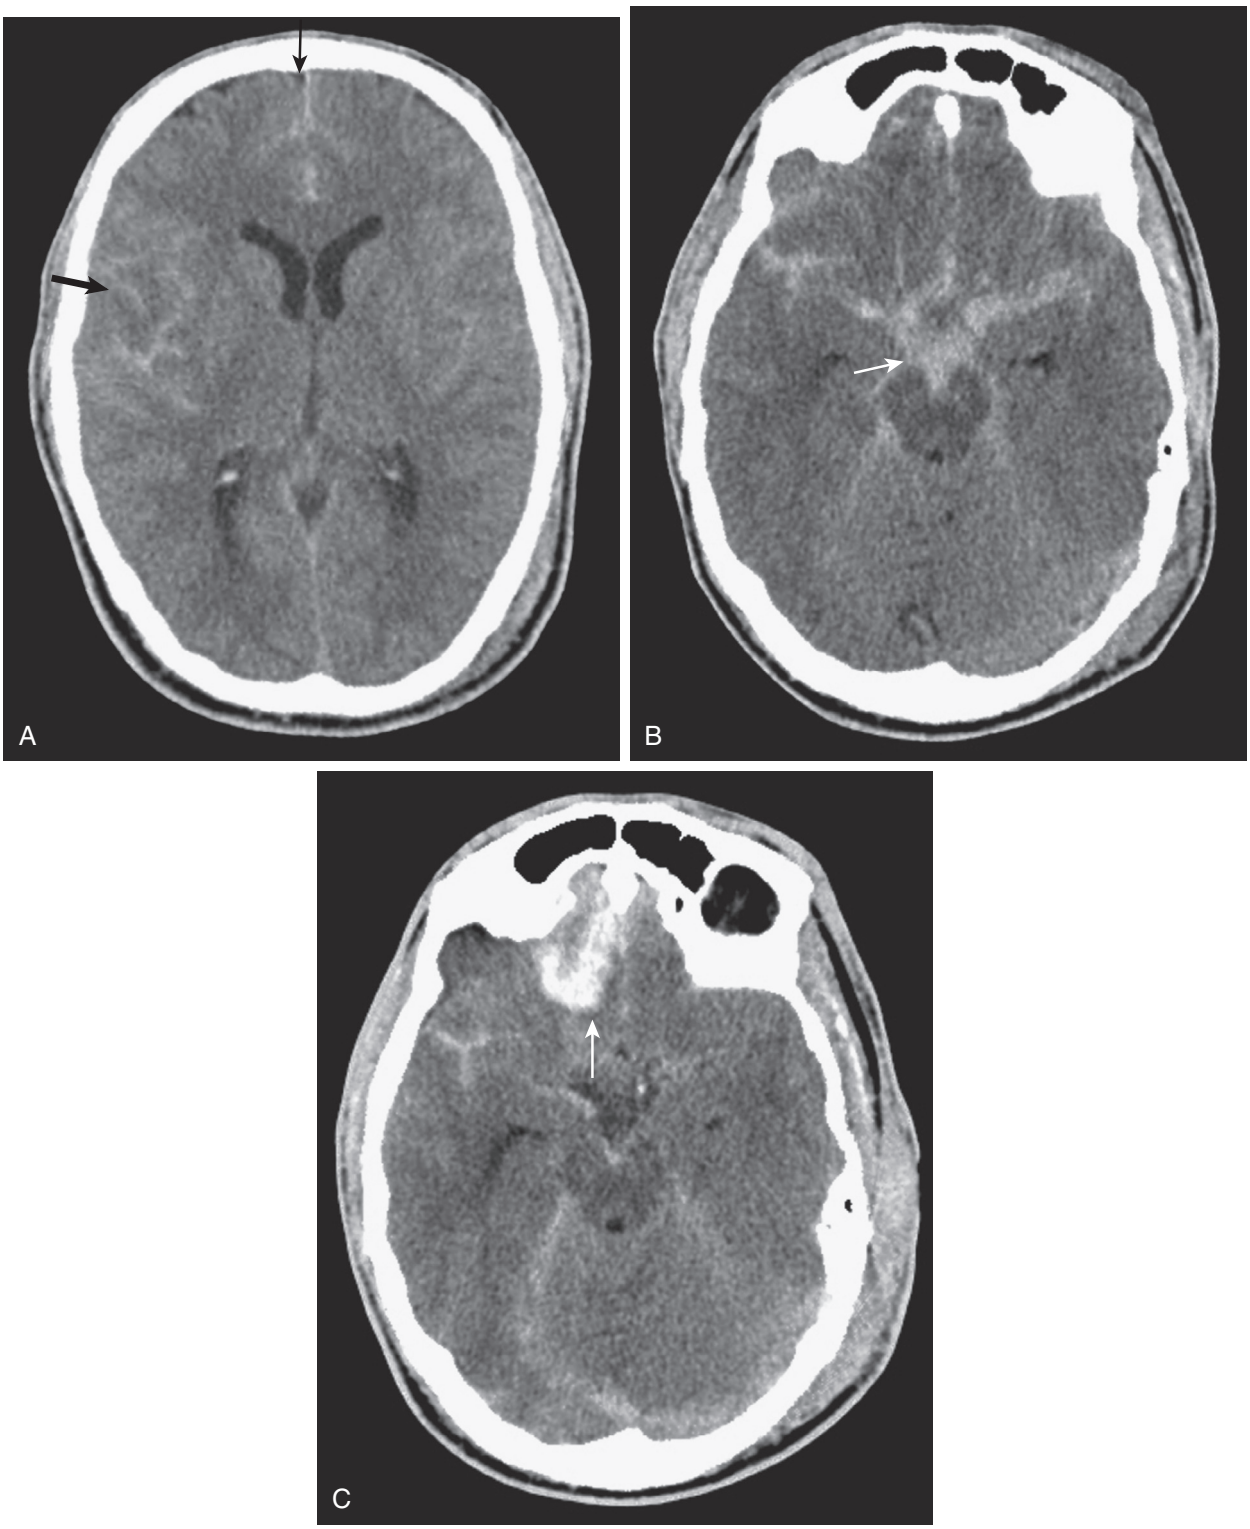
Contusions typically involve the crests of the gyri but in more severe injury may extend into the substance of the white matter. If the pia-arachnoid is torn, contusions are classified as cortical lacerations.[133–135]

Contusions represent one end of a spectrum of injury on which hematomas, which are well-defined, homogeneous collections of blood, are the other end (Fig. 63.10B). The amount of energy delivered may have only been enough to cause failure of small vessels, resulting in contusions. If more energy is delivered, failure of larger vessels may occur, resulting in hematomas. Alternatively, the hemorrhagic component of a contusion may continue to bleed and coalesce into a more discrete hematoma. In general, the most common traumatic parenchymal lesions are contusions,[130] and they tend to evolve.[124,128,129,136,137]

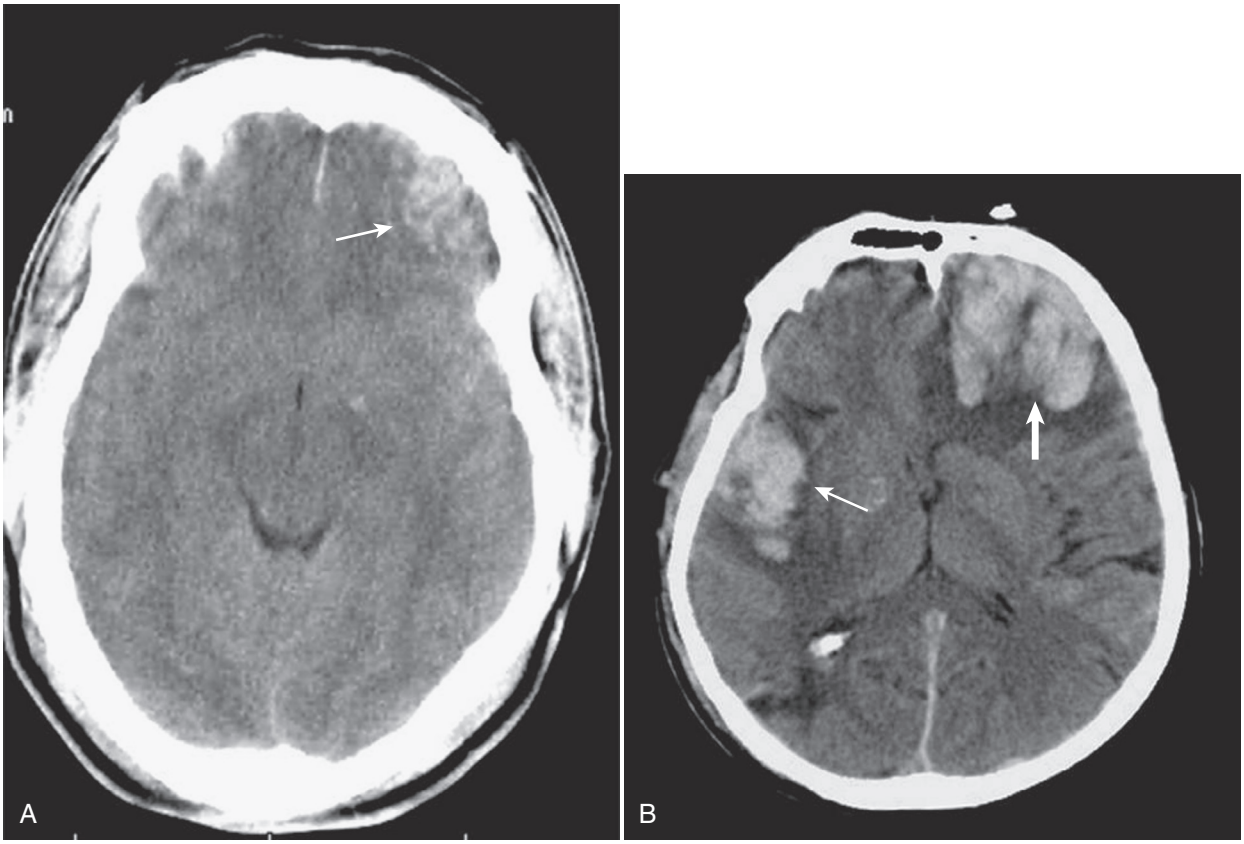
Risk factors for the progression of intraparenchymal hemorrhage include the presence of SAH (see Fig. 63.9C) and subdural hematoma, as well as the size of the clot on the initial CT scan. Enlargement of contusions occurs approximately 40% of the time, which justifies early follow-up CT scanning.[138] In addition to the problem of progressive enlargement of existing contusions is a phenomenon of *d*elayed *t*raumatic *i*ntracerebral *h*emorrhage (DTICH). DTICH is defined as a new hemorrhage identified on a CT scan in an area of brain that was normal on the admission CT scan. These delayed hemorrhages are reported to occur in up to 7% of patients with severe head injuries.[92]

Contusions can be subdivided into two groups. *Coup* contusions occur in the brain tissue under the impact site and are usually associated with an acceleration injury. *Contrecoup* contusions are located away from the point of impact and are usually associated with a deceleration injury.[133,134,139–141]

Understanding the biomechanics of how a contrecoup contusion develops is useful. In general, biologic tissues tolerate strain better if they are deformed slowly rather than quickly. For example, a 150-mL hematoma with accumulation of blood over minutes is likely to be lethal, whereas a 150-mL slow-growing meningioma may have no appreciable effect on the patient's level of consciousness. In trauma, the cause of tissue damage may be any of three types of induced strains: compression, tension, and shear. The skull, brain, and blood vessels will tolerate compression better than tension, and tension better than shear. These strains are induced by contact or inertia (relative to acceleration-deceleration), or both. Contact injuries are a result of impact, which may cause inward



• **Fig. 63.9** The patient was a 25-year-old man who sustained a brain injury in a motorcycle accident. A, Computed tomography (CT) scan immediately after the accident demonstrates traumatic subarachnoid hemorrhage (SAH) in cortical sulci *(thick arrow)* and anterior interhemispheric fissure *(thin arrow)*. B, CT scan at the level of the circle of Willis reveals a distribution of subarachnoid blood *(arrow)* throughout the suprasellar cistern, a pattern similar to that seen with a ruptured aneurysm. Findings on an immediate cerebral angiogram to rule out an aneurysm were normal. C, Follow-up CT scan obtained 8.5 hours later demonstrates an intraparenchymal contusion *(arrow)* that was not seen on the initial study, with rapid clearing of the traumatic SAH in the suprasellar cistern.



• **Fig. 63.10** A, Computed tomography (CT) scan demonstrates a typical left frontal basal contusion *(arrow)* where the brain interfaces with the rough base of the anterior cranial fossa. B, CT scan demonstrates left frontal *(thick arrow)* and right temporal hemorrhagic *(thin arrow)* contusions. The floor of the middle (temporal) fossa also is quite rough. This scan also illustrates the continuum from contusion to hematoma. Note the large, homogeneous areas within the contusions that could be classified as hematomas.

deformation of the skull with local effects, and of shock waves, which can produce remote effects. As a consequence of contact the head is set in motion, which leads to inertial injury. Inertial injuries may cause damage by differential acceleration of the skull and brain. In addition, acceleration-deceleration can independently produce strains in the brain itself. The two clinically relevant types of acceleration are translational (when the brain moves in a straight line) and angular. Most injuries are a combination of both.[142]

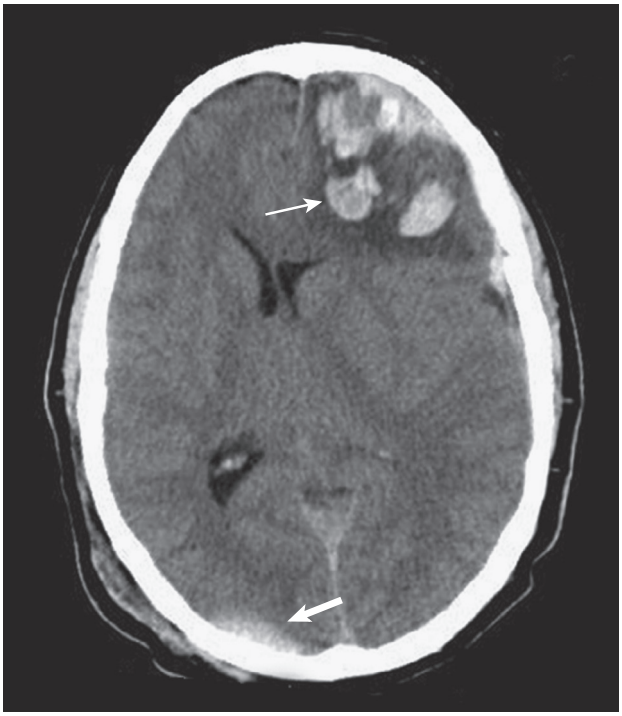
These effects are best illustrated by a case example of a 37-year-old man who falls from a height onto the back of his head and presents with a deteriorating level of consciousness. His CT scan (Fig. 63.11) reveals soft tissue swelling at the point of impact in the right occipital region with a small underlying hemorrhage, as well as a large, hemorrhagic contusion in the left frontal lobe. The mechanism involved is primarily translational (linear) deceleration. The skull stops suddenly as it hits the ground, but the brain continues to move toward the impact site, where compression is induced (Fig. 63.12).

As the brain is moving toward the inner table of the skull at the impact site, it also is moving away from the skull on the opposite side, creating regions of low pressure and tensile strains. Contributing to the extensive tissue damage in the left frontal lobe may also be movement of the brain across the rough surface of the anterior cranial base.[130,142]

The same amount of energy is delivered to the brain in nearly a straight line, with the compressive injury at the point of impact resulting in much less damage than the contrecoup injury caused by tension. In view of the dramatic differential susceptibilities of the brain and blood vessels to compressive, tensile and shearing strains induced in trauma, it is understandable that diffuse injuries can be caused by seemingly less violent trauma when the head undergoes an injury with a large component of angular acceleration-deceleration. This is the motion that can induce shearing strains, which the tissues tolerate poorly (see the Diffuse Axonal Injury section).

Surgical decision making is more straightforward for epidural and subdural types of hematomas, in which the extra-axial mass causing compression is simply on the surface of the brain. Contusions and hematomas, however, are intra-axial masses intimately associated with surrounding regions of brain that may be salvageable. It is one thing to surgically evacuate an extra-axial hematoma *compressing* the dominant frontal lobe, and quite another to operate on a large contusion *within* the dominant frontal lobe.

In 2006 guidelines were published after a thorough review of the relevant but scientifically weak literature. The reviewers reported that patients with parenchymal mass lesions and signs of progressive neurologic deterioration referable to the lesion, medically refractory intracranial hypertension, or signs of mass effect on CT scan should be considered for surgery. Patients with GCS scores of 6 to 8 with frontal or temporal contusions greater than 20 mL in volume with midline shift of at least 5 mm or cisternal compression on CT scan and patients with any lesion greater than 50 mL in volume should be considered for operative treatment. Patients with



• **Fig. 63.11** Computed tomography scan demonstrates a relatively small right occipital hemorrhage *(thick arrow)* underlying the point of impact as confirmed by the overlying soft tissue swelling of the scalp and a large, left frontal hemorrhagic contrecoup contusion *(thin arrow)*.

parenchymal mass lesions who do not show evidence of neurologic compromise, whose ICP is controlled, and who demonstrate no significant signs of mass effect on CT scan may be managed nonoperatively with intensive monitoring and serial imaging. For patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation, the guidelines also recommended, as treatment options, subtemporal decompression, temporal lobectomy, or hemispheric decompressive craniectomy (Fig. 63.13). With regard to timing of surgery, the literature at one time supported a bifrontal decompressive craniectomy within 48 hours of injury as a treatment option for patients with diffuse, medically refractory posttraumatic cerebral edema and resultant intracranial hypertension,[129] but newer data are less clear cut. In 2016 the BTF released updated guidelines that are less supportive under specific circumstances (see the Decompressive Craniectomy section).[143]

Hypothalamic-Pituitary Injury

Injury to the pituitary and hypothalamus can complicate head injury. A prolonged loss of consciousness often is reported in patients with such injuries. Up to 80% of cases are associated with a fracture through the skull base. Injuries include (in decreasing order of frequency) pericapsular hemorrhage, hypothalamic infarction, posterior pituitary hemorrhage, anterior pituitary infarction, and rupture of the infundibulum.[144–146] Clinically measurable decreases in pituitary hormone production are not seen until at least 75% of the gland is destroyed. Complete loss of production requires destruction of at least 90% of the gland.

Derangements in pituitary function can result in decreased production of any of the pituitary hormones. Of particular clinical significance is impairment of adrenocorticotropic hormone release that can result in secondary adrenal insufficiency. Physiologic stressors such as trauma, surgery, or infection can result in Addisonian crisis, with potentially life-threatening results. Diabetes insipidus has been reported in a significant number of patients with severe head injuries, with a high percentage of cases remaining permanent.[147] Injuries to the pituitary often are not suspected in the acute period, and the diagnosis of hypopituitarism is therefore often delayed (Fig. 63.14).

Diffuse Axonal Injury

The term *diffuse axonal injury* (DAI) describes brain damage in a group of patients who become immediately unconscious or go into coma at the time of the head trauma.[82] Depending on the severity of the injury, patients may have mild, moderate, or severe DAI. A large number of patients with severe head injury will have DAI. Rapid angular acceleration and/or deceleration of the head can induce shearing strains at the gray-white junction, corpus callosum, or brainstem.[134,148] The result can be diffuse tearing of axons and small blood vessels. These lesions initially may be hemorrhagic, but as they become chronic, shrinking, softening, and scarring ensue, often with cyst formation.[41,149] The lesions usually are microscopic but can be large and macroscopic. Although small, focal, petechial hemorrhages may be visualized, the initial CT scan often is normal.[150] Most of the clinical and experimental studies support that the diffuse injury occurs at the time of initial impact and is not the result of other adverse factors, such as decreased brain oxygenation, increased ICP, or brain swelling,[149,151] although these factors tend to accentuate the amount of damage.

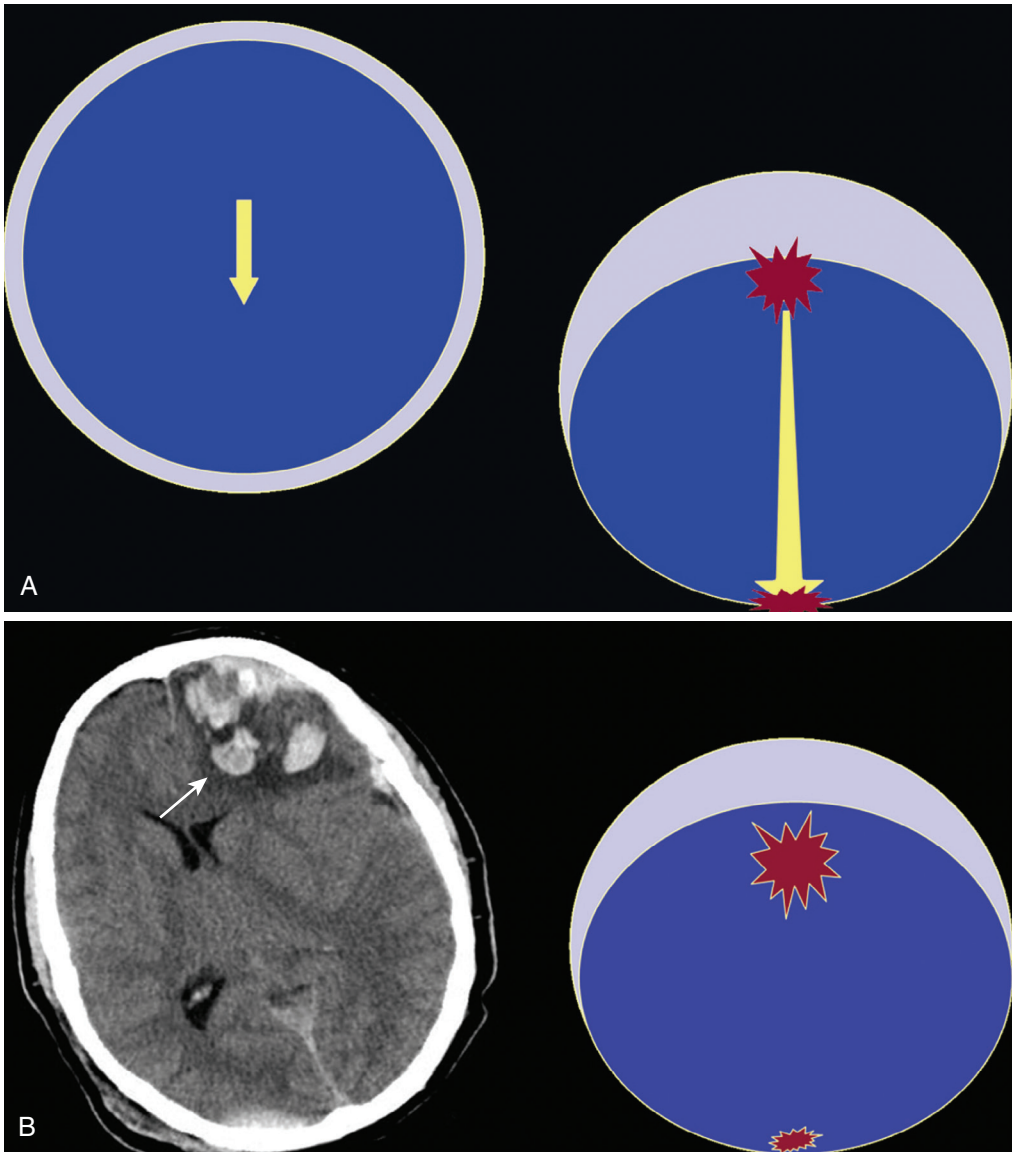
The term *gliding contusions* was originally introduced by Lindenberg and Freytag[152] to describe hemorrhagic lesions in parasagittal white matter; this brain injury concept has been reanalyzed.[153] Gliding contusions frequently are found in association with DAI and acute subdural hematomas. Two mechanisms have been considered in relation to the formation of these contusions. First, during angular acceleration, more movement and displacement of the cortical gray matter occur than of the deep white matter; accordingly, most of the tissue injury occurs at the gray-white junction because shearing strains predominate. The second mechanism involves excessive displacement of the bridging veins during brain acceleration. Patients with severe DAI who survive may be profoundly disabled, but some patients with mild or moderate DAI may recover with mild or no disability.[82] The importance of recognizing DAI in the initial evaluation cannot be overstressed; this will affect the management and outcome. Clinically, these patients will have impaired consciousness secondary to bicortical damage, possibly in association with unremarkable imaging findings and normal ICP.

Penetrating Brain Injury

A penetrating brain injury (PBI) involves an object breaching the scalp, skull, and dura.

Classification

A common classification method for these injuries is by velocity of the penetrating object. Low-velocity PBIs include wounds from nail guns, arrows, and knives and some types of gunshot wounds (Fig. 63.15). Gunshot wounds are divided into low-velocity injuries, such as from civilian handguns and shrapnel, and high-velocity injuries, from rifles and military weapons[154] (see Table 63.1). It is



• **Fig. 63.12** A, Schematic representing the head falling in a straight line. Rapid deceleration of the skull occurs as the brain continues to move toward the impact site. The energy is applied in a linear trajectory, resulting in a compressive strain generated at the impact site and a tensile strain at the opposite point *(right diagram)*. The same energy delivered to the brain results in more damage by tension than compression. B, A comparison of this schematic with that for a similar mechanism of injury would demonstrate why a contrecoup contusion (*arrow* on computed tomography scan, *left*) generally is more severe than the injury sustained as a result of compression at the point of impact.

estimated that between 6000 and 7000 people die each year in the United States from gunshot wounds to the brain.[133–142,154–156]

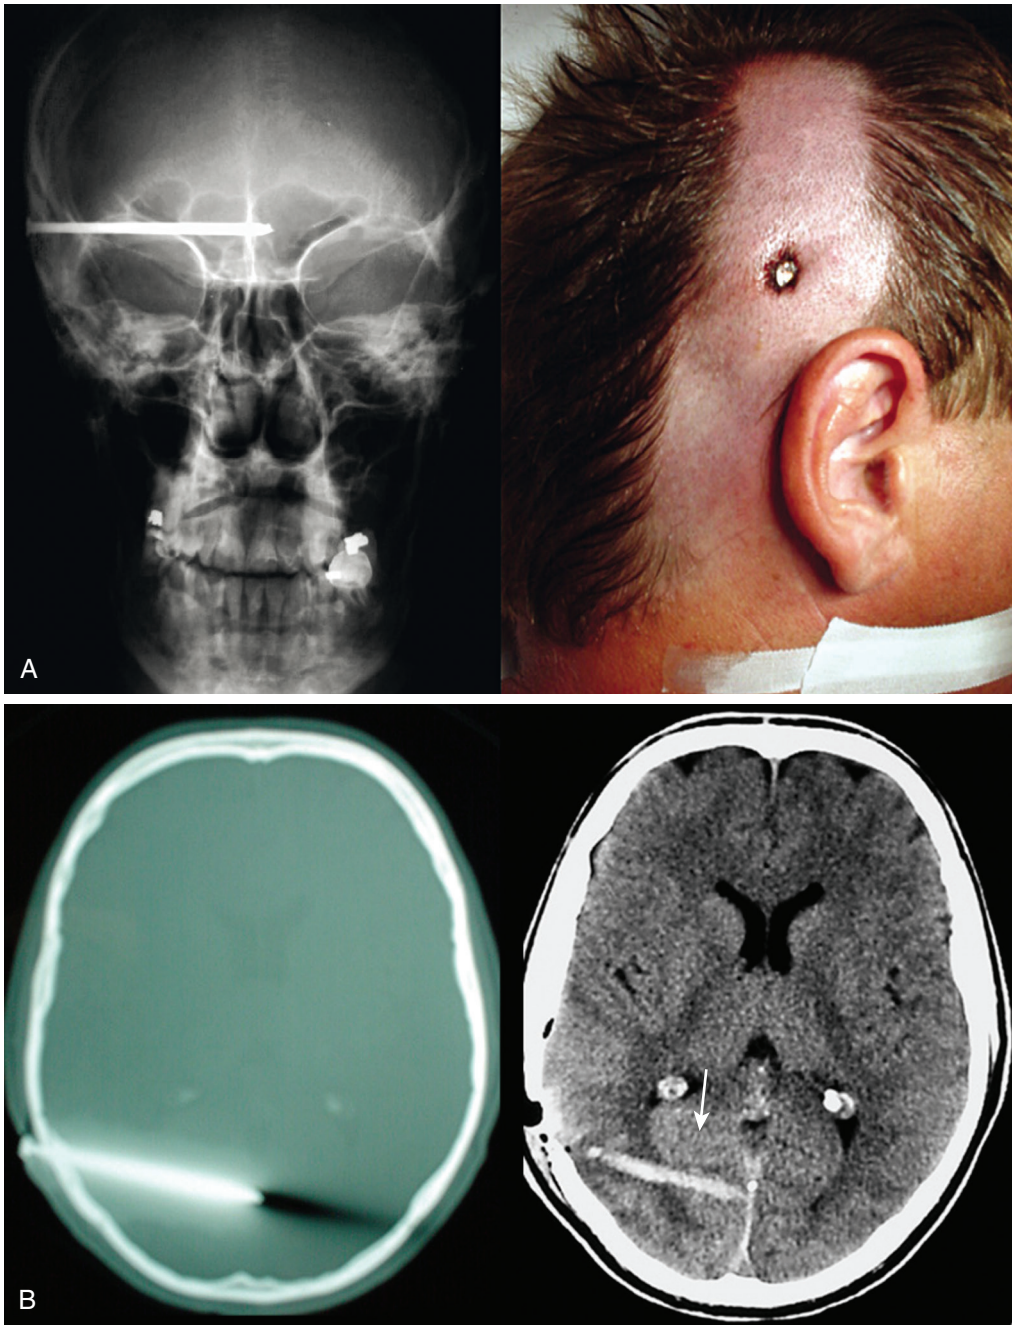
An Israeli report described an intermediate type of injury from spherical bolts whereby the ball bearings used by suicide bombers, having unique ballistics, may cause a type of "stab wound" injury to the brain.[154]

Ballistics

The biomechanics of PBI are important and require an understanding of the dynamics of projectiles—that is, ballistics. Ballistics can be divided into three phases. The first phase, internal ballistics, deals with the source of the projectile and its intrinsic dynamics (e.g., rifle, bomb). External ballistics, the second phase, focuses on the flight of the projectile itself and the deviation of its longitudinal axis relative to the line of flight, referred to as yaw motion. Collision of the projectile with any object during this external phase will change the speed, angle, and yaw. The third phase is referred to as terminal ballistics, which is the physical interaction between the projectile and the body.[154]

As the projectile directly crushes tissue, it forms a permanent cavity, and as surrounding tissue is compressed, a temporary cavity also is formed. As the missile breaks through the skull, secondary projectiles of bone fragments may be generated, causing independent, secondary permanent, and temporary cavities.[154,157–160]

Terminal ballistics are influenced by many factors, such as size, shape, and stability of the penetrating object; however, most authors (but not all) believe that entrance velocity is the most important factor in determining the degree of tissue damage.[154,157,159,161–163] Experimental evidence has demonstrated an immediate increase in ICP with a pressure wave transmitted throughout the cranial



• **Fig. 63.13** A 32-year-old man presented awake and alert after accidental discharge of a nail gun to the head while working at a construction site. A, *Left*, An anteroposterior radiograph of the skull demonstrates the nail. *Right*, On this intraoperative photograph, the head of the nail can be seen indenting the surface of the scalp. B, Preoperative bone-windowed computed tomography (CT) scan *(left)* and immediate postoperative brain-windowed CT scan *(right)* demonstrate the blood-stained tract after removal.

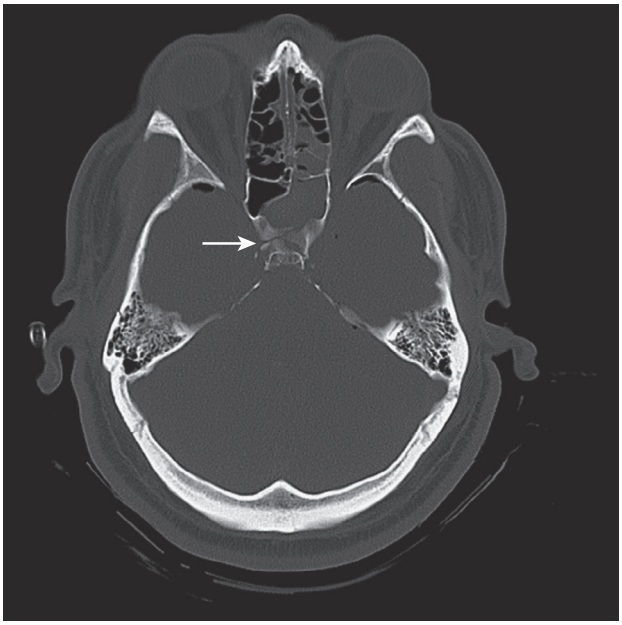
cavity, which probably accounts for the transient respiratory arrest observed in PBI.[154,164] High-velocity injuries (velocity > 320 m/s) cause shock waves that emanate from the front of the missile. These shock waves can reflect off the inside of the skull and summate, producing significant pressure gradients with remote effects.

Initial Resuscitation

In general, initial resuscitation in the trauma bay should be in accordance with current recommendations for patients with head injuries. During this initial resuscitation it is important to recognize that hypotension in PBI either is a terminal event or is related to other injuries. Once resuscitation has been accomplished, a CT scan is essential. Although skull films seldom add to the information obtained from a CT scan,[154] our group has found plain films to be very helpful in PBI, particularly in industrial accidents, in which the shape of the penetrating object may be unknown.

Surgical Management

Most of what is known about the surgical management of PBI comes from the battlefield, beginning with World War I, when

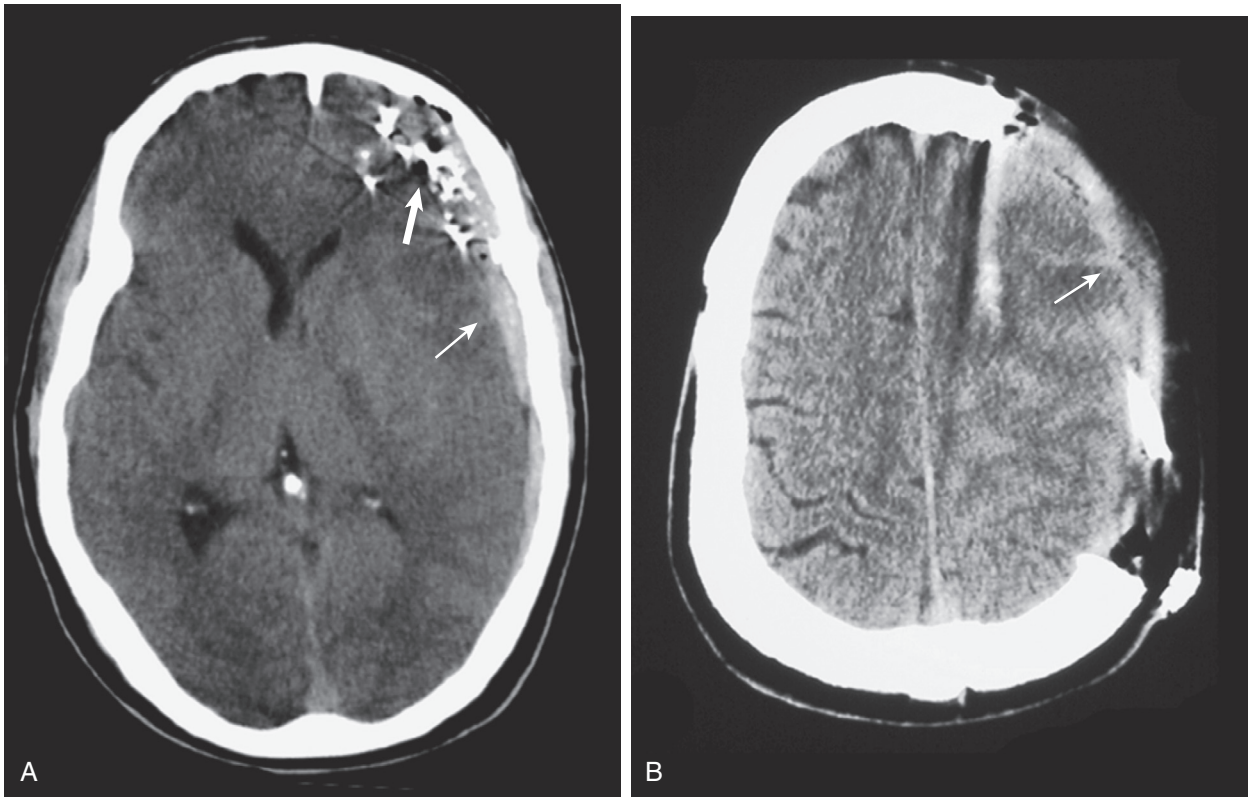


• **Fig. 63.14** Computed tomography scan through the skull base in bone window demonstrating fractures through the sella turcica *(arrow)*.

Harvey Cushing, the father of American neurosurgery, described his technique of en bloc craniectomy under aseptic conditions: thorough debridement of scalp, brain, metal, and bone fragments; and watertight closure of the scalp. Using this management strategy a century ago, in the absence of antibiotics, Cushing reported a significant drop in postoperative mortality from 55% to 28%.[165,166]

Mortality decreased even further in World War II, primarily because neurosurgical personnel were present in forward military hospitals and antibiotics were introduced. The operative approach, however, was largely the same: that of radical debridement. Treatment consisted of four tiers: emergent life-saving maneuvers through hemostasis and cerebral decompression; prevention of infection through extensive debridement; preservation of brain tissue; and restoration of anatomic structures through accurate closure of the dura and scalp. Although untested against other management strategies, this approach became the standard of treatment for PBI by default. Indeed, in the U.S. military, thorough debridement of intracranial bone and metal fragments was official military policy through the Vietnam War.[166]

The overall mortality rate from PBI sustained during relatively modern wartime conditions ranges from 8% to 43% and generally is considered to be in the 20% range.[166–175] The mortality rate from military gunshot wounds has been reported to be 2.5 to 4



• **Fig. 63.15** The patient was a 27-year-old man with a self-inflicted gunshot wound to the head who presented with a deteriorating level of consciousness. The patient put the muzzle of a handgun to the right medial orbital roof. The bullet traversed the frontal sinus and traveled through the left frontal lobe. A, Computed tomography (CT) scan demonstrates bullet fragments *(thick arrow)* and an associated left frontotemporal acute subdural hematoma *(thin arrow),* requiring surgical evacuation and hemicraniectomy for anticipated swelling. B, Postoperative CT scan demonstrates edematous hemisphere herniating out through the cranial defect *(arrow)*. There was damage to the anterior cranial base with contamination secondary to involvement of the frontal sinus. Surgical repair of the skull base was delayed because of the anticipated cerebral edema, and the antibiotic treatment was started. When the cerebral swelling resolved, there was no evidence of cerebrospinal fluid rhinorrhea or infection. The patient never required the delayed repair of the anterior cranial base anticipated. He made an excellent neurologic recovery and returned to work as a professional recruiter several months after replacement of his cranial bone flap.

times more than from shrapnel.[166–169,174] Of interest, mortality rates from wartime PBIs in the U.S. military from World War II through the Vietnam War did not change significantly,[176] which is consistent with the relatively unchanged management strategy of complete removal of intracranial bone or metal fragments, using repeated surgery as necessary.[177]

Aggressive debridement was intended to reduce complications such as infection, epilepsy, and cerebral edema. However, studies reveal that additional surgery to remove retained fragments results in significant morbidity and mortality.[174,178,179] Primary surgery for conservative debridement is now common practice for salvageable patients, with judicious use of decompressive craniectomy when necessary for selected cases.

The use of broad-spectrum antibiotics in recent wars has resulted in data suggesting that retained bone fragments are not independently associated with an increased risk of infection. Therefore aggressive debridement is no longer supported.[166,180] The use of broad-spectrum antibiotics in PBI has now become common practice.[154]

Multiple studies have looked at post-PBI epilepsy and reported an incidence of 22% to 53%.[171,181,182] Several studies suggest that it is not necessary to remove all bone fragments to decrease the chance of developing epilepsy, but the value of removing metal fragments in this regard remains unclear.[166,171,173,181,182] In military PBI, it appears that vigorous debridement is associated with increased morbidity and mortality and is not necessary to prevent infection, has no obvious efficacy in preventing epilepsy, and does not appear to improve survival.[166]

A CSF leak resulting from a PBI is the variable most highly correlated with intracranial infection.[166,170,171,174,183–186] One study found that most CSF leaks appeared within 2 weeks of the injury and less than half of them closed spontaneously. The incidence of infection was approximately 10 times higher in the group with CSF fistulas than in the group without leaks, and the mortality was greater as well.[185] Because CSF leaks are the primary predictor of the development of intracranial infection,[171,173,175] it is important to fix or prevent a CSF leak; therefore a watertight closure of the scalp entry wound is necessary.[185]

To accomplish this objective, various surgical interventions are available. Small entrance wounds without underlying surgical pathology may be cleaned up and closed in the emergency department.[186] Complex entry wounds or those with underlying surgical pathology require more extensive surgical manipulation, which may include extending the incision to allow vigorous superficial debridement; complete excision of devitalized tissues including muscle, fascia, and periosteum; extension and debridement of the bony entry or exit site by craniectomy; and similarly generous debridement of the dural opening with watertight closure, using grafting as necessary.[a]

Predictive Factors

Increased mortality in penetrating head injury is associated with increasing age, suicide attempts, hypotension, coagulopathy (particularly with lower GCS scores), respiratory distress, low GCS score, bilateral fixed and dilated pupils, high ICP, and cisternal effacement on CT scan. Mortality is also increased with traumatic injuries in which a missile tract perforates the skull (through-and-through injury) or with injuries that involve both hemispheres, multiple lobes, or the ventricular system.[166]

[a]References 165, 172, 174, 176, 187, and 188.

In civilian gunshot wounds to the head, a specific vector analysis from Los Angeles County demonstrated a region of involvement that resulted in 100% fatality and is designated as the zona fatalis. This region consists of the midbody of the ventricle, the body of the corpus callosum, and the cingulum.[188]

No effect has been demonstrated for weapon caliber on outcome, independent of total kinetic energy, and no relation between midline shift and outcome has been established.[166] Using predictive factors, Harrington and Apostolides have proposed a treatment algorithm for patients with gunshot wounds to the head. Patients with lesions causing mass effect and a postresuscitation GCS score of 7 or greater undergo surgery, and patients with a GCS score of 3 or 4 with bilaterally fixed pupils after resuscitation receive no treatment beyond wound closure. In patients with GCS scores of 5 or 6, treatment should be individualized, depending on pupillary findings and other conditions.[189]

Special Problems

Special problems that may be encountered with PBI include those associated with craniofacial entrance wounds: an increased incidence of hematoma formation, direct vascular injury, extensive contamination owing to paranasal sinus involvement (see Fig. 63.15), and CSF fistulas.[154]

Other special problems include dural venous sinus involvement, tangential wounds, and traumatic aneurysms, with 0.4% to 0.7% of all intracranial aneurysms being caused by penetrating trauma.[190]

In PBI, mechanical loading of the cerebral vasculature, by either the contact forces of the projectile or the shearing forces of a pulsating temporary cavity, may cause partial or complete transection of an arterial wall. Such damage can result in SAH or formation of intracerebral and intraventricular hematomas.[166,191,192]

Damage to the arterial wall also may cause the development of a traumatic intracranial aneurysm. These aneurysms are primarily false aneurysms, which could heal or change in size over time, but they are especially vulnerable to rupture and can lead to delayed traumatic intracerebral hematoma, SAH, or both.[190,193–195]

Patients with an increased risk of vascular injury include those in whom the trajectory passes through or near the sylvian fissure, supraclinoid carotid, cavernous sinus, or a major venous sinus. The development of substantial and otherwise unexplained SAH or delayed hematoma also should prompt consideration of a vascular injury.[166]

Cerebral angiography (CTA or conventional) remains the usual technique to detect intracranial aneurysms.[192,194,196] Because a majority of traumatic intracranial aneurysms are not true aneurysms, excluding the aneurysm by surgical clipping may not be possible and may require trapping between clips on the parent vessel[166] or endovascular management.

Course in the ICU

Not surprisingly, intracranial hypertension is common after PBI.[185,197–199] Early ICP monitoring should be considered when the ICU clinician is unable to assess the patient's neurologic status accurately; if the need to evacuate a mass lesion is unclear; or if CT scanning results suggest elevated ICP.[166] Another practical use for ICP monitoring is ongoing assessment of a patient with a depressed level of consciousness to look for an early sign of progressive intracranial pathology, which may require repeated imaging and surgical decompression.[185,197,199]

Cerebral autoregulation may be defective after PBI[185,197,199] and cerebral edema can appear rapidly, contributing to medically

refractory intracranial hypertension. Systemic hypertension may exacerbate intracranial hypertension after PBI.[166]

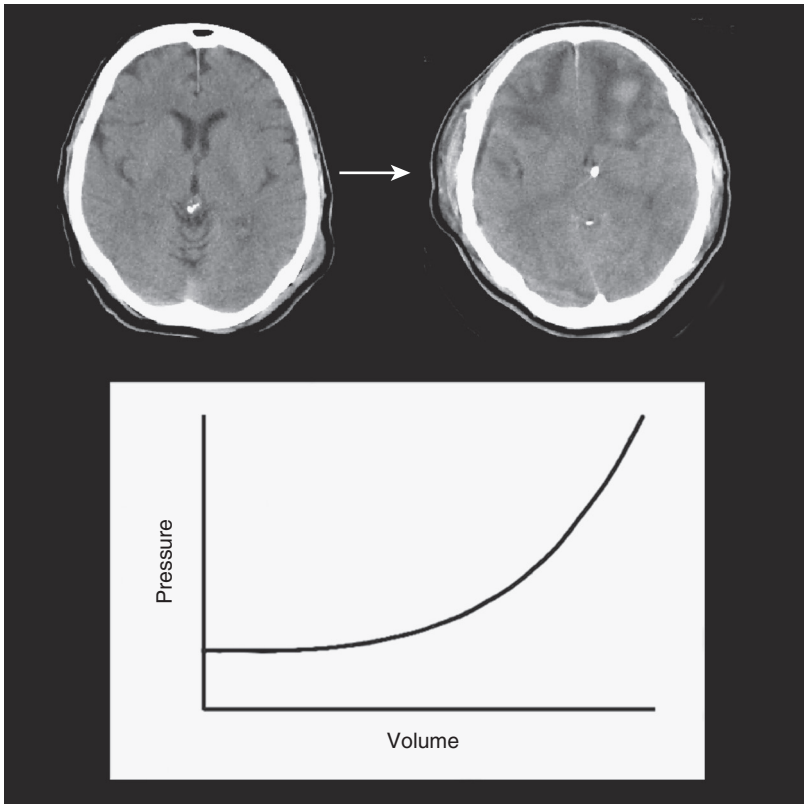
Treatment is not necessarily futile, and some patients with intracranial hypertension can be managed successfully and survive with acceptable morbidity.[185,197,199,200] However, the literature does not clearly relate successful treatment of intracranial hypertension after PBI to an improved outcome. Insufficient good data are available to guide management strategies for intracranial hypertension after PBI. It cannot be assumed that the intracranial pathology is the same as in nonpenetrating TBI. Because of the paucity of data, however, treatment in the ICU generally follows the methods for nonpenetrating TBI as outlined in Guidelines for the Management of Severe Traumatic Brain Injury.[166,201]

Secondary Head Injury

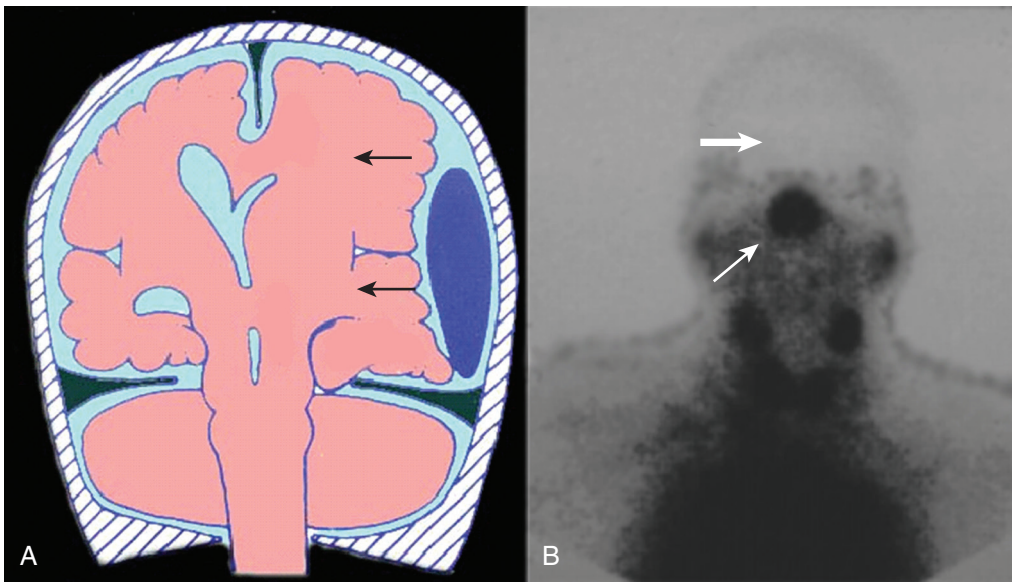
Basic Concepts

Management of primary head injury may require surgical intervention driven by the presence of pathologic masses (hematomas) in anatomic spaces. Management of secondary head injury generally involves nonsurgical interventions driven by pathologic derangement of physiologic processes.

The three functional volumetric compartments in the head are blood, brain, and CSF. The volumes of these three functional compartments are approximately 1200 mL for brain, 150 mL for CSF, and roughly 150 mL for the variable blood compartment. The total volume of the intracranial compartment is relatively fixed and relatively incompressible. Therefore if volume is added to one of these three compartments, a compensatory loss of volume from another compartment will occur; otherwise, ICP will rise. To illustrate this point, a pressure-volume curve for the intracranial compartment is shown in Fig. 63.16. Initially, as volume is added to the system, no significant change in pressure occurs. With cerebral edema, for example, as the brain compartment increases in volume, venous capacitance vessels collapse, which moves blood volume out of the system; therefore overall net volume does not change and ICP remains stable. As the brain continues to swell and increase in volume, the ventricles compress, which moves CSF out of the system, again keeping overall net volume and ICP relatively stable. At some point the system loses this buffering capacity, and as more injury-related volume accumulates, ICP starts to rise. The rise in ICP is gradual, progressive, and nonlinear. As the system continues to be stressed with additional volume, it progressively loses compliance and, in effect, gets stiffer. The result is that increasingly smaller volumes introduced into the system result in higher changes in ICP. Using MRI methods to study cerebral edema, Marmarou and colleagues noted a rise in ICP when edema was only 1% higher than the normal water content of brain tissue. These investigators also showed that when water content increased in a



• **Fig. 63.16** Pressure-volume curve of the intracranial compartment using cerebral edema as an example (see text). The computed tomography (CT) scan above the graph on the *left* is an image of a normal brain. The CT scan on the *right* demonstrates severe cerebral edema in a trauma patient with obliteration of most of the subarachnoid space, reducing cerebrospinal fluid (CSF) volume to make room for the swelling brain. Initially, as CSF moves out of the system, overall net volume does not change significantly. This part of the process is represented by the flat part of the curve toward the *left* and reflects the buffering capacity of the brain to respond to gradual increases in volume.



• **Fig. 63.17** A, Increased intracranial pressure can be associated with hematomas causing mass effect, shift, and possibly herniation. The resultant pathostructural changes from such unbalanced forces *(arrows)* usually are managed surgically. With increased intracranial pressure, cerebral perfusion may be impaired, resulting in ischemia—the ultimate secondary injury. Intractable intracranial hypertension and inadequate perfusion can lead to brain death, as demonstrated by the nuclear flow study shown in B. Note the absence of flow to the brain *(thick arrow),* compared with the overly generous blood supply to the face, sometimes referred to as the "hot nose sign" *(thin arrow)*.

contused hemisphere, ICP increased exponentially. These findings demonstrate the importance of small changes in intracranial volume, particularly when the buffering capacity of the system has been exhausted.[202]

Increased ICP may be associated with mass effect secondary to hematomas causing direct mechanical compressive damage to intracranial structures that requires surgical decompression in the operating room. Increased ICP also may result in inadequate perfusion, requiring medical management in the ICU (Fig. 63.17).

The heart delivers blood at a given mean arterial blood pressure (MABP), the systemic perfusion pressure, to the base of the skull. The blood pressure then has to overcome whatever pressure is inside the head for blood flow to get in, and whatever is left over will be the pressure that perfuses the brain—that is, cerebral perfusion pressure (CPP). Simple in concept and calculation, CPP is defined as the MABP minus ICP (CPP = MABP − ICP). It is the physiologic variable that defines the pressure gradient driving CBF and metabolic delivery and is therefore closely related to ischemia.[203,204]

Technically, the MABP should be measured as the mean carotid pressure with the arterial line transducer zeroed at the level of the foramen of Monro (as opposed to the right atrium),[205] but this approach is not common in clinical practice. Normal values generally are considered to be 60 to 80 mm Hg for CPP and approximately 10 mm Hg or less for ICP.

The ultimate cause of secondary injury is typically ischemic, and the fundamental goal in dealing with severe TBI is to ensure adequate CBF relative to the metabolic demand of the brain. It is, however, impractical to continuously measure CBF at the bedside. Fortunately, CBF is dependent on CPP—which can easily and continuously be measured at the bedside. Therefore a fundamental management strategy for treating a patient with a head injury is to maintain adequate CPP by lowering ICP, accomplished by reducing intracranial volume.

Surgical methods for reducing intracranial volume include evacuating an intracranial hematoma, removing part of the frontal or temporal lobe, and placing a ventriculostomy to drain CSF. Other methods for reducing intracranial volume are applicable in the ICU setting, where management strategies are directed at treating volume in the blood and brain compartments.

Cerebral Blood Volume

In discussing cerebral blood volume (CBV), it is useful to divide this topic into the arterial and venous compartments.

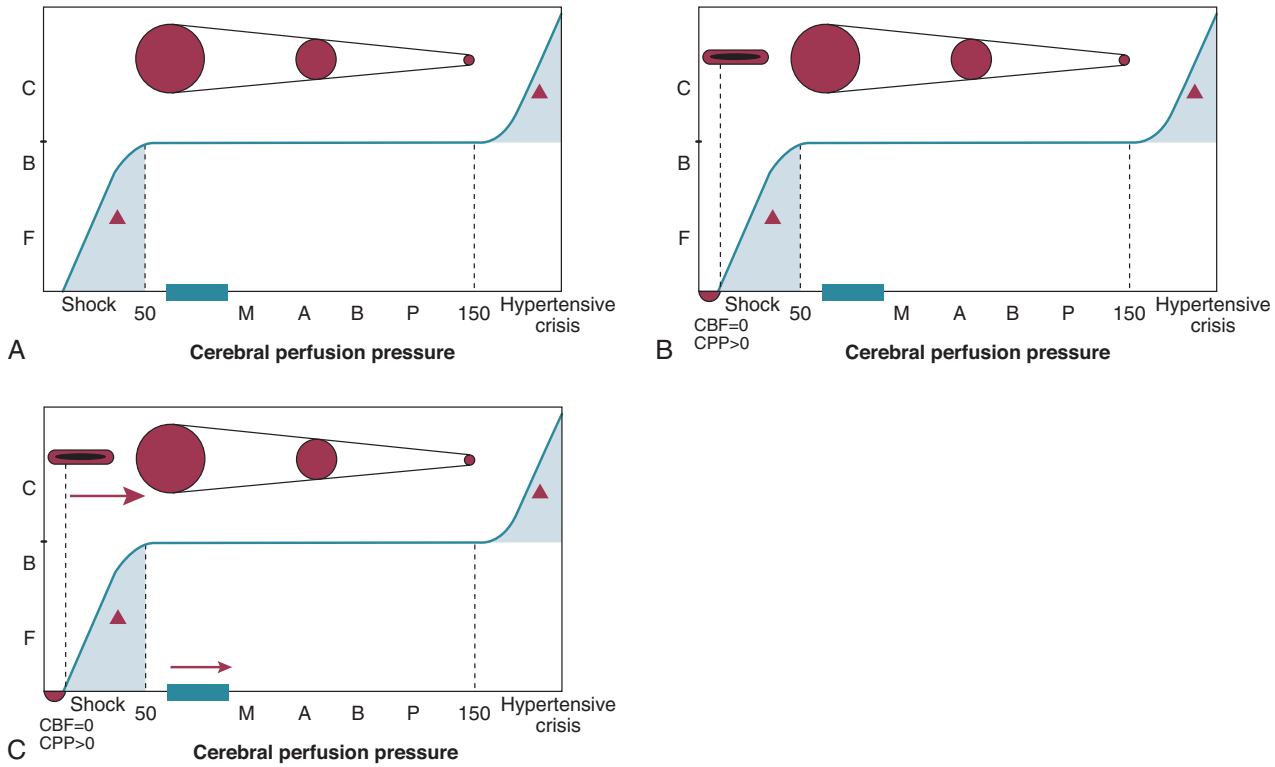
Arterial Blood Compartment

Blood Pressure

Systemic blood pressure has a direct effect on arterial CBV. Normally, CBF will remain relatively constant over a wide range of perfusion pressures as cerebrovascular resistance (CVR) automatically adjusts. The autoregulation curve (Fig. 63.18) demonstrates the relationship among CBF, perfusion pressure, and CVR. As MABP goes up, CVR increases to maintain a stable CBF.

The CVR increases by vasoconstriction, which reduces the volume of blood in the brain. Conversely, as MAPB drops, CVR goes down by means of vasodilation, which increases the volume of blood in the brain. This is a very powerful system; a cerebral arteriole has the ability to change its diameter by up to 200%. It also is quite fast, responding to sudden changes in pressure within 3 to 5 seconds.

Most people have had the experience of suddenly jumping out of bed after having been recumbent for several hours and then feel the "lights going out" as the cerebral vasculature rapidly dilates as it tries to keep up with the even faster, sudden drop in perfusion pressure. CBF transiently falls off the autoregulation curve for the time it takes (3–5 seconds) for cerebrovascular resistance to adjust to the lower perfusion pressure.



• **Fig. 63.18** A, The autoregulation curve demonstrates how the brain maintains a relatively constant cerebral blood flow *(CBF)* over a wide range of perfusion pressures by changing the caliber (resistance) of the cerebral vasculature, which necessarily leads to changes in intracranial volume. Under normal circumstances, when intracranial pressure (ICP) is negligible, the MABP is equivalent to cerebral perfusion pressure (CPP); however, when ICP is elevated, it is the CPP that is "read" by the brain. CPP will drive CBF, causing changes in cerebrovascular resistance, unless overridden by other superimposed processes such as hyperventilation, which may be pathologic or intentionally altered for a therapeutic effect. Although we have the ability to autoregulate over a wide range of perfusion pressures, the normal range is at the lower end of the curve *(horizontal blue bar)*. B, The normal resting state of the cerebrovasculature is collapsed. These vessels have critical opening and closing pressures that are slightly different from each other. With the vessel open, it typically will collapse at a slightly lower pressure than is required to open it from a collapsed state. C, After a significant injury, the potential exists to increase the critical closing pressure, which could shift the autoregulation curve to the right. *MABP,* Mean arterial blood pressure.

A normal MABP range for a young, healthy adult is approximately 70 to 90 mm Hg, and a normal ICP generally is considered to be approximately 10 mm Hg or less, which is consistent with the normal range of CPP values between 60 and 80 mm Hg. Normal ranges are at the low end of the autoregulation curve, which maintains normal CBF between MABPs ranging from approximately 50 to 150 mm Hg. It is clear from the autoregulation curve that CBF becomes a direct, linear function of MABP when outside the ability of the cerebrovascular bed to maximally dilate (MABP < 50 mm Hg) or constrict (MABP > 150 mm Hg).

The normal range of 50 to 150 mm Hg is not rigidly fixed, and individual variations are common. A hypotensive patient with an MABP of 20 mm Hg is clearly in shock, but a 21-year-old athlete with an MABP of 45 mm Hg after minor surgery may still be autoregulating. A clinical assessment is necessary in borderline situations, and one of the most important indicators of shock is a change in mental status. In this example, if the athlete demonstrates a change in mental status, he is likely to be off his autoregulation curve and in shock.

At the other end of the spectrum is chronic hypertension. Is a 74-year-old patient with long-standing hypertension who presents with an MABP exceeding 150 mm Hg by a few points having a hypertensive emergency? Again, a change in mental status may be the indicator that autoregulatory capacity has been exceeded, and the patient may be diagnosed with hypertensive encephalopathy.

CVR is often increased by trauma. At the beginning of the autoregulation curve, CBF is zero at a perfusion pressure greater than zero. A measurable pressure in the vessel exists, yet no blood flow occurs, indicating vascular collapse (see Fig. 63.18). The cerebrovasculature in its resting state is collapsed; it takes a certain amount of energy (pressure) to open the vessels. These vessels each have critical opening and closing pressures. After a head injury, free radicals can be released, which tend to make biologic tissues less compliant. This in turn may make it more difficult for the vessels to stay open—that is, more pressure is required to keep the vessels from closing, which could shift the autoregulation curve to the right (see Fig. 63.18).[206–209] This is the theoretical basis for the studies that led to the earlier recommendations to keep the minimum CPP in patients with head injuries above normal minimal values—that is, at 70 mm Hg or greater.[210]

Cerebral Perfusion Pressure

A low perfusion pressure jeopardizes ischemic regions of the brain. Increasing intravascular hydrostatic pressure by increasing CPP

can help improve cerebral perfusion. Although CPP can be manipulated and enhancement of CPP may help to avoid both global and regional ischemia, the level at which CPP is best maintained is not entirely clear,[210] and considerable interest has been directed toward attempts to determine the optimum CPP for a patient with a head injury. Some studies suggested that increasing CPP to greater than 70 mm Hg leads to improved outcomes.[211]

A combination of studies of TBI in which CPP was actively maintained at approximately 70 mm Hg in patients with a GCS score less than 8 reported a mean mortality rate of 21%, which was substantially less than the 40% mortality rate reported for similar patients in the Traumatic Coma Data Bank (TCDB). Good recovery and moderate disability rates were 54% in the patients whose CPP values were maintained in the 70-mm Hg range, compared with the 37% reported in the TCDB. However, it could not be concluded that the improved outcomes in these studies were a result of CPP management because none of the reported studies was a randomized, prospective trial of this treatment[204,209,212–216]; and in some studies, another treatment was actually the focus of the study.[212,213]

In a prospective study of 21 patients with severe TBI in whom brain tissue partial pressure of oxygen ($BtiO_2$) was monitored, ischemic episodes during the first week after injury were associated with unfavorable neurologic outcomes. Elevation of the CPP improved $BtiO_2$, but raising CPP above 68 mm Hg did not cause a further increase in $BtiO_2$. In the investigators' analysis, a CPP greater than 60 mm Hg emerged as the most important factor determining a sufficient $BtiO_2$.[204,217]

Another prospective, controlled trial of 189 adult patients with a motor GCS score of 5 or lower within 12 hours of head injury randomly assigned patients to an "ICP-targeted protocol" in which CPP was kept above 50 mm Hg or to a "CBF-targeted protocol" in which CPP was kept above 70 mm Hg. The investigators in this study found no significant difference in outcome. In this trial, the mean CPP for patients managed in the CBF-targeted protocol was 76 mm Hg and for those in the ICP-targeted protocol, 72 mm Hg. These differences were small but statistically significant.[218]

Contant and associates used data from this trial to examine risk factors for acute respiratory distress syndrome (ARDS) and consequences of its development. The risk of ARDS was five times greater among patients in the CBF-targeted group than in those in the ICP-targeted group and was associated with a more frequent use of epinephrine and a higher dose of dopamine.[203,219] Patients in whom ARDS developed were two and a half times more likely to develop refractory intracranial hypertension[219] and almost three times more likely to be in a vegetative state or dead at 6 months after injury.[219,220] These outcomes may be a direct consequence of ARDS and the related therapeutic limitations of treating raised ICP and low CPP in the presence of ARDS.[203]

Analysis of data from a study investigating the value of a neuroprotective agent in 427 patients with severe TBI revealed that the critical CPP threshold was 60 mm Hg. Although CPPs persistently less than 60 mm Hg were associated with a significant decline in outcomes, no effect on neurologic outcomes was observed for patients who had CPPs that were higher, and specifically no difference was observed among those whose CPPs averaged 60 mm Hg and those at 70 mm Hg or higher.[203,221]

In 1995 and 2000, the BTF in cooperation with the American Association of Neurological Surgeons and the Joint Section for Neurotrauma and Critical Care published guidelines for the management of severe head injury. From the data available, based on the theoretical need to increase the minimum CPP because of a change in critical opening pressures (see Fig. 63.18), the guidelines recommended maintaining a minimum CPP of 70 mm Hg or greater—10 mm Hg above the accepted norm. In 2003 this group updated the recommendation for CPP management and published a guideline that CPP should be maintained at a minimum of 60 mm Hg. In the absence of cerebral ischemia, aggressive attempts to maintain CPP above 70 mm Hg with fluids and pressors should be avoided because of the risk of ARDS.[203] In 2007 the recommendations were again modified with a level 3 recommendation to target CPP values within the range of 50 to 70 mm Hg.[204] In 2016 the guidelines stated that CPP values should be between 60 and 70 mm Hg.[143] Clearly, guidelines change as new data become available and readers are strongly advised to check for the most up-to-date recommendations.

Carbon Dioxide

Carbon dioxide is a powerful regulator of cerebrovascular resistance. At any given physiologic perfusion pressure, the partial pressure of arterial carbon dioxide ($PaCO_2$) can act rapidly and severely to affect CBF in a linear fashion by vasodilating or vasoconstricting the cerebrovascular bed. For every 1-mm Hg change in $PaCO_2$, a 3% change in CBF can occur.[222]

Allowing the $PaCO_2$ to rise to levels between 60 and 80 mm Hg can result in a doubling of CBF, through vasodilation with a concomitant increase in CBV. Conversely, aggressive hyperventilation of a patient down to a $PaCO_2$ of 20 mm Hg or less can result in cutting CBFs in half, along with a reduction in CBV. Hyperventilation was a mainstay in the therapeutic management strategy of treating patients with head injuries because it had such immediate and measurable effects on ICP. Lowering $PaCO_2$ causes rapid vasoconstriction, resulting in reduced CBV, which translates to reduced intracranial volume, which lowers ICP and increases CPP. However, hyperventilation reduces ICP by taking blood *away* from the brain, when the goal is to prevent ischemia. As seen on the autoregulation curve, the cerebrovasculature is fine-tuned to the existing perfusion pressure, providing a normal level of CBF. Aggressive hyperventilation can override the normal effect of MABP and cause a marked increase in CVR to the point at which a very high perfusion pressure would be needed to match the degree of severe vasoconstriction induced to maintain a normal level of CBF. This is the mechanism involved when a normal person hyperventilates, vasoconstricts, and becomes lightheaded as CBF falls. It is important to recognize that this individual has a normal MABP, ICP, and CBF before the $PaCO_2$ decreases.

Despite the fact that hyperventilation lowers ICP, the degree of vasoconstriction can be disproportionate relative to the enhancement in CPP. For example, at an MABP of 80 mm Hg with an ICP of 30 mm Hg and a CPP of 50 mm Hg, aggressive hyperventilation could reduce ICP to 15 by reducing intracranial volume, thereby improving CPP to 65. But aggressive hyperventilation can cause severe vasoconstriction. At maximal vasoconstriction, the cerebrovascular bed would need an MABP of 150 mm Hg with a normal ICP to maintain a normal CBF.

The data on CBF in patients with severe head injuries indicate that phases of CBF change over time after TBI, with hypoperfusion occurring in the first 24 hours.[222] Multiple studies have identified brain ischemia in up to 35% of serious head injuries within the first 12 hours.[204,222–228] It appears that this reduction happens almost immediately. Mean CBF values measured less than 4 hours after head injury in adults were 32 mL/100 g per minute in survivors and 20 mL/100 g per minute in nonsurvivors (normal CBF averages

approximately 55 mL/100 g per minute).[228] Low CBF, to ischemic levels (<18 mL/100 g per minute), was observed in 31% of patients with severe head injury measured an average of 3 hours after trauma.[204,229]

Because of the consistent data regarding reduced CBF early after trauma, attempts at further reductions using hyperventilation have come under close scrutiny. Some evidence suggests that hyperventilation carries a particular risk of causing cerebral hypoxia when $PaCO_2$ is 30 mm Hg or less, or within the first 24 hours[230,231] because of a further reduction of an already low CBF.[229] It has become clear that hyperventilation decreases $BtiO_2$ because of decreased CBF in most patients, which negates the perceived benefit of improving intracranial and cerebral perfusion pressures.[217,230–236]

The 2016 BTF guidelines recommend that chronic prolonged hyperventilation therapy (partial pressure of carbon dioxide [PCO_2] ≤25 mm Hg) should be avoided after severe TBI. However, they recognize the potential need for hyperventilation as a temporizing measure.[143]

Oxygen

Within a normal physiologic range, oxygen causes little or no change in CBF (Fig. 63.19). Beyond a partial pressure of arterial oxygen (PaO_2) of approximately 300 mm Hg, CBF can begin to wane. Oxygenation does become very important at PaO_2 levels considered to be hypoxic. Below a PaO_2 of 60 mm Hg in most patients with head injuries, the cerebrovasculature can vasodilate rapidly, causing an increase in CBV with poorly oxygenated blood, with an attendant increase in intracranial volume and pressure.

With careful clinical monitoring, our group has observed sudden ICP spikes as a result of acute oxygen desaturation that occur seconds before the pulse oximeter reading starts to deteriorate. With a moderate degree of clinical certainty, the BTF has recommended that hypoxia, defined as apnea or cyanosis in the field or a PaO_2 less than 60 mm Hg, must be scrupulously avoided or corrected immediately. Therefore in contrast with $PaCO_2$, manipulation of PaO_2 is not a useful tool for medical management of a patient with a head injury, and hypoxia must be avoided.[204]

In view of the powerful effects of hypoxia and hypercarbia, early intubation in significant head injury is important if gas exchange is compromised.

Metabolism

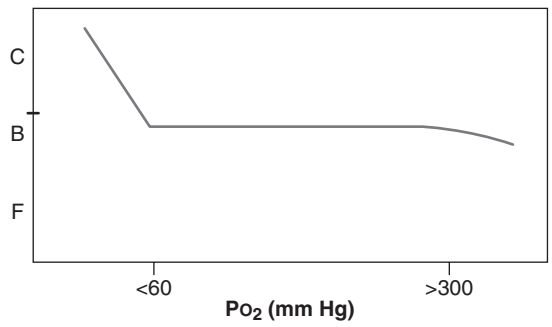
Under normal circumstances, the cerebral metabolic rate of oxygen ($CMRO_2$) is directly related to CBF; this is referred to as a coupled relationship. As metabolic demand increases, the cerebrovasculature will vasodilate to supply an appropriate increase in CBF; and conversely as $CMRO_2$ decreases, the cerebrovasculature will vasoconstrict to maintain a coupled relationship between supply and demand. As demand exceeds supply and the ability of the brain to extract more oxygen wanes, ischemia develops. Therefore as the $CMRO_2$ increases, there will be an appropriate vasodilatory response in the brain with its attendant increase in CBV and, potentially, ICP, with a resultant decrease in CPP. Clearly, if the primary event is an increase in demand and the end result is a reduction in supply, the gap between supply and demand increases, and with it the potential for ischemia. Under physiologic conditions whereby the $CMRO_2$ is coupled to CBF, various clinical states will demonstrate an appropriate balance of the two. For example, a comatose patient will have low $CMRO_2$, and a patient having a generalized seizure will have a high $CMRO_2$.

The metabolic state of the brain is sensitive to changes in temperature; lower temperatures lower $CMRO_2$, and vice versa. Recognition of this relationship has led to interest in using hypothermia as a therapeutic tool in severe head injury, both as a way to lower ICP and as a neuroprotective strategy by reducing demand in the face of limited supply. Although hypothermia can be a useful adjunct to standard treatments for controlling elevated ICP, it is difficult to find good data to prove a benefit in outcome. Clifton and associates found that ICP was lower in patients managed with hypothermia, but no improvement in outcome was observed, and the complication rate was higher than in a normothermic group. These investigators concluded that lowering body temperature to 33°C within 8 hours after injury was not effective in improving outcomes in patients with brain injuries.[237] A Cochrane review of therapeutic hypothermia for head injury studied 14 trials with more than 1000 participants and found no evidence that hypothermia is beneficial in the treatment of head injury, and that it increased the risk of pneumonia nearly twofold.[238] A different meta-analysis, using clinical trials of moderate or poor quality, identified preliminary findings suggesting a greater decrease in mortality risk when target temperatures are maintained for more than 48 hours, as well as an association with better outcomes.[239,240] The 2016 BTF guidelines state that early (within 2.5 hours), short-term (48 hours after injury) prophylactic hypothermia is not recommended to improve outcomes in patients with diffuse injury.[143]

Although it is not clear that hypothermia is helpful, hyperthermia is believed to be harmful to a patient with a severe head injury.[241] As the temperature rises, so does the $CMRO_2$, with a concomitant increase in CBV. If the patient has lost enough compliance, then small changes in intracranial volume can result in large changes in ICP (see Fig. 63.16) and CPP can fall.

A frequent scenario is development of a fever in a trauma patient with a high ICP and poor compliance who is barely meeting metabolic needs. Metabolic requirements increase as CBV and ICP increase and CPP decreases, widening the gap between supply and demand, resulting in ischemia.

Another consideration in the management of $CMRO_2$ is drug effect. Pentobarbital is the gold standard drug for reducing cerebral metabolism and can be used in cases of refractory intracranial hypertension to induce a barbiturate coma. A condition of burst suppression is achieved, meaning that the continuous EEG recording demonstrates periods of an isoelectric tracing (straight line) interrupted by bursts of cortical electrical activity. This therapy results in vasoconstriction appropriate for the degree of reduction in metabolism, with an attendant decrease in ICP. This has the



• **Fig. 63.19** Graph demonstrating the relationship of cerebral blood flow *(CBF)* to oxygen (partial pressure of oxygen *[Po_2]*). Within a physiologic range, oxygen is of no use as a therapeutic tool. The cerebral vasculature will vasodilate under hypoxic conditions, so hypoxia must be avoided.

theoretical advantage of improving supply to a brain with reduced metabolic demands. However, despite the evidence for cerebral protection in experimental models, little clinical evidence is available to suggest that induced barbiturate coma improves outcome after severe head injuries in humans. Other drugs that reduce the $CMRO_2$ and CBF are other barbiturates such as thiopental, as well as the substituted phenol propofol, the hypnotic agent etomidate, and the water-soluble short-acting benzodiazepine midazolam.[241]

According to the 2016 BTF guidelines administration of barbiturates to induce burst suppression measured by EEG as *prophylaxis* against the development of intracranial hypertension is not recommended. The guidelines also state that high-dose barbiturate administration is recommended to control elevated ICP refractory to maximum standard medical and surgical treatment, but hemodynamic stability is essential both before and during barbiturate therapy. Finally, the BTF guidelines state that although propofol is recommended for the control of ICP, it is not recommended for improvement in mortality or 6-month outcomes, and caution is required as high-dose propofol can produce significant morbidity.[143]

Viscosity

When autoregulation is intact, lowering the blood viscosity improves flow dynamics and results in an appropriate increase in CVR to maintain a constant, normal CBF.[242–246]

This vasoconstriction reduces intracranial volume. From a rheologic standpoint, there is an advantage to lowering viscosity by hemodilution, but this is at the expense of oxygen-carrying capacity. Reducing the hematocrit from 45% to 30% can theoretically double CBF, and oxygen-carrying capacity would be reduced by only a third. By generalizing experimental and clinical data involving ischemia and hematocrit, it is reasonable to consider an optimum hematocrit of approximately 30% to 35%.[247]

A common mechanism for lowering viscosity in traumatic head injury is the use of mannitol, which causes an immediate influx of extravascular water, leading to hemodilution. The vasoconstriction resulting from this reduction in viscosity allows the same CBF and oxygen delivery to be maintained by means of smaller vessels and with a lower intracranial volume (see the Hyperosmolar Therapy section). In addition, mannitol will dehydrate the red blood cells themselves by about 15%, which further improves blood flow dynamics.[247]

Venous Blood Compartment

In general, vascular organization of most organ systems is anatomically similar—for example, the renal artery travels with the renal vein. The brain, however, has two entirely different anatomic systems for arterial supply and venous drainage. The paired carotid and vertebral arteries provide the arterial supply to the brain but have no corresponding venous counterparts. Blood leaves the brain through cortical and deep draining veins that empty into the superior sagittal, transverse, and sigmoid sinuses. These dural sinuses are open, semirigid structures that empty into bilateral jugular veins, which communicate directly with the right heart through the superior vena cava. There are no valves in this entire venous system. This means that right heart pressures are in direct continuity with the superior sagittal sinus within the intracranial compartment. When measured with the patient lying supine, ICP cannot be lower than central venous pressure. Of more importance, right heart pressures will be directly transmitted to the intracranial compartment, a relevant dynamic involved with a Valsalva maneuver.

During a Valsalva maneuver, intrathoracic pressure increases and venous return to the right heart decreases. Decreased venous return means decreased venous outflow from the brain. This results in a rapid, instantaneous increase in CBV as the arterial side continues to supply the brain with blood that is not draining out on the venous side. A Valsalva maneuver also will decrease cardiac output along with a decrease in venous return, but it is a disproportionate change. A common neurosurgical practice is to have the anesthesiologist induce a controlled Valsalva maneuver toward the end of a brain procedure during the final stages of hemostasis, just before beginning the closure. Intrathoracic pressure is elevated to approximately 30 mm Hg for 10 seconds as the surgeon looks for any areas of bleeding while the brain immediately swells as it engorges with blood. An intrathoracic pressure of 30 mm Hg will overcome a normal central venous pressure and essentially interrupt venous outflow from the brain. The concomitant decrease in cardiac output with a pressure of 30 mm Hg will have much less of an effect than on the venous side; therefore a relatively large volume of arterial blood will continue to fill the brain. Even a normal brain with normal compliance will immediately be affected by decreased venous outflow with a Valsalva maneuver because it happens faster than the buffering capacity of the brain can react (see Fig. 63.16). In fact, one mechanism the brain uses to buffer increases in volume is to collapse venous capacitance vessels, which in the case of decreased venous outflow from the brain, cannot occur.

Other common ways in which venous outflow from the brain can be compromised is with anything that interferes with jugular venous drainage such as a tight-fitting rigid cervical collar or thrombosis from an internal jugular line. It is not uncommon to have dominant venous outflow on one side and, following head rotation to that side, increased resistance to venous outflow. Gravity also has a role, with head elevation enhancing venous outflow from the brain. We generally keep our patients with the head elevated at 30 degrees, neck straight and free of lines, with a good-fitting cervical collar that is not too tight.

Brain Compartment

Another functional volumetric compartment is the brain itself. One of the consequences of TBI is an acute increase in total brain water.[248]

The volume of the brain parenchyma can be affected by therapeutic dehydration induced with the use of osmotic agents. These agents can be used to treat cerebral edema in an effort to remove a pathologic accumulation of fluid. Dehydration also can be used to manipulate the volume status of an otherwise normal but threatened brain compartment to emergently manage an increase in ICP as a temporizing measure before surgery, such as with extra-axial hematoma or hydrocephalus. The agents most commonly used to effect these changes are mannitol and hypertonic saline solution.

Cerebral Edema

By definition, brain edema is an abnormal accumulation of fluid within the brain parenchyma that produces a volumetric enlargement of the brain tissue.[202] The three types of cerebral edema are vasogenic, neurotoxic, and cytotoxic. Vasogenic edema occurs when the blood-brain barrier opens, resulting in movement of vascular fluid into the extracellular spaces of the brain.[249] Neurotoxic edema involves astrocytic and dendritic swelling secondary to the neurotoxic effects of excitatory amino acids, particularly glutamate, seen with

reperfusion.[202] Cytotoxic edema results from retention of water within swollen cells, most commonly found in stroke, in which interruption of energy supply leads to pump failure and an intracellular increase in sodium and water.[202]

It is ischemia, associated with energy failure at the level of mitochondria, that contributes to cytotoxic brain edema and intracranial hypertension.[248–256] Earlier studies led to the general acceptance that traumatic brain swelling was primarily a result of vascular engorgement, which caused increased ICP.[257–261] Although opinions differ, more recent work has demonstrated that cerebral edema may be primarily responsible for brain swelling, not vascular engorgement.[237,262] Marmarou and colleagues have used sophisticated MRI techniques to demonstrate that traumatic brain edema is predominantly a cellular phenomenon in both focal and diffuse brain injury.[202]

Although cellular edema predominates, it is likely that edema formation in head injury is complicated, with time-dependent contributions of both vasogenic and cytotoxic mechanisms. Experimental evidence points to transient compromise of the blood-brain barrier occurring immediately after injury, with resultant vasogenic edema. Studies indicate early closure of the blood-brain barrier, after which cytotoxic, cellular edema predominates.[202,263–265]

Hyperosmolar Therapy

Mannitol

Mannitol, an inert six-carbon alcohol of the corresponding sugar mannose, causes cellular dehydration by increasing serum osmolarity. The use of mannitol to lower ICP in patients with head injuries is based on two mechanisms of action of this drug. It establishes an osmotic gradient across the blood-brain barrier to reduce water content,[266,267] and it causes cerebral vasoconstriction through rheologic effects that decrease blood viscosity and enhance CBF and MABP (see the earlier Viscosity section).[247,268,269] This vascular mechanism of action has a strong, independent effect, such that CBF can be enhanced even when ICP is not substantially reduced.[270,271]

With patients with head injuries, mannitol is used in two clinical scenarios. The first is that of a patient with signs of herniation secondary to a surgical clot, when mannitol is given on the way to the operating room to buy time until emergent decompression is accomplished. Generally, higher doses of up to 1.2 to 1.4 g per kg can be given in this situation.[272,273]

The second clinical scenario is one of cerebral edema, when mannitol is given to control ICP. Unlike with its use for emergency surgical clots, there is no consensus on the optimal dosing regimen of mannitol in the ICU to manage ICP. Doses ranging from 0.25 g per kg to 1.0 g per kg may be effective. Mannitol can be given in response to high ICP, or it can be used prophylactically regardless of ICP, using serum osmolarity as an endpoint of treatment,[274] although some evidence indicates that it is most effective when used in the presence of high ICP or low perfusion pressure.[269,275]

Regardless of how mannitol is used, it is intended to induce a hyperosmolar, normovolemic state. Therefore because of its osmotic diuresis, replacement of urinary water and electrolyte losses is critical to avoid hypovolemia and hypotension. Mannitol typically is given as a bolus at a rate not to exceed 0.1 g/kg per minute to avoid hypotension.[274] Caution should be exercised in patients with a propensity toward congestive heart failure, because the early effects of bolus administration cause intravascular volume expansion[274] Because of its strong diuretic effect, the use of an indwelling urinary catheter is necessary.

Mannitol can extravasate into the interstitium of the brain, with breakdown of the blood-brain barrier, which may be a cause of cerebral edema. This is thought to be less of an issue with bolus dosing as opposed to continuous infusion.[276] Because of this particular concern with mannitol toxicity, many clinicians prefer to use the smallest doses of mannitol necessary and to administer it only for proven intracranial hypertension.[277]

Another concern is renal failure, which is a rare complication of mannitol therapy. It is generally believed that the kidneys are at risk above a serum osmolarity of 320 mOsm/L[278,279]; however, kidney damage may in fact be due to high serum concentrations of mannitol itself, as opposed to high serum osmolarity. It is suggested that keeping the osmolar gap (measured serum osmolarity minus calculated serum osmolarity) below 55 mOsm/kg H_2O may be better than using serum osmolarity alone to direct mannitol therapy.[274,279]

To summarize, mannitol therapy in the ICU is effective given as boluses for elevated ICP while keeping the patient normovolemic and hyperosmolar with an osmolar gap less than 55 mOsm/kg.

Furosemide, a loop diuretic, has some effectiveness for removing extracellular fluid from the brain. Although it does not work as fast as mannitol, furosemide commonly is used in conjunction with that agent because of a synergistic effect on ICP.[280]

Hypertonic Saline Solution

In many ICUs, hypertonic saline solution is being used with increasing frequency for the treatment of raised ICP in patients with TBI.[281] It is known that patients with hypotension after severe TBI have twice the mortality rate of normotensive patients[282]; therefore aggressive resuscitation with IV fluids is recommended in the guidelines for the management of patients with severe TBI.[283] However, the important concern for the development of cerebral edema is reason enough to limit the amount of free water available to the injured brain during this early period. The use of hypertonic saline solution, both to increase mean arterial pressure and to decrease ICP, is a logical approach to limit secondary injury and improve neurologic outcome.

The rapid infusion of a small volume of hypertonic solution originally was designed for the prehospital treatment of hemorrhagic shock,[284–287] and a trial found a trend toward a reduction of ICP in a double-blind, randomized, controlled trial of prehospital fluid resuscitation using hypertonic saline solution in comatose and hypotensive patients with head injuries (although no improvement in outcome was demonstrated).[288]

The rapid infusion of small volumes of hypertonic solution leads to an osmotic gradient that mobilizes parenchymal fluid into the vascular compartment,[289,290] resulting in hemodilution, endothelial shrinkage, and improved blood flow in the microcirculation,[291,292] as well as improved cardiac output.[284,285,293] Hypertonic saline solution has been shown to reduce brain bulk and ICP[294–297] and to be effective in lowering ICP both in bolus form and as a maintenance fluid.[298–300]

It is widely believed that the mechanism of action of both hypertonic saline solution and mannitol in reducing ICP is their hyperosmolar properties, although additional mechanisms are likely to be in play. Some authors have found hypertonic saline solution to be more effective than mannitol in selected patients.[301,302]

Concerns about central pontine myelinolysis and acute renal failure appear to be unfounded on the basis of clinical experience; however, a rebound effect may occur in some patients.[303] A trial also reported no episodes of acute anemia or hypokalemia associated with 23.4% saline solution administration, nor were there any

episodes of convulsions, congestive heart failure, or coagulopathy after the administration of hypertonic saline solution.[301]

In the United States, 3% sodium chloride is readily available. An initial dose of 1.5 to 3.0 mL/kg with a target for a serum sodium concentration of approximately 155 mEq/L is reasonable,[297] although 23.4% saline solution has been shown to be safe and effective in the treatment of intracranial hypertension.[301] As with hyperosmolar therapy for mannitol, it is important to maintain a normovolemic state at all times during treatment.

The 2016 BTF guidelines state that although hyperosmolar therapy may lower ICP, there was insufficient evidence about effects on clinical outcomes to support a specific recommendation, or to support use of any specific hyperosmolar agent, for patients with severe TBI.[143]

Cerebrospinal Fluid Compartment

CSF is produced mostly by the choroid plexus located in the ventricles. CSF flows from the lateral ventricles (first two ventricles) through the foramina of Monro into the third ventricle, and from there the fluid moves through the aqueduct of Sylvius to the fourth ventricle. From the fourth ventricle, CSF moves out of the ventricular system through the foramen of Magendie in the midline and the foramina of Luschka laterally. CSF then enters the subarachnoid space, circulates around the surface of the cerebellum, brainstem, and spinal column, then up through the tentorial hiatus forming basal cisterns. The clear and colorless fluid migrates over the cerebral hemispheres toward the midline where, through a semiactive process, it is transported from the subarachnoid space into the superior sagittal sinus by the arachnoid granulations.

CSF is made at a continuous rate of approximately 0.3 mL/min. With a total volume of approximately 150 mL (roughly 10% of intracranial volume), the entire CSF volume is replaced three times a day. A little less than one-third of the total volume is in the ventricular system.

In severe head injury, CSF can be displaced from the intracranial compartment as pressure differences between the superior sagittal sinus and the intracranial compartment increase (see Fig. 63.16). The spinal CSF compartment also is an important physiologic sink, and this contribution of CSF flow to ICP is another justification for nursing patients with TBIs with the head elevated.[302]

A standard way of managing the CSF compartment in the trauma patient is by draining CSF through an indwelling ventricular catheter (ventriculostomy). This has proved to be a relatively safe and effective tool in lowering intracranial volume and pressure, although ventricles in younger trauma patients commonly are smaller and harder to access and have less CSF to drain.

Specific Treatment Considerations

Decompressive Craniectomy

Decompressive craniectomy is an alternative to the medical and direct surgical methods for reducing intracranial volume. This is a surgical strategy for managing a dangerous increase in intracranial volume by expanding the size of the intracranial compartment and converting it from a semi-rigid to an elastic container. The necessary expansion is accomplished by removing a large portion of the skull and opening the dura (see Fig. 63.13). Craniectomy can be used on one side for a swollen hemisphere causing unilateral midline shift, or bilaterally for diffuse intracranial hypertension without significant midline shift.

Intractable intracranial hypertension despite maximal medical therapy is associated with a high risk of morbidity and death.[303–305] In one multicenter trial, an 86% mortality rate was found among patients whose condition failed to respond to an induced pentobarbital coma[306]—the last line of defense in medical management. Similarly, a significant relationship has been recognized between an ICP higher than 25 mm Hg and a poor outcome.[307]

Because of these ominous facts, craniectomy to increase the space available for the swollen brain has been used to lower ICP, although early outcome studies of hemicraniectomy yielded poor results.[308–310] More contemporary experiences, however, have achieved better results. In 2006 Aarabi and colleagues reviewed 10 reports published since 1988, with a total of 323 patients treated with decompressive craniectomy for posttraumatic brain swelling and intractable intracranial hypertension, and calculated a collective mortality rate of 22.3%, with good outcomes in 48.3%, with the rest of the patients (29.4%) remaining severely disabled or in a vegetative state.[250] These results compared favorably with six previous reports in which the mortality rates ranged from 42% to 100% when ICP greater than 20 mm Hg remained refractory to medical management. Reported complications included subgaleal collections, which resolved over the course of weeks to months; delayed wound healing; bone flap resorption and infections; increased swelling and hemorrhagic contusions; and parenchymal lucencies, possibly caused by ischemia.[a] Despite the reported complications, contrast-enhanced ultrasonography used to assess cerebral perfusion after decompressive craniectomy found an average fivefold improvement in microvascular blood flow.[321,322]

Despite the apparent reduction in mortality over the years, craniectomy has not consistently been shown to improve functional outcomes. A trial published in 2011 was a multicenter, randomized, controlled Decompressive Craniectomy (DECRA) trial to test the efficacy of bifrontotemporoparietal decompressive craniectomy in adults with TBI. The authors found that in patients with severe diffuse TBI and increased ICP that was refractory to first-tier therapies, the use of craniectomy, compared with medical management alone, decreased the mean ICP and the duration of both ventilatory support and the ICU stay. However, the patients who had craniectomy had a significantly worse outcome at 6 months, as measured by the score on the extended Glasgow Outcome Scale.[323] The DECRA trial was followed by the Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure (RESCUEicp) trial in 2016, which was designed using methods more consistent with common clinical practice. Compared with medical management, this trial demonstrated that surgery resulted in fewer deaths at the expense of more vegetative survivors and patients surviving with lower severe disability. However, compared with medical management, at 12 months there was a higher rate of upper severe disability, defined as independent in the home, which may be an acceptable outcome to some patients and their families. These trials have further reinforced the mortality benefit of decompressive craniectomy and highlight important issues regarding the quality of life afterward.

The poor outcomes of decompressive craniectomy reported in these trials may result from choice of surgical approach, patient selection, and/or timing of the procedure. All of the patients in the DECRA trial and nearly two-thirds of the patients in the RESCUEicp trial had bifrontotemporoparietal craniectomies. When a unilateral craniectomy is performed, it must be large enough to prevent damage to the edges of the brain herniating out into the

[a]References 11, 221, 289, 303, 307, 311–320.

cranial defect. Several recent studies support the use of a large unilateral craniectomy (12 cm × 15 cm) to optimize outcomes.[324–327] The timing of surgical decompression may also be important, as some studies suggest that early craniectomy (within 24 hours of injury) is associated with better outcomes, especially for younger patients with higher GCS scores on presentation.[325,328,329]

The BTF released specific guidelines in 2016 before the publication of the RESCUEicp study and made the following level IIA recommendation:

> Bifrontal decompressive craniectomy is not recommended to improve outcomes as measured by the Glasgow Outcome Scale–Extended (GOS-E) score at 6 months post-injury in severe TBI patients with diffuse injury (without mass lesions), and with ICP elevation to values >20 mm Hg for more than 15 minutes within a 1-hour period that are refractory to first-tier therapies. However, this procedure has been demonstrated to reduce ICP and to minimize days in the intensive care unit.[143]

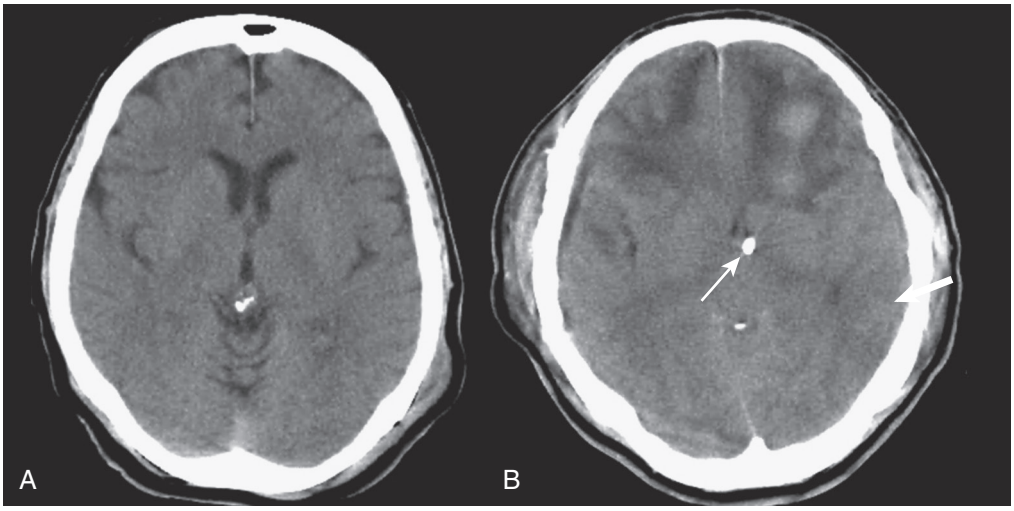
Management of Intracranial Hypertension

Acute, severe TBI is a dynamic process with the potential for dangerous changes that can evolve over hours to days; therefore all patients need to be observed closely. Ideally, ongoing assessment by neurologic examination should be at least hourly. In most patients with a GCS score of 8 or less, however, airway protection mechanisms will be impaired, necessitating intubation and, therefore, sedation, which makes an accurate neurologic assessment problematic. An ICP measuring device is usually needed at this point to adequately monitor the patient, in lieu of a reliable examination (see Chapter XX).

The medical management of intracranial hypertension in the ICU generally occurs after surgical decompression of hematomas, and in patients presenting without a surgical lesion. The threshold for treating intracranial hypertension has historically been 20 mm Hg[330]; however, a 2016 update of the BTF guidelines for the management of severe TBI made a specific level IIB recommendation to treat ICP above 22 mm Hg because values above this level are associated with increased mortality.[143] The management strategy generally is divided into tiers of therapy. The first tier is sedation, analgesia, and intubation without hyperventilation, keeping the head elevated and the neck straight and uncompressed. The routine use of paralytic agents may increase the risk of pulmonary complications; therefore muscle relaxants should be used for ICP control when sedation is inadequate.[331] If ICP exceeds targeted thresholds despite these maneuvers, moving to the next level of care is indicated, which includes CSF drainage if a ventriculostomy is being used, mannitol, or hypertonic saline solution. Beyond the first 24 hours, mild hyperventilation to keep P_{CO_2} in the mid-30s can be used. Throughout the clinical course it also is necessary to maintain an adequate CPP of at least 60 mm Hg by ensuring normovolemia and a safe MABP. If ICP is refractory to these treatments, the next step is use of decompressive hemicraniectomies or barbiturate coma (or both). Historically, surgical decompression has been reserved as a radical, end-of-the-line treatment after the patient has failed to respond to burst-suppression barbiturate coma; however, craniectomy in selected patients is moving up in the treatment algorithm of most centers, despite the literature that remains unclear (Fig. 63.20).

When ICP increases, it is important to understand why and then try to correct th underlying problem if possible. In any given patient with a head injury in whom the brain has lost its buffering capacity and compliance, small increases in intracranial volume can cause a significant rise in pressure. When ICP rises, CPP falls. If autoregulation is intact, this will usually result in a decrease in CVR and vasodilation, with its attendant increase in CBV and increase in intracranial volume. This, of course, leads to a further increase in ICP, and the cycle perpetuates itself. This is the mechanism of a plateau wave, a sustained elevation of ICP.[247]

In managing these patients, it is critical to try to determine the source of the problem. Perhaps the patient became hypovolemic and the blood pressure dropped, or a ventilator change caused hypercarbia or hypoxia. Maybe the patient is inadequately sedated or having an unrecognized seizure while pharmacologically paralyzed. The problem may be as simple as a high fever or a rigid cervical collar compressing the jugular veins. Whatever is driving this process must be corrected to break this dangerous plateau wave.



• **Fig. 63.20** A, Computed tomography (CT) image of a normal brain. B, CT scan of the brain of a patient with severe traumatic brain injury and medically intractable intracranial hypertension. Between the poorly controlled cerebral edema and the indwelling ventriculostomy, almost no cerebrospinal fluid can be identified on the scan, which shows complete obliteration of cortical sulci *(thick arrow)* and basal cisterns *(thin arrow)*. Given the absence of shift, bilateral hemicraniectomies were required.

If the cause cannot be determined, a new CT scan may be needed, and therapeutic maneuvers should be used to help turn things around, such as increasing sedation, further head elevation, ventricular drainage, administration of mannitol or hypertonic saline solution, pressors when needed, and brief periods of cautious hyperventilation.

Anticoagulation

It is intuitive that severe coagulopathy is associated with increased mortality after head injury.[332–340] Penetrating or blunt brain injury can be associated with the massive release of thromboplastin from neuronal tissue, thereby initiating the coagulation process, which evolves to an exaggerated fibrinolytic response and disseminated intravascular coagulopathy (DIC).[333] This brain injury–induced coagulopathy may lead to significant secondary injury and delay the invasive monitoring necessary for the aggressive management of intracranial hypertension.[341] The criteria for the diagnosis of DIC include abnormal results of clotting studies, thrombocytopenia, low fibrinogen, and, in some cases, elevation in levels of products of fibrinolysis (D-dimer or fibrin degradation products).[342] The DIC caused by head trauma is relatively common and frequently is detected by a prolonged prothrombin time and elevated international normalized ratio (INR). Its presence may be an indication for more intense clinical observation and follow-up CT scanning. An important component of DIC is coagulation; however, in the setting of active bleeding, anticoagulation is not indicated. The therapeutic focus is on hemostasis and replacement of diluted or consumed blood elements and components.[337,338]

Typical treatment of coagulopathy may consist of fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC) administration; however, there can be a variable effect on brain injury–induced coagulopathy. Recombinant activated factor VII (rFVIIa) may improve coagulopathy in patients with head injuries.[335] Originally developed for the treatment of individuals with hemophilia, rFVIIa also may be helpful in reversing the effects of anticoagulants and antiplatelet drugs.[335,339–349] It is a vitamin K–dependent glycoprotein, similar to the human plasma-derived factor VIIa, which appears to promote hemostasis by activating the extrinsic pathway of the coagulation cascade.[350] Its mechanism of action is not fully understood but includes interaction with platelets or tissue factor to augment thrombin generation and platelet activation.[339,341,343,344] Factor VIIa seems to be the bottleneck, the critical factor most depleted when patients are profoundly anticoagulated.[351] The use of rFVIIa to correct a coagulopathy before neurosurgical intervention was reported in 1998 in a hemophiliac patient with an EDH requiring craniotomy for evacuation.[352] Although not specifically evaluated for use in DIC, rFVIIa has been administered to neurosurgical patients in whom DIC was likely to be present.[338,347] Recombinant FVIIa has been used in the absence of hemophilia for neurosurgical emergencies such as EDH and SDH, SAH and intracerebral hemorrhage (ICH), tumor resection, and during placement of ICP monitors.[342,345,347,39] A retrospective study found improved outcomes, without complications, when rFVIIa was used for coagulopathic patients requiring urgent neurosurgical intervention.[353] The incidence of thrombosis after rFVIIa is low, but thrombosis is an extremely important potential complication[343,347,348,354,355] and is of particular concern in DIC.[337] The risk of thrombosis should be carefully considered in patients with a premorbid risk of thrombosis to avoid unintended consequences, such as ischemic stroke or myocardial infarction. Precise dosing for conditions other than hemophilia has not been confirmed[341]; the U.S. Food and Drug Administration has approved rFVIIa only for use in hemophilia; other uses are considered off-label.

In addition to the coagulopathy induced by a brain injury, neurosurgeons and intensivists often are faced with managing patients with traumatic ICH who are taking pharmacological anticoagulants. The use of these drugs is expected to increase as the population ages.[338] These patients must have normal coagulation rapidly restored to prevent further bleeding and to make surgical intervention possible.

Warfarin is a common anticoagulant that works as a vitamin K antagonist. Reversal can be achieved by vitamin K, FFP, PCC, or rFVIIa. Although all of these options reduce the INR, their efficacy, timeliness, and safety vary. It takes about 4 days to normalize coagulation if warfarin is stopped. With IV vitamin K, full reversal begins 4 to 6 hours after administration but may take up to 24 hours to lower the INR.[356] FFP contains vitamin K–dependent factors and is effective at reducing the INR within several hours; however this may take up to 30 hours, depending on the degree of anticoagulation. Additionally, FFP administration may cause pulmonary edema, intravascular volume overload, and transfusion-related reactions.[357] Active intracranial bleeding can be rapidly fatal and faster reversal agents are often required. PCCs contain variable amounts of factors II, VII, IX, X; proteins C, S, and Z; and heparin. Four-factor PCCs (e.g., Kcentra) are distinguished from three-factor products by the inclusion of appreciable amounts of factor VII. Several studies suggest that PCC use leads to faster INR reversal, less hematoma expansion, and similar or better mortality rates and functional outcomes compared with FFP.[358–361] rFVIIa results in rapid INR reversal similar to that of PCC; however, there are limited data to support improved hemostasis, mortality, or functional outcomes compared to other reversal strategies.[357] rFVIIa has also been associated with a slightly higher arterial thrombosis rate.[362] The INR is particularly sensitive to factor VII levels and INR correction may occur despite inadequate levels of factors II, IX, and X that are required for hemostasis. In addition, rFVIIa is expensive compared with other reversal strategies.[357] Considering all these factors, the Neurocritical Care Society and Society of Critical Care Medicine published guidelines in 2016 that recommend immediate administration of IV vitamin K (10 mg) and four-factor PCC (weight- and INR-based dosing), with FFP reserved for situations when PCC is not available. They recommend against rFVIIa use for warfarin reversal in patients with ICH.[357]

In hospitalized patients receiving unfractionated heparin, reversal occurs approximately 60 minutes after an IV infusion is stopped. If reversal needs to be faster, protamine sulfate is recommended. Protamine is dosed at 1 mg for every 100 units of heparin given in the previous 2 to 3 hours with a maximum single dose of 50 mg. Subcutaneous heparin is usually not reversed.[338] With low–molecular-weight heparin, a partial thromboplastin time is variably altered and not a reliable measure of its effect. Reversal of low–molecular-weight heparin LMWH is recommended for patients receiving therapeutic doses in the setting of ICH.[338] rFVIIa may be used a second-line agent.[357]

A common situation is the presentation of a patient with a head injury who is taking an antiplatelet agent such as aspirin or other nonsteroidal antiinflammatory drug (NSAID). Acetylsalicylic acid (ASA) inhibits platelet aggregation for the life of the affected platelet, which is approximately 10 days. This occurs even at the lowest dose of 81 mg/day. A period of 5 to 6 days typically is needed after stopping aspirin to replace approximately half of the circulating platelets (10% per 24 hours). The effect of ASA on platelets is complete and irreversible. If treatment is necessary, platelet transfusion should ideally be administered after three to

five terminal half-lives of the ASA to avoid pharmacologic inhibition of the transfused platelets. A 2013 trial found that platelet transfusion reduced the rate of postoperative hemorrhage, average postoperative hemorrhage volume, disability rate, and mortality rate in ASA-inhibited patients with acute hypertensive basal ganglia hemorrhage undergoing craniotomy.[363] In contrast to the positive results in surgical patients, several studies in nonsurgical patients with ICH have shown that platelet transfusions were associated with an increase in adverse events, such as hypotension, fever, cardiac and respiratory events, and decline in neurologic status.[364–366] Platelet transfusion is also associated with serious risks, including transfusion-related acute lung injury, thrombosis, DIC, hemolytic transfusion reactions, and transfusion-associated sepsis. As a result of these findings, the Neurocritical Care Society and Society of Critical Care Medicine recommend platelet transfusion only for ASA-inhibited patients with ICH if they undergo neurosurgical intervention.[357] The guidelines were published before publication of the 2016 PATCH (Pre-hospital Anti-fibrinolytics for Traumatic Coagulopathy and Haemorrhage) trial, which unexpectedly found an increased risk of death or dependence with platelet transfusion for ICH patients using ASA.[367] The findings of the PATCH trial will likely serve to reinforce the recommendation that platelets should not be transfused for patients with an ICH who are taking ASA unless operative intervention is required.

Desmopressin (DDAVP) may secondarily improve platelet adhesion to endothelial defects and is therefore also recommended to overcome aspirin-induced platelet dysfunction. The recommended dosage of DDAVP is a single administration of 0.4 μg/kg IV. Other NSAIDs have various anticoagulant effects. If significant NSAID use has occurred before a neurosurgical emergency, the same interventional strategy may apply but is not formally recommended.[357] Data confirming efficacy of DDAVP in counteracting an antiplatelet effect are not available.[338]

Other antiplatelet agents include adenosine diphosphate receptor inhibitors (e.g., clopidogrel, ticlopidine) and glycoprotein receptor-blocking agents (e.g., abciximab, eptifibatide, tirofiban). Abciximab, clopidogrel, and ticlopidine irreversibly alter platelet aggregation[368–371] through a mechanism that is additive to the antiplatelet effects of aspirin. The platelets are permanently affected; once the drug is stopped, recovery of normal platelet function requires about a week until new platelets are produced. Rapid correction requires platelet transfusion, and DDAVP also may have a beneficial short-term effect.[338] Eptifibatide and tirofiban are highly effective in generating 80% to 95% reversible inhibition in platelet aggregation.[368,369,371–374] Stopping the medication allows return of normal platelet function within approximately 48 hours for abciximab and within 4 to 8 hours for the others. Platelet transfusion increases the proportion of unaffected platelets and is the primary intervention.[338]

Fibrinolytic and thrombolytic agents disrupt formed clots.[374–376] These drugs have a prolonged half-life and frequently are used in combination with heparin or other agents to ensure continued therapeutic anticoagulation. Because circulating fibrinogen is decreased during thrombolysis, cryoprecipitate, a source of concentrated fibrinogen, is the basis for reversing treatment.[338] When cryoprecipitate is contraindicated or not available in a timely manner, antifibrinolytic agents such as tranexamic acid (10–15 mg/kg IV over 20 minutes) or ε-aminocaproic acid (4–5 g IV) may be used.[357] Although fibrinolytic and thrombolytic agents have well-recognized applications for cardiac[377] and neurologic[378,379] problems, their use generally is not seen in patients presenting with head injury.

Additional anticoagulant classes include the factor Xa inhibitors and direct thrombin inhibitors. Factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban) exert their anticoagulant effect by preventing factor Xa–dependent conversion of prothrombin to thrombin and they are reversed with four-factor PCC. Direct thrombin inhibitors such as bivalirudin, desirudin, argatroban, and lepirudin are also reversed with four-factor PCC. Dabigatran is a direct thrombin inhibitor with a specific antidote, idarucizumab. Activated charcoal is also recommended to aid in the reversal of both anticoagulant classes.[357]

Hypothermia also is known to cause and worsen coagulation abnormalities,[341,380] the treatment for which is rewarming. Certain medical conditions also may affect coagulation, and therefore may be important as underlying factors in patients with a head injury. DDAVP increases the release of factor VIII and von Willebrand factor and is used to treat mild hemophilia A, von Willebrand disease, and chronic renal and liver disease, as well as acquired and congenital platelet disorders.[380–384]

DDAVP has a significant antidiuretic effect and will increase free water reabsorption in the kidney, potentially leading to overhydration and hyponatremia. This may cause serious problems in a patient with a severe head injury with cerebral edema, poor compliance, and high ICP.

Unintended, iatrogenic worsening of coagulopathy may result with use of hetastarch solutions, which may be administered to increase intravascular volume. These solutions may lower von Willebrand factor levels and alter platelet function. Low–molecular-weight hetastarch preparations are available that may cause less severe changes; however, if the patient requires correction of a coagulation abnormality, these solutions should be avoided if possible.[384–387]

Seizure Prophylaxis

A well-known complication of moderate to severe TBI is post-traumatic seizure (PTS). PTS can be divided into two subgroups. Seizures occurring within the first 7 days after brain injury are classified as early PTS. Those occurring more than 7 days after injury are classified as late PTS.[388] In patients with severe TBI, the rate of clinical PTS may be as high as 12%, whereas that of subclinical seizures detected on EEG may be as high as 25%. Nonconvulsive electrographic seizures can also occur, leading to cerebral metabolic crisis, delayed increases in ICP, and worse clinical outcome.[389] The risk factors for early PTS include GCS score of 10 or lower; immediate seizures; posttraumatic amnesia lasting longer than 30 minutes; linear or depressed skull fracture; penetrating head injury; subdural, epidural, or intracerebral hematoma; cortical contusion; age 65 years or younger; or chronic alcoholism.[390] PTS occurs as a result of multiple mechanisms, depending on whether the TBI is penetrating or nonpenetrating. Penetrating TBI results in gliosis, or scarring of the cerebral cortex, whereas nonpenetrating TBI may result in focal contusions or intracranial hemorrhages. Hemoglobin breakdown products may have toxic effects on neuronal function and lead to PTS. A series of stepwise changes occurs in the neuronal network after an epileptogenic insult. Early changes include new gene transcription and modification of neurotransmitter receptors and ion channel proteins. Late changes are anatomic and include axonal sprouting and dendritic modifications.[390,391] These late changes may lead to posttraumatic epilepsy (PTE), which is defined as recurrent seizures more than 7 days after injury.[392]

Several population-based studies have shown that rates of PTE are substantially higher than the risk of developing epilepsy in the general population. The overall incidence of PTE is approximately 1.5% to 4.5% and in patients with severe TBI it is even higher, approximately 13% to 37%.[393,394] Those most at risk for PTE are

individuals who have have the following: severe TBI and early PTS; acute intracerebral hematoma or cortical contusion; post-traumatic amnesia lasting longer than 24 hours; age younger than 65 years; or premorbid history of depression.[395]

Seizure prophylaxis refers to the practice of administering anticonvulsants to patients with TBI to prevent the occurrence of PTS. The rationale for routine seizure prophylaxis is that there are potential benefits to preventing seizures after TBI, such as limiting hypoxia, increased intracranial pressure, increased metabolite production, and higher metabolic demands, as well as preventing the development of PTE.[396]

Historically, phenytoin has been the drug of choice for post-traumatic seizure prophylaxis. Numerous studies have shown that phenytoin reduces the incidence of early PTS, but it has no effect on the incidence of late PTS.[390,397–400] The drug, however, is associated with several disadvantages. It has a narrow therapeutic window and requires regular serum level monitoring. There is a well-established side effect profile that includes IV site reactions, exfoliative dermatitis, granulocytopenia, permanent B-cell immunodeficiency, and fatal phenytoin hypersensitivity syndrome. Phenytoin-associated hypotension is also an important consideration for polytrauma patients in shock.[401] There are data to suggest that phenytoin has negative neurobehavioral effects, especially with prolonged use.[402] It may also negatively affect cognition, particularly involving tasks with significant motor and speed components.[403] Phenytoin is metabolized through the cytochrome P450 system and thus can cause numerous drug interactions.[401] These concerns regarding the side effects of phenytoin have prompted the search for a safer alternative.

Levetiracetam is a drug that has rapidly gained in popularity owing to its demonstrated efficacy and favorable side effect profile.[404] It has a greater than 95% bioavailability, does not require regular serum monitoring, and has few drug interactions.[405] Multiple groups have studied the effectiveness of levetiracetam compared to phenytoin in the prophylaxis of PTS. No statistically significant difference between the two drugs has been found.[401,406–409] One study found that levetiracetam, as compared with phenytoin, was associated with better long-term neurologic outcomes.[408] This finding adds to earlier data suggesting that levetiracetam has a neuroprotective effect.[410,411] A subsequent report, however, found that long-term functional outcomes in patients with TBI were not affected by treatment with phenytoin or levetiracetam. The only significant difference these researchers found is that patients treated with phenytoin had a higher incidence of fever during hospitalization.[407]

Older antiepileptic drugs such as phenobarbital, valproate, diazepam, and carbamazepine have not been as extensively researched and available results are mixed. Given their side effect profiles and pharmacodynamic properties, there is no clear advantage to using these agents over phenytoin.[390,398]

In conclusion, the 2016 BTF guidelines state

> Prophylactic use of phenytoin or valproate is not recommended for preventing late PTS. Phenytoin is recommended to decrease the incidence of early PTS (within 7 days of injury), when the overall benefit is felt to outweigh the complications associated with such treatment. However, early PTS have not been associated with worse outcomes. At the present time there is insufficient evidence to recommend levetiracetam over phenytoin regarding efficacy in preventing early post-traumatic seizures and toxicity"[143]

Nonetheless, levetiracetam is commonly used in trauma centers to decrease the incidence of early PTS.

Nutritional Support

TBI causes the release of inflammatory mediators and alters cellular signals, resulting in hypermetabolism, hypercatabolism, hypoalbuminemia, refractory nitrogen wasting, and immunosuppression.[412] Hyperglycemia is also a component of the stress response to head injury. It is both a significant indicator of the severity of injury and a significant predictor of outcome from head injury.[413] It follows that the goals of nutritional support after TBI are to provide sufficient calories to satisfy the body's increased metabolic needs, maintain nitrogen balance, control blood glucose levels, and prevent immunosuppression. The timing and method of feeding are also important considerations.

The general consensus among researchers is that 25 to 30 kcal/kg per day is probably an appropriate feeding regimen, although indirect calorimetry is preferred.[414,415] A protein intake of approximately 1.5 g/kg per day should be appropriate for TBI patients to improve synthesis of protein and preserve lean body mass.[416,417]

With regard to the timing of feeding, lower mortality rates were found when patients were fed during the first 5 to 7 days after a TBI. Patients with TBI who were not fed within 5 days of injury were twice as likely to die compared with patients who were fed. Patients with TBI who were not fed within 7 days had a four times greater likelihood of death.[418] Additionally, early and aggressive parenteral nutrition administration to patients with severe TBI increases total CD4 count and T-lymphocyte responsiveness.[419]

The 2016 BTF guidelines recommend feeding patients to attain basal caloric replacement at least by the fifth day and, at most, by the seventh day after injury to decrease mortality. They also recommend transgastric jejunal feeding to reduce the incidence of ventilator-associated pneumonia.[143]

Role of Steroid Therapy

On the basis of class 1 evidence originating from a prospective randomized trial comparing dexamethasone and placebo in 300 patients with head injuries, dexamethasone was found to be ineffective in improving outcome or reducing ICP in patients with severe brain injury.[3,314] Methylprednisolone, when given in high doses to patients with moderate and severe head injuries, is associated with increased mortality.[420] Therefore the use of steroids is not recommended in their management. Accordingly, the 2016 BTF guidelines did not recommended steroids for improving outcome or reducing ICP. In fact, for patients with severe TBI, high-dose methylprednisolone was associated with increased mortality and is contraindicated.[143]

Conclusions

The management of TBI will remain a major medical and surgical challenge for the foreseeable future. Despite concentrated basic research directed at elucidating the metabolic factors that mediate the transition from primary to secondary tissue damage, nothing has been found that might have clinical efficacy. As the percentage of the population older than 70 years of age continues to rise, ICU physicians will face an ethical dilemma when dealing with brain hemorrhages in this age group. At present, physicians are left with the application of best protocol-driven critical care management, supported by timely neurosurgical intervention, and a societal commitment to protective and preventive programs.

Key Points

- The management of severe head injuries remains a major challenge to neurosurgeons.
- Timely surgical intervention is important.
- Hyperventilation, although very effective in reducing high intracranial pressure (ICP), must be used judiciously; otherwise, it may become more harmful than helpful. Glucocorticoids have no significant therapeutic benefit in managing severe head injuries.
- A simple-to-use, reproducible neurologic status scoring system, the Glasgow Coma Scale, enables meaningful and consistent multidisciplinary communication from the accident scene through intensive care and beyond.
- Mannitol and hypertonic saline solution can be useful in patients with head injuries to lower ICP.
- Decompressive craniectomy can be used to increase the space available for the swollen brain, thereby lowering ICP. Patient selection and realistic expectations are important in surgical decision making.

Review Questions

1. A colleague reports to you that a patient's Glasgow Coma Scale (GCS) score is E (eye opening) 3, V (verbal) 4, M (motor) 5. How would you interpret this?
   a. Eyes open to pain, oriented, withdraw from painful stimuli
   b. Eyes open spontaneously, oriented, follow commands
   c. Eyes open to voice, confused, withdraw from painful stimuli
   d. Eyes open to voice, confused, localize to painful stimuli
   e. Eyes open spontaneously, speech is inappropriate, withdraw from painful stimuli
   Answer: d. See the Glasgow Coma Scale section and Table 66.1.
2. Which of the following treatment options is recommended for the reversal of warfarin in patients with a traumatic intracerebral hemorrhage?
   a. Recombinant factor VIIa (rFVIIa) and platelets
   b. Vitamin K and protamine sulfate
   c. Vitamin K and prothrombin complex concentrates (PCC)
   d. rFVIIa and desmopressin
   e. PCC and idarucizumab
   Answer: c. See the Anticoagulation section.
3. Cerebral perfusion pressure can be defined as which of the following? Abbreviations are MABP (mean arterial blood pressure), CVR (cerebrovascular resistance), ICP, intracranial pressure.
   a. MABP − CVR
   b. MABP + ICP
   c. (MABP − ICP)/CVR
   d. MABP − ICP
   Answer: d. See the Secondary Head Injury section.
4. The 2016 Brain Trauma Foundation guidelines recommend which of the following goal values in severe traumatic brain injury?
   a. ICP < 20 mm Hg and CPP > 70 mm Hg
   b. ICP < 22 mm Hg and CPP 60 to 70 mm Hg
   c. ICP < 20 mm Hg and CPP 60 to 70 mm Hg
   d. ICP < 22 mm Hg and CPP > 70 mm Hg
   e. ICP < 22 mm Hg and CPP 50–60 mm Hg
   Answer: b. See the Cerebral Perfusion Pressure and Management of Intracranial Hypertension sections.
5. Antiepileptic drugs such as phenytoin and levetiracetam have been shown to reduce the incidence of early posttraumatic seizures. This effect has not been found to extend beyond what time frame?
   a. 12 hours
   b. 1 day
   c. 1 week
   d. 1 month
   e. 1 year
   Answer: c. See the Seizure Prophylaxis section.

  Nutrition and Metabolism
  Renal
  Hematologic Considerations
  Infectious Complications
Rehabilitation (Phase IV)

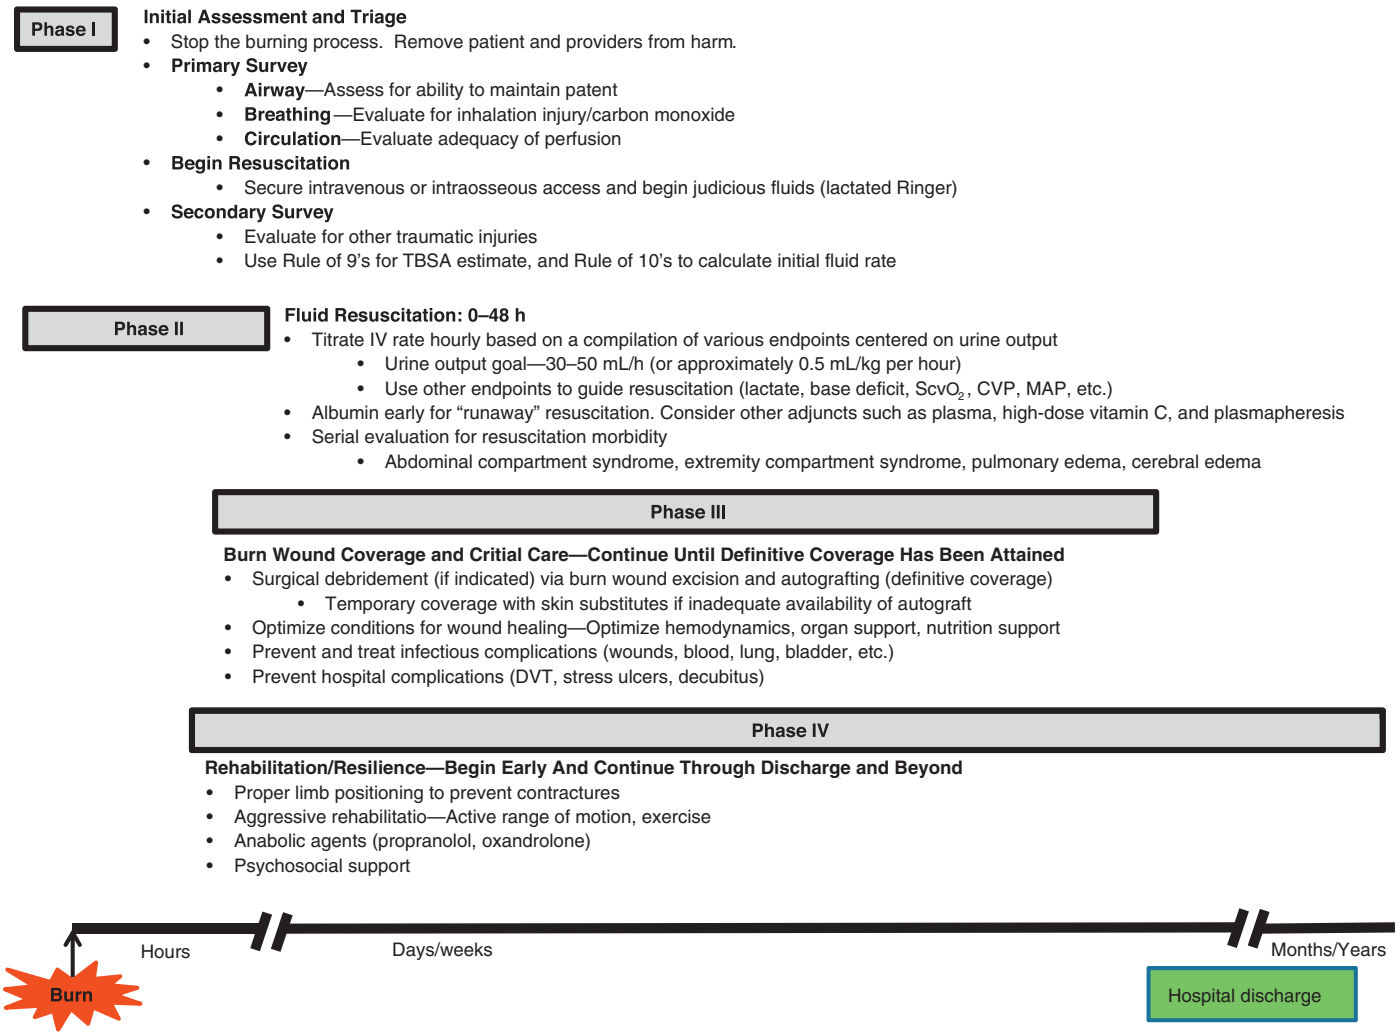
Introduction

Care of the critically ill burn patient is among the most challenging in critical care medicine. Although many fundamental principles of critical care remain similar to the care of other populations, other aspects of burn care make it very unique. For example, the first 24 to 48 hours after severe burn is characterized by a profoundly augmented and dysregulated host response that is only seldom observed in the worst categories of acute illness. Concomitant smoke inhalation injury or trauma only adds to this exaggerated response. Massive fluid resuscitation, generally prescribed to prevent multiple-organ failure and death, can be viewed as an additional insult to injury, particularly if not monitored closely. Severely burned skin then must be removed in the form of surgical burn wound excision, which typically occurs within the first week after the burn is sustained, and replaced with autograft harvested from areas of unburned skin. This procedure can only be described as controlled massive hemorrhage as intraoperative blood loss can be as high as 4 L for burns involving greater than 40% total body surface area (TBSA). For these patients, it may take multiple staged surgeries to achieve the goal of 100% definitive coverage as donor skin becomes a precious and unavailable commodity and may need to be reharvested after sufficient healing. The patient's intensive care unit (ICU) course is characterized by a high risk of bloodstream infections (BSIs) as well as a high risk of pneumonia for those with smoke inhalation injury. When these complications occur, an exaggerated host response can be expected with subsequent organ failure and high risk of death. Even if the patient can overcome the first infectious complication, recurrence is highly likely and will continue until 100% definitive autograft skin coverage has been achieved. All the while, the patient remains in an intensive care setting, subject to all the common ICU-related complications that can accumulate during a prolonged ICU stay. Simply put, burn patients face all the same issues that other critically ill populations typically face. However, unlike most other populations, fighting and overcoming the first, second, or even third insult or ICU complications is only the beginning. It is akin to a war of attrition. The goal of any good intensivist is to help preserve as much organ function as possible during this stage of care where patients are at risk of a near-perpetual barrage of physiologic insults in the form of repeated surgeries, blood loss, and infectious, iatrogenic, and other common ICU complications. At the same time, careful attention must be paid to optimize the conditions of wound healing with adequate nutrition while optimizing acute rehabilitative care to minimize the inevitable hypercatabolic muscle wasting as well as debilitating scar contractures that occur downstream.

This chapter provides intensivists a comprehensive expert review of the most state-of-the-art care of critically ill burned adults. Many principles from recent advances in critical care are extrapolated from studies from the general ICU population where appropriate. In other areas, advances specific to the critical care of burn patients are emphasized.

Epidemiology

Throughout the world, approximately 11 million people annually sustain burns severe enough to seek medical attention, ranked fourth among all injuries. Of these, 300,000 die yearly as a result. In the United States, approximately 5 to 16 per 100,000 per year sustain burns large enough to require hospital admission historically.[1] In 2011, burns were listed as a primary diagnosis in approximately 486,000 emergency department visits across the United States, and approximately 10% of patients required hospital admission.[2] The annual death rate caused by fire and burn has dramatically decreased over the past four decades. In 1981, the age-adjusted



• **Fig. 64.1** The four major phases of burn care. Initial assessment and triage (phase I); resuscitation (phase II); burn wound coverage and critical care (phase III), and rehabilitation (phase IV). *CVP,* Central venous pressure; *DVT,* deep vein thromboses; *IV,* intravenous; *MAP,* mean arterial pressure; *$ScvO_2$,* central venous oxygen saturation.

fire- and burn-related death rate was 2.99 per 100,000. This decreased to 1.39 per 100,000 in 1989.[3] In 2015, the death rate was a near 40-year low of 0.89 per 100,000.[4] This remarkable decrease in the death rate likely represents the combined impact of major advances in burn prevention and management. It should be seen as no coincidence that a relative explosion in peer-reviewed burn-related research occurred in 1980s and 1990s that correlated with many scientific medical advances.[5] Even still, there is much more work to be done. According to the American Burn Association (ABA) National Burn Repository, which contains more than 200,000 entries from major burn centers in North America from 2005 to 2015, the overall mortality among the entire spectrum of burn sizes was 3.1%. However, more than 75% had a burn size less than 10% TBSA; among these the mortality was 0.6%. Among those with greater than 10% TBSA, the mortality was 11%, whereas among those with burns greater than 40% TBSA, the mortality was 47%.[6] Although big burns (>40% TBSA) represent less than 4% of all reported burn admissions, the proportional clinical load required to care for these patients is significantly skewed. As a result, patients with greater than 40% TBSA burns have an average hospital stay that is 8-fold higher with a resultant cost that is 15-fold higher than smaller burns.[6] Hence, much of critical care in burns specifically involves this category of patients.

Phases of Burn Care

Burn care can be compartmentalized into four main phases: initial assessment and triage (phase I); resuscitation (phase II); burn wound coverage and critical care (phase III); and rehabilitation (phase IV) (Fig. 64.1).

Initial Assessment and Triage (Phase I)

Prehospital Evaluation

The main principle of prehospital care is to remove the patient from the site of injury, render a rapid systematic care to identify and treat immediately life-threatening conditions (such as airway compromise), and triage the patient appropriately to the best available medical care. Fortunately, the systematic approach applied in the care of burn patients as adopted by the ABA and taught in Advanced Burn Life Support courses throughout North America

is aligned with the Advance Trauma Life Support program developed by the American College of Surgeons (ACS) Committee on Trauma.[7]

Primary Survey

The main principles of systematically assessing a patient's condition, resuscitating, and stabilizing them, and arranging for interhospital transfer to ensure optimal care are identical. This systematic evaluation begins with the primary survey, which prompts the provider to rapidly evaluate, identify, and address immediately life-threatening conditions (airway, breathing, circulation).

Initial Assessment and Management of Inhalation Injury

Initial assessment of burn patients must always include an evaluation of the possibility of inhalation injury. The Advanced Burn Life Support course categorizes inhalation injuries into three distinct entities: upper airway, lower airway, and poisoning.[8] Inhalation injury can present as supraglottic injury, chemical injury to the respiratory tract, toxicity owing to agents such as carbon monoxide (CO) and cyanide, or a combination of all of the above. These are discussed separately in the following text.

Indications for Intubation

For the most part, indications for intubation during the acute prehospital setting are no different than those for the general trauma population. Generally, these include inability to protect the airway and inability to maintain adequate gas exchange. Inability to protect the airway secondary to alterations in mental status is the most frequent reason for intubation in the field. It should be noted that mental status alterations are not typically present owing to burns alone. In fact, many patients with extensive burns are able to maintain an adequate airway and carry a normal conversation. An altered mental status should alert the provider of the possibility of poisoning (see the "Poisoning: Carbon Monoxide and Cyanide" section) or an acute intracranial process. It should be noted that evidence of facial burns alone should not be reason to prophylactically intubate a patient in the prehospital setting. One large retrospective study determined that up to one-third of patients intubated by prehospital providers are done so owing to prophylaxis as an indication.[9] Most of these intubations may be unnecessary, especially if transport times to the regional burn center are relatively short (<1 hour). As a result, there has been widespread interest in the burn community to develop educational and training strategies to decrease the number of unnecessary intubations. Once it is ensured the airway is patent or secured, breathing is controlled, and circulation is adequate, intravenous (IV) or intraosseous access is achieved and judicious fluids initiated (see the "Fluid Resuscitation: The First 48 Hours (Phase II)" section).

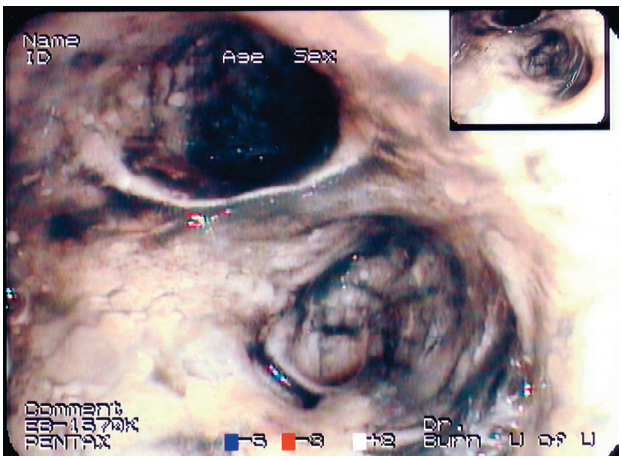
Upper Airway Injury

Upper airway injury as it relates to burns often has a true thermal component.[8] In most cases, the mechanism is a flash flame burn to the face whereby direct thermal injury has occurred to the oropharynx. Less commonly, steam, scald, or chemical burns can involve the upper airway. Flash flame burns are often seen in a flash fire from pouring gasoline on a hot grill or smoking while using oxygen. Additionally, the most severely burned patients who have extensive and deep burns to the face can also present with this type of injury. The typical physical findings of facial burns—singed nasal and facial hair and denuded oral mucosa—are present. Those who have vocal cord involvement and present with hoarseness should be considered to have severe injury. Acutely, there is a high risk of progressive airway occlusion from pharyngeal and supraglottic edema. Over the 24 hours after the burn, edema of the face and tongue can be extreme, also contributing to airway challenges (Fig. 64.2). Hence, these patients must have close follow-up and be intubated early if there are any clinical concerns of impending airway compromise.

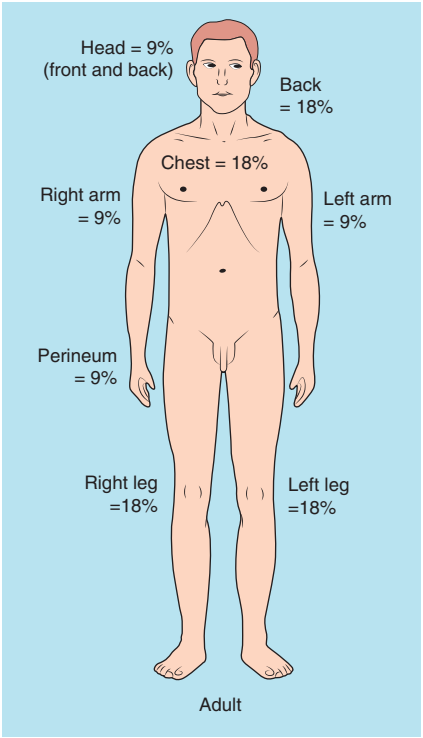
• **Fig. 64.2** This young man was burned playing with matches and gasoline, sustaining burns to 60% total body surface area, including his entire face. On presentation, he was alert and breathing comfortably. Arterial blood gas values (including carboxyhemoglobin) and chest x-ray findings were normal. Based on the extent and location of his injuries, elective nasotracheal intubation was performed. Six hours later the patient displays massive facial edema. Eyes are swollen shut, and oral excursion is severely restricted. If he lost his endotracheal tube at this point, his airway could not be maintained. Note that the tube is tied around his head securely, not taped in position. He will need to remain intubated for at least 3 to 5 days until most of this edema resolves.

Lower Airway Injury: Smoke Inhalation

Involvement of the lower airways (below the glottis) is predominantly a chemical injury.[8] This occurs as a result of patients repeatedly inhaling the toxic by-products of combustion in an enclosed space. This injury typically involves the mucosa of the entire tracheobronchial tree and is best detected by direct visualization under a fiberoptic bronchoscopy (Fig. 64.3). Clinical manifestations of this injury occur over time as the chemical irritation to the tracheobronchial mucosa causes increased secretions owing to



• **Fig. 64.3** Bronchoscopic appearance of the carina of a man who was dragged unconscious from a burning house. Carbonaceous deposits are apparent in his trachea, and more extensively in the mainstem bronchi. This finding is diagnostic of inhalation injury.



• **Fig. 64.4** The rule of nines.

increased production from goblet cells combined with obliteration of the ciliated pseudocolumnar cell lining the mucosa, resulting in inability to clear airways. These patients are at high risk for developing mucous plugs and pneumonia. Over a few days, mucosal sloughing can occur, which complicates the problem as blood and fibronacious debris mix with abundant mucous and further increase the risk of mucous plugs. Deeper into the hospitalization, patients develop tracheomalacia and bronchiectasis. Finally, involvement of the small airways can manifest as small reactive airways disease with the potential for asthma-like symptoms. Diagnosis and ICU management of inhalation injury are discussed later in this chapter.

Poisoning: Carbon Monoxide and Cyanide

Poisoning caused by CO most often occurs concomitantly in patients burned in an enclosed space.[8] CO has an affinity for hemoglobin of more than 200 times greater than oxygen and exposure results in hypoxia and ischemia. CO acts to displace oxygen from hemoglobin (forming carboxyhemoglobin [COHb]) and decreasing oxygen delivery. Symptoms of CO toxicity include confusion, stupor, coma, seizures, and myocardial infarction is diagnosed using a CO-oximeter. The mainstay of initial treatment of CO poisoning remains delivery of supplement 100% oxygen, which shortens the half-life of COHb to about 45 minutes. Hyperbaric oxygen therapy (HBO) has been used to treat CO poisoning and can further reduce the COHb half-life to about 20 minutes.[10] In those who are able to undergo therapy, HBO appears to reduce the risk of long-term cognitive neurologic sequelae.[11] However, in burns, logistical challenges have limited the wide use of HBO as acute care of severe burn is very resource intensive. Unless an HBO chamber is easily accessible and does not interfere with the comprehensive acute care, this will continue to limit wider adoption. Hopefully, continued advancements in HBO technology combined with increased ICU accessibility with ICU- and ventilator-compatible monochambers may result in increased application.

Evidence of CO toxicity should alert clinicians about the possibility of hydrogen cyanide (HCN) toxicity. HCN is a by-product of thermal combustion of various household nitrogen-containing products, such as wool, silk, paper, nylon, and polyvinyl chloride. The significance of HCN and thus the need to treat it has been controversial in the burn community.[10] Previous reports have suggested that significant HCN exposure is rare in flame burns as it is rapidly consumed because of a low flash point.[12] Hence, it is consumed as rapidly as it is produced. Regardless, it is important to look for evidence of HCN toxicity as the prevalence is not zero.[13] The clinical challenge is the lack of a rapid and reliable test to detect cyanide poisoning. A lactate elevation disproportionate to the degree of shock combined with the confirmed presence of COHb should trigger a high level of suspicion and rapid treatment. The current standard of care is to administer 5 g of hydroxocobalamin (Cyanokit, Meridian Medical Technologies, Inc., Columbia, MD) intravenously over 15 minutes.[10] This B_{12} vitamin binds to HCN to form a nontoxic cyanocobalamin that is excreted in the urine. A second dose of 5 g may be administered in patients with persistent clinical deterioration. The advantage of erring on the side of treatment is that this therapy comes with very little risk. The traditional treatment for HCN toxicity, sodium nitrite and sodium thiosulfate, should be avoided in burns as the methemoglobinemia it deliberately induces can be fatal in the setting of CO toxicity.

Secondary Survey

Next a secondary survey is conducted to evaluate for other traumatic injuries while also determining the depth and size of the burn. The rule of nines is recommended for use in the prehospital setting to quickly estimate the percent TBSA involvement (Fig. 64.4). Of note, only second- and third-degree burns (partial- and full-thickness burns) are incorporated into the TBSA estimate. For those who are severely burned or deemed to require specialty care because of anatomically challenging burns, optimal care is typically delivered at a center specializing in burn care. The ABA has published specific burn center referral criteria to aid in the appropriate triage of patients in the prehospital setting.[8] These criteria are listed in Box 64.1.

• BOX 64.1 American Burn Association Referral Criteria

1. Second-degree burn over 10% TBSA
2. Burns to face, hands, genitalia
3. Perineum, crossing joints
4. Any third-degree burn
5. Inhalational injury
6. Electrical or chemical burn
7. Concomitant trauma
8. Comorbid conditions

Concomitant Trauma

The presence of concomitant trauma in the setting of a major burn occurs in a variety of settings to include fires involving motor vehicles, aircraft, explosions, electrical injury, and trauma sustained while escaping fires. Historically, combined injury involving burn and trauma has been reported to be relatively low at 5% to 7% in the civilian setting.[14] The prevalence of concomitant trauma among military burn admissions has been reported to be much higher compared with civilian burns during wartime. Authors at the United States Army Institute of Surgical Research (USAISR) Burn Center reported that 37% of all military burns had additional nonburn injuries compared with just 11% of civilian burns ($P < 0.0001$).[15] Clearly, concomitant trauma is associated with an additive risk of death among patients with burns and should be taken very seriously.[14] During the secondary survey, it is important follow the systematic head-to-toe evaluation as advocated by the Advance Trauma Life Support program.[7] It is important for burn providers to appreciate that burns themselves are not immediately life-threatening while a missed traumatic injury can be. Necessary operations (i.e., thoracotomy, laparotomy, bone fixation) and other lifesaving procedures (i.e., chest tubes, ventriculostomy) should not be delayed by the presence of burn. Intensivists must also appreciate the complexity that trauma will add in the acute care of these patients. Care must be individualized and the various principles of critical care applied accordingly. Optimal care of the patient with combined burn and trauma is delivered by a multidisciplinary team with close coordination between the burn and trauma services.

Fluid Resuscitation: The First 48 Hours (Phase II)

Care of a severely burned patient during the first 48 hours can only be described as an extreme and sustained presentation of distributive shock encountered in only a few critically ill populations. Extensive capillary leak, which can last up to 72 hours after the burn, results in systemic extravasation of proteins, electrolytes, and plasma into the interstitial tissue, depleting the intravascular plasma volume substantially. This often feeds into a near-perpetual spiral of decreased end-organ perfusion, cell death, and shock typical of distributive shock-like states. The magnitude of the host immune-inflammatory response is directly proportional to both the extent (TBSA) and depth (partial vs. full thickness) of tissue damage that has occurred as a result of the burns themselves. Other concomitant insults such as smoke inhalation injury and trauma add to the magnitude of the response. Additional variables that complicate the presentation include overall premorbid physical condition, age, preexisting chronic medical conditions, drug or alcohol intoxication, and timing of presentation to receive medical aid. Finally, other presentations unique to burns include exposure to electricity or an endless variety of chemical compounds. The numerous premorbid conditions, mixed and matched with various types of burn injuries (flame, scald, chemical, electrical) and other burn-related insults (inhalation, trauma from blast), create a vast variety of presentations that make each patient presentation very unique and challenging. Thus an individualized approach is necessary to optimally care for these patients against the backdrop of applying key fundamental critical care principles.

• BOX 64.2 Traditional Resuscitation Formulas

Evan Formula (1952)

First 24 h: NS at 1 ml/kg per % TBSA burn + colloids at 1 mL/kg per % burn + plus 2000 mL glucose in water

Second 24 h: One-half the first 24 h of crystalloid and colloid requirement + the same amount of glucose in water as in the first 24 h

Brooke Formula (1953)

First 24 hours: LR at 1.5 mL/kg per % TBSA burn + colloid at 0.5 mL/kg per % TBSA burn

Second 24 h: Switch to D5W 2000 mL

Parkland Formula (1974)

First 24 h: LR at 4 mL/kg per % TBSA; give half in first 8 hours and the remaining over next 16 hours

Second 24 h: Colloid at 20%–60% of calculated plasma volume to maintain adequate urinary output

Modified Brooke formula (1979)

First 24 h: LR at 2 mL/kg per % TBSA burn, one-half in the first 8 h and half in the remaining 16 h

Second 24 h: Colloid at 0.3–0.5 mL/kg per % TBSA burn + D5W to maintain urine output

Adapted from Bacomo FK, Chung KK. A primer on burn resuscitation. J Emerg Trauma Shock. *2011;4:109–113.*

Over the past half century, various fluid resuscitation formulas have been proposed and used to guide burn providers. These formulas each estimate the amount each patient may require during the course of a 24- to 48-hour resuscitation postburn period (Box 64.2).[16] The goal is to maintain optimal end-organ perfusion during this time with volume replacement at the lowest physiologic cost. Underresuscitation results in decreased end-organ perfusion, resulting in cell apoptosis, organ failure, and death. On the other hand, overresuscitation is just as morbid, leading to compartment syndromes (extremities, abdomen, and orbits) as well as pulmonary and brain edema. This constellation of complications can be labeled as "resuscitation morbidity" and has been associated with death.[17]

The ABA practice guidelines suggest that the most common resuscitation formulas used to derive the initial fluid rate estimate a crystalloid requirement of 2 to 4 mL/kg per % TBSA in the first 24 hours.[18] A recent international survey study of burn shock resuscitation practices revealed a large variation in practice among 101 respondents from all over the world.[19] Still the Parkland formula was preferred in nearly 70%. However, in a study comparing those patients whose care was initiated with a standardized resuscitation

strategy with the initial rate derived using the modified Brooke formula compared with those who had the initial rate derived using the Parkland formula, the modified Brooke formula resulted in significantly less fluid without any difference in outcome.[20] The formulas also estimate that 50% of the total 24-hour volume is to be infused over the first 8 hours while it is expected that the remaining 50% will be infused over the remaining 16 hours. These are mere estimates and predict how an ideal resuscitation should be delivered over the first 24 hours. Patients are far from ideal and uniform. Thus the fluid rate is not arbitrarily decreased by half at the 8-hour mark. Clinicians should titrate IV fluid rates based on how the patient responds. Ultimately, these formulas are used to derive a starting point (i.e., initial fluid rate). This starting point matters very little, provided it is within the boundaries of an initial rate that would have been derived by formulas that estimate 24-hour estimated volumes between 2 and 4 mL/kg per % TBSA. The traditional formulas require a minimum of four computations to derive the fluid rate. This was identified as a potential reason that prehospital providers were not using a formula to initiate burn resuscitation in the field.[21] The most recent version of the Advanced Burn Life Support course recommends a flat initial rate of 500 mL/h for all adults in the prehospital setting.[8] This may be more than what is needed for a relatively small burn and not high enough for large burns. A better method for this setting is desired.

The Rule of 10

The (USAISR) Rule of 10 consists of three steps and only one simple computation in most cases (Box 64.3). The first step is to estimate the burn size (% TBSA) to the nearest 10. Second, that number is multiplied by 10 to derive the initial fluid rate in milliliters per hour. For every 10 kg above 80 kg, add 100 mL/h to this rate.[22] This quick calculation enables providers to rapidly derive the initial fluid rate in adults (>40 kg) and allows the emphasis to be placed, appropriately, on the resuscitation itself. The rule of 10 was recently validated in an in silico analysis of 100,000 simulated "patients" as it calculated a reasonable starting point for a wide range of burn sizes and weights in adults.

Once fluid resuscitation is initiated, the crystalloid rate should be titrated up or down on a regular basis (e.g., hourly) while targeting a compilation of endpoints centered on maintaining a urine output around 0.5 to 1.0 mL/kg per hour in adults. Various algorithms and clinical protocols have been proposed.[17,23,24] One such algorithm is depicted in Fig. 64.5. The goal of burn resuscitation is to provide adequate fluid necessary to avoid end-organ failure while avoiding "fluid creep."[25] Again, we must emphasize the importance of applying an individualized approach while adhering to basic critical care principles as the response to fluid therapy varies based on a number of variables. One fundamental critical care principle to keep in mind is the importance of optimizing perfusion and oxygen delivery to the end-organs until cellular dysoxia has been reversed and the underlying pathologic state is controlled. The compilation of endpoints to assess the adequacy of end-organ perfusion and oxygen delivery is no different than the various endpoints used while resuscitating patients with conditions such as sepsis and hemorrhage. The only difference in patients with burns is the expectation that the pathologic state driving the circulatory and distributive shock will persist up to 48 to 72 hours in most cases.

• BOX 64.3 The Rule of 10

1. Estimate burn size to the nearest 10
2. % TBSA × 10 = Initial fluid rate in milliliters per hour (for adult patients weighing 40–80 kg)
3. For every 10 kg above 80 kg, increase the rate by 100 mL/h

TBSA, *Total body surface area.*

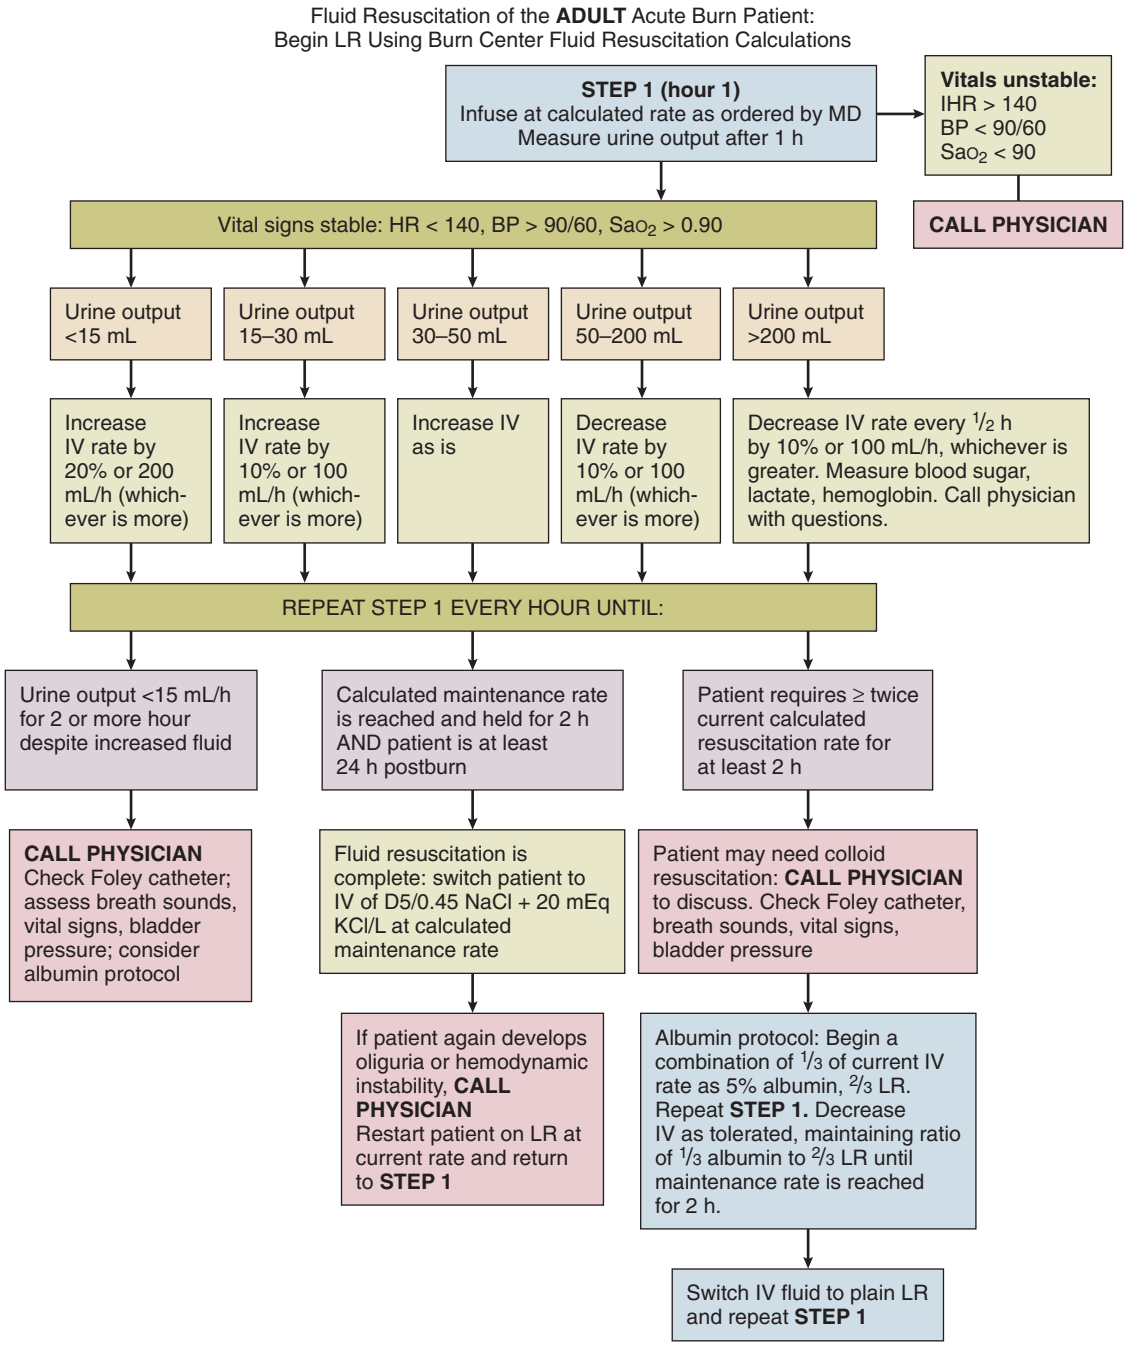
Runaway Resuscitation

During the course of resuscitating a patient with severe burns, it is important for providers recognize the point at which resuscitative adjuncts may be necessary to prevent resuscitation-related morbidity. Box 64.4 lists the different types of complications that can occur as a result of overresuscitation. A resuscitation volume greater than 250 mL/kg in a 24-hour period is often used as a benchmark and is otherwise known as the Ivy index.[26] In this study, exceeding this volume was associated with the development of abdominal compartment syndrome. Thus at any point during the first 24 hours of burn resuscitation, if the projected 24-hour volume exceeds the Ivy index, we recommend the addition of adjuncts listed in Box 64.5. This 24-hour projection is typically done at 8 to 12 hours after the burn injury to determine the need for adjuncts. Albumin is the first adjunct we recommend.

Colloids: Albumin or Plasma

Rescue therapy in the form of colloid infusion with albumin has been described a "colloid rescue."[24] A recent meta-analysis concluded that existing evidence, although somewhat limited, demonstrates improvement of burn shock resuscitation outcomes with albumin.[27] The military's Joint Trauma System Clinical Practice Guidelines recommend that 5% albumin should be initiated as early as 8 hours after a burn if certain conditions are met. These conditions include the hourly IV fluid rate exceeds 1500 mL/h or the projected 24-hr total fluid volume approaches 250 mL/kg. A 5% albumin infusion is recommended using the weight and % TBSA titration depicted on Table 64.1. Typically, this can be added to the crystalloid rate with the goal of decreasing it over the next few hours or adjustments to the crystalloid rate can be made as the albumin infusion is initiated as suggested by the algorithm in Fig. 64.5. Typically, the 5% albumin infusion rate is continued until the 48-hour mark or until the shock state has clinically resolved.

In some centers, plasma is used as the colloid of choice. O'Mara et al. conducted a randomized evaluation of colloid resuscitation with plasma versus crystalloid only and demonstrated a decrease in 24-hour fluid volumes and significantly less intraabdominal hypertension.[28] An alternative approach is to add plasma to 5% albumin infusions in those who are at high risk for resuscitation morbidity. The rate of the combined infusion should be individualized and be geared toward optimizing a compilation of endpoints centered on maintaining urine output. As always, the potential benefit of plasma should be balanced against the known risks of pooled blood product transfusions, which include transfusion-associated lung injury and a variety of infectious complications. Semisynthetic colloids such as hydroxyethyl starch (HES) solutions, succinylated gelatins, urea-linked gelatin-polygeline preparations, and dextrans can also be used.[29] However, use of HES is associated with coagulopathy in high doses, thereby limiting its use. Additionally, HES has been associated with increased prevalence of acute kidney injury (AKI) and death in RCTs, which has affected its wide adoption.[29] Whether these issues apply to all semisynthetic colloids is not well known.



• **Fig. 64.5** Burn fluid resuscitation protocol used at the University of Utah. Physicians order an initial infusion rate of lactated Ringer solution based on Parkland formula calculations and indicate the target maintenance rate. The nursing staff measures hourly urine output and increases or decreases fluids based on this response. If patients develop unexpected changes in vital signs or do not respond appropriately, physicians are contacted. An option for the use of colloid-containing resuscitation is included for patients whose requirements fail to decline. This regimen permits close titration of fluids without requiring hourly physician input. *BP,* Blood pressure; *D5/0.45,* glucose 5.0% and sodium chloride 0.45%; *HR,* heart rate; *KCl,* potassium chloride; *LR,* lactated Ringer solution; *MD,* physician; *NaCl,* sodium chloride.

Vitamin C

Ascorbic acid, or vitamin C, is an inexpensive, readily available essential nutrient that acts as an antioxidant and reactive oxygen species scavenger.[30] Animal studies have demonstrated decreased fluid requirement, edema, and reduction in capillary leak.[30] In one study of sheep, high-dose vitamin C infusion decreased net fluid balance and reduced indices of plasma lipid peroxidation when compared with crystalloids, which suggests an overall decrease of cell damage.[31] Tanaka et al. reported the results of a randomized clinical trial (RCT) demonstrating a decrease in crystalloid fluid volume when high-dose vitamin C at 66 mg/kg per hour was

added to the resuscitation.[32] This study also demonstrated improved oxygenation and a decrease in mechanical ventilation duration. Mortality was no different between the groups. A subsequent 3-year retrospective study demonstrated decreased overall resuscitation volumes with high-dose vitamin C without an increased risk of AKI among 17 patients who received the intervention compared with 16 who did not.[33] There is some concern for an osmotic diuresis with this approach with a potential risk of worsening hypovolemia and increasing AKI. Hence, urine output becomes unreliable in the setting of high-dose vitamin C. Additionally, vitamin C has been linked with oxalate nephropathy in nonburn populations and has recently been reported in postmortem examinations of burn patients treated with this adjunct.[34] One other concern is the presence of pseudohyperglycemia seen in these patients as a result of vitamin C interfering with the point of care glucose measurements.[35] Clearly, robust clinical trials are needed to fully characterize its benefits and potential side effects.

Hypertonic Saline Solution

Hypertonic saline solution preparations have been advocated as an adjunct to avoid volume overload since the 1970s. The most widely reported preparation of hypertonic saline solution is hypertonic lactated saline solution. This preparation has 300 mEq/L of sodium, 88 mEq/L of chloride, and 212 mEq/L of lactate. Oda et al. reported a significant decrease in 24-hour fluid volume which correlated with less intraabdominal hypertension in patients resuscitated with hypertonic lactated saline solution compared to lactated Ringer solution.[36] Another hypertonic sodium preparation, lactated Ringer solution plus 160 mEq/L sodium acetate (sodium [Na] = 290 mEq/L), used in burn resuscitation was reported to be associated with increased AKI and death.[37] Regardless, neither of these hypertonic preparations is widely available. On the other hand, hypertonic saline solution in the form of 3% normal saline solution can be used on a limited, intermittent basis. However, it is not recommended at high volumes (>1 L) because of its significant chloride load, which has also been associated with metabolic acidosis, AKI, and death.[38,39] The authors do not recommend the routine use of hypertonic preparations for burn resuscitation.

Therapeutic Plasma Exchange and Other Blood Purification Strategies

Plasma exchange or plasmapheresis has been described as a therapy initiated in anticipation of difficult burn resuscitations or as a rescue therapy during burn shock. Retrospective studies in this population have demonstrated a decrease in the resuscitative fluid requirement, an increase in mean arterial blood pressure, an increase in urine output, and a decrease in lactate levels.[40,41] Except in a few centers, wide adoption of this technique has been limited. During therapy plasma exchange necessitates replacement of the removed plasma volume with either albumin or plasma. One exchange treatment involves at least 5 L of either type of colloid. Repeat treatments, which are often needed, place a significant strain on hospital resources over time. The main therapeutic target for such a therapy involves the indiscriminant removal of proinflammatory and antiinflammatory mediators, which are presumed to be profoundly dysregulated.[42] Hemofiltration is an alternate blood purification approach that could be used in this setting. Evidence suggests a potential clinical benefit of high-volume hemofiltration (doses >70 mL/kg per hour) in the treatment of circulatory shock in other clinical conditions.[43,44] In burns, hemofiltration at a relatively high dose appeared to have a therapeutic effect among those with circulatory shock, mostly from sepsis.[45] A recent RCT failed to detect a significant difference between two doses of hemofiltration (70 mL/kg per hour vs. 35 mL/kg per hour) in the treatment of non-burn ICU patients with septic shock.[46] The Randomized Controlled Evaluation of Hemofiltration in Adult Burn Patients with Septic Shock and Acute Renal Failure (RESCUE) trial (NCT01213914), which recently closed to enrollment, should provide some additional insight with regard to the efficacy of this therapy in burns for the purposes of blood purification. Regardless, it should be noted that this therapy is very difficult to carry out early in burn shock owing to the relative hemoconcentration (i.e., hematocrit >50%) that exists in the immediate postburn period, resulting in clogged filters. Hence, we recommend waiting until sufficient normalization of the hematocrit has occurred in the course of a burn resuscitation (hematocrit 35% to 40%).

Resuscitation Morbidity

As already discussed, a runaway resuscitation is associated with extreme edema in both burned and unburned tissue. Intensivists must understand the clinical implications and the interplay between this degree of edema against burned tissue and relatively nonexpandable regions of the body. In some areas, the clinical consequence may be catastrophic. The various types of resuscitation morbidity

typically occur during the first 48 hours after the burn but can be delayed in presentation in some cases. Hence, intensivists must constantly be on guard and look for evidence of these complications, especially if patients are not following the typical trajectory of hemodynamic and end-organ recovery as burn shock is resolving.

Airway Edema/Facial Swelling

Endotracheal intubation is essential in those with evidence of thermal injury to the oropharynx primarily for airway protection. Edema of the glottis is often maximal at 24 to 48 hours and can persist for a few days. Thus it is very important during this period to assess the need for airway protection separate from the need for the ventilator. This is particularly important in those with isolated facial burns with upper airway injury. A patient may not need ventilator support for gas exchange, but he or she may need airway protection because of the risk of airway obstruction without the endotracheal tube. The decision to extubate must incorporate an assessment of airway edema and patency. This is often done by assessing for the presence of a cuff leak. In general, a review of the literature supports the use of a cuff leak volume of 110 mL as a standard cutoff to determine adequacy of the cuff leak below which postextubation stridor and reintubation rates are likely to be high.[47] Absence of a cuff leak or a cuff leak volume below 100 mL is considered a positive test result. A cuff leak greater than 110 mL is associated with a very low likelihood of extubation failure with a specificity of 99% and negative predictive value of 98%.[47] Serial direct fiberoptic laryngoscopy can be performed to track the resolution of edema in some cases, although measurement of cuff leak is much more objective. Treatment with a short course of steroids may be of benefit but has not been well studied in burns. If the decision is made for a trial of steroids (10 mg of IV dexamethasone), it appears maximal benefit is achieved by giving a dose at least 8 to 12 hours beforehand. For those in whom total body fluid overload is suspected, a trial of diuresis may be helpful. For those at great risk, extubation over an airway exchange catheter has been advocated, although this is technically challenging. Those with postextubation stridor may be managed with an additional dose of steroids (4–6 mg dexamethasone), racemic epinephrine nebulization, and heliox (mixture of helium and oxygen).[47] This should be considered an emergency. Thus providers should not delay the reestablishment of a definitive airway and be ready for an emergent surgical airway if necessary. This is not the time for a trial of noninvasive ventilation, for example. In general, the authors suggest waiting until a sufficient cuff leak (>110 mL) is present before a trial of extubation. If the cuff leak is absent or low, then adjuncts described (steroids and/or diuresis) can be attempted until cuff leak improves.

Facial edema can also be severe enough to make reestablishing an airway extremely challenging. In addition to the presence of a cuff leak, intensivists should incorporate the perceived ease of reintubation into their decision-making process for extubation. Until the patient has a cuff leak and facial edema has decreased to the point where successful reintubation could be achieved, the patient should remain intubated for airway protection. Other maneuvers to expedite resolution of airway and facial edema in burns include head of bed elevation and early mobilization. Early ambulation of intubated patients has been widely advocated in critical care for patients who meet certain criteria.[48] Patients who are awake, spontaneously breathing, and intubated primarily for airway protection often meet these criteria and can be ambulated safely.

• **Fig. 64.6** Example of thoracic, abdominal, and lower extremity escharotomies.

Eschar Syndrome (Extremities, Thorax, Abdomen)

Eschar is the leathery noncompliant skin that results from deep burns to the epidermis and dermis.[23] Circumferential eschar creates unique problems in different areas of the body. For example, eschar surrounding the thorax will decrease overall pulmonary compliance, making adequate ventilation of patients challenging. Abdominal eschar can also restrict lung compliance, particularly when abdominal wall and bowel edema has reached a critical threshold. Circumferential eschar to the extremities will eventually lead to compromise of arterial blood flow during the course of burn resuscitation as tissue edema ensues underneath. In all of these scenarios, empiric surgical release of regions of eschar is indicated in the form of escharotomies (Fig. 64.6). It is important to note that the need for escharotomies is seldom a true "emergency." Rather, the procedure is urgent and often done empirically or even prophylactically. There is time to optimize conditions to perform the procedure in the ICU or operating room setting. Thus these procedures should not be done in the emergency department unless a prolonged transport time (>6 hours) is anticipated. Surgical incisions should only be necessary through true eschar. Ideally, electrocautery should be used to minimize bleeding. The depth of the incision should be to the level of the subcutaneous fat, whereas the length should extend through the entire extent of the circumferential portion of the eschar. Although full-thickness burns are insensate, patients often require IV analgesics. For thoracic and abdominal escharotomies, lung compliance should be assessed before and after the procedures. Extremity escharotomies require the assessment of perfusion by detection of distal arterial pulses, usually by palpation or via Doppler signal. Upon completion of escharotomies, wounds should be covered with nonrestrictive dressings. Extremities should then be elevated as much as possible to minimize swelling.

Extremity Compartment Syndrome

Severe burn injury can also result in compartment syndrome of any muscle compartment in the body and is not always adjacent to burned tissue. Those with electrical injury are particularly at risk for compartment syndromes and should be closely monitored. Intensivists should always look for the classic findings of pain, pallor, paralysis, paresthesia, and pulselessness, although these are often obscured when patients are heavily sedated and intubated.[49] Intractable pain can be among the first clues of the possibility of compartment syndrome. Additionally, it is important to serially

monitor pulses throughout burn resuscitation. Also, serial assessment for laboratory evidence of myonecrosis, such as elevation of serum myoglobin, creatine phosphokinase, and aspartate aminotransferase, is clinically helpful in detecting occult compartment syndromes. Finally, intensivists should not underestimate the value of a serial manual palpation of major compartments. Those compartments thought to be at risk should be investigated by measuring compartment pressures. This can be performed at the bedside using an 18-gauge needle attached to a transducer. If available, compartment pressure measuring device such as an intracompartmental pressure monitor (Stryker, Kalamazoo, MI) can be used. An absolute pressure that exceeds 30 cm of H_2O generally indicates a compartment at risk and is an indication for decompression. Others have advocated the use of "ΔP" (diastolic blood pressure-intramuscular pressure), with a value less than 30 being the cutoff for compartmental ischemia.[49] As in escharotomies, perfusion should be serially assessed even after fasciotomies are performed owing to the potential need for extension as fluid resuscitation continues. Generally, prophylactic fasciotomies are discouraged because of the increased risk of infection.[23]

Abdominal Compartment Syndrome

Abdominal compartment syndrome resulting in a decompressive laparotomy is a significant resuscitation-related morbidity associated with a mortality near 90% in those with large burns.[50,51] Hence, measures should be taken to prevent abdominal compartment syndrome with resuscitation adjuncts as previously described, while optimizing nonsurgical management when it is encountered. For those at risk, measurement of bladder pressures is recommended to estimate intraabdominal pressure (IAP). There is no consensus regarding the appropriate volume used to measure IAP. We recommend a volume of between 25 and 50 mL, maintaining consistency in whatever volume is used, for serial measurements using a transducer located at the level of the symphysis pubis.[23] Diagnosis of abdominal compartment syndrome should be suspected in patients with abdominal distention, decreased lung compliance with a progressive drop in minute ventilation, hypotension, acidosis, and oliguria. A persistent IAP of 20 mm Hg or higher with organ failure is indicative of abdominal compartment syndrome and should be managed urgently.[52] Various medical treatment options include improving abdominal wall compliance by optimally relaxing the patient, optimally evacuating the gastrointestinal (GI) tract, drainage of any peritoneal fluid, and minimizing volume. Box 64.6 lists the various medical treatment options.

Of the various medical therapies, early albumin and improved burn resuscitation documentation decreases abdominal compartment syndrome–associated outcome.[53] Other resuscitative adjuncts such as vitamin C can be used as a rescue maneuver in this situation.[30] Latenser et al. demonstrated that percutaneous decompression of peritoneal fluid was effective at decreasing intraabdominal hypertension and preventing abdominal compartment syndrome.[54] We recommend temporary placement of a pigtail drainage catheter through an incision similar to that required for a diagnostic peritoneal lavage. Aside from a full decompressive laparotomy, other less invasive surgical approaches include escharotomy (if not already done) and component separation. Oda and colleagues demonstrated that escharotomy improved cardiopulmonary function and gut perfusion in patients with ACS.[55] O'Mara et al. described a modified separation of parts technique that effectively released intraabdominal hypertension with a reversal of physiologic derangements associated with abdominal compartment syndrome in a swine model.[56] This involves sequentially releasing the muscular fascia to allow the abdominal wall to relax; this technique is often used as a method of releasing tension to allow closure of an abdominal wall defect. Based on the recent experience of the burn community, decompressive laparotomy, the only definitive acute therapy, should be performed as a last resort.

• BOX 64.6 Medical Treatment Options to Reduce Intraabdominal Pressure in Burns

1. Improve abdominal wall compliance
   a. Sedation/analgesia
   b. Neuromuscular blockade
   c. Body positioning (laying patient flat in a reverse Trendelenburg position)
2. Evacuate intraluminal contents
   a. Gastric decompression via orogastric or nasogastric tube.
   b. Rectal decompression or enema
3. Evacuate abdominal fluid collections
   a. Percutaneous drainage of fluid[54]
4. Minimize positive fluid balance
   a. Colloid rescue (albumin/plasma)
   b. Renal replacement therapy/ultrafiltration

Adapted from Cheatham ML, Malbrain MLNG, A, et al. Results from the International Conference of Experts on Intra-abdominal Hypertension and Abdominal Compartment Syndrome. II. Recommendations. Intensive Care Med. *2007;33:951–962.*

Orbital Compartment Syndrome

High resuscitation volumes in burns are associated with elevated intraocular pressures (IOPs).[57,58] Increased IOP can result in optic nerve ischemia and result permanent vision loss. Hence, an ophthalmology consultation should be obtained for all patients with large burns for whom a large resuscitation is anticipated to assist with serial IOP measurements. An IOP above 30 mm Hg is indicative of orbital compartment syndrome and is a surgical emergency.[59] Rapid decompression with lateral canthotomy and inferior cantholysis remain the mainstays of management. In some cases, where facial burns are present along with a large burn, this procedure can be done empirically.

Cerebral Edema

Cerebral edema is among the most underrecognized and underreported resuscitation-related morbidities. In one pediatric burn autopsy study, cerebral edema leading to brain herniation was seen in more than half of their brain-related deaths.[60] It is unclear if these episodes were correlated to fluid volume. Clearly, those who have anoxic injury or traumatic brain injury are at high risk for developing brain edema during resuscitation. However, the association between crystalloid volume and brain edema is well described in the literature in both injured and uninjured brain.[61,62] In the experience of the authors, cerebral edema resulting in ischemia and herniation can occur with massive resuscitation in burns. However, there are no studies in the literature that have characterized the prevalence and impact of this problem in the burn population. Thus this represents a tremendous gap in knowledge in the burn literature.

Optimizing Burn Wound Coverage (Phase III)

Surgical Management

This phase of care likely has the most impact on burn survival. Early surgical excision of the burn wounds and definitive coverage with autograft has been the standard of care since the early 1970s

and has been widely recognized as among the greatest advancements in burn care.[63–65] Before wide adoption of this technique, burn eschar would often be left in place and allowed to separate over time as large quantities of fibroproteolytic proteins were released by neutrophils and bacteria present at the wound bed. This resulted in the separation of leathery eschar from granulation tissue below that eventually healed into a mass scar. Most patients died of overwhelming sepsis while waiting for this to happen. The advent and wide adoption of topical antimicrobials significantly improved outcomes.[66] However, it was not until widespread adoption of early surgical excision that significant gains could be made in terms of length of stay and survival. This technique dramatically shortened the severe hypermetabolic state and period of infectious risk while decreasing pain, allowing for earlier mobilization, relatively preserving muscle mass, and ultimately improving functional recovery among survivors.

Intensivists should be aware that the most expert critical care will have little impact on ultimate outcome if definitive coverage of the burn wound does not occur. Definitive coverage can be defined as the replacement of devitalized skin with autologous skin and should be viewed in the same light as achieving source control in sepsis. Autologous split-thickness skin is harvested from all available areas of nonburned skin and managed as a superficial partial-thickness wound. Definitive coverage can be achieved in one operation for burns less than 30% to 40% TBSA, as enough areas of normal skin exist available for harvest. Autograft is often meshed to expand the area of coverage. The goal after surgery is to maintain optimal wound healing conditions to achieve 100% engraftment with minimal graft loss. Graft loss can occur if wound excision has been inadequate or if wound infection sets in. In patients with larger burns, definitive coverage must occur in stages as autologous skin is not sufficiently available. Hence, excised burn wound must be covered temporarily with skin substitutes (i.e., cadaver skin [allograft] or pig skin [homograft]), providing temporary coverage for up to 14 days. This allows previous donor sites to heal sufficiently to allow for a reharvest of autograft. Depending on the relative skin thickness, donor sites may be harvested multiple times.

In addition to allograft and homograft, artificial skin substitutes that can be used to provide temporary coverage are listed on Table 64.2.[67] These artificial skin substitutes have characteristics and indications for use that are specific to each product with local expertise based on experience with the product. For superficial partial-thickness burns, some of these temporary products can be used while the skin heals underneath and hence they act as definitive coverage. For those with larger percent TBSA burns, cultured epithelial autograft (CEA) can be used. Epicel (Genzyme, Cambridge, MA) is cultured skin that is derived by an autologous skin biopsy that is harvested to provide keratinocytes. This is then expanded over 2 to 3 weeks into sheets of epidermal autograft. CEA can be used to cover large areas but it is very fragile owing to its monolayer characteristic. Hence, significant expertise is required for optimal graft take. A recent review suggests CEA should be used in conjunction with acellular dermal matrices for optimal outcomes.[68]

Critical Care (Phase III Continued)

Regardless of the surgical strategy used for timely definitive coverage, intensivists should keep in mind that every aspect of critical care should be geared toward optimizing conditions for wound healing. Optimizing critical care management complements surgical intervention of burn wounds to optimize overall outcomes. A comprehensive organ system approach is most practical when managing critically ill burn patients.

Neurologic

During the course of acute burn care, intensivists can anticipate a variety of neurologic issues that can affect outcome and alter long-term function. The most common manifestation of neurologic dysfunction in the ICU is delirium. The etiology is often multifactorial and is typically associated with an underlying organic problem such as sepsis or shock. It is important to use an assessment tool such as the Confusion Assessment Method for the ICU (CAM-ICU) score to screen for this on a regular basis as prevalence can be as high as 80% among mechanically ventilated burn patients.[69] Mainstays of therapy include minimizing polypharmacy, frequent reorientation, management of the sleep-wake cycle, sleep hygiene, minimization of benzodiazepine use, and judicial use of atypical antipsychotics. Evidence guiding the management of established delirium in burns is scant. In general, atypical antipsychotics, such

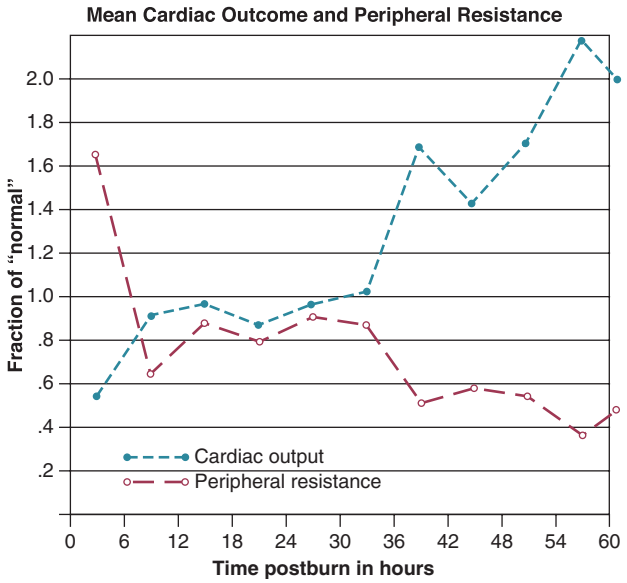
as risperidone, olanzapine, or quetiapine, are preferred over haloperidol because of the potential for extrapyramidal side effects. Use of dexmedetomidine appears to have some promise in delirium management.[70] Finally, melatonin may have a role in restoring sleep regulation and decreasing delirium.[71]

Sedation and Analgesia

Perhaps the most challenging aspect of burn care may be the day-to-day management of sedation and analgesia. Patients with severe burn experience tremendous discomfort. Although areas of full-thickness burns with complete damage to nerve ending are considered to be insensate, many areas have incomplete damage that readily trigger pain. The added inflammatory host response augments pain sensitivity at the site of the nerve endings and induces hyperalgesia. Thus any mechanical manipulation, such as wound care, showers, and rehabilitation, typically amplifies pain and anxiety. Patients experience background pain, breakthrough pain, and procedural pain that may require different approaches to therapy. Additionally, the approach may differ based on whether the patient is supported by a ventilator or not. Pain control with adequate doses of opioids without causing respiratory depression is the mainstay of therapy. Acutely, IV fentanyl or morphine infusions can be used for background pain. All opioids, with the exception of methadone, downregulate the mu receptor and have potential downstream consequences, such as tolerance, hyperalgesia, and a high propensity for chronic pain syndromes. Hence, patients should be transitioned to methadone as the preferred opioid for background pain once they are able to tolerate oral medications. Often a well-coordinated sedation strategy can augment effective analgesia, making the patient's pain more bearable. Negative consequences of deep sedation include hemodynamic instability and inability to participate in rehabilitative activity. Guidelines for sedation and analgesia published by Society of Critical Care Medicine can be applied in burns effectively.[72] An assessment tool such as the Richmond Agitation-Sedation Scale score should be applied to avoid oversedation.[72] Also, avoidance of benzodiazepines and leading with dexmedetomidine or propofol as primary agents is reasonable in patients with burns. Often ketamine may be needed because of its favorable hemodynamic profile, its opioid-sparing effects, and its potential to decrease long-term neurocognitive dysfunction.[73] In nonintubated patients, dexmedetomidine is often used as an adjunct to opioids to relieve anxiety with minimal impact on respiratory drive. The addition of ketamine to dexmedetomidine has been advocated in this setting as well.[74,75] Combining ketamine and dexmedetomidine was associated with less respiratory depression when compared to ketamine and propofol while providing the same level of sedation and analgesia in burned children.[76] The principles of multimodal therapy for the treatment of pain may be applied in burns while avoiding the pitfalls of polypharmacy. Acetaminophen can be used as an adjunct but should be limited when liver dysfunction is present. IV acetaminophen has been particularly helpful in those with gut motility issues. Nonsteroidal antiinflammatory drugs should be avoided acutely in critically ill burn patients owing to the likelihood of frequent volume shifts. They may be considered in those who are in stable condition to transfer out of the ICU. Studies to address neuropathic pain, particularly after electrical injury, phantom limb pain after amputation, or long-term management of postburn allodynia, have been mixed. Although gabapentin has been shown to be ineffective,[77] pregabalin appears helpful in burns as demonstrated in a RCT.[78] Finally, regional anesthesia may be considered in select patients with regional procedural or postprocedural pain.[72]



• **Fig. 64.7** This classic graph shows characteristic postburn changes in cardiac output and peripheral vascular resistance in a group of seven patients (mean burn size 64.5% total body surface area [TBSA]) resuscitated with the Brooke formula (lactated Ringer solution 1.5 mL/kg per % TBSA; albumin 0.5 mL/kg per % TBSA; plus 2000 mL dextrose/water in the first 24 hours). Cardiac output falls acutely before blood volume has changed appreciably and then rebounds gradually, with return to normal by 24 to 36 hours and thereafter remaining above normal. Peripheral vascular resistance shows an opposite effect. (From Pruitt BA Jr, Mason AD Jr, Moncrief JA. Hemodynamic changes in the early postburn patient: the influence of fluid administration and of a vasodilator (hydralazine). *J Trauma*. 1971;11:36–46.)

Cardiovascular

Hemodynamic changes acutely after severe burn have been well characterized[79] (Fig. 64.7). An initial decrease in cardiac output and high peripheral vascular resistance is replaced by a high cardiac output and low peripheral vascular resistance state with a relative normalization at 36 hours or so. It has been demonstrated that cardiac index and heart rate remain elevated in burns, up to 160% of predicted, through discharge from the hospital.[80] This is due to a general hypercatabolism64-7 and a sustained hypercatecholamine state. Stress hormones such as serum and urine cortisol also remain elevated throughout the hospital course.[80] Intensivists need to consider these burn-specific characteristics hemodynamically managing patients through various insults that occur during the course of a typical hospitalization to include surgery and episodes of sepsis and respiratory failure. For example, when the sustained sympathetic tone is suddenly removed in the form of induction of general anesthesia or rapid sequence intubation for respiratory failure, the potential for sudden hypotension is high. This sudden drop in blood pressure was found to be related more to burn size than the agent used for induction.[81]

Hemodynamic Support

When choosing among the various strategies and vasoactive agents to treat hemodynamic instability, intensivists must keep in mind that the conditions for wound healing must simultaneously be optimized. This begins with ensuring optimization of intravascular volume and ends with ensuring adequate end-organ perfusion. Various endpoints exist to assess intravascular volume and cardiac

output, such as central venous pressure, pulmonary capillary wedge pressure, variations in pulse pressure, and variations in stroke volume.[82] It is our opinion that a compilation of endpoints should be used in conjunction with an experienced clinician applying the principles and art of the fluid challenge.[83] This age-old technique involves identifying the fluid, the rate, the critical endpoint, and safety limits to ensure the rapid correction of the hypovolemic state while minimizing risks.[83] Over the course of a burn hospitalization, the choice of fluid should be driven by the need to minimize wound edema and total volume. Hence, blood products should be used preferentially as a first-line treatment for volume expansion if the patient is anemic or coagulopathic. As a second-line treatment, colloid in the form of albumin is preferred over crystalloid as a volume expander.

Once intravascular volume is optimized, vasopressors should be added to maintain vascular tone and ensure end-organ perfusion. During this time, continuous assessment of intravascular volume should be combined with an assessment of end-organ perfusion with global (i.e., lactate, base deficit, and central/mixed venous saturation) or regional markers if available.[84] Currently, norepinephrine, vasopressin, and epinephrine are advocated as first-, second-, and third-line agents in the management of septic shock.[85] However, the choice of vasoactive medication should be individualized and driven by the need to optimize end-organ perfusion while keeping the vulnerable wound bed in mind. Burn patients have been documented as having a robust sympathetic tone with elevations in endogenous catecholamines that is sustained throughout the course of the hospitalization.[86] As such, addition of more catecholamines has potential detrimental effects to microcirculation and the wound bed.[87] On the other hand, vasopressin is known to rapidly decline to inappropriately low levels during critical illness.[88] Hence, vasopressin is ideal given this affinity as a direct vasoconstrictor and its potentiation of circulating catecholamines.[89] It can be used as a first-line agent in some cases and as a second-line agent to decrease the norepinephrine dose. In select patients who are euvolemic and without risk of myocardial ischemia, dobutamine can be added to increase stroke volume and improve forward flow without affecting microcirculation.[90] Use of dopamine should be avoided because of the increased prevalence of tachyarrythmias,[91] whereas use of phenylephrine should be minimized because of its detrimental impact on peripheral microcirculation.[92] In those with relative catecholamine resistant shock, relative adrenal insufficiency must be considered. This is especially relevant in patients who may have received etomidate for their induction for intubation.[93] Other reasons for catecholamine-resistant shock include severe acidosis, hypophosphatemia, and hypocalcemia.[94] In addition to optimizing intravascular volume and addressing any reversible causes of shock, alternative strategies to treat catecholamine-resistant shock in burns include plasmapheresis,[40] high-volume hemofiltration,[45] and methylene blue.[95,96] Angiotensin II appears to have some promise as a catecholamine-sparing agent in resistant shock but is not yet widely available.[97] Overall, optimizing the conditions for wound healing from a cardiovascular standpoint requires an aggressive approach to minimize and reverse circulatory shock when it is encountered.

Pulmonary

Intensivists encounter a variety of challenging pulmonary problems while caring for burn patients in the ICU. Dealing with the diagnosis and manifestations of smoke inhalation is perhaps the most unique to this population. The prevalence of smoke inhalation injury, generally limited to lower airway involvement, is approximately 10% to 20% among patients admitted to burn centers.[10] Proposed diagnostic criteria are limited to the severity of bronchoscopic findings only and do not take parenchymal involvement into consideration[98] (Table 64.3). Although chest radiography alone on admission was rarely helpful in determining the presence or severity of inhalation injury,[99] detecting the presence of parenchymal involvement via a chest computer tomography scan was shown to correlate with a higher likelihood of downstream pulmonary complications.[100] However, conducting a chest computed tomography scan on admission for all patients admitted with a suspicion of smoke inhalation may not be practical. Combining chest radiography findings with fiberoptic bronchoscopy may be helpful but has not been studied.

TABLE 64.3 Abbreviated Injury Score Grading Scale for Inhalation Injury on Bronchoscopy

Grade	Class	Description
0	No injury	Absence of carbonaceous deposits, erythema, edema, bronchorrhea, or obstruction
1	Mild injury	Minor or patchy areas of erythema, carbonaceous deposits, bronchorrhea, or bronchial obstruction
2	Moderate injury	Moderate degree of erythema, carbonaceous deposits, bronchorrhea, or bronchial obstruction
3	Severe injury	Severe inflammation with friability, copious carbonaceous deposits, bronchorrhea, or obstruction
4	Massive injury	Evidence of mucosal sloughing, necrosis, endoluminal obstruction

Adapted from Albright JM, Davis CS, Bird MD, et al. The acute pulmonary inflammatory response to the graded severity of smoke inhalation injury. *Crit Care Med.* 2012;40:1113–1121.

Once a diagnosis has been made, pulmonary challenges owing to lower airway injury result in a variety of anatomically clinical problems that require active management. As discussed, lower airway injury is typically a chemical injury that results in damage to the normal tracheobronchial mucosa with involvement that can extend all the way down to the level of the alveoli. The most immediate problem encountered in the intubated patient with smoke inhalation is the collection of carbonaceous debris mixed with desiccated proximal tracheobronchial mucosa and bloody thick mucus that can result in life-threatening airway obstruction. The mainstay of management is maintenance of a well-humidified circuit and frequent bronchoscopy to ensure a patent tracheobronchial tree. Nebulized heparin has been shown to be beneficial in decreasing fibrinaceous clots without increasing the risk of bleeding.[10] Adding N-acetylcysteine to heparin appears to have some additive benefit. Farther down the tracheobronchial tree, reactive airways can result in significant problems with ventilation characterized by air trapping and hypercapnia. Inhaled bronchodilators may be helpful in this case.[101] In select cases, inhaled glucocorticoids may be helpful, especially if patients have a history of underlying

• BOX 64.7 Adjunctive Therapies for the Manifestations of Smoke Inhalation Injury

- Proximal airway obstruction
  - Nebulized heparin 5000 units every 4–6 h
  - Add N-acetylcysteine to heparin nebulization
- Reactive lower airway disease
  - Bronchodilators (β_2-agonist, muscarinic receptor antagonist)
  - Inhaled corticosteroids

asthma or chronic obstructive pulmonary disease.[101] As with any treatment strategy, the regimen should be individualized as assessed by the bedside intensivist (Box 64.7)

Ventilator Management in Burns

Even in the absence of inhalation injury, burns alone introduce unique challenges owing to a variety of issues including those derived from massive fluid resuscitation combined with an often noncompliant chest wall as well as a baseline hypermetabolic state that increases minute ventilation requirements. The addition of inhalation injury adds a variety of other variables that make ventilator management far from routine. Thus it is difficult to extrapolate standard mechanical ventilator practice guidelines to this population. A recent survey of mechanical ventilator practices in North America demonstrated wide practice variation with no one predominant ventilator mode preferred.[102] A striking finding was that less than half the respondents regularly were prescribed a low–tidal volume strategy as widely advocated for the general critical care population.[102] Quite frankly, strict adherence to a low–tidal volume strategy in a patient with a high metabolic demand and pulmonary mechanics impeded by decrease chest wall compliance and intraabdominal hypertension is ineffective. This was demonstrated in a recent RCT in which one of three burn patients failed to meet oxygenation and ventilation goals when randomly assigned to a strict low–tidal volume strategy as prescribed by the ARDS Network.[103] Among those with smoke inhalation injury, two-thirds required an alternative mode because of inadequate gas exchange with low–tidal volume ventilation. Alternatively, high-frequency percussive ventilation (HFPV), a pressure-limited, time-cycled mode of ventilation that delivers high-frequency bursts of subtidal volumes, was found to be just as "lung protective" with a similar inflammatory signature and fewer ventilator-induced events.[103] Additionally, HFPV has been shown to decrease the incidence of ventilator-associated pneumonia in patients with inhalation injury while improving gas exchange at lower peak and mean airway pressures.[104,105] Thus HFPV is the preferred mode in many burn centers, particularly in the setting of smoke inhalation injury.[106] We advocate an individualized approach to ventilator management with the adherence to the basic principles of lung protection regardless of ventilator mode.[107]

Acute Respiratory Distress Syndrome in Burns

Among burn patients who require mechanical ventilation, acute respiratory distress syndrome (ARDS) has been reported to occur in 34% to 54% depending on the definition of ARDS.[108–110] It is clear that categorizing ARDS via the Berlin definition into mild, moderate, and severe disease is useful in burns.[111] There is a clear stepwise and significant increase in mortality from mild (17%), moderate (44%), and severe ARDS (60%).[110] Once ARDS is diagnosed, intensivists should adhere as much as possible to the principles of lung protection by minimizing volutrauma, barotrauma, and atelectrauma while meeting gas exchange goals. The potential value of HFPV in this population has already been discussed. Other alternative modes of ventilation such a pressure-regulated volume control, airway pressure release ventilation, and high-frequency oscillatory ventilation are regularly used by the burn community with varying success.[102] High-frequency oscillatory ventilation has been well described in the setting of severe ARDS, reducing barotrauma and facilitating early burn surgery.[112] Various nonventilator adjuncts can be leveraged on an individualized case-by-case basis. These include fluid restriction and aggressive diuresis in conjunction with albumin infusion,[113] neuromuscular blockade with cisatracurium,[114] prone ventilation,[115] and even corticosteroid infusions.[116,117] Despite concerns for graft loss, prone ventilation applied in burn patients with severe ARDS did not significantly affect wound healing while demonstrating improvement in oxygenation.[118] Many centers have recently incorporated extracorporeal membrane oxygenation for severe ARDS in patients with burns with some success.[119]

Tracheostomy in Burns

The decision to perform a tracheostomy in burn patients is multifactorial and should take into consideration clinical stability, preexisting and concurrent comorbidities, and anatomic barriers such as deep burns to the neck. However, despite the inherent challenges, the majority of burn centers agree on tracheostomies being generally indicated when the expected time of mechanical ventilation exceeds 2 weeks.[102] In one survey, the majority of burn surgeons prefer performing an open procedure in the operating room rather than a percutaneous tracheostomy at the bedside. This is likely due to the fact that percutaneous tracheostomy may be challenging owing to anatomic considerations. One study, however, demonstrated that percutaneous tracheostomy was associated with a lower complication rate and could be safely performed at the bedside in burn patients, most of whom had neck burns.[120]

Gastrointestinal

The GI tract represents a complex end-organ that is highly susceptible to decreased perfusion in early stages of shock. Intensivists must be highly attentive to the various presentations of end-organ dysfunction of the GI tract. GI dysfunction can manifest in a variety of ways. Decreased motility of the proximal gut is the most likely and clinically apparent presentation characterized by nausea, emesis, tube feeding intolerance, or small bowel ileus. The presence of gastric emptying abnormalities should be considered when deciding the appropriate route of medications. In severe cases, proximal GI dysfunction can present as gastritis or an erosive ulcer heralded by an upper GI bleed as the result of persistent mucosal hypoperfusion. The development of a gastric ulcer has been historically linked with burns and is classically known as a Curling ulcer.[121] The combination of early enteral feedings and acid suppression has resulted in the reported decrease of this complication.[122] Distal GI dysfunction can manifest as constipation, diarrhea, or colonic pseudo-obstruction.[123] Distinguishing hypoperfusion-related GI dysfunction from other metabolic (electrolytes) or iatrogenic causes (opioids) can be quite challenging. Constipation can often be treated by providing laxatives such as polyethylene glycol or lactulose on a regular basis. Methylnaltrexone 12 to 24 mg subcutaneously daily appears to be effective in antagonizing the opioid-related slowing of

the entire gut and relieves some of these symptoms.[124] In patients in whom all reversible causes of colonic pseudo-obstruction have been identified and treated, neostigmine may be useful.[125] Perhaps the most catastrophic presentation of GI dysfunction is intestinal ischemia with full-thickness necrosis presenting with or without abdominal compartment syndrome.[51] The heterogeneous nature of the GI tract makes it extremely difficult to characterize this end-organ as a single entity. A standard consolidated definition of GI dysfunction for critically ill patients with four stages of severity coined "acute gastrointestinal injury" (AGI) has been proposed.[126] This standardized definition has not yet been adopted widely in the critical care or the burn community. It does represent, however, an opportunity for further research to determine if these staging criteria can reliably characterize this end-organ dysfunction in the burn population. Biomarkers of such as citrulline may also be helpful in detecting GI dysfunction at the cellular level.[127] Currently close monitoring of upper GI symptoms, gastric residuals, stool output, and evidence of ischemia remain the mainstays of detecting GI dysfunction.

Other Abdominal Complications in Burns

Intensivists must be aware of other intraabdominal issues that may be specific to the burn population. Perhaps the most ubiquitous abnormality among patients with large burns are hepatic enzyme elevations.[128] Abnormal hepatic enzymes reflect the profound hypermetabolic and hypercatabolic stress response characterized by an accentuated cycle of glucose, lipid and protein synthesis, and degradation.[129] The liver, because of its complex metabolic, inflammatory, immune, and acute-phase functions, plays a central role in recovery from burns. Nearly all patients with large burns develop fatty infiltration (steatosis) of the liver over time. Other variables such as gasoline involvement, which occurs in up to a quarter of all burn admissions,[130] can contribute to the severity of liver injury owing to effects from hydrocarbon toxicity.[131] Thus it is not surprising that those with baseline liver dysfunction at the time of burn injury have a significantly higher mortality than those without.[132,133] Shock liver is the most severe ischemic end-organ manifestation and presents with profoundly elevated liver enzymes, hyperbilirubinemia, and coagulopathy. A relatively uncommon but clinically significant complication is acute acalculous cholecystitis. In one large series over a 21-year period, the prevalence was 0.18% (20 cases among 10,762 patients).[134] Diagnosis of cholecystitis in burn patients is extremely challenging as physical symptoms can often be obscured owing to burns (pain, fever, and so on). Thus intensivists must maintain a high index of suspicion when encountering sepsis with a source that is not readily obvious. Finally, acute pancreatitis is associated with increased mortality in burns.[135] In one series, 40% patients with large burns developed pancreatic enzyme elevations with an associated increase in risk of mortality.[136] Likely cholecystitis, symptoms of pancreatitis are often obscured by the nature of burn injury and subsequent care. Thus increased vigilance on the part of the treatment team is necessary.

Nutrition and Metabolism

The hypermetabolic and hypercatabolic state in burns is multifold greater in both magnitude and duration when compared with other critically ill populations.[137,138] Optimizing nutritional requirements during ICU care is critical in promoting wound healing while mitigating against the metabolic derangements that result in loss of lean muscle mass, increase in fat mass, and immune compromise over time.[139,140] Intensivists face a fine balance between meeting the high energy needs of the hypercatabolic burn patient while avoiding the negative consequences of nutrient overconsumption. Nutrition support after a burn injury is highly complex owing to several physiology-, injury-, and treatment-related variables that come into play in determining energy expenditure. Many of these variables, such as age, premorbid nutritional status, need for mechanical ventilation, sedation, and activity level, are no different than other ICU populations. Burn care–specific variables that intensivists must incorporate into energy expenditure estimates include initial burn size, pain control, need for frequent surgical procedures, degree of wound closure, and the impact of environmental temperature regulation. It is important to recognize that like other ICU populations, energy expenditure changes throughout the course of the hospitalization must be reassessed for burn patients on a regular individualized basis. Daily contributions of a dedicated registered dietician with burn experience integrated as part the multidisciplinary burn team are invaluable in optimizing care. Energy requirements can be estimated using a variety of predictive equations. Among all variety of predictive equations, the Carlson and Milner equations appeared to correlate best with actual energy expenditure as measured by indirect calorimetry[141–143] (Box 64.8).

• BOX 64.8 Predictive Equations That Best Estimate Energy Expenditure in Burns

- Carlson (1992)[141]
  BMR × [0.89142 + (0.01335 × TBSA)] x BSA x 24 x AF
- Milner (1994)[142]
  [BMR × (0.274 + 0.0079 × TBSA − 0.004 × PBD) + BMR] × 24 × BSA × AF
- BMR (kcal/m^2 per hour)
  Men: 54.337821 − (1.19961 × Age) + (0.02548 × Age^2) − (0.00018 × Age^2)
  Women: 54.73942 − (1.54884 × Age) + (0.03580 × Age^2) − (0.00026 × Age^2)
- BSA (m^2)
  Square root of (Height in cm × Weight in kg)/3600

AF, Activity factor (typically 1.2–1.4)[143]; BMR, basal metabolic rate (in kcal/m^2/h) in healthy population; BSA, body surface area; TBSA, total body surface area burns.

Once energy expenditure and the estimated caloric requirement have been determined, intensivists must ensure the right amount of nutrition is delivered. Although underfeeding can predictably affect wound healing and muscle mass, overfeeding can also be problematic. In one series of 250 burn patients, overfeeding significantly above the resting energy expenditure as measured by indirect calorimetry increased only fat mass with little impact on lean muscle mass.[144] Excess calories from carbohydrates leads to hyperglycemia that can exacerbate systemic inflammation and promote further decrease in muscle mass.[145] As such, no more than 5 mg/kg per minute of glucose should be infused.

Perhaps the most important macronutrient in burns is protein. Provision of dietary protein and/or amino acids is essential for minimizing net protein catabolism and muscle protein breakdown. It appears that higher than normal intake of protein may appear worthwhile, but intake of 1.5 g/kg per day does not appear to provide much advantage while it increases concentrations of urea and ammonia.[146] Although up to 3 g/kg of protein has been recommended in children, 1.5 to 2 g/kg is generally advocated in adults

per recent guidelines.[147–149] It is clear, however, that net protein catabolism and eventual loss of muscle mass persist in burns regardless of the amount of protein intake. Anabolic agents, such as oxandrolone, have been shown to increase lean body mass recovery, decrease length of stay, and improve overall outcomes, including wound healing.[150,151] β-Blockade with propranolol has also been shown to reverse muscle protein catabolism thought to be mediated by endogenous catecholamines in burned children.[152] This intervention is currently being evaluated in a RCT in adults (ClinicalTrials.gov Identifier NCT01902810). Insulin appears to be a another promising anabolic agent that has been shown to reduce protein catabolism and increase skeletal muscle protein synthesis.[153,154] However, use of insulin as a primary anabolic agent in the absence of hyperglycemia in burns lacks definitive trials and has not been widely adopted. Specific amino acids, such as glutamine, which plays a role in maintaining gut barrier function, have been associated with decreased infections, decreased length of stay, and reduced mortality via either the enteral or IV routes.[155] Although a small amount of fat is necessary to prevent deficiency of essential fatty acids, excess fat may exacerbate the immunosuppressed state and lead to increased infection and sepsis.[156,157] Finally, essential vitamins such as vitamins A, C, and D as well as trace elements such as iron, copper, selenium, and zinc are all recommended to optimize wound healing and skeletal, neuromuscular, and immune function.[147–149]

Overall, early enteral nutritional support has been correlated with shorter hospital stays, accelerated wound healing, and decreased risk of infection.[158] Hence, enteral feedings should be initiated as soon as possible after the burn injury if the patient is hemodynamically stable, being weaned from vasopressors, with minimal gastric output.[149] Some clinical judgment is required as to what constitutes the right time to initiate enteral feedings. In those with larger burns, postpyloric enteral feedings may offer an advantage to minimize interruptions in nutrition delivery over gastric feedings, which many institutions hold before surgery. In patients unable to tolerate enteral feedings, early parenteral nutrition has been advocated as early as 24 hours after burn injury.[147]

Environmental Temperature Control

Increasing ambient temperature to mitigate the loss of thermoregulation and decrease the impact of hypermetabolism has been a long-standing practice among many burn centers around the world. As such, rooms are commonly heated to as high as 100°F. A recent review demonstrated limited data demonstrating the physiologic benefits of this routine practice in the ICU.[159] Although avoiding hypothermia is certainly considered important in maintaining hemostasis intraoperatively, clinical studies in nonburn patients have not demonstrated an associated increased blood loss.[159] Excessive ambient temperatures also have the potential to cause detriment to both the patient and ICU staff. Elevated temperatures may be an occupational hazard to the staff with an additional downside of affecting cognitive performance. The effect of a warm ICU on the growth of nosocomial bacteria and fungi is of some concern, as is increased perspiration of staff with the possibility of wound contamination during dressing changes and other procedures. Alternative measures to maintain core temperature in burn patients are much needed. Additionally, further studies to elucidate the physiologic impact of increased environmental temperature on burn hypermetabolism will be helpful. In the meantime, the current practice of reflexively increasing room temperature when caring for burn patients requires careful consideration. Again, an individualized approach in this regard may prove to be optimal as evidence of this practice is extremely weak at best.

Renal

Historically, the prevalence of AKI among burn patients has been difficult to pinpoint owing to the lack of a standard definition. What has been well documented is its association with an exceedingly high mortality of 80% to 100%.[160–162] Over the past decade, standard definitions of AKI have been applied to the burn population. A recent comprehensive review determined that AKI occurred in 25% of patients among burn patients and was associated with a median mortality of 35% when defined by the Risk, Injury, Failure, Loss, and End-stage renal disease (RIFLE) consensus classification.[163] Among those requiring renal replacement therapy (RRT), mortality was reported as 80%.[163] The Acute Kidney Injury Network (AKIN) criteria were later applied and found to be more sensitive in the detection of AKI.[164] The Kidney Disease Improving Global Outcomes (KDIGO) consensus panel has further refined these criteria but they have yet to be applied to burns.[165] Although these definitions have been helpful in better characterizing this end-organ and linking AKI severity to a stepwise increase in mortality, they still do not provide a comprehensive picture. Further clarity on the role of various injury biomarkers in burns, such as cell cycle arrest markers and urinary neutrophil gelatinase-associated lipocalin, will help complement these function-specific diagnostic criteria.[166,167] Once the diagnosis is made, the mainstay of therapy for AKI includes the maintenance of adequate organ perfusion and the prevention of secondary insults such as nephrotoxins. In select patients, the use of fenoldopam, a selective dopamine-1 agonist, at a dose of 0.03 to 0.09 mg/kg per minute, may be considered as it may be helpful in preserving renal function and increases urine output without inducing hypotension.[168] Vasoactive medications such as fenoldopam or atrial natriuretic peptide were not recommended for routine treatment of AKI in the general ICU population.[165]

Renal Replacement Therapy in Burn Patients

In the management of burn patients with severe AKI, a traditional approach of waiting for classic triggers for initiation of RRT (such as acidosis, severe electrolyte abnormalities, intractable fluid overload, and uremic complications) may result in an unacceptably high mortality. An aggressive approach of initiating RRT with early AKI combined with metabolic derangements led to an absolute reduction in mortality by 30% when compared with historical control subjects, most of whom never met classic criteria for renal replacement and thus were not offered RRT.[44] A recent RCT demonstrated a survival benefit with a similarly aggressive approach in a nonburn ICU population.[169] Such a study would be helpful in the burn population. However, the likelihood of an adequately powered randomized controlled study is unlikely to be feasible in the near future in this unique population. The Randomized Controlled Evaluation of Hemofiltration in Adult Burn Patients with Septic Shock and Acute Renal Failure (RESCUE) trial recently closed to enrollment after 6 years because of difficult and slow recruitment (ClinicalTrials.gov Identifier: NCT01213914). Findings from this study and a concurrent observational study among RESCUE trial participating burn centers will help provide some future guidance for burn providers. However, findings are unlikely to be definitive. Again, an individualized approach, with extrapolation of findings and interventions from similar populations, is most likely to result in optimal outcomes.

Hematologic Considerations

Acutely, the most common burn-specific hematologic abnormality that intensivists encounter is hemoconcentration. In large burns, hematocrit levels often exceed 60%. Practically speaking, this degree of hemoconcentration results in significant sludging that may affect blood flow, especially to the distal extremities. Thus this important variable must be considered when assessing distal pulses early after a burn injury. Often allowing a few more hours of fluid resuscitation allows for normal flow. Additionally, a savvy clinician can take advantage of this expected abnormality to uncover subtle clinical defects. For example, a "normal" hematocrit despite a large burn could signal the presence of a chronic anemia. Hemoconcentration that fails to normalize over the course of a fluid resuscitation can be indicative of underresuscitation. Normalization of the hematocrit level is expected within 24 to 36 hours and may even fall below normal as the blood becomes hemodiluted. Other acute direct burn-related cellular changes can occur to the blood, including intravascular hemolysis, spherocytosis, fragmentation, and vesiculation.[170] Pseudothrombocytosis as the result of red cell microvesicles being incorrectly counted as platelets has also been reported.[171]

Burns can uniquely affect other cell lines. A reactive leukocytosis is common after immediately after burns, reflective of a generalized stress response. In up to 46% of patients, this is followed by a relative leukopenia down to an average nadir of 5/μL of blood around 3 days after the burn.[172] On the other hand, thrombocytopenia as defined by less than 150,000/μL of blood has been reported to occur in up to 60% of burns.[172] Generally thereafter a reactive leukocytosis and thrombocytosis is thought to be a normal physiologic response to the stress of burns and a variety of subsequent physiologic insults during the course of burn care. One study demonstrated the poor congruence between BSI and white blood cell count owing to its lack of specificity in burns.[173] Severe thrombocytopenia as defined by less than 20,000/μL of blood has been associated with increased mortality.[172]

Anemia in Burns

Over the course of a hospitalization, nearly all patients with significant burns experience anemia. This anemia is due to a combination of blood loss from surgery as well as multifactorial issues related to critical illness.[174] Estimating perioperative blood loss during burn surgery has been a significant challenge and hence the focus of clinical researchers over the past few decades. Providers must carefully predict blood transfusion requirements to avoid waste of cross-matched blood. In one study, more than half of the red blood cell units typed and cross-matched were not transfused during surgery.[175] For planning purposes, it appears that burn patients require approximately 2 units of packed red blood cells (pRBCs) per 1000 cm^2 of burn wound excised.[176] Clearly, this estimate should be individualized as variables such as age, presence of a coagulopathy, and delays in burn excision affect intraoperative transfusion needs. During the course of a burn hospitalization, total transfusions are, not surprisingly, tied to TBSA. For example, one study demonstrated that an average of 4, 8, 12, and 20 units of pRBCs were transfused for patients with less than 10%, 11% to 19%, 20% to 40%, and greater than 41% TBSA burns, respectively, over the course of a hospitalization.[175] Another study found an average of 14 and 30 units of pRBCs were transfused for patients with more than 20% and more than 50% TBSA burns, respectively.[177] Various techniques to minimize transfusion requirements have been described.[174] Intraoperative techniques minimizing intraoperative blood loss, such as epinephrine tumescence and tourniquet application, appear to be quite effective and have been widely adopted.[174] Extrapolating the accumulating evidence in the critical care literature regarding restrictive transfusion practices to burns may also be helpful in decreasing total in-hospital transfusions.[174] Preliminary evidence suggests that mild to moderate anemia has little impact on wound healing in the setting of adequate perfusion.[178] A recent multicenter RCT confirmed that a restrictive strategy in burns resulted in a decrease of blood transfusions by half without a noticeable impact on various outcomes.[178a] Finally, the role of erythropoietin in addressing the blunted endogenous erythropoietin response in critically ill burns is unclear. Two trials in burns demonstrated that exogenous erythropoietin administration had no impact on transfusions.[179,180] The lack of impact of erythropoietin on transfusion requirement was corroborated in a large RCT in trauma. However, an alternative protective benefit may be plausible as erythropoietin seemed to convey a survival advantage despite an increase in thrombotic complications.[181] More studies are clearly needed.

Venous Thromboembolism

The prevalence of venous thromboembolism reported in the literature varies widely, from as low as 0.25% to as high as 23%.[182–187] A major reason for this wide variation is likely due, in part, to the detection of occult deep vein thromboses (DVT) during active surveillance. Clearly the higher rates were detected and reported in prospective studies in which routine surveillance was conducted.[184,186] It is unclear if treatment of previously occult DVT affects outcome in a positive way. In burn patients the initiation of anticoagulation is not without complication. As such, it should not be surprising that only 75% of burn centers surveyed routinely prescribed prophylaxis.[188] The most recent study identified various risk factors associated with a predisposition for DVTs to include male sex, age, smoking, alcoholism, the percent TBSA, use of a central line, and increased number of surgeries and blood transfusions.[187] Those with these risk factors should probably undergo routine prophylaxis while keeping in mind that optimizing chemoprophylaxis may be challenging in this population.[189] Clearly more clinical trials are needed to provide more definitive guidance with regard to identification and quantification risk, understanding the role of routine surveillance, and optimization of chemoprophylaxis.

Infectious Complications

As many as 61% of all deaths in burns occur as a result of infection.[190] This should not be surprising as severe burns are characterized by the loss of the cutaneous protective barrier to infection, immune-inflammatory dysregulation, and a frequent use of invasive devices. Perhaps among the most significant challenges intensivists face while caring for burn patients includes early detection of sepsis. The typical manifestations of systemic inflammation, which include fever, tachycardia, and leukocytosis, are regularly seen in burn patients even in the absence of infection. Thus prior sepsis definitions that relied on these variables to detect systemic inflammatory response syndrome were too sensitive in the burn population. As a result, the burn community proposed more burn-specific indicators.[191] These include temperature (>39°C or <36°C); a higher threshold for tachypnea (>25 breaths/min without ventilation or >12 L/min with ventilation); a higher threshold for tachycardia (>110 beats/min); thrombocytopenia (<100,000/μL of blood); hyperglycemia (untreated glucose >200 mg/dL, >7 units/h insulin infusion, or >25% increase in insulin dosing over 24 hours); and enteral feeding intolerance (abdominal distention, residuals over

twice the feeding rate, or diarrhea >2500 mL/24 hr).[191] The presence of three or more of these findings increases the likelihood of systemic infection and is a reasonable prompt for clinicians to initiate further workup, and if indicated, initiation of broad-spectrum antibiotics. The quick Sepsis-Related Organ Failure Assessment (qSOFA) was advocated by the most recent sepsis consensus conference.[192] Two of three qSOFA elements (altered mental status, respiratory rate ≥22 breaths/min, and systolic blood pressure ≤100 mm Hg) were determined to best identify patients at risk for clinical deterioration in a large metadata-driven model.[192] Although not yet validated in burns, it is reasonable incorporate qSOFA along with the burn-specific indicators to identify burn patients who may have sepsis. Once a determination is made, broad-spectrum antibiotic coverage should be initiated promptly.

Wound Infections

In addition to early surgical excision, wide adoption of topical antimicrobial agents for burn wounds has virtually eliminated death from invasive, gram-negative burn wound infection.[193] Table 64.4 lists the most common topical antimicrobial agents.[194] The diagnosis of invasive wound infection should still be entertained if there has been a delay in surgical excision or if there are areas of poor wound healing from either temporary or definitive coverage. Signs include obvious discoloration of the wound bed, exudate, and a spreading margin of erythema around the wound edges and is confirmed by full-thickness biopsy and histopathology. Later in the ICU course, the possibility of invasive fungal wound infection should be entertained as it is a major cause of morbidity and mortality.[195,196] Invasive wound infection typically requires broad-spectrum antimicrobials to include antifungals if fungus is suspected and rapid surgical excision.

Other Infections

Pneumonia is a frequent cause of infection in the burn ICU with a prevalence of 25% to 38%.[197] Inhalation injury increases the risk of pneumonia as a result of damage to the ciliary layer of the tracheobronchial mucosa, sloughing leading to distal airway obstruction, and immune dysfunction. Preventive measures include all the bundle elements found to be important in the general ICU population.[198] Application of HFPV may be considered a preventive strategy based on its mechanism of allowing for improved pulmonary secretion mobilization and data suggesting a decreased prevalence of pneumonia.[104,105]

BSI was diagnosed in 33% of 11,793 patients entered into the national burn repository.[199] *Staphylococcus aureus* was the most frequent isolate associated with BSI followed by *Pseudomonas aeruginosa.* A large bacteriology study also revealed *S. aureus* as the most common pathogen among burn patients in the United States.[200] Interestingly this study demonstrated a change in recovered pathogen over time. Although *S. aureus* was most commonly recovered during the first 15 days, *P. aeruginosa* and *Klebsiella pneumoniae* were most commonly recovered after 15 days. Bacteriology recovery patterns differed in military service members burned and transferred from the Middle East with *Acinetobacter baumanii* most predominant organism found early.[200] In addition to geographic and longitudinal differences in bacteriology, a well-known challenge in the care of infections among burns is the high prevalence of multidrug-resistant organisms. Burn clinicians must take these factors into consideration when choosing empiric antibiotic coverage. Efforts to decrease the rate of BSI in burns include frequent catheter exchanges (either over a wire or to a new access site) and routine use of antimicrobial-coated catheters.[201–203]

Other pertinent burn population infectious complications deserve specific mention. Although relatively rare, with a reported prevalence of 0.3%, a diagnosis of established endocarditis among burn patients is associated with a mortality of 100%.[204] Any burn patient with persistent or recurrent bacteremia should have a workup for infectious organisms. *Clostridium difficile* infection is a clinically important infection in burn patients and should be suspected in those with unexplained diarrhea with septic physiology.[205] Viral infections such as herpes simplex virus and cytomegalovirus have been reported to play a role in contributing to burn morbidity.[206] There is no consensus, however, regarding a specific prophylactic or treatment strategy with these infections. Diagnosis of a true

TABLE 64.4 Topical Antimicrobial Agents

Product	Application	Penetration	Side Effects
Mafenide acetate cream	Apply 1/16-inch layer twice daily[a]	Penetrates eschar	Painful on application, metabolic acidosis
Silver sulfadiazine cream	Apply 1/16-inch layer twice daily[a]	Poor eschar penetration	Transient leucopenia
Mafenide acetate solution	Dress wounds with multiple layers of coarse gauze and apply solution to keep gauze continually moist	Partially penetrates eschar	Electrolyte disorders
Silver nitrate solution	Dress wounds with multiple layers of coarse gauze and apply solution to keep gauze continually moist	Poor eschar penetration	Painful on application
Silver-impregnated dressings (Acticoat, Silverlon, Silverseal)[b]	Moisten dressing with sterile water, cut to size, secure to wound with secondary dressing, change in 3–5 days	Poor eschar penetration	

[a]Consider alternating mafenide in the morning with silver sulfadiazine in the evening.
[b]Application information obtained from package insert.

invasive viral infection is exceedingly difficult as it requires histologic evidence. A balance of risk-benefit must be weighed when deciding to treat patients empirically with antiviral drugs. Finally, pharmacokinetics and pharmacodynamics are extremely complex in burns with significant patient-to-patient variability and fluctuations over time.[207] As such, the importance of incorporating a dedicated clinical pharmacist with burn experience into the daily workflow of a burn ICU cannot be understated.

Rehabilitation (Phase IV)

Despite the focus during the acute phase of patients with severe burns appropriately placed on survival from the original injury and subsequent ICU complications, a concurrent emphasis should also be placed on overall function when the patient leaves the hospital. As a result, functional survival should be the ultimate goal of ICU care. Optimal care to achieve functional survival begins immediately upon admission. A true multidisciplinary burn team must incorporate both physical and occupational therapists early during care. Even patients who are heavily sedated using mechanical ventilation can have certain rehabilitative principles incorporated into their care plan. Some of these measures range from elevation of limbs to decrease edema during the resuscitative phase to application of splints to prevent contractures after burn surgery, to incremental weight-bearing to engage core muscles, to early ambulation when appropriate.[208,209] Unfortunately, evidence demonstrating benefit of specific and early rehabilitative interventions in burn care is lacking. A recently completed multicenter observational study in burns should be helpful in further linking specific rehabilitative interventions with patient outcomes (ClinicalTrials.gov Identifier: NCT01161810). Finally, the psychosocial challenges for both the patient and the family members after immediately after burn injury must not be ignored.[210] Social workers, vocational counselors, and psychologists should all contribute to the care of severely burned patients as part of the multidisciplinary burn team.

Key Points

- All ICU therapeutic interventions should be individualized to the patient: one size does not fit all.
- Optimal fluid resuscitation is guided by basic critical care principles of optimizing perfusion centered on adequate urine output at the least physiologic cost.
- Early excision of all full-thickness and deep partial-thickness burns and timely definitive coverage are the keys to survival.
- Every effort should be made to optimizing the conditions for wound healing by limiting vasopressors, minimizing edema, and providing adequate nutrition.
- The hypermetabolic and catabolic response to severe burns is multifold greater than for the general trauma population.
- Clinicians must be aggressive in identifying and treating infectious complications early.
- A multidisciplinary team approach to care is vital for optimal burn care.
- Functional survival is the ultimate goal.

Review Questions

1. In patients with critically ill burns of total body surface area (TBSA) greater than or equal to 40%, which of the following is the most common early and acute hematologic abnormality?

a. Thrombocytopenia
b. Leukopenia
c. Anemia
d. Hemoconcentration

Answer: d. Acutely, the most common burn-specific hematologic abnormality that intensivists encounter is hemoconcentration. In large burns, hematocrit levels often exceed 60%. Hemoconcentration that fails to normalize over the course of a fluid resuscitation can be indicative of underresuscitation. A reactive leukocytosis is common immediately after burns, reflective of a generalized stress response. In up to 46% of patients, this is followed by a relative leukopenia. Thrombocytopenia (defined by <150,000/μL of blood) has been reported to occur in up to 60% of burns. Generally thereafter, a reactive leukocytosis and thrombocytosis is considered a normal physiologic response to the stress of burns and a variety of subsequent physiologic insults during the course of burn care.

2. Acute kidney injury (AKI) occurs in large TBSA burns (>40%) in critically ill patients approximately which percentage of the time?

a. 2%
b. 25%
c. 10%
d. 50%

Answer: b. Historically, the prevalence of AKI among burn patients has been difficult to pinpoint because of the lack of a standard definition. What has been well documented is its association with an exceedingly high mortality. Over the past decade, standard definitions of AKI have been applied to the burn population. A recent comprehensive review determined that AKI occurred in 25% of patients among burn patients and was associated with a median mortality of 35% when defined by the Risk, Injury, Failure, Loss, and End-stage renal disease (RIFLE) consensus classification. Among those requiring renal replacement therapy (RRT), mortality was reported as 80%.

- Psychotropic Drugs
- Sedatives
- Stimulants
- Valproic Acid

Poisonings may result from intentional or unintentional ingestion, inhalation, injection, or skin contact. Toxic complications can also result from therapeutic use of medications. Although the mortality rate from toxin exposures is low, patients requiring hospitalization are often cared for in the intensive care unit (ICU). Limited evidence-based information on management of poisonings is available because the variety of drugs and doses that patients are exposed to limit the ability to conduct clinical trials of specific interventions. In addition, animal and human volunteer studies fail to fully replicate the clinical situations that are commonly encountered. Therapeutic recommendations are based on extrapolation of data from animal models, human volunteer studies, case reports, pharmacokinetic information, known pathophysiology, consensus opinion, and a limited number of clinical trials. Toxicologists and local poison control centers are valuable sources of additional information for the clinician.

The approach to the poisoned patient requires an organized evaluation and management plan that often requires the input of emergency physicians, primary care physicians, intensive care clinicians, and clinical pharmacists. The basic steps include initial resuscitation and stabilization, diagnosis, gastrointestinal (GI) decontamination and toxin elimination, institution of specific antidotes or interventions, and supportive care. This chapter addresses these components of management with regard to poisonings and toxicities most likely to be encountered in ICU patients. Although discussed separately, these steps are usually initiated concurrently in a severely ill patient.

Resuscitation and Stabilization

The initial management of seriously ill poisoned patients requires assessment of airway patency, breathing difficulties, circulatory problems, and the level of consciousness. These issues, along with immediate resuscitation interventions, are usually addressed in the emergency department but may be continued in the ICU (Box 65.1).

Diagnosis

History

A complete history should be obtained regarding the involved substance or substances, including the route of exposure, quantity used, time of exposure, form of medication (regular or sustained-release), and chronicity of use to determine the significance of the presenting symptoms. Specifically, the clinician should inquire about the patient's baseline mental and health status and the medical, occupational, and social history. A detailed medication history should include information about over-the-counter, prescription, illicit, and nutritional or herbal medications. Intentional ingestions often involve multiple coingestants or alcohol, or both. Additional or corroborating information should be obtained from family, friends, paramedics, or witnesses, if available. All available containers found at the site should be brought in for examination.

Physical Examination

The initial physical examination should focus on vital signs and neurologic findings that may provide physiologic clues to the toxicologic cause. Many toxic substances affect the autonomic nervous system, which is responsible for changes in vital signs mediated by the sympathetic and parasympathetic pathways. Attention to these initial and subsequent clinical signs is of paramount importance in identifying patterns or changes suggesting a particular drug or category of drugs (Table 65.1). Changes in the clinical examination after a therapeutic intervention or the administration of an antidote should be noted. Continued

• BOX 65.1 Approach to Resuscitation and Stabilization of the Poisoned Patient

Assess airway and breathing:
- Supplemental oxygen for patients with low oxyhemoglobin saturation; FIO_2 1.0 for carbon monoxide or cyanide exposure
- Intubation and mechanical ventilation for airway protection, airway obstruction, hypoventilation, or hypoxemia

Assess hemodynamic status:
- Isotonic fluids initially for hypotension; vasopressor if condition is refractory to fluids
- Treat significant arrhythmias

Assess mental status

Consider the following for altered mental status[1]:
- 50% glucose (25–50 g IV)
- Thiamine (100 mg IV)
- Naloxone (0.4–2 mg IV or IM initially)
- Flumazenil (not routinely recommended)[a]

[a]*See section on benzodiazepines for further information.*

monitoring and reevaluation are necessary because drug effects may not be present on initial evaluation.

Altered mental status is common in a toxicologic emergency. A detailed assessment of neurologic status should be made to determine if there is any alteration in level (stupor/coma or agitation) or content of consciousness (confusion/delirium). The evaluation should include an assessment of pupillary reactivity, ocular movements, and motor responses. Ruling out structural versus toxic or metabolic reasons for the altered state is important. Drug-induced seizures are often difficult to treat and may respond only to specific antidotal therapy. In general, benzodiazepines are more effective in terminating drug-induced seizures than other agents.

Pupils should be assessed for size and reactivity, and ocular movements should be evaluated for the presence of sustained nystagmus. Agents associated with miosis include organophosphates/carbamates (mydriasis also seen), other cholinergic agents, opioids, acetone, clonidine, phencyclidine, phenothiazines, and nicotine. Both anticholinergics and sympathomimetics may cause mydriasis; the pupils are reactive to light with cocaine but unreactive in diphenhydramine overdose. Opioid withdrawal may also result in dilated pupils. The pupillary assessment may be difficult in the setting of multiple coingestants, whereby the response may be blocked or partially manifested. Horizontal nystagmus is commonly seen with alcohols, lithium, carbamazepine, solvents, and primidone. Phenytoin, sedative-hypnotics, and phencyclidine may cause a combination of vertical, horizontal, or rotatory nystagmus.

The clinical examination should also include evaluation of bowel sounds (decreased/hyperactive), skin (moist/dry), and mucosa (secretions).

Toxidromes

A complex of signs and symptoms may be identified by physical examination and grouped into a toxic syndrome, or "toxidrome." In many cases, recognition of this toxic pattern is more important than identifying a specific offending agent. Identifying a toxidrome enables the clinician to initiate the assessment, derive a differential diagnosis, and formulate a treatment plan. The most common toxidromes are listed in Table 65.2.[2] Importantly, the clinician should note that patients may not present with a classic toxidrome owing to variable manifestations of toxins and overlapping features that exist between toxidromes.

Laboratory Tests

A laboratory test for a patient exposed to toxic agents should be helpful in diagnosis or monitoring.[3] Select laboratory examinations may be used when appropriate to determine the three gaps of toxicology—the anion gap, the osmolar gap, and the oxygen saturation gap. An arterial blood gas analysis will identify hypoxemia or hypoventilation, as well as acid-base abnormalities. Agents associated with a gap in oxygen saturation (>5% difference between measured and calculated saturation) include carbon monoxide (CO) and

methemoglobin inducers. In these exposures, a pulse oximeter inaccurately reflects the oxygen saturation of tissues and co-oximetry is necessary to identify abnormal hemoglobins. Determination of electrolytes with blood urea nitrogen and creatinine will detect renal abnormalities and allow calculation of the anion gap. Some common drugs associated with an anion gap acidosis are listed in Box 65.2. Hypoperfusion must also be considered as a cause of metabolic acidosis. An osmolar gap (>10 mOsm/L) may be caused by any small particle (toxin) that increases the measured osmolarity as measured by freezing point depression. Such agents include ethanol, ethylene glycol, glycerol, isopropyl alcohol, mannitol, methanol, propylene glycol, and sorbitol. An electrocardiogram (ECG) should be obtained when potential cardiac toxicity exists.

A qualitative urine drug screen is a combination of tests that serves to identify common drugs encountered in overdoses. However, a "tox screen" is usually unnecessary because the results rarely alter management, many toxins are not detectable, and positive results do not assess the severity of exposure. Quantitative determination of drug/toxin concentrations in blood is indicated by history and clinical examination to diagnose the intensity of toxicity, monitor the treatment or course of a patient, or define indications for specific interventions. Serum concentration measurements may be required as criteria for therapy or to assess the effectiveness of therapy. Because of the ubiquity of acetaminophen in over-the-counter and prescription preparations and the potential for significant morbidity and even death, a level should be obtained in any suspected polydrug ingestion.

Gastrointestinal Decontamination

GI decontamination techniques in the poisoned patient with an oral ingestion have included gastric emptying procedures (ipecac-induced emesis, gastric lavage), adsorption of drugs (activated charcoal), and increasing transit through the GI tract (cathartics, whole bowel irrigation [WBI]). Use of these interventions has decreased owing to uncertain evidence of benefit and recognition of adverse effects of the techniques. The consideration of a GI decontamination technique depends on the toxicity of the substance ingested, potential for deterioration in respiratory and mental status, severity of symptoms, dose, time since ingestion, presence of spontaneous emesis, and contraindications of the procedure.

Ipecac, which contains emetic alkaloids, stimulates gastric mucosal sensory receptors and the chemoreceptor trigger zone in the brain to produce vomiting. The amount of ingested drug removed by ipecac-induced emesis is highly variable, and no benefit of ipecac has been confirmed even when administered less than 60 minutes after ingestion. Currently, ipecac is not used in the management of poisoning victims.[4] Complications associated with ipecac administration include aspiration pneumonitis, esophageal rupture, Mallory-Weiss tear, pneumomediastinum, and protracted vomiting that can delay administration of activated charcoal.

Gastric lavage with a large-bore (36F–40F) orogastric tube is a technique used to empty the stomach of orally ingested substances that can be associated with significant complications. After insertion of the tube, lavage is accomplished with sequential 250 mL aliquots of normal saline solution or water until no pill fragments are retrieved. Intubation for airway protection is required before the procedure in patients with a depressed level of consciousness or potential for sedation. Gastric lavage should not be used routinely in the management of poisoned patients, if at all.[5] The clinician must

consider contraindications and the potential risks if gastric lavage is considered. Serious complications include aspiration pneumonitis, esophageal perforation, and cardiovascular instability. Gastric lavage is contraindicated with ingestions of substances such as acid, alkali, or hydrocarbons when the risk of aspiration is increased. Patients with a risk of GI perforation or severe bleeding diathesis or who are combative should also not be subjected to gastric lavage.

Single-dose activated charcoal potentially adsorbs the toxin in the GI tract and minimizes systemic absorption. The optimum dose of activated charcoal has not been established, but the usual dose for adults is 25 to 100 g (1 g/kg). Activated charcoal is not effective in adsorbing iron, lithium, cyanide, strong acids and bases, alcohols, and some hydrocarbons. Use of activated charcoal may be considered when a potentially toxic amount of a substance adsorbed by charcoal has been ingested within 1 hour.[6,7] Later administration may be appropriate if clinical factors suggest the ingested substance has not yet been completely absorbed. Activated charcoal is contraindicated in patients with a depressed level of consciousness unless intubated, when administration increases the risk of aspiration, or the patient is known or suspected to have a GI perforation. Few complications are associated with the appropriate use of single-dose activated charcoal. Emesis has been reported but may be related to sorbitol administered with charcoal or the ingested toxin.

Cathartics have been administered in poisoning ingestions based on the hypothesis that absorption and overall bioavailability of the agent are decreased by reducing contact time in the GI tract. Sorbitol (70% solution with activated charcoal) is the most commonly used cathartic, but magnesium citrate and magnesium sulfate have also been used. No clinical studies have demonstrated beneficial effects of cathartics in poisoned patients. A cathartic alone has no role in the management of poisonings, and even the routine use of a cathartic in combination with activated charcoal cannot be recommended.[8] A cathartic should not be administered in patients with ileus, GI obstruction or perforation, recent GI surgery, or hemodynamic instability. Complications of cathartics include nausea, vomiting, and abdominal cramping. Multiple doses of magnesium-containing cathartics may result in significant dehydration and electrolyte abnormalities.

WBI has been proposed as a technique to prevent absorption of ingested poisons by rapidly expelling the bowel contents. WBI involves the enteral administration (usually by nasogastric tube) of large volumes (1–2 L/h in adults) of polyethylene glycol electrolyte lavage solution; this is continued until the rectal effluent is clear or elimination of the toxin has been confirmed. During the procedure, the head of the bed should be elevated to 45 degrees to decrease the likelihood of vomiting and aspiration. No data exist to suggest improved patient outcomes with WBI. Currently, there are no established indications for WBI, but it may be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs, iron, lithium, and illicit drug packets.[9] WBI is contraindicated in the presence of ileus, GI obstruction or perforation, GI bleeding, hemodynamic instability, or intractable vomiting. In the patient with decreased level of consciousness or respiratory depression, the airway must be protected before instituting WBI.

Enhanced Elimination

Multiple-dose activated charcoal (MDAC) therapy involves the repeat oral administration of activated charcoal to prevent absorption of drugs that persists in the GI tract and to enhance elimination of drugs already absorbed into the body by functioning as an adsorbent "sink" at several sites in the gut.[10] First, it can interrupt enterohepatic circulation of drugs or metabolites that are actively secreted into bile. Second, it can adsorb drugs or metabolites that enter the gut by active secretion or passive diffusion and prevent reabsorption. Finally, it may prevent desorption of drugs, particularly acidic substances that bind two to three times less avidly to activated charcoal in the alkalotic milieu of the intestinal lumen than in the acidic environment of the stomach. Drugs with a prolonged elimination half-life after overdose and a small volume of distribution are more likely to have elimination enhanced significantly by MDAC.

One suggested regimen for administering MDAC is to follow the initial dose of activated charcoal with 0.5 to 1 g/kg every 4 hours. Alternatively, it is possible to administer charcoal as an aqueous solution by continuous infusion via a nasogastric tube at a rate of 0.25 to 0.5 g/kg per hour (not <12.5 g/h). Additionally, the smaller doses (and volumes) administered more frequently may reduce the likelihood of vomiting. It may still be necessary to give an antiemetic intravenously to ensure effective administration. The dosing schedule will be dictated by clinical parameters, such as patient cooperation, level of consciousness, the presence of ileus and vomiting, laboratory parameters, plasma concentrations of drug, and clinical improvement. Patients receiving MDAC should be monitored carefully for the development of constipation or obstruction and for the prevention of aspiration.

There is no convincing evidence that MDAC reduces morbidity and mortality rates in poisoned patients.[11] However, MDAC may be considered if the patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline and may obviate the need for invasive extracorporeal techniques. Insufficient evidence exists to support routine use of MDAC in ingestions of other substances.

Forced diuresis involves the intravenous (IV) administration of large volumes of isotonic fluids and diuretics to enhance renal excretion of drug or metabolite. This method is of limited clinical benefit and should not be used because of the potential for fluid overload and acid-base disturbances.

Urinary alkalinization is beneficial in increasing renal clearance of weak acids such as salicylates and phenobarbital. These weak acids are ionized at alkaline urine pH, trapped in the renal tubules, and not reabsorbed. Alkalinization can be initiated by adding 75 to 150 mEq sodium bicarbonate to 1 L of 5% dextrose in water. Urine pH should be tested every hour, and the rate of the bicarbonate infusion should be titrated to achieve a urine pH of 7.5 to 8.5. Alkalinization may be difficult to achieve if metabolic acidosis is present. Hypokalemia is a common complication and requires correction to facilitate urinary alkalinization. Increasing the urine pH with carbonic anhydrase inhibitors such as acetazolamide is not recommended because metabolic acidosis will worsen. Urine alkalinization can be considered in patients with significant salicylate ingestions who do not require hemodialysis. Phenobarbital poisonings are more effectively treated with MDAC.[12]

Hemodialysis is useful to increase the clearance of certain drugs and metabolites, as well as to correct metabolic acidosis induced by some substances. The concentration gradient of the unbound toxin provides the driving force for clearance. The following criteria should be applied to a drug to determine the potential for enhanced elimination by hemodialysis: low volume of distribution (<1 L/kg), single-compartment kinetics, low endogenous clearance (<4 mL/min per kilogram), molecular weight less than 500 Da, water solubility, and low plasma protein binding. Drugs for which hemodialysis should be considered in the presence of a significant

intoxication include methanol, ethylene glycol, salicylates, lithium, valproic acid, boric acid, and thallium.

Hemoperfusion is a form of extracorporeal toxin removal, whereby whole blood is passed through an adsorbent-containing (charcoal) cartridge. In general, if a compound is well adsorbed by activated charcoal, then charcoal hemoperfusion clearance may exceed that of hemodialysis. In contrast to hemodialysis, substances with a high degree of plasma protein binding can be removed. However, advancements in hemodialysis and the limited availability of hemoperfusion cartridges have resulted in decreased use of hemoperfusion. The risks of hemoperfusion are similar to those of hemodialysis. Additionally, hypoglycemia, hypocalcemia, and hypothermia may occur.

Continuous renal replacement therapies have been used less frequently for drug removal in the treatment of poisoning.[13] Clearance rates achieved with these techniques are considerably lower than those achieved with hemodialysis. Such therapy may be instituted after hemodialysis or hemoperfusion to further remove the drug after it slowly redistributes from tissue to blood. This is a potential option for agents such as lithium or procainamide. Continuous renal replacement techniques may also be advantageous in hemodynamically unstable patients who cannot tolerate conventional hemodialysis or hemoperfusion. Despite many case reports demonstrating significant drug clearance, there are no data demonstrating that these techniques affect outcome.

Specific Poisonings

Alcohols

Ethylene Glycol and Methanol

Methanol and ethylene glycol are toxic alcohols that have similar properties in overdose. Toxicity can occur through ingestion, inhalation, or dermal absorption. Cardiopulmonary and central nervous system (CNS) symptoms are common, and both agents can produce an anion gap metabolic acidosis and an osmolar gap. However, absence of an osmolar gap or anion gap does not exclude a toxic ingestion. The osmolar gap may be normal if all alcohol is metabolized to acid metabolites, and an anion gap may be normal if metabolism of alcohol has not yet produced acid metabolites (e.g., concomitant ethanol ingestion or early presentation). If toxic alcohol ingestion is suspected, regardless of whether the patient is symptomatic, blood should be immediately sent for serum methanol, ethylene glycol, and ethanol levels, and definitive treatment initiated based on the clinical history and acid-base status. Significant toxicity is associated with methanol and ethylene glycol levels greater than 50 mg/dL. The severity of acid-base disturbances appears to be directly correlated with the likelihood of survival.

Ethylene glycol is found in antifreeze and deicing solutions. Ethylene glycol causes acidemia as a result of metabolism by alcohol dehydrogenase to glycolic and oxalic acids. Oxalate crystals in the urine may be detected on microscopic examination, but they may not be present in the majority of exposed patients. Three classic phases of ethylene glycol toxicity have been described: neurologic, cardiopulmonary, and renal. During the first 0.5 to 12 hours after ingestion, ethylene glycol produces transient inebriation without the usual odor of ethanol, along with GI symptoms (nausea, vomiting). After toxic metabolites form (4–12 hours after ingestion), a metabolic acidosis develops along with CNS depression. The CNS symptoms may progress to coma associated with hypotonia, hyporeflexia, and occasionally seizures, meningismus, and cerebral edema. In the second stage (12–24 hours after ingestion), tachycardia and hypertension often occur along with progression of metabolic acidosis. Hypoxia may result from aspiration, heart failure, or acute respiratory distress syndrome. Death is most common in this stage. In the third stage (24–72 hours after ingestion), oliguria, flank pain, acute tubular necrosis, and renal failure develop.

Methanol is found in windshield washer fluid, solvents, and bootleg whiskey. It is metabolized by alcohol dehydrogenase to formaldehyde, which is then metabolized by aldehyde dehydrogenase to formic acid. Uncoupling of the mitochondrial oxidative metabolism produces lactic acid. The metabolic derangements are caused by lactic and formic acid; the latter is responsible for ocular disturbances. When methanol is ingested, peak levels occur within 30 to 60 minutes but there is often a latent period of about 24 hours (range 1–72 hours) before the development of toxic symptoms or metabolic acidosis. GI (abdominal pain, nausea, vomiting), CNS (dizziness, headache, seizures, coma), and ocular toxicities (blurred vision, photophobia, retinal edema, disc hyperemia, blindness) are seen.

Practice guidelines are available for the treatment of ethylene glycol and methanol intoxication.[14,15] If the patient has symptoms and is significantly acidemic, sodium bicarbonate may be administered as a temporizing measure to enhance formate and oxalate elimination by ion trapping. Fluid overload and hyperosmolarity may result from bicarbonate administration. Hydration is helpful because ethylene glycol is well excreted by the kidney as long as renal function is maintained. The definitive treatment of intoxication with methanol or ethylene glycol is inhibition of the alcohol's metabolism and hemodialysis to remove the alcohol and toxic metabolites and to correct metabolic abnormalities. Hemodialysis should be considered for the following conditions: deteriorating vital signs despite intensive supportive care, significant metabolic acidosis (pH < 7.25–7.3), blood level of methanol or ethylene glycol higher than 25 mg/dL, or any evidence of renal failure or electrolyte imbalances unresponsive to conventional therapy.[14,15]

Antidotal treatment of significant poisoning involves inhibition of alcohol dehydrogenase to prevent metabolism of the alcohols to toxic metabolites with ethanol or fomepizole. Ethanol (IV or oral) allows preferential metabolism of ethanol over methanol and ethylene glycol. Ethanol should be administered to maintain a blood level of 100 to 150 mg/dL. A loading dose should be followed by a maintenance infusion according to the established dosing requirements for nondrinkers, drinkers, and during hemodialysis.[14,15] Problems encountered during ethanol administration include CNS depression, hypoglycemia, dehydration, and fluctuating serum concentrations. A second IV line using 0.9% sodium chloride may be necessary to avoid development of hyponatremia because of the large free water content and significant hypertonicity (1713 mOsm/L) of 10% ethanol solution. If IV ethanol is not available, oral ethanol can be used.

Fomepizole, a competitive inhibitor of alcohol dehydrogenase, is approved for use in ethylene glycol and methanol overdose.[16] It is easier to administer than ethanol, does not cause sedation, and is associated with fewer severe and serious adverse events.[17] Fomepizole administration should be considered instead of ethanol if the patient develops altered consciousness, seizures, or a significant metabolic acidosis. Administration of ethanol or fomepizole should continue after dialysis until the serum ethylene glycol or methanol concentration is undetectable or less than 20 mg/dL or acidosis is resolved and the patient is asymptomatic. In the absence of renal dysfunction and a significant metabolic acidosis, the use of fomepizole potentially could obviate the need for hemodialysis, even though the serum ethylene glycol or methanol concentration

exceeds 50 mg/dL.[18] If patients with high serum concentrations of ethylene glycol are not treated with hemodialysis, then their acid-base balance should be monitored closely and hemodialysis instituted if a metabolic acidosis develops.

Additional therapeutic measures for ethylene glycol ingestions may include thiamine 100 mg IV and pyridoxine 50 mg every 6 hours until the ethylene glycol level is zero and no acidosis persists. If the patient becomes hypocalcemic as a result of precipitation of calcium oxalate crystals, calcium should be replaced. In methanol overdose, it may be reasonable to also administer IV folate (folinic or folic acids) at 50 to 75 mg IV every 4 hours for at least 24 hours to provide the cofactor for enhancing formic acid elimination.

Isopropyl Alcohol

Isopropyl alcohol may also be ingested, particularly by individuals with chronic alcoholism with no access to ethanol. It is found in rubbing alcohol and some hand sanitizers in high concentrations. Oral absorption occurs rapidly (within 0.5 hour), and it undergoes metabolism to acetone, carbon dioxide, and water. Symptoms may include severe abdominal pain, GI bleeding, nausea, and vomiting. Isopropyl alcohol is two to three times more potent than ethanol as a CNS depressant, and acetone is comparable with ethanol. Patients frequently present with headache, lethargy, ataxia, or coma. Respiratory depression occurs secondary to the CNS depression. Laboratory findings include an osmolar gap without a metabolic acidosis.[19] Patients may, however, have a fruity odor on their breath from acetone, and ketonemia and ketonuria may also be present. Treatment is supportive with fluid administration for significant dehydration. Hemodialysis should be considered when isopropyl alcohol levels exceed 400 to 500 mg/dL, evidence of hypoperfusion exists, coma is present, or a failure to respond to supportive therapy is noted.

Propylene Glycol

Propylene glycol is another alcohol that can cause toxicity in critically ill patients receiving high doses of IV medications containing the alcohol as a solvent. Medications that contain propylene glycol include lorazepam, diazepam, phenobarbital, pentobarbital, nitroglycerin, phenytoin, esmolol, etomidate, and sulfamethoxazole/trimethoprim. Propylene glycol toxicity is more commonly observed with lorazepam because of the use of high doses in some patients and the high concentration of propylene glycol—approximately 830 mg/mL.[20] Common manifestations of propylene glycol accumulation are anion gap metabolic acidosis and increased osmolar gap.[21] Additional toxicities include renal dysfunction, hemolysis, cardiac arrhythmias, seizures, and CNS depression or agitation. Clinical studies suggest that an elevated osmolar gap correlates with propylene glycol accumulation. Accumulation can occur when doses of lorazepam exceed 0.1 mg/kg per hour and when renal or hepatic insufficiency is present. Although toxicity is more common after long periods of lorazepam infusion (>3 days), toxicity has occurred with short-term, high-dose use. The treatment of choice is to stop the lorazepam infusion and sedate with an agent that does not contain propylene glycol. Hemodialysis removes propylene glycol but is usually not required unless severe renal dysfunction develops.

Analgesics

Acetaminophen

Acetaminophen (N-acetyl-p-aminophenol [APAP]) is present in many prescription and over-the-counter medications and is frequently a coingestant with other drugs. In addition, unintentional overdoses result from patients unknowingly ingesting multiple products containing APAP (particularly APAP-narcotic combinations). Because APAP overdose may result in significant hepatotoxicity and even death that is preventable, it is important to recognize and initiate appropriate therapy. With higher doses of APAP, a greater proportion is hepatically metabolized by the cytochrome P450 (CYP) system of mixed function oxidases (CYP 450) to the toxic metabolite, N-acetyl-p-benzoquinone imine (NAPQI), which can result in cell injury and death. Hepatic glutathione facilitates detoxification and elimination of NAPQI with therapeutic doses of APAP, but glutathione supply is overwhelmed in APAP overdoses. The clinical course of APAP toxicity has been divided into stages on the basis of the development of hepatotoxicity (Table 65.3).[22]

If possible, an estimate of the quantity and dosage form of APAP ingested and the time of ingestion should be obtained. In adults, hepatic toxicity can occur after ingestion of more than 7.5 to 10 g during 8 hours or less but has been reported with exposures of 4 g. The maximum daily dose of acetaminophen has been reduced to 3 g because of concerns for toxicity. The risk of toxicity may be increased in patients with low glutathione stores (malnutrition, fasting state, chronic alcoholism) or induction of CYP 450 enzymes (chronic alcoholism, phenytoin or carbamazepine use). For patients with a recent single, acute ingestion, an APAP level should be obtained at least 4 hours after ingestion. Liver enzyme levels need to be evaluated only if the APAP level indicates potential toxicity or the clinical examination suggests hepatic injury. If the time of ingestion is unknown, an APAP level should be obtained on admission. An APAP level and liver function tests should be determined in patients presenting late (>24 hours after ingestion), patients with multiple ingestions over time, or chronic ingesters of APAP.

Activated charcoal does adsorb acetaminophen, and it is reasonable to administer charcoal up to 2 hours after ingestion. Acetaminophen is absorbed rapidly from the GI tract, so later use of charcoal is not warranted unless gastric emptying is likely to be delayed. Administration of activated charcoal will not interfere with subsequent administration of oral N-acetylcysteine (NAC) therapy.

TABLE 65.3 Stages of Acetaminophen Toxicity

Stage	Time Course (After Ingestion)	Characteristics
I	0–24 h	Asymptomatic or nausea, vomiting; normal LFT results
II	24–72 h (latent stage)	Right upper quadrant pain; abnormal LFT results and PT; renal dysfunction possible
III	72–96h (hepatic stage)	Encephalopathy, jaundice, bleeding, renal dysfunction; maximal hepatic injury, synthetic dysfunction
IV	4 days–2 weeks (recovery stage)	Recovery of liver function

LFT, Liver function test; *PT*, prothrombin time.

NAC is the antidote for APAP poisoning, but the optimal route and duration of treatment are still debated. NAC limits toxicity by combining with NAPQI and by serving as a precursor of glutathione, which inactivates NAPQI. For patients with a single, acute ingestion of APAP, the serum acetaminophen level assessed at least 4 hours after ingestion is compared with the Rumack-Matthew nomogram. Treatment with NAC is initiated in the United States if the value falls above the lower possible hepatotoxicity line. Only the initial APAP level is used in making the decision to initiate or continue NAC treatment. Subsequent levels are unnecessary unless extended-release preparations are ingested (see later text). The Rumack-Matthew nomogram is not useful for patients with multiple ingestions of APAP over time, chronic ingesters, or those ingesting extended-release forms (see later discussion). If APAP levels are not available, NAC treatment should be initiated if more than 150 mg/kg or 10 g acetaminophen is ingested. For extended-release APAP, a second level 4 hours after an initial nontoxic level should be evaluated to assess for delayed absorption. If the second value is above the lower line on the Rumack-Matthew nomogram, NAC treatment is initiated.

NAC is most effective in preventing toxicity if administered within 8 hours of ingestion. NAC therapy can be initiated pending results of the APAP level if the patient is presenting late or APAP level results will be delayed. The oral regimen for NAC includes a loading dose of 140 mg/kg followed by 17 oral maintenance doses of 70 mg/kg administered 4 hours apart (72-hour regimen). Because of the odor of the oral form, a nasogastric tube for administration and antiemetic therapy may be necessary to control vomiting, which occurs in up to 50% of patients. If the patient vomits the loading dose or any maintenance dose within 1 hour of administration, the dose should be repeated. IV NAC is administered as a loading dose of 150 mg/kg over 60 minutes followed by 50 mg/kg infused over 4 hours and then 100 mg/kg infused over 16 hours (21-hour regimen). Anaphylactoid reactions may occur in 14% to 18% of patients with IV NAC. Oral and IV regimens of administering NAC are similar in efficacy.[23] However, either the oral regimen or prolonged IV NAC administration, both of which deliver a higher dose of NAC, may be more appropriate in patients who present later after ingestion (>18 hours) and when large amounts of APAP are ingested.[24,25] If the patient has a serum APAP level in the potentially toxic range, the aspartate aminotransferase or alanine aminotransferase level should be evaluated daily. If results are abnormal, additional tests, such as bilirubin, prothrombin time, creatinine, blood urea nitrogen, blood glucose, and electrolytes, should also be obtained. In patients with elevated liver enzymes, NAC may be continued beyond the full course of therapy until transaminases are decreasing.

Chronic ingesters of APAP or patients with multiple ingestions over time are problematic when determining the need to administer NAC. There are no established guidelines for administration of NAC in these circumstances and when patients present beyond 24 hours after ingestion. A marker of toxicity that may be useful is the evaluation of aspartate aminotransferase and alanine aminotransferase. If enzymes are elevated at the time of presentation (>50 IU/L) or the APAP level is greater than 10 µg/mL (>10 µmol/L), a course of NAC should be strongly considered. A course of NAC should also be administered to patients with hepatic failure caused by APAP.

Patients with evidence of toxicity from APAP should be monitored for signs and symptoms of hepatic failure. This includes evaluating mental status and frequently assessing blood glucose levels. If fulminant hepatic failure develops, appropriate consultation with a hepatologist should be obtained. Transplantation may be an option in severe cases.

Opioids

An epidemic of illicit and prescription opioid use has led to marked increases in associated morbidity and mortality. The rates of death from prescription opioid overdose quadrupled between 2000 and 2014 in the United States.[26] In addition, the rate of death from heroin use has increased sharply since 2010.[26] Prescription opioids can be abused through ingestion, nasal insufflation, inhalation, and IV use. Fentanyl (sometimes extracted from analgesic patches) and related drugs, such as acetyl fentanyl, butyryl fentanyl, and carfentanil (used in large animal sedation), are often abused intravenously but nasal insufflation has also been described. Heroin is rapidly absorbed by all routes of administration, including IV, intranasal, intramuscular, subcutaneous, and inhalation, but most fatal overdoses occur with IV administration. Toxicity depends on the potency of the agent, dose ingested, tolerance of the individual, and concomitant use of other drugs.

All opioids can result in a toxidrome characterized by depressed level of consciousness, respiratory depression, and miosis. However, manifestations may be variable depending on the drug used and the presence of other drugs or alcohol. Miosis is not seen with meperidine, propoxyphene, and tramadol toxicity. Although tramadol and tapentadol typically result in depressed level of consciousness and respiratory depression, presentations with agitation have also been described. Additional clinical findings may include hypotension, pulmonary edema, bronchospasm (heroin), ileus, nausea, vomiting, and pruritus. Seizures may be a manifestation of toxicity with meperidine, propoxyphene, and tramadol. Methadone use is associated with QT-interval prolongation and ventricular arrhythmias.

Diagnosis of an opioid overdose is made by characteristic clinical findings, exposure history, qualitative urine toxicology assay, and response to naloxone. Qualitative urine assays may not detect all opioid derivatives (e.g., fentanyl). Tramadol use may result in a false-positive urine toxicology assay for phencyclidine.[27]

The immediate priorities in a patient with opioid toxicity are support of ventilation, correction of hypotension, and reversal of the toxic effects with an opioid antagonist. If reversal of respiratory depression cannot be accomplished quickly, intubation may be necessary. Isotonic fluids should be administered for hypotension. Naloxone, a potent competitive opioid antagonist, is the antidote for opioid toxicity, including toxicity from tramadol and tapentadol. It can be administered intravenously, intramuscularly, subcutaneously, intranasally, by sublingual injection, by nebulization, or through an endotracheal tube. The initial dose of naloxone in a suspected opioid overdose is 0.04 to 2 mg; the lower dose should be considered in patients with chronic addiction to avoid precipitating acute withdrawal symptoms. Doses of 2 mg have been used with nebulization and intranasal administration. The goal of therapy is to restore adequate spontaneous respirations rather than complete arousal. Doses of naloxone up to 10 to 20 mg may be required to reverse the effects of synthetic opioids, such as pentazocine, methadone, and fentanyl.

The effects of naloxone last approximately 60 to 90 minutes, necessitating continued observation of the patient for possible resedation. Patients may require continuous infusion of naloxone to maintain adequate respirations, particularly with long-acting opioids. The dose for infusion is typically one-half to two-thirds of the initial amount of naloxone that reversed the respiratory depression administered on an hourly basis. Adjustments of the

dose should be made to achieve clinical endpoints and avoid withdrawal symptoms. Nalmefene, a long-acting opioid antagonist, has also been used to treat opioid overdoses, but prolonged withdrawal symptoms may be a concern.[28] Potential APAP toxicity should be considered in patients ingesting opioids formulated with APAP. Patients should also be observed for potential complications of opioid overdose, including aspiration pneumonitis and noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema is usually self-limited (24–36 hours) and managed with supportive care that may include intubation and mechanical ventilation.[29] Other complications that may be related to injection drug use include wound botulism, endocarditis, rhabdomyolysis, and compartment syndrome.

Salicylates

Salicylates should be considered as a potential toxin if a metabolic acidosis with an anion gap of unknown cause is present. The uncoupling of mitochondrial oxidative phosphorylation by salicylates results in metabolic acidosis and hyperthermia, and the stimulation of medullary respiratory centers results in tachypnea and respiratory alkalosis. Initial symptoms of toxicity include tinnitus and nausea or vomiting. Systemic acidosis promotes penetration of salicylate into the CNS, resulting in a depressed level of consciousness, coma, and seizures. Coagulopathy, transient hepatotoxicity, and hypoglycemia may also develop. Noncardiogenic pulmonary edema occurs more frequently in chronic salicylate toxicity than in acute overdose. The organ dysfunction and acid-base findings of salicylate intoxication can mimic sepsis and mislead clinicians.

Activated charcoal can be used for GI decontamination. Salicylates in large ingestions or enteric-coated forms can result in gastric concretions providing a depot for continued absorption; multiple doses of activated charcoal can be considered in this situation or when levels continue to rise despite other therapy.[11,30] A salicylate ingestion is considered toxic if symptoms are present, if more than 150 mg/kg has been ingested, or if levels are higher than 35 mg/dL at 6 hours after ingestion. The Done nomogram was developed in pediatric ingestions and does not provide good clinical correlation with toxicity in adults. Acute intoxication with salicylate levels in excess of 35 mg/dL at 6 hours after ingestion should be treated with sodium bicarbonate to alkalinize the urine to a pH 7 to 8, which increases the renal clearance of salicylate metabolites through ion trapping.[12] Alkalemia shifts the gradient of movement of salicylate from brain and tissues to blood.

Fluid status must be closely monitored, along with coagulation parameters, complete blood cell count, acid-base status, electrolytes, and urine pH. Hemodialysis may be required for levels greater than 100 mg/dL in an acute ingestion, seizures, persistent alteration in mental status, refractory acidosis, persistent electrolyte abnormalities despite adequate therapy, or fluid overload resulting from sodium bicarbonate therapy. Additional indications for hemodialysis may include congestive heart failure (relative), noncardiogenic pulmonary edema, hepatotoxicity with coagulopathy, or renal insufficiency

Carbon Monoxide

CO poisoning may be accidental or intentional and continues to be a significant cause of morbidity in the United States. Sources of CO include motor vehicle exhaust fumes, gasoline-powered generators, poorly functioning heating systems, and inhaled smoke. CO binds to hemoglobin with an affinity 200 to 250 times greater than oxygen. Toxicities result from impaired release of oxygen at the tissue level, causing cellular hypoxia and possibly direct CO-mediated damage at the cellular level. The clinical manifestations of CO poisoning are nonspecific and may suggest other illnesses unless exposure is known or suspected. Headache, nausea, and vomiting are common. Cellular hypoxia may also result in confusion, angina, arrhythmias, syncope, and seizures. Tachycardia and tachypnea are frequently present as compensatory mechanisms for hypoxia. Classic findings of cherry red lips, cyanosis, and retinal hemorrhages occur rarely. Symptoms can range from mild to severe, and carboxyhemoglobin levels do not necessarily correlate with symptom severity. After recovery from acute CO exposure, delayed neuropsychiatric sequelae may occur.

Diagnosis requires a high level of suspicion. Carboxyhemoglobin levels can be measured in venous or arterial blood and must be interpreted carefully. Carboxyhemoglobin levels may be as high as 10% in smokers and are higher in urban compared with rural areas. An elevated level of carboxyhemoglobin may often be diagnostic, but a normal level does not rule out the diagnosis. The carboxyhemoglobin level may have decreased because of removal of the patient from the exposure and intervention with oxygen before hospital arrival.

Management of CO poisoning includes a detailed evaluation of neurologic and cardiorespiratory status. Acid-base status should be determined and an ECG examined for evidence of ischemia or arrhythmia. Oxygen is the antidote and shortens the half-life of carboxyhemoglobin by competing for binding with hemoglobin. High-concentration oxygen should be instituted as soon as possible and continued until the carboxyhemoglobin level has decreased to normal. Pulse oximetry overestimates arterial oxygenation because carboxyhemoglobin is misinterpreted as oxyhemoglobin. Analysis of arterial blood by co-oximetry is required for an accurate assessment of oxygen content. Intubation may be necessary in patients exposed to CO from fire. Hyperbaric oxygen therapy shortens the half-life of carboxyhemoglobin to 15 to 30 minutes compared with 40 to 80 minutes when patients breathe 100% oxygen. However, controversy exists over the specific indications for instituting hyperbaric oxygen therapy in CO poisoning.[31–33] Coma has been used as an indication for hyperbaric oxygen therapy; other suggested indications include a period of unconsciousness, neurologic findings other than headache, carboxyhemoglobin level greater than 40%, pregnancy with carboxyhemoglobin level greater than 15%, cardiac ischemia or arrhythmia, history of ischemic heart disease with carboxyhemoglobin level greater than 20%, and symptoms that do not resolve with normobaric oxygen after 4 to 6 hours. Hyperbaric oxygen treatment may decrease postexposure cognitive deficits.[34]

Cardiovascular Drugs

Cardiovascular drugs are increasingly involved in adult overdose exposures and fatalities. Although a large number of cardiovascular drugs are available, the most clinically relevant agents are β-blockers, calcium channel blockers, and digoxin. Note that the clinical manifestations and management of β-blocker and calcium channel blocker toxicity share similarities.[35]

β-Blockers

β-Adrenergic blockers differ in their lipid solubility, oral availability, first-pass effect, protein binding, metabolism, β_1 selectivity, membrane stabilization, and intrinsic sympathomimetic activity. Clinical findings with β-blocker toxicity include bradycardia, atrioventricular (AV) conduction abnormalities (QRS prolongation,

first-degree AV block), and hypotension. The hypotension is primarily due to the negative inotropic effects of these agents. With the exception of sotalol, ventricular fibrillation and other arrhythmias are not usually seen. The more lipophilic β-adrenergic antagonists, such as propranolol, metoprolol, acebutolol, and timolol, can cause delirium, coma, and seizures. Hypoglycemia is rare in adults. Toxicity generally occurs within 6 hours of ingestion of immediate-release preparations. Ingestion of sotalol or extended-release preparations may result in delayed toxicity, and these patients should be observed for 24 hours or longer if absorption is delayed. Propranolol is associated with the highest mortality rate, which may reflect its greater toxicity attributable to membrane-stabilizing effects.[36] Bradyarrhythmias and asystole usually precede death.

GI decontamination techniques may be considered based on the specific drug and quantity involved, time of ingestion, and clinical condition of the patient. Extracorporeal removal is ineffective for lipid-soluble β-blockers because of the large volume of distribution. Hemodialysis may be rarely considered for atenolol, a water-soluble β-blocker.

The initial focus of treatment is to reverse hypotension rather than to increase heart rate. Increases in heart rate do not always result in improvements in blood pressure. Although atropine is frequently administered for bradycardia, it is usually ineffective. Isotonic fluids can be administered for hypotension, but caution is warranted owing to the negative inotropic effects of β-blockers on myocardial function. Pharmacologic interventions that have been used in β-blocker overdoses include glucagon, calcium, high-dose insulin therapy, catecholamines, IV lipid emulsion, and phosphodiesterase inhibitors.[35] Many patients with significant toxicity require treatment with multiple agents. Glucagon is administered as 2 to 5 mg IV followed by a dose of 10 mg if necessary. If there is a positive clinical response, a continuous infusion (usually 2–10 mg/h) is necessary owing to the short duration of action of glucagon. Glucagon is a chronotropic and inotropic agent that stimulates cyclic adenosine monophosphate by bypassing adrenergic receptors. Evidence for efficacy is limited to animal studies and use as a first-line agent is debated.[37] Adverse effects of glucagon include nausea, vomiting, hyperglycemia, and hypocalcemia.

Calcium salts may be considered as another intervention for reversing hypotension if digoxin ingestion has been excluded.[35,38] Although calcium is more likely to be effective in calcium channel blocker toxicity, efficacy has been reported in some cases of β-blocker toxicity. Calcium chloride 10% (1 g by slow IV push, preferably through a central venous catheter) may be administered initially, and up to 3 g is recommended. If access is limited, 10% calcium gluconate can be administered but an increased dose is required.

High-dose regular insulin infusions and glucose administration to maintain euglycemia have been shown to be effective in β-blocker and calcium channel blocker toxicity and are now often recommended as first-line therapy.[38,39] The beneficial effect may be caused in part by the metabolic effects of decreasing cardiac uptake of free fatty acids and increasing carbohydrate use. Reported insulin doses have been variable, but a bolus dose of regular insulin 1 unit/kg is recommended followed by an infusion of 1 unit/h.[39] Doses of insulin up to 10 units/h may be considered if the patient is unresponsive to interventions. A glucose infusion should be initiated at the same time to maintain euglycemia and a glucose bolus may also be needed. Careful monitoring of glucose and potassium is required.

Catecholamine infusions are frequently administered in β-blocker toxicity concomitantly with other interventions. No agent is known to be more effective than others, and response to various agents is often inconsistent in these clinical situations. Very large doses may be required owing to the β-adrenergic receptor antagonism; as a result, tachyarrhythmias can occur. The combination of dobutamine and norepinephrine may allow for titration of desired effects against cardiac output and blood pressure. Alternatively, phenylephrine may be used in conjunction with dobutamine. Epinephrine has been shown to be more effective than isoproterenol.[40] Infusion of any vasoactive agent should be started at usual doses and rapidly escalated to achieve a clinical response, but it should be stopped if there is a further fall in blood pressure or no beneficial effect.

Case reports suggest that bolus administration of 20% lipid emulsion (1.5 mL/kg lean body mass) may be beneficial in refractory hemodynamic collapse owing to β-blocker and calcium channel blockers. A repeat bolus can be given for persistent instability. An infusion of 0.25 mL/kg per minute is usually continued for at least 10 minutes after hemodynamic stabilization. The exact mechanism of effect is unknown, but it has been proposed that lipids serve as a "sink" for the toxin that reduces free drug levels and limits distribution to tissues. Another possibility is that the fatty acids of lipids improve inotropy by providing an energy source for myocytes.[41] Adverse effects of lipid emulsion include interference with laboratory analyses owing to lipemia, pancreatitis, acute respiratory distress syndrome, and potentially asystole.[41,42]

Phosphodiesterase inhibitors such as milrinone and enoximone have been reported to be effective in some cases of human ingestions.[35,38] These agents may be considered in patients in whom other pharmacologic interventions fail, although experience is limited and they may cause further hypotension through peripheral vasodilation. Invasive hemodynamic monitoring may be needed in some patients.

Ventricular pacing (transthoracic or transvenous) may be considered, but electrical capture is often unsuccessful. Even when pacing increases the heart rate, blood pressure often fails to improve. Intraaortic balloon pump, extracorporeal membrane oxygenation, and cardiopulmonary bypass are potential options to maintain circulation until drug is metabolized in the unstable patient unresponsive to other interventions.

Calcium Channel Blockers

Calcium channel blockers have varying degrees of negative inotropic effect (verapamil), vasodilatory effect (nifedipine, diltiazem), depression of rate of discharge of the sinus node (verapamil, diltiazem), and slowed conduction through the AV node (verapamil, diltiazem). Verapamil and diltiazem are most commonly associated with severe toxicity. All are well absorbed with clinically significant protein binding (80%) and a large volume of distribution. All undergo extensive hepatic metabolism, many through the cytochrome P450 system, and have varying degrees of active metabolites.

Signs and symptoms of toxicity occur within 6 hours for immediate-release formulations but are delayed for sustained-release preparations. Gastric concretions can form, acting as a further reservoir for sustained absorption. Nausea, vomiting, and hypotension are usually accompanied by bradycardia with verapamil and diltiazem or reflex tachycardia with nifedipine. Conduction abnormalities associated with verapamil and diltiazem may include first-degree block, Wenckebach block, junctional rhythm, third-degree AV block, and AV dissociation. Hypoperfusion secondary to decreased cardiac output may lead to tissue ischemia, metabolic acidosis, and CNS symptoms such as lethargy, confusion, and

coma. Hyperglycemia can result from a decrease in insulin secretion and insulin resistance and may be a marker of severe exposure.

Activated charcoal is the preferred method of GI decontamination in recent ingestions. As with β-blockers, initial treatment of symptomatic calcium channel blocker overdose should be aimed at treating hypotension and significant conduction defects. Calcium salts should be administered as first-line therapy in toxicity owing to calcium channel blockers.[43] The recommended dose is 1 to 2 g of 10% calcium chloride every 10 to 20 minutes. If blood pressure improves with calcium chloride, an infusion can be considered at doses of 0.2 to 0.4 mL/kg per hour. Ionized calcium concentrations can be monitored, but high serum concentrations may be necessary for beneficial effects. High-dose insulin therapy (dosed as for treatment of β-blocker toxicity) should be initiated if calcium is ineffective in reversing toxicity.[39,43] As with β-blocker overdose, large doses of catecholamines may be required. Norepinephrine can be used to increase blood pressure, and epinephrine may be effective in improving contractility and heart rate.[43] Use of vasopressin alone is not recommended. Atropine can be administered for bradycardia but is often ineffective and any effects are transient.

Second-line therapies should be considered when toxicity does not respond to initial interventions. Higher doses of insulin and lipid emulsion administration are options.[41,43] Glucagon and transvenous pacing can also be considered as second-line interventions.[37] Venoarterial extracorporeal membrane oxygenation or cardiopulmonary bypass may be helpful for refractory hypotension.

Digoxin

Digoxin toxicity results from the complex influence of the drug on the electrophysiologic properties of the heart, as well as the cumulative result of the direct, vagotonic, and antiadrenergic actions of digoxin. The alterations in cardiac rate and rhythm occurring in digoxin toxicity can produce almost every type of arrhythmia. Toxicity should be suspected if there is evidence of increased automaticity (ectopic rhythms) or depressed conduction (prolonged PR interval, AV node blockade, decreased QT interval). Early in acute intoxication, depression of sinoatrial or AV node function may be reversed by atropine, but atropine subsequently does not reverse the direct and vagomimetic actions of the drug. Noncardiac manifestations of acute digitalis intoxication include anorexia, confusion, visual disturbances, nausea or vomiting, and increased potassium ion concentrations.

GI decontamination in digoxin overdose consists of activated charcoal, if the timing is appropriate. Late administration of activated charcoal or MDAC may be considered owing to enterohepatic metabolism of the drug.[16] Forced diuresis, hemoperfusion, and hemodialysis are not effective in hastening the elimination of digoxin because of the large volume of distribution (4–10 L/kg). Only 1% of total body stores of digoxin is present in the serum; of that, 25% is protein bound.

The treatment for life-threatening digitalis toxicity is administration of digoxin-specific antibody fragments.[44,45] Administration of digoxin-specific antibody fragments results in a sharp decrease in free digoxin levels, an increase in total serum digoxin, an increase in renal excretion of digoxin bound to Fab (fragment, antigen binding), and a decrease of serum potassium toward normal. The time to response is approximately 30 minutes (range 20–90 minutes). Indications for administration of digoxin-specific antibody fragments include life-threatening tachy-bradyarrhythmias, potassium concentration greater than 5 mEq/L in the setting of suspected digoxin toxicity, rapidly progressive cardiac or GI symptoms, an increasing potassium concentration, serum digoxin concentration greater than 15 ng/mL at any time or more than 10 ng/mL at steady state, ingestion of more than 10 mg of digoxin in a previously healthy adult, and to establish the diagnosis. In the event that digoxin-specific fragments are not immediately available, other interventions may be considered. Atropine may work for severe supraventricular bradyarrhythmias or varying degrees of AV block if administered early. β-Blockers may be used for supraventricular and ventricular tachycardias. Magnesium sulfate may be an effective temporizing measure for the treatment of ventricular arrhythmias in the absence of digoxin-specific antibodies, even in the presence of hypermagnesemia. Limited evidence suggests phenytoin or lidocaine may be considered. All class Ia antiarrhythmic drugs are contraindicated. Isoproterenol should be avoided because there is an increased risk of ventricular ectopy in the presence of toxic digoxin levels. Transthoracic or transvenous pacing has limited value in this setting.[45]

Hypokalemia, hyperkalemia, and hypomagnesemia can exacerbate digoxin cardiotoxicity and should be aggressively corrected. When hyperkalemia exists with toxic digoxin levels and ECG evidence of potassium toxicity, the serum potassium should be treated with conventional interventions if digoxin-specific Fab fragments are not immediately available. Calcium administration in the presence of digoxin toxicity is not usually recommended for hyperkalemia because it may worsen digoxin-induced intracellular hypercalcemia. Intractable ventricular fibrillation or tachycardia may result.

After digoxin-specific antibodies have been administered, serum digoxin levels are no longer reliable because they represent free and bound digoxin. The digoxin-specific antibodies are effective even in anephric patients. In renal insufficiency, the Fab half-life is prolonged 10-fold with no change in volume of distribution. Fab concentrations remain detectable for 2 to 3 weeks. Although there is no dissociation of the complex in renal insufficiency, free digoxin levels rebound (redistribution from tissue sites) and Fab fragments leave the vascular space over 7 to 14 days.[46] During this time symptoms may recur and a second dose may be necessary.

Cyanide

Inhalation or ingestion of cyanide is rare but can produce severe poisoning rapidly leading to death. A history of potential cyanide exposure is extremely important in suggesting the diagnosis because rapid cyanide assays are not available and clinical manifestations are nonspecific. Cyanide exposure may occur from incomplete combustion of products containing carbon and nitrogen in fires and from industrial processes such as electroplating, metal refining, photography, fumigation, and gold or silver extraction. Cyanogenic substances are also found in a variety of plants, although severe toxicity is rare. Iatrogenic cyanide intoxication may occur during nitroprusside administration with high doses or in the presence of hepatic dysfunction.

Cyanide is a nonspecific inhibitor of enzymes; inhibition of mitochondrial cytochrome oxidase results in anaerobic metabolism with decreased adenosine triphosphate production, lactic acidosis, and decreased oxygen utilization. Clinical characteristics of acute cyanide poisoning are rapid deterioration, loss of consciousness, anion gap metabolic acidosis, and cardiopulmonary failure. CNS signs and symptoms include headache, anxiety, agitation, confusion, seizures, and coma. Cardiovascular responses manifest as initial bradycardia and hypertension, followed by hypotension with reflex tachycardia that can progress to terminal bradycardia and hypotension. Ventricular arrhythmias and myocardial ischemia also occur.

Pulmonary findings include cardiogenic and noncardiogenic pulmonary edema. GI symptoms of abdominal pain, nausea, and vomiting are less common. A bitter almond odor from vomitus or gastric contents is described in cyanide poisonings but may not be present and is often not detectable by health care personnel.

Early diagnosis, rapid administration of antidote, and aggressive supportive care are necessary to stabilize patients with severe cyanide poisoning. A cyanide level may be requested for confirmation, but results will not be available to guide immediate care. Intubation and mechanical ventilation are usually required. Fluids, inotropes, and vasopressors may be indicated for hypotension. If the poison was ingested, gastric lavage may be considered but should not delay the administration of antidote.

As soon as cyanide poisoning is suspected, hydroxocobalamin or a cyanide antidote kit should be administered.[47] Hydroxocobalamin, a vitamin B_{12} precursor administered at an initial dose of 5 g, is a commonly used antidote for acute cyanide poisoning.[48] It displaces cyanide from the cytochrome oxidase and forms cyanocobalamin, which is then excreted in the urine or metabolized by hepatic rhodanese. A second dose of 5 g can be administered for severe poisoning or lack of clinical response. Thiosulfate has been administered with hydroxocobalamin but efficacy is unclear.

The cyanide antidote kit contains amyl nitrite ampules, 3% sodium nitrite, and 25% sodium thiosulfate. Amyl nitrite is used initially when lack of IV access delays the administration of sodium nitrite. It is an immediate source of nitrite that oxidizes hemoglobin to methemoglobin, which has a higher affinity for cyanide than cytochrome oxidase. Cyanmethemoglobin is formed, which eventually dissociates, but at such a rate that cyanide can be metabolized by hepatic rhodanese. The ampules are crushed in a gauze sponge and initially intermittently inhaled. This is followed by IV administration of 300 mg of sodium nitrite (10 mL 3% solution) as soon as possible. The optimum methemoglobin level that should be achieved is unknown, but clinical responses have occurred with levels of 3.6% to 9.2%. The second component of the antidote package is 25% sodium thiosulfate (12.5 g for adults), which provides sulfur for conversion of cyanide to thiocyanate by hepatic rhodanese. Thiocyanate is then excreted by the kidneys. Hyperbaric oxygen has also been proposed for treating cyanide toxicity, but data supporting efficacy are not available.

Dietary and Nutritional Agents

Dietary and nutritional products are categorized as supplements and can be marketed without testing for safety or efficacy. Although some herbs and supplements may have inherent toxicity, poisoning may result from product misuse, contamination of the product, or through interaction with other medications.[49–51] Patients and their families should always be questioned regarding use of nutritional supplements, herbal preparations, weight loss or performance-enhancing products, energy drinks, or natural remedies when considering possible toxin exposure as a cause of clinical abnormalities. Adverse effects resulting from these products should be reported to the appropriate authorities such as U.S. Food and Drug Administration.

Herbal teas may contain aconitine or digoxin-like substances.[52] Management is usually supportive. A digoxin level should be obtained in any patient demonstrating symptoms consistent with digoxin toxicity. The level may not correlate with clinical findings because numerous cardiac glycosides will not cross-react in the digoxin immunoassay. With significant toxicity, digoxin-specific antibody fragments should be administered.

Products containing ephedrine and ephedrine-free products are often used for weight loss. These products can result in manifestations similar to a sympathomimetic syndrome with cardiovascular and cerebrovascular complications.[53–55] Similarly, caffeinated energy drinks can precipitate atrial and ventricular arrhythmias.[56]

Hepatoxicity may occur with numerous single herbal and nutritional agents such as kava and black cohosh but also occurs with marketed weight loss and performance-enhancing products with multiple, often ill-defined ingredients.[57]

Toxicity from ingestion of herbal preparations and nutritional supplements may result from product contaminants. Products may contain heavy metals, unlisted drugs, or other ingredients.[58] The California Department of Health Services, Food and Drug Branch, screened 260 Asian patent medicine products and found 32% contained undeclared pharmaceuticals or heavy metals.[59] Unusual symptoms or toxidromes in patients ingesting such products may require the assistance of the local health department or toxicologist to identify a possible toxin.

Methemoglobin Inducers

Methemoglobin results from the oxidation of ferrous iron in hemoglobin to ferric iron. Methemoglobin is not able to bind oxygen and high concentrations lead to a functional anemia that results in cellular hypoxia by limiting oxygen delivery. The most common inducers of methemoglobin in the health care setting are topical spray anesthetics (benzocaine, tetracaine, butyl aminobenzoate) and dapsone. Procedures using topical anesthetics that are associated with the development of methemoglobinemia are transesophageal echocardiography, GI endoscopy, intubation, and bronchoscopy.[60] Predisposing factors include sepsis, anemia, and hospitalization. Dapsone may cause prolonged methemoglobinemia in patients with AIDS because of its long half-life.

Clinical manifestations are related to the impaired oxygen delivery, and the severity varies with the concentration. Cyanosis is apparent when methemoglobin concentrations are 10% or greater owing to the deep color of methemoglobin. Concentrations of 20% to 50% may cause headache, dyspnea, dizziness, and fatigue, and concentrations greater than 50% can result in metabolic acidosis, arrhythmias, tachypnea, seizures, lethargy, and depressed level of consciousness. Diagnosis requires measurement of methemoglobin concentrations in arterial or venous blood gas assays by co-oximetry. Pulse oximetry is not usually accurate for determining the presence or concentration of methemoglobin depending on the specific characteristics of the monitor. A helpful clue is the observance of a saturation gap between the measured oxyhemoglobin saturation by pulse oximeter and the calculated oxyhemoglobin saturation provided by arterial blood gas assay. In the presence of methemoglobin, the calculated concentration will be higher than the measured saturation by pulse oximeter. Co-oximetry is required to identify the abnormal hemoglobin.

Methylene blue is the antidote for methemoglobinemia and should be administered when there are significant symptoms indicating impaired oxygen delivery.[61] In addition, individuals with lower methemoglobin concentrations may also warrant treatment if further oxidant stress may increase the concentrations. High-flow oxygen should be administered. The usual dose of methylene blue is 1 to 2 mg/kg IV over 5 minutes. Clinical improvement in symptoms and cyanosis is usually evident within a few minutes. A second dose can be administered if cyanosis does not resolve within 1 hour. Although there is concern for methylene blue causing hemolysis in patients with glucose-6-phosphate

dehydrogenase (G6PD) deficiency, this information will not usually be known at the time of treatment and methylene blue should not be withheld in symptomatic patients.

Organophosphate and Carbamate Agents

Organophosphates and carbamates are cholinesterase inhibitors that are usually a component of insecticides. However, nerve agents used in chemical warfare such as sarin and VX are also organophosphate compounds. Cholinesterase inhibitors exert toxicity by blocking the activity of acetylcholinesterase, resulting in acetylcholine accumulation at cholinergic receptors. When organophosphates or carbamates bind to acetylcholinesterase, they form a conjugate that is infinitely more stable than the acetylcholine-acetylcholinesterase conjugate. The carbamate-acetylcholinesterase bond spontaneously hydrolyzes in minutes to hours so that acetylcholinesterase is eventually regenerated (reversible binding). Most carbamate poisonings spontaneously resolve within 24 to 48 hours and do not have significant morbidity or mortality risk. Phosphorylated or phosphonylated enzymes resulting from organophosphate exposure, however, degrade over days to weeks, making acetylcholinesterase essentially inactive (irreversible binding). For the physiologic enzyme activity to return, new enzyme must be generated or antidote given. After the acetylcholinesterase is phosphorylated over 24 to 48 hours, "aging" occurs, and the enzyme can no longer spontaneously hydrolyze and is permanently inactivated.[62]

Organophosphates may be absorbed by virtually any route, including transdermal, transconjunctival, inhalation, across the GI or genitourinary mucosa, and through direct injection. Onset of systemic symptoms may occur in 5 minutes with inhalation, and most patients develop symptoms within 12 hours of ingestion, unless exposure to fat-soluble organophosphates (e.g., fenthion, clorfenthion) has occurred or if significant metabolic activation must occur (e.g., parathion, malathion). Cholinesterase poisoning manifests as a cholinergic toxidrome and signs and symptoms are listed in Table 65.4. Pulmonary toxicity from bronchorrhea, bronchospasm, and respiratory depression is the primary concern.[63]

Diagnosis of poisoning with these agents is usually based on a history of exposure and clinical manifestations. Early intubation is usually indicated with significant toxicity, and use of succinylcholine should be avoided because of prolonged paralysis. Initially, atropine 2 to 4 mg is given intravenously and repeated every 5 minutes with increasing doses, if needed, to reverse muscarinic toxicity. If there are no CNS symptoms, glycopyrrolate may be substituted. The endpoint of atropinization is clearing of secretions. Tachycardia is not a contraindication to atropine use because it may represent hypoxia and autonomic stimulation. The tachycardia may resolve with improved oxygenation. In massive exposures, hundreds of milligrams of atropine may be required over days or weeks. A continuous infusion of atropine should be initiated at 0.05 mg/kg per hour and titrated to effect. After the patient's condition is adequately stabilized, atropine must be carefully and slowly withdrawn because secretions will likely return if the drug is still bound to acetylcholinesterase or leaches from fat stores. Inhaled ipratropium can be considered if bronchoconstriction is present.[62]

Atropine does not reverse nicotinic effects, and patients with significant respiratory muscle weakness are usually treated with an oxime. Oximes regenerate acetylcholinesterase at muscarinic, nicotinic, and CNS sites. Treatment with oximes may be most effective when started early. Oximes are usually continued as long as atropine is continued. The evidence for benefit of any oxime in pesticide poisoning is limited.[64] Pralidoxime (2-PAM) is available in the United States and is usually administered as a loading dose (1 to 2 g in normal saline solution 500 mL administered over 30 minutes) and then as a continuous infusion at 200 to 500 mg/h to maintain serum levels higher than 4 μg/L.[65] Higher dosing regimens have also been proposed.[63] Pralidoxime may also be protective against the development of the intermediate syndrome and other long-term neurologic sequelae. Pralidoxime therapy is usually not needed if the toxin is known to be a carbamate.

In addition to acute toxicity, organophosphates may cause persistent effects, which may manifest while the patient is in the ICU and last several weeks to months. These effects include organophosphate-induced delayed neurotoxicity and delayed polyneuropathy that occur 1 to 3 weeks after exposure.[62] Recovery may occur gradually or not at all. Another complication is intermediate syndrome.[66] The syndrome develops 24 to 96 hours after resolution of an acute, severe cholinergic crisis, and patients develop acute respiratory paralysis, weakness in the bulbar musculature, nuchal weakness, proximal limb weakness, and depressed reflexes. Electromyography studies show decremental conduction with repetitive nerve stimulation and suggest both presynaptic and postsynaptic nerve impairment. Recovery takes 2 to 4 times longer than the development.

TABLE 65.4 Signs and Symptoms of Cholinesterase Poisoning

Muscarinic Effects	Nicotinic Effects	CNS Effects
Salivation	Muscle fasciculations, cramping, weakness	Restlessness
Lacrimation	Diaphragmatic fatigue	Headache
Urination	Respiratory failure	Tremor
Diarrhea	Areflexia	Drowsiness
Nausea, vomiting	Paralysis	Confusion, delirium
Bronchorrhea	Hypertension	Slurred speech
Bronchoconstriction	Mydriasis	Ataxia
Miosis	Tachycardia	Seizures
Bradycardia		Psychosis
		Respiratory depression

CNS, Central nervous system.

Psychotropic Drugs

Cyclic Antidepressants

Deaths caused by overdose with cyclic antidepressants have declined significantly because of the increasing use of alternative antidepressants. The principal toxicities of cyclic antidepressants result from central and peripheral anticholinergic activity, α-adrenergic antagonism, and inhibition of norepinephrine reuptake. They also exert a membrane-depressant local anesthetic effect on the myocardium by blocking rapid sodium influx during phase 0 of the action potential. Clinical toxicities include a depressed level of consciousness, wide-complex arrhythmias, seizures, and hypotension. Acidosis, hypoxia, and seizures may increase the risk of wide-complex arrhythmias. Anticholinergic effects include mydriasis, fever, dry skin, delirium, agitation, tachycardia, ileus, and urinary retention. Life-threatening events usually occur within 6 hours of ingestion,

most often in the first 2 hours.[67] Several electrocardiographic criteria have been proposed to predict complications: QRS duration greater than 0.1 second correlates with risk of seizures, QRS duration greater than 0.16 second correlates with increased risk of arrhythmias, and the presence of an R wave in lead aVR greater than 3 mm predicts seizures and arrhythmias.[68,69] However, the performance of these criteria in predicting complications including death is relatively poor.[70]

If poisoning with a cyclic antidepressant is suspected, electrocardiographic monitoring should be instituted and IV access obtained. Intubation may be needed in patients with CNS depression who are unable to protect their airway. If wide-complex arrhythmias (or ECG changes described previously), hypotension, or seizures are present, stabilization requires immediate alkalinization of the blood and sodium loading with sodium bicarbonate.[71] Sodium bicarbonate should be administered in 50 to 100 mEq (1–2 mEq/kg) boluses to alkalinize the blood pH to 7.5 to 7.55. Clinical endpoints are normalization (narrowing) of the QRS complex, reestablishment of an adequate blood pressure, and termination of seizure activity. Alkalinization appears to decrease the free drug by increasing protein binding and shifting the concentration gradient away from tissues. Sodium loading may have a greater benefit by overcoming the blockade of the myocardial sodium channels. The bolus doses of sodium bicarbonate should be immediately followed with a continuous infusion, which can be prepared by adding 150 mEq (sodium bicarbonate) to 1 L of 5% dextrose in water. This should be titrated to the desired blood pH, QRS interval, and blood pressure. The infusion may be discontinued after 4 to 6 hours if the width of the QRS complex remains less than 100 msec without the administration of sodium bicarbonate. Hyperventilation to achieve blood alkalinization may be less effective but useful in patients who cannot tolerate the sodium and volume load or in those in whom pulmonary edema develops from treatment with sodium bicarbonate.[71,72] Hyperventilation without the administration of sodium bicarbonate may also be considered for patients with cerebral edema, head trauma, or poorly controlled congestive heart failure. Hypertonic saline solution has been effective in treating cardiac toxicity refractory to initial blood alkalinization.[73,74]

If torsades de pointes is associated with QT prolongation, magnesium sulfate 1 to 2 g IV over 2 to 5 minutes should be administered.[71] Hypotension refractory to volume expansion is best treated with a direct-acting catecholamine such as norepinephrine or phenylephrine in the setting of depleted norepinephrine stores.[75] If hypotension remains refractory to fluids and vasopressors, the use of an intraaortic balloon pump may be considered as a temporizing measure. IV lipid emulsion has also been reported to successfully treat refractory hemodynamic instability associated with cyclic antidepressant toxicity.[41]

After the patient with a known or suspected cyclic antidepressant overdose has been stabilized and the airway protected, activated charcoal is indicated. Gastric lavage should be performed only if the patient is seriously ill and the ingestion occurred within 1 hour of presentation. A second dose of activated charcoal may be given in several hours if it seems plausible that the drug still remains in the GI tract in the case of a massive ingestion or hypotension. MDAC to enhance elimination is not warranted given the extremely large volume of distribution (10–50 L/kg) and the low-protein binding of cyclic antidepressants.[16] Forced diuresis, hemodialysis, and hemoperfusion are ineffective. Physostigmine should also be avoided because of the potential anticholinergic toxicity of seizures and asystole.

If the patient has had altered mental status, seizures, or cardiac arrhythmia, the patient should remain in the ICU for 12 hours after all supportive therapeutic interventions have been discontinued. If the patient remains asymptomatic with a normal ECG during this phase of observation, the patient may then be transferred for additional care.

Lithium

Although lithium is used to treat bipolar affective disorder and other psychiatric disorders, its narrow therapeutic index predisposes to toxicity.[76] After oral ingestion, lithium is absorbed within 1 to 2 hours, reaching peak blood levels in 2 to 4 hours with regular preparations or in 4 to 12 hours with sustained-release preparations. Lithium does not bind to plasma proteins and is excreted almost entirely by the kidneys. Toxicity may occur with acute, acute on chronic, or chronic ingestions. Drugs that increase lithium reabsorption (angiotensin-converting enzyme inhibitors, thiazides, spironolactone, nonsteroidal antiinflammatory drugs), sodium restriction, volume depletion, and intrinsic renal dysfunction increase the risk of toxicity. Lithium levels do not necessarily correlate with toxic symptoms. With an acute ingestion, the patient may be asymptomatic with a lithium level of 6 to 8 mmol/L. In chronic lithium ingestion, a high total-body lithium burden results in more toxicity at lower serum levels.

The clinical presentation of patients with lithium toxicity varies with the type of ingestion. In an acute ingestion, nausea, vomiting, and diarrhea occur early with CNS symptoms developing later because of a delay in tissue distribution. In chronic ingestions, neurologic abnormalities are usually the major presenting manifestations. Patients with acute on chronic ingestions may manifest GI and neurologic symptoms. Neurologic abnormalities include tremor, hyperreflexia, agitation, fasciculations, clonus, and altered mental status. Confusion may be followed by lethargy, coma, and seizures. The tremor, hyperreflexia, and clonus usually precede altered mental status. Lithium can impair urine-concentrating ability in acute ingestions and cause nephrogenic diabetes insipidus and renal dysfunction in chronic ingestions that result in volume depletion. Although myocardial dysfunction and rhythm abnormalities have been reported in lithium toxicity, they occur infrequently. Lithium toxicity may produce flattened or inverted T waves and U waves on ECG.

Lithium toxicity is confirmed by assessment of the serum lithium level. A lithium level should be assessed immediately and 2 hours later to evaluate for increasing levels. Levels higher than 2.5 mmol/L in a chronic ingestion or higher than 4 mmol/L in an acute ingestion are potentially life-threatening. Renal function and volume status should also be assessed.

Management decisions in treating lithium toxicity may depend on the type of ingestion (acute versus chronic) and the product ingested (regular versus sustained-release). Lithium is not adsorbed by activated charcoal, but charcoal may be administered if other drugs are ingested or suspected. A forced diuresis is not effective in enhancing lithium excretion, but isotonic fluids should be administered to replete and maintain intravascular volume and promote adequate urine output.[76,77] Diuretics can worsen lithium toxicity and should be avoided. WBI has been proposed for GI decontamination with acute or acute on chronic ingestions, ingestion of sustained-release products, or when serial lithium levels are rising. Despite the lack of proven clinical benefit, this approach may be considered with appropriate precautions. Hemodialysis is effective in removing lithium, but indications for treatment and duration of therapy have varied.[78] Proposed indications that have

not been validated include renal dysfunction, severe neurologic dysfunction, inability to tolerate fluid replacement, lithium level higher than 4 or 5 mmol/L in an acute overdose, and lithium level higher than 2.5 mmol/L in chronic toxicity. The lithium level, duration of exposure, and severity of clinical symptoms should be balanced against the risks of the procedure before initiating hemodialysis. Hemodialysis clears lithium only from the plasma, and a rebound increase can develop from drug redistribution. A lithium level should be assessed immediately after hemodialysis and 6 to 8 hours later. Repeat dialysis can be considered if the lithium level increases or neurologic toxicity persists at that time. Although a lithium level of 1 mmol/L is recommended as the endpoint for hemodialysis, no systematic investigations have established the ideal endpoint for optimal outcome. Because of redistribution of lithium, improvement of neurologic toxicity lags behind the decrease in plasma level. Prolonged monitoring of lithium levels may be necessary, especially when sustained-release preparations are ingested. Continuous renal replacement therapy has also been used to remove lithium and may be associated with less rebound.[78] This technique results in a slower lithium clearance compared with hemodialysis and is not recommended if hemodialysis is available and can be tolerated. Sodium polystyrene sulfonate resin has been proposed to bind and remove lithium, but it is not currently recommended and may result in hypokalemia, hypernatremia, and fluid overload.

Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) and related antidepressants have decreased lethality and fewer adverse cardiovascular effects compared with cyclic antidepressants. Manifestations of an acute SSRI overdose may include nausea, vomiting, dizziness, blurred vision, and rarely CNS depression. Seizures and a wide QRS complex occur rarely but may be more likely with citalopram and bupropion, a unicyclic antidepressant. A syndrome characteristic of SSRIs is the serotonin syndrome, which may occur after a single dose, therapeutic doses, overdose, or when combined with other serotonergic agents, such as monoamine oxidase inhibitors, cyclic antidepressants, lithium, opioids (meperidine, tramadol, dextromethorphan, and pentazocine), amphetamine, serotonin-norepinephrine reuptake inhibitors (venlafaxine, duloxetine), trazodone, and drugs that inhibit hepatic cytochrome P450.[79,80] The pathophysiology is related to excessive stimulation of central and peripheral serotonergic receptors. Clinical manifestations include altered mental status ranging from agitation to coma; autonomic dysfunction including diaphoresis, tachycardia, hyperthermia, unstable blood pressure, and diarrhea; and neuromuscular abnormalities that may range from tremors to myoclonus and rigidity.[80] Severe cases may be complicated by rhabdomyolysis, renal failure, disseminated intravascular coagulation, or acute respiratory distress syndrome.

Management of an acute overdose of SSRIs is largely supportive. Gastric lavage is not warranted because of the low toxicity of these compounds, but use of activated charcoal may be considered. An ECG should be obtained to assess for a wide QRS complex or other electrocardiographic abnormality. Although clinical experience is limited, there are reports of sodium bicarbonate administration resulting in narrowing of the QRS complex. The treatment of serotonin syndrome is primarily supportive therapy after discontinuing the precipitating agents. Intubation and mechanical ventilation may be necessary for patients with significant alteration of mental status. Benzodiazepines are useful for control of agitation and external cooling for sustained hyperthermia. Rarely, neuromuscular blockers may be necessary for control of muscle rigidity or tremor. The syndrome usually resolves in 24 to 72 hours. Treatment of patients with serotonin antagonists has been proposed, but experience is limited to case reports. Cyproheptadine in varying dose regimens (12–32 mg/24 h) has been most commonly recommended as a treatment option. Currently there is no role for the use of bromocriptine or dantrolene.[80]

Sedatives

Benzodiazepines

Although ingestions are relatively common, fatalities from benzodiazepines alone are uncommon. Benzodiazepine overdose results in a typical sedative-hypnotic toxidrome characterized by depressed level of consciousness, respiratory depression, hyporeflexia, and potentially hypotension and bradycardia. The clinical manifestations may be exacerbated by concomitant ingestion of other agents with sedating properties, such as ethanol, opioids, or antidepressants. Alprazolam is commonly seen in overdoses owing to wide availability and may result in greater toxicity than other benzodiazepines.[81] Flunitrazepam is a benzodiazepine not approved for use in the United States that has been associated with sexual assault. Diagnosis of benzodiazepine ingestion is primarily based on the history and clinical manifestations. Many benzodiazepines are detected in qualitative urine toxicology assays, but a negative test result does not rule out exposure. If warranted, gas chromatography/mass spectrometry can be requested for definitive detection.

Managing benzodiazepine ingestions should be guided by the clinical presentation of the patient. The airway is assessed and stabilized if necessary. Activated charcoal is the primary method of GI decontamination for recent ingestions. Supportive care with intubation and mechanical ventilation may be necessary for patients with significant toxicity. Hypotension usually responds to volume infusion.

Flumazenil is a competitive benzodiazepine receptor antagonist that will reverse the sedative effects of benzodiazepines. It may be a helpful diagnostic tool in evaluating a patient with overdose but should not be routinely used as a substitute for adequate airway protection.[82] A dose greater than 1 mg is seldom necessary in overdose victims. The short half-life of flumazenil (0.7–1.3 hours) makes resedation likely because of the longer half-life of benzodiazepines. Continuous monitoring must be instituted if flumazenil is used to arouse the patient. Flumazenil use has been associated with seizures in patients with chronic benzodiazepine use and when cyclic antidepressants are present.[82,83] It is best to avoid flumazenil in those situations and in patients with a seizure disorder or when a drug capable of causing seizures has been ingested. Slow titration of flumazenil (0.1 mg/min) and limiting the total dose to 1 mg may minimize the risk of seizures. If seizures occur with flumazenil, benzodiazepines (often in higher doses) may be effective.

Gamma-Hydroxybutyrate

Gamma-hydroxybutyrate (GHB), a naturally occurring substance found in the brain and peripheral tissues, is banned in many countries except for the treatment for narcolepsy. It is one of several agents characterized as a "date rape" drug and has been promoted to build muscle, improve performance, produce euphoria, induce fat loss, and enhance sleep. Deaths resulting from respiratory failure have been attributed to GHB and related agents.[84] The drug is usually available as a colorless, odorless liquid with a mild, salty taste that is easy to mask in drinks. GHB is rapidly absorbed from the stomach (usually within 10–15 minutes) and readily crosses the blood-brain barrier. It is metabolized to carbon dioxide and

water without active metabolites. Stimulatory effects occur from resulting increased dopamine levels in the brain and sedative effects by potentiation of endogenous opioids. The manifestations of GHB toxicity are dose related and include agitation, coma, seizures, respiratory depression, and vomiting.[84,85] Other effects include amnesia, tremors, myoclonus, hypotonia, hypothermia, decreased cardiac output, and bradycardia. Coma and respiratory depression may be potentiated by the concomitant use of ethanol. GHB is not detected by urine toxicology assays but can be detected in plasma or urine by gas chromatographic and mass spectrophotometric techniques. Diagnosis is usually determined by the clinical course and history of exposure elicited after the patient recovers. Gamma-butyrolactone, also known as 2(3H)-furanone dihydro, and 1,4-butanediol, also called tetramethylene glycol, have been abused with the same adverse effects as GHB including death. Both agents are metabolized in the body to GHB.[84]

The primary management for ingestion of these drugs is supportive care with particular attention to airway protection and ventilation. In some cases, intubation and mechanical ventilation are required. Gastric lavage and activated charcoal are not indicated because of the small amounts involved and the rapid absorption. Naloxone and flumazenil are of no benefit. Patients with mild intoxication may be observed in the emergency department and released after symptoms resolve. A rapid recovery of consciousness from an obtunded condition is frequently observed. In patients requiring intubation and mechanical ventilation, symptoms can be expected to resolve within 2 to 96 hours unless complications such as aspiration or anoxic injury have occurred. The concomitant use of alcohol may prolong the CNS depression. Although physostigmine has been used to awaken patients with GHB intoxication, its use is not recommended.[86]

A withdrawal syndrome has been described in patients who frequently ingest high doses of GHB (every 1–3 hours).[84,85] Mild symptoms such as anxiety, insomnia, nausea, vomiting, and tremors begin within 6 hours of the last dose and may progress to severe delirium with autonomic instability (usually mild) requiring hospitalization and sedation. The duration of symptoms requiring treatment may be as long as 2 weeks. Benzodiazepines are the initial choice for management, and high doses may be required. Propofol and barbiturates have also been used successfully.

Propofol

Propofol is a sedative-hypnotic used for general anesthesia, procedural sedation, prolonged sedation in critically ill patients, and treatment of status epilepticus. It has also been implicated in abuse, accidental overdose, suicide, and even murder.[87] A potentially fatal toxicity associated with more prolonged infusions of propofol is known as propofol-related infusion syndrome (PRIS).[88] The syndrome is usually associated with doses of propofol greater than 4 mg/kg per hour for longer than 48 hours' duration. However, metabolic acidosis has been reported within 1 to 4 hours after the initiation of propofol infusion. Predisposing factors that have been associated with PRIS include young age, CNS or respiratory illness, vasopressor use, glucocorticoid use, greater severity of illness, sepsis, and impaired oxygen delivery. Clinical features of the syndrome can include refractory bradycardia progressing to asystole, other arrhythmias, myocardial failure, lactic acidosis, rhabdomyolysis, renal failure, and hypertriglyceridemia.[88,89] The pathophysiology is hypothesized to be related to mitochondrial utilization of free fatty acids and genetic predisposition.

Propofol infusions should be limited to less than 4 mg/kg per hour and no longer than 48 hours of infusion when possible. Prompt recognition of early signs of PRIS (elevated serum lactate, elevated creatine kinase, hypertriglyceridemia) is essential for successful intervention. Another clinical clue to possible PRIS is the unexplained need for increasing doses of pressor or inotropic agents. Management includes discontinuation of propofol and the use of alternative sedative agents. The most effective treatment for severe PRIS is cardiorespiratory support and hemodialysis or hemofiltration to decrease blood levels of metabolic acids and lipids.[89]

Stimulants

Amphetamines/Methamphetamines

Amphetamines, methamphetamines, and related agents cause central and peripheral release of catecholamines, which result in a sympathomimetic toxidrome (see Table 65.2). Hallucinations (visual and tactile) and acute psychoses are frequently observed. The clinical manifestations associated with abuse of these agents may last up to 24 hours owing to the longer duration of pharmacologic effects. The acute adverse consequences are similar to those seen with cocaine abuse (see later text) and include myocardial ischemia and arrhythmias, pulmonary hypertension, seizures, intracranial hemorrhage, stroke, hepatotoxicity, rhabdomyolysis, necrotizing vasculitis, and death.[90] Chronic use of these drugs may result in dilated cardiomyopathy.[91] Poor oral hygiene and severe dental caries ("meth mouth") can be clues to chronic methamphetamine use.[92]

Methamphetamine hydrochloride in a crystalline form called "ice," "crank," or "crystal" is one of the more popular drugs in this class. It has high purity and can be orally ingested, smoked, insufflated nasally, or injected intravenously. An amphetamine-like drug (3-4-methylenedioxymethamphetamine) is a designer drug commonly known as ecstasy, XTC, or MDMA that acts as a stimulant and hallucinogen.[93] It results in serotonin release in the brain with inhibition of serotonin reuptake and has been reported to produce serotonin syndrome. Complications are usually a result of the drug effects and excessive physical activity. Complications include hyperthermia, hyponatremia (excessive water intake or syndrome of inappropriate antidiuretic hormone secretion), rhabdomyolysis, renal failure, cardiac collapse, cerebral infarction/hemorrhage, and multiple-organ failure. MDMA and other amphetamines will usually be detected on qualitative toxicology assays of urine but false-positive and false-negative results occur.

Management of amphetamine intoxication is primarily supportive. Gastric lavage is not recommended because absorption after oral ingestion is usually complete when patients present. Activated charcoal may be considered if a recent oral ingestion is known to have occurred. Further interventions are dependent on patient complaints and clinical findings. A careful assessment for complications should be made, including measurement of core temperature, obtaining an ECG, and evaluating laboratory data for evidence of renal dysfunction and rhabdomyolysis. IV hydration for possible rhabdomyolysis is warranted in individuals with known exertional activities pending creatine phosphokinase results. Benzodiazepines, often in high doses, are used to control agitation and recent reports suggest dexmedetomidine may be effective.[94] Antipsychotic medications, such as haloperidol, risperidone, and quetiapine, have also been used for agitation and psychosis.[94] Seizures are best treated with benzodiazepines.

Cocaine

Cocaine abuse is declining but still results in significant medical complications.[95] Cocaine hydrochloride is water soluble and can be injected intravenously, ingested, or snorted intranasally. Crack

or rock cocaine is the alkaloid form primarily abused by inhalation. The onset, peak, and duration of physiologic effects of cocaine vary with the route of use, form of cocaine used, and concomitant use of other drugs.[95] Both forms of cocaine are absorbed from all mucosal surfaces and undergo hydrolysis by plasma and liver cholinesterases. The major metabolites, benzoylecgonine and ecgonine methyl ester, are excreted in the urine and can be detected by qualitative urine assays. The metabolites of cocaine may be detectable in urine for 24 to 36 hours after use, but prolonged detection can occur in frequent users of high doses.

Cocaine inhibits the presynaptic reuptake of biogenic amines, such as norepinephrine, dopamine, and serotonin, throughout the body including the CNS. Characteristic clinical findings of a sympathomimetic syndrome include tachycardia, mydriasis, hypertension, hyperthermia, diaphoresis, euphoria, and agitation. The sympathetic stimulation also results in multiple potential complications (Box 65.3). Complications such as myocardial ischemia or cerebral infarction may occur several days after the last use of cocaine. Complications of transporting cocaine in body cavities may include rupture of packets with drug absorption and bowel obstruction.

No specific antidote exists for cocaine. Treatment is primarily aimed at detecting complications, intervening as indicated, and preventing further injury. Benzodiazepines should be used liberally for control of agitation. Haloperidol is reserved for overt psychosis because of its potential for lowering the seizure threshold.

No large clinical trials have evaluated therapeutic strategies for myocardial ischemia resulting from cocaine use. Aspirin should be administered if the risk of intracranial hemorrhage is low because a significant number of patients have thrombotic occlusion as the cause of ischemia. Benzodiazepines and nitroglycerin are first-line agents for relief of chest pain, but small clinical studies have yielded conflicting results on the benefit of combining the agents.[96] α-Adrenergic blockers such as phentolamine and calcium channel blockers have been recommended as second-line treatment for unrelieved pain but are rarely necessary.[96] β-Blockers were often considered to be contraindicated in the management of potential ischemia related to cocaine because of the potential for unopposed α-adrenergic–mediated vasoconstriction leading to elevated blood pressures. However, β-blocker use was not found to be detrimental in two retrospective studies of patients with recent cocaine use and may be beneficial in some patients.[97,98] It may be appropriate to avoid administration of β-blockers in patients manifesting acute sympathomimetic findings. In addition, routine use of IV β-blockers is no longer recommended for acute coronary syndromes. Reperfusion interventions, primarily percutaneous coronary interventions, should be considered for patients with myocardial infarction.[96] Ventricular arrhythmias are not common and may be related to cocaine blockade of myocardial sodium channels leading to QRS and QT-interval prolongation. Wide-complex arrhythmias may respond to treatment with sodium bicarbonate.[99] Class IA antiarrhythmic drugs such as procainamide should be avoided. Treatment of life-threatening arrhythmias should otherwise follow advanced life support guidelines.

Cerebral complications should be managed by standard interventions specific for the injury. Seizures are best managed with benzodiazepines. The reported incidence of underlying vascular malformations in intracranial hemorrhage has been variable, but if present these problems may require specific intervention. Severe hyperthermia is managed the same as heat stroke with either conductive or evaporative cooling.[100] When there is suspicion of rhabdomyolysis, IV hydration should be instituted immediately pending assessment of renal function and creatine phosphokinase levels. Asymptomatic transporters of cocaine packets should be managed conservatively with activated charcoal, possible WBI, and supportive care. Surgery is reserved for patients exhibiting manifestations of cocaine poisoning or GI perforation or obstruction.[101] Contamination of cocaine with other drugs or fillers can result in toxicities that are not directly related to the effects of cocaine. Levamisole, an anthelminthic agent used in veterinary medicine, has been found in cocaine supplies and linked to the development of reversible agranulocytosis.[102] Retiform purpura and skin necrosis secondary to thrombotic vasculopathy have also been linked to cocaine contaminated with levamisole.[103,104] The potential for suicidal intent should be recognized in cocaine abusers, and psychiatric consultation may be appropriate after stabilization.

Mephedrone/Methylenedioxypyrovalerone (Bath Salts)

Mephedrone and 3,4-methylenedioxypyrovalerone (MDPV) are synthetic stimulants marketed in products sold as bath salts to

avoid regulation. MDPV inhibits reuptake of dopamine and norepinephrine, and mephedrone may act as a monoamine reuptake inhibitor.[105] The products have been ingested, snorted, smoked, and injected and are often used in combination with alcohol or other drugs. These agents are not detected by qualitative toxicology screens.

Clinical manifestations are similar to those of other stimulant drugs and include agitation, tachycardia, hyperthermia, hypertension, mydriasis, chest pain, palpitations, seizures, hallucinations, delusions, and paranoia.[105,106] Symptoms may be prolonged for more than 24 hours after use of mephedrone despite a short expected half-life.[106] Management includes IV benzodiazepines for significant agitation and psychotic symptoms. Symptoms may recur as sedation wears off, requiring repeat dosing. A thorough clinical evaluation is required to identify other complications, such as rhabdomyolysis, myocardial ischemia, and organ dysfunction. Seizures are best treated with IV benzodiazepines.

Synthetic Cannabinoids

Synthetic cannabinoids include a heterogeneous group of drugs that are full agonists of cannabinoid receptors in the brain and spinal cord and have a greater risk for toxicity compared with marijuana. These substances are often sprayed on herbal potpourri products marketed as incense that can be inhaled or ingested. Liquid forms may be used in e-cigarettes.[107,108] Synthetic cannabinoids are not detected in routine urine toxicology assays. Clinical manifestations related to use of these products vary from mild to severe. Serious adverse effects of synthetic cannabinoids may include agitation, psychosis or delirium, tachycardia, arrhythmias, myocardial ischemia, respiratory depression, hyperemesis, hyperthermia, renal failure, rhabdomyolysis, stroke, seizures, and death.[107,108] Management of toxicity from synthetic cannabinoids is mainly supportive and includes the use of benzodiazepines for agitation.

Valproic Acid

Use of valproic acid (VPA) for seizure disorders, psychiatric disorders, migraine prophylaxis, neuropathic pain, and cancer therapy has resulted in increased toxicity reported with therapeutic doses and overdoses. The most common manifestation of toxicity in overdoses is CNS depression with higher drug levels associated with an increased incidence of coma and respiratory depression requiring intubation.[109] Cerebral edema may occur 48 to 72 hours after overdoses and may be related to hyperammonemia that usually occurs in the absence of hepatotoxicity. The increase in ammonia may be related to carnitine deficiency, renal abnormalities, or defects in the urea cycle.[109] Large VPA ingestions can result in refractory hypotension. Pancreatitis has been associated with chronic ingestion and acute overdose. Metabolic abnormalities of VPA toxicity include hypernatremia, hyperammonemia, anion gap metabolic acidosis, hypocalcemia, and acute renal failure. Hepatotoxicity is rare with VPA overdoses, but mild, asymptomatic abnormalities may occur with chronic use.

Initial and serial VPA levels should be obtained because of delayed peak serum levels in overdose. Patients may be comatose with normal serum VPA concentrations caused by unmeasured metabolites. An ammonia level should be obtained in patients with altered level of consciousness. Activated charcoal should be administered if the patient presents early after ingestion. MDAC may be beneficial because of a potential enterohepatic recirculation of drug, but routine use is not currently recommended. Although VPA is highly protein bound, protein binding is saturated at high serum concentrations, resulting in more free drug being available for removal by extracorporeal techniques. Hemoperfusion, combined hemodialysis-hemoperfusion, or high-flux hemodialysis may be considered in patients with severe or persistent hemodynamic instability, coma, or metabolic acidosis.[110] No antidote exists for VPA toxicity, but L-carnitine administration has been proposed for patients with VPA toxicity and hyperammonemia. Chronic VPA therapy has been associated with carnitine deficiency and case reports suggest that L-carnitine administration is safe.[111] However, there is no evidence that L-carnitine alters clinical outcome and more rigorous study is needed. Dosing of L-carnitine in reports has been variable but a suggested regimen is 100 mg/kg IV bolus or infusion over 15 to 30 minutes, followed by 50 mg/kg (maximum 3 g/dose) every 8 hours until the ammonia level is decreasing and the patient clinically improves.[111]

Key Points

- Evaluating and managing the poisoned patient involves resuscitation and stabilization, diagnosis, GI decontamination and toxin elimination, institution of specific antidotes or interventions, and supportive care.
- In the poisoned patient with altered mental status, hypertonic dextrose, thiamine, and naloxone should be considered for administration.
- Patterns of signs and symptoms identified by physical examination may often suggest a toxidrome that is associated with classes of toxins.
- Single-dose activated charcoal is most effective when administered within 1 hour of toxin ingestion; later administration may be appropriate if clinical factors suggest the toxin has not yet been completely absorbed.
- Recognition of potential acetaminophen toxicity is essential for appropriate treatment and prevention of morbidity.
- Findings of bradycardia and hypotension should suggest possible ingestion of a β-blocker or calcium channel blocker.
- Dietary and nutritional supplements can result in significant cardiac, hepatic, and cerebrovascular toxicities.
- Cyclic antidepressant toxicity with increased QRS duration or wide-complex tachyarrhythmia requires immediate alkalinization of the blood with sodium bicarbonate or hyperventilation.
- The initial treatment for patients presenting with a clinical syndrome suggesting a stimulant toxin (cocaine, amphetamines, bath salts, synthetic cannabinoids) is IV benzodiazepines for control of agitation.
- Be aware of potential toxicities that can develop in ICU patients exposed to propylene glycol–containing medications, topical anesthetics, and propofol.

Review Questions

1. A 28-year-old patient was found unconscious in a park. In the emergency department, his vital signs were heart rate 62 beats/min, blood pressure 88/40 mm Hg, respiratory rate 10 breaths/min, and temperature 36.6°C. He was noted to have small pupils that were minimally reactive and he did not withdraw to pain in any extremity. The emergency department physician administered 0.2 mg of naloxone without effect. The intensivist was called for admission and consultation. Which of the following is the most appropriate intervention at this time?
   a. Administer norepinephrine
   b. Intubate the patient
   c. Administer a higher dose of naloxone
   d. Administer flumazenil

   Answer: c. The patient's presentation is classic for an opioid toxidrome with depressed level of consciousness, respiratory depression, and miosis. The next step in the care of the patient is to administer higher doses of naloxone to assess for response given that many synthetic opioids such as methadone, oxycodone, and fentanyl require higher doses for reversal of effects. Although intubation may be considered, it is usually not needed if adequate arousal is achieved with naloxone. Hypotension often responds to fluids and naloxone and vasopressors should be reserved for refractory cases. Flumazenil should not be administered because of the potential for seizures, and the clinical presentation is more consistent with an opioid overdose.
2. A 40-year-old man is admitted to the ICU after ingesting a total of 60 tablets of acetaminophen 500 mg and 50 tablets of hydrocodone/acetaminophen (5 mg/325 mg) on multiple occasions over the past 48 hours. He is lethargic but arousable. Vital signs are blood pressure 118/70 mm Hg, heart rate 96 beats/min, RR 18 breaths/min, and temperature 37°C. His acetaminophen level is 50 µg/mL. Liver function test results are total bilirubin 1.0 mg/dL, alanine aminotransferase 100 IU/L, aspartate aminotransferase 85 IU/L, and alkaline phosphatase 110 IU/L0. Which one of the following interventions is most appropriate?
   a. Check the Rumack-Matthew nomogram to determine the need for N-acetylcysteine.
   b. Continue supportive care and monitor liver function test results.
   c. Initiate N-acetylcysteine therapy.
   d. Administer lactulose,

   Answer: c. The indications for a full course of N-acetylcysteine in this patient are the presence of any acetaminophen level and elevated transaminases in a patient with multiple ingestions of acetaminophen over time. The Rumack-Matthew nomogram is of no help in this situation because it was developed for single acute ingestions in patients who present within 24 hours. Continuing with supportive care and monitoring without administering N-acetylcysteine would likely result in continued worsening of hepatic injury. The liver injury is not sufficient at this point to cause hepatic encephalopathy, so lactulose to improve mental status would not be helpful.
3. A 65-year-old woman is admitted to the intensive care unit (ICU) with hypotension. Her husband found multiple empty pill bottles at home. Her regular medications include extended-release verapamil, lisinopril, and pravastatin. On arrival to the ICU vital signs are blood pressure 78/40 mm Hg, heart rate R 38 breaths/min, respiratory rate 16 breaths/min, temperature 93°C. Normal saline solution (1 L) is administered and calcium chloride 1 g is administered twice with no improvement of blood pressure. Which one of the following is the next best intervention?
   a. Transcutaneous pacing
   b. IV atropine
   c. Lipid emulsion
   d. High-dose insulin

   Answer: d. High-dose insulin therapy is recommended as the next intervention for calcium channel blocker toxicity if calcium is ineffective. Although atropine is often administered, it is usually ineffective. Transcutaneous pacing may increase the heart rate but not the blood pressure because hypotension is usually due to the negative inotropic effects of the drug. Lipid emulsion is an option for those patients who may be refractory to high-dose insulin but it is not recommended as an initial intervention.

Hypothermia

Cold exposure has been recognized as a cause of death since ancient times. In the year 492 BC, the Persians were sailing to launch their attack against the Greeks when they encountered bad weather and lost about 300 ships and 20,000 soldiers. Herodotus wrote "…[Some were dashed by the rocks, and some of them did not know how to swim and perished for that cause, others again by reason of *cold*."

To recognize hypothermia, it must be possible to measure a temperature. The first thermometer for clinical use was invented in 1612. It was a foot long and required 20 minutes to register a temperature. The invention of the mercury thermometer by Fahrenheit in 1714 made the tool more practical. However, it was not until the late nineteenth century that the thermometer became a clinical tool. This use was established after the invention of a small thermometer that only required 5 minutes to obtain a temperature (1866) and after Carl Wunderlich's publication (1868), which presented data on nearly 25,000 patients and analyzed temperature variation in 32 diseases. In the early 1900s, temperature was routinely measured and physiologic experiments started to appear. By the 1930s to 1940s, therapeutic hypothermia for malignancy and anesthesia was investigated. By the middle of the twentieth century, accidental hypothermia was established as a disease entity.[1]

This section discusses the epidemiology, definition, pathophysiology, clinical diagnosis, clinical manifestations, and management of hypothermia. Despite some similarities in pathophysiologic mechanisms, accidental hypothermia and induced hypothermia should not be compared, as accidental hypothermia occurs unexpectedly and is uncontrolled.

Epidemiology

Accidental hypothermia continues to be a public health problem. The Centers for Disease Control and Prevention reports that between 1999 and 2011, a total of 16,911 deaths in the United States (an average of 1301 per year) were attributed to excessive natural cold.[2]

Approximately 50% of all hypothermia-related deaths occur in persons older than 65 years of age. The age-adjusted mortality rate is three times higher for men than it is for women. In blacks and other races, the mortality rate is higher than that of whites.[2,3] Blacks have decreased heat production and lower rectal temperatures in response to cold exposure.[4] Other populations at risk include the elderly, people with preexisting chronic medical conditions, and people with alcoholism and drug intoxication.[2,3,5] Emerging populations include wilderness enthusiasts and winter sport participants.[6]

Despite advances in medical care, hypothermia remains a challenge to health care providers, with in-hospital mortality rate reaching 40%[7] and an overall mortality rate ranging from 17% to 80%.[8] The prompt recognition and appropriate management play a key role in improving outcomes.

Definition

Hypothermia is defined as a core body temperature lower than 35°C (<95°F). It has been further classified by severity according to the degree by which the core temperature has decreased from baseline into mild, moderate, and severe. Mild hypothermia is defined by a core body temperature of 32°C to 35°C (90°F–95°F). Moderate hypothermia reflects a core body temperature of 28°C to 32°C (82°F–90°F). Severe hypothermia is a core body temperature of less than 28°C (<82°F). Some reports refer to severe hypothermia below 30°C. In trauma patients, hypothermia carries a poorer prognosis. In this case, the definition is even more conservative, with severe hypothermia starting below 32°C. This subclassification has important implications regarding the anticipated physiologic changes and subsequently the use of appropriate therapeutic modalities.[9,10]

Heat Regulation

Body temperature is regulated through a balance between heat production and heat dissipation.[11] Heat production occurs mostly from the metabolic activity of energy-consuming processes within the viscera, namely, the heart, liver, and brain. Heat production in these organs is estimated to be between 40 and 60 kcal/m^2 per hour. Normally heat production is increased by food intake and muscle activity. Different stresses such as fever, infection, and cold exposure also increase heat production.

Heat loss occurs through different forms. Radiation cooling (infrared emissions) accounts for approximately 60% of heat loss. It occurs primarily from the head and unisolated parts of the body. Conduction (direct transfer of heat to an adjacent cooler object) and convection (direct transfer of heat to convective air currents) account for around 10% to 15% of heat loss. Evaporation from the skin and respiratory tract accounts for 25% to 30%. Conduction is an important mechanism in immersion accidents because thermal conduction of water is 30 times that of air. Convection is important in windy conditions by removing the warm isolating layer of air around the body.[6,10,11]

Upon cold exposure, the hypothalamus initiates mechanisms for heat conservation and heat production. Heat conservation is achieved by peripheral vasoconstriction, reducing heat conduction to the skin, and behavioral responses such as wearing more clothes and seeking a warmer environment. Heat production is achieved through stimulation of muscular activity via shivering, which can increase the basal metabolic rate by two to five times. A nonshivering thermogenesis occurs via increased levels of catecholamines and thyroxine.[12] This coordinated physiologic response occurs typically for temperatures between 32°C and 35°C. It lasts only for a few hours, after which muscle fatigue and glycogen depletion ensue. As the core temperature drops below 32°C (90°F), shivering thermogenesis abates, and nonshivering thermogenesis slows. By temperatures below 20°C to 24°C, the different mechanisms of heat production completely fail.[13]

Clinical Presentation

Etiologic Factors (Fig. 66.1)

Factors that predispose to hypothermia are related to impaired thermoregulation, increased heat loss, and decreased heat production. A combination of these factors is often noted in a hypothermic patient.

1. *Impaired thermoregulation* is of critical importance in the elderly, mentally ill, and patients with chronic medical conditions such as Parkinson disease, stroke, multiple sclerosis, and diabetes mellitus. Such populations often use multiple medications, including anxiolytics, antidepressants, phenothiazines, barbiturates, opioids, antipsychotics, oral antihyperglycemics, β-blockers, and α-blockers. These drugs can cause further impairment in thermoregulation.[14] In addition, the elderly and chronically ill may exhibit maladaptive behavior (decreased mobility and inability to communicate effectively), which increases the chance of remaining in an environment with prolonged cold exposure.[14]
2. *Increased heat loss* can be environmental or nonenvironmental.
   a. Hypothermia commonly occurs during winter weather and in cold climates. People with inadequate insulation and continued cold exposure are especially at risk.
   b. Patients with dermatologic dysfunction, such as burns, psoriasis, and exfoliative dermatitis, can have increased heat loss.
   c. Large amounts of unheated IV fluid resuscitation, whether crystalloids or blood, coupled with unheated humidified oxygen, predispose hospital and trauma patients to greater heat loss.
   d. Conditions that cause vasodilation should be highlighted in this category and include alcohol, anesthesia, and toxins released in disease entities such as sepsis.
3. *Decreased heat production* is noted in some specific types of disorders:
   a. Endocrine dysfunction such as hypopituitarism, hypothyroidism, hypoadrenalism, and hypoglycemia.
   b. Malnutrition and starvation, which cause decreased insulative subcutaneous fat and are often associated with hypoglycemia.
   c. Conditions that alter the level of consciousness, causing decreased shivering mechanism. Drugs such as phenothiazines and tricyclic antidepressants as well as alcohol can induce impairment of shivering.[6]

Diagnosis

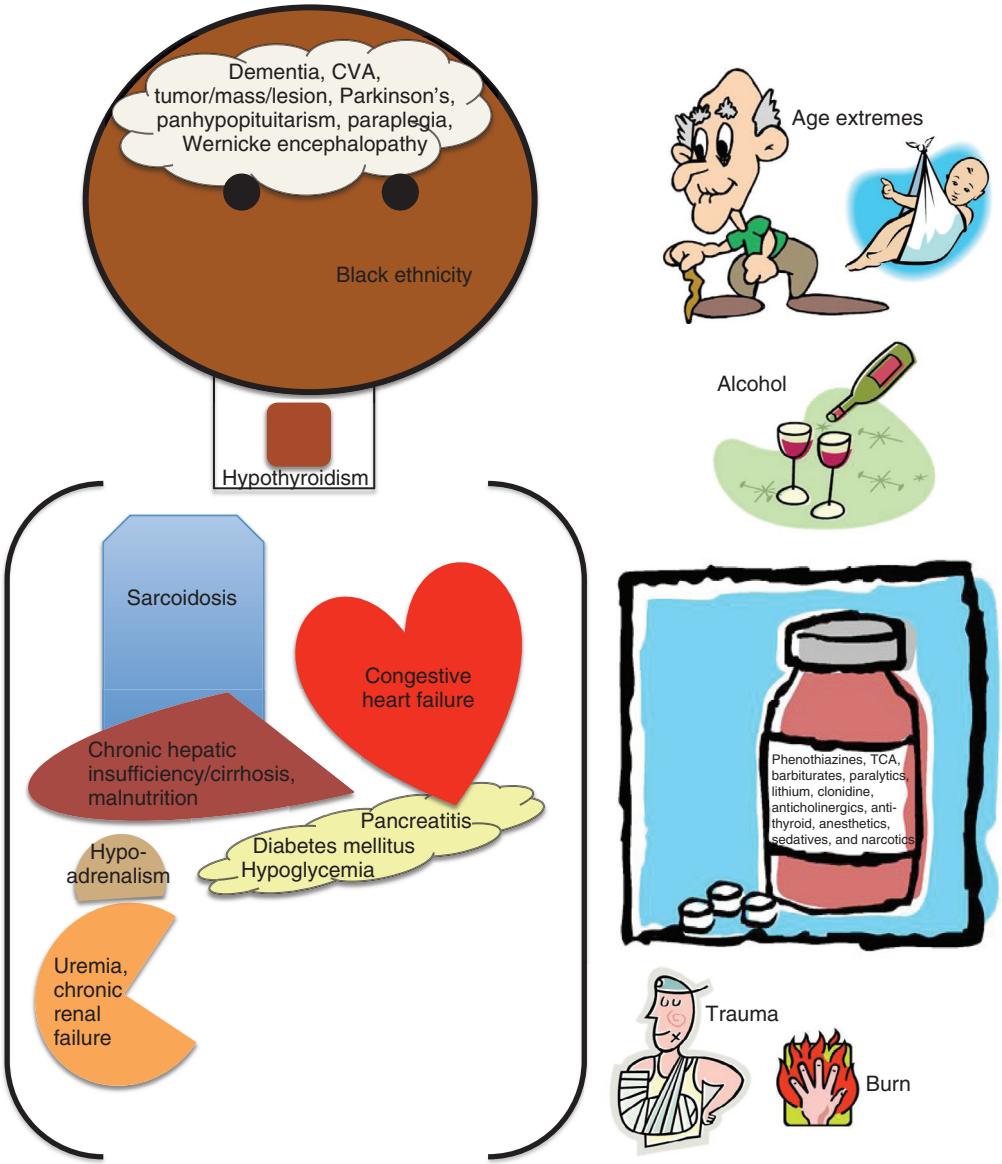
Diagnosis via rectal, esophageal, or bladder probe should be performed using a thermometer capable of measuring temperatures as low as 25°C (77°F). The most accurate recommended thermometer is the esophageal probe inserted into the lower one-third of the esophagus, an average of 24 cm below the larynx in adults. It should be noted that standard clinical thermometers do not register below 34.4°C (94.4°F).[15] Combined methods for temperature monitoring may allow better detection of further changes.

End-Organ Manifestations (Fig. 66.2)

Almost every organ in the body is affected by hypothermia.[16] The initial mechanisms mimic intense sympathetic stimulation, which fades as body temperature drops. Although hypothermia is divided into three stages, it is important to note that the physiologic changes follow a continuum.[16]

Cerebral Effects

Hypothermia is associated with progressive decrease in neuronal metabolism between 35°C and 25°C. This is a protective effect of hypothermia and allows tolerance to periods of cardiocirculatory collapse in contrast with the normothermic state.[6,17,18] Neurologic symptoms begin with mild hypothermia. Between 34°C and 35°C, loss of fine motor skills, lack of coordination, dysarthria, and amnesia take place. Ataxia and apathy are noted around 33°C.[19] Below 32°C, progressive decrease in level of consciousness and pupillary dilation develops. Cerebrovascular autoregulation is lost below 25°C. Deep tendon reflexes diminish and flaccid muscular tone takes place below 27°C. By 23°C, corneal and oculocephalic



• **Fig. 66.1** Diseases and factors associated with hypothermia. *CVA,* Cerebrovascular accident; *TCA,* tricyclic antidepressant. (Reprinted with permission of Zoulficar Kobeissi, MD.)

reflexes are absent. The electroencephalogram pattern flattens at 19°C to 20°C. The lowest temperature reported for an adult survival with hypothermia is 13.7°C.[6,15,20] Therefore one has to be very careful in assessing brain death when a patient remains hypothermic.[8]

Cardiovascular Effects

The initial response (34°C–36°C) includes increased heart rate, blood pressure, and carbon dioxide secondary to elevated catecholamine production and peripheral vasoconstriction, resulting in increased in oxygen consumption.[6] A core temperature decrease of as little as 0.3°C is associated with a 7% increase in oxygen consumption. The increase in oxygen requirement results in anaerobic metabolism, acidosis, and significant cardiopulmonary stress, further worsening the abnormal physiology of hypothermia.[16] Below 34°C, progressive bradycardia and decrease in cardiac output and blood pressure take place. Below 28°C, 50% of patients show bradycardia with a 50% decrease in heart rate. Bradycardia is chiefly related to progressive decreased spontaneous depolarization of pacemaker cells. The conduction system is also affected, with prolongation initially noted in the PR interval, then QRS complex, then QT intervals.[21] Atropine is ineffective. The myocardium becomes irritable. As temperature falls lower than 32°C, atrial fibrillation is common, usually preceding ventricular fibrillation that may occur spontaneously when temperature falls below 28°C (82°F). Asystole usually occurs at temperatures less than 25°C.[22]

Respiratory Changes

Early in hypothermia (34°C–36°C) the respiratory drive is stimulated. The minute ventilation increases in response to increased oxygen consumption and CO_2 production. Below 33°C, respiratory depression takes place. Minute ventilation decreases. Depressed cough reflex and ciliary action coupled with increased production of mucus (bronchorrhea) increase the risk of atelectasis and aspiration. Noncardiogenic pulmonary edema has also been reported.[23,24]

Renal Changes

The initial response to hypothermia includes increased renal blood flow secondary to an increase in blood pressure and cardiac output, inducing diuresis. As hypothermia progresses below 32°C and cardiac output declines, renal blood flow and glomerular filtration rate decrease, resulting in acute renal failure. Urinary output persists in this stage, known as cold diuresis. In cold diuresis, impaired renal tubular sodium reabsorption maintains ongoing urinary flow. This response explains why hypothermia patients may present with profound intravascular volume depletion.[6,16,25]

Gastrointestinal Changes

Ileus, bowel wall edema, depressed hepatic detoxification, punctate gastric erosions, and rarely hemorrhagic pancreatitis are among the gastrointestinal manifestations of hypothermia.[16]

Laboratory Evaluation

Laboratory evaluations should be obtained to assess metabolic status and organ dysfunction. The following are common laboratory findings during hypothermia. They usually change with rewarming and require frequent monitoring.

Arterial Blood Gases

As temperature decreases, the oxyhemoglobin dissociation curve shifts to the left. For every 1°C drop in temperature, pH increases by 0.015, partial pressure of arterial oxygen (PaO_2) decreases by 7.2%, and partial pressure of carbon dioxide ($PaCO_2$) decreases by 4.4%. Because all arterial blood gas (ABG) samples are warmed to 37°C (98.6°F) when measured, the pH appears lower and the PaO_2 and $PaCO_2$ appear higher than the patient's actual values. Most knowledge on acid-base status during hypothermia comes from cardiovascular surgery reports. Although most literature does not recommend correction of temperature to guide therapy, the use of corrected values should be strictly individualized.[26–28]

Complete Blood Cell Count

Hemoconcentration, an increase in hematocrit secondary to a decrease in plasma volume, is common (2% for each 1°C-decrease in temperature). An initial low hemoglobin suggests acute

hemorrhage or preexisting anemia. White blood cells may decrease; therefore any history suggestive of infection should prompt treatment with antibiotics in high-risk groups such as the elderly, neonates, and the immunocompromised.[29]

Coagulation Factors

Hypothermia induces inhibition of coagulation factors. It also induces thrombocytopenia secondary to bone marrow suppression and splenic and hepatic sequestration, as well as reduction in platelet adhesions and aggregation. Prolonged bleeding time and clotting times are common. Coagulation tests in the laboratory are performed at temperatures below 37°C. If results are normal, they may not negate the presence of underlying hypothermia-induced coagulopathy. The key treatment in this condition is rewarming, not supplementation of coagulation factors.[30,31] Rewarming, however, increases the clotting response. Clinicians should use caution during this process, as patients are more susceptible to negative cardiovascular events.[4]

Blood Urea Nitrogen/Creatinine/Electrolytes

As mentioned earlier, acute renal failure with intravascular volume depletion and decreased renal perfusion is encountered. This is usually associated with higher levels of blood urea nitrogen (BUN) and creatinine (Cr) secondary to decreased clearance. Recurrent evaluation of electrolytes is essential during rewarming because no consistent pattern is present. Either hypokalemia or hyperkalemia may complicate the course of hypothermia and should be corrected promptly. Hypothermia masks the usual electrocardiogram changes seen in normal hyperkalemia.[6,8,16]

Blood Glucose

Hyperglycemia is initially noted as hypothermia inhibits insulin release and insulin uptake by membrane receptors at temperatures below 30°C. It is further exacerbated by increased catecholamines. Insulin at these temperatures is ineffective. Exogenous insulin should be avoided, as it may cause rebound hypoglycemia during rewarming.[32]

Other Laboratory Abnormalities

Hyperamylasemia is common and may be related to a preexisting pancreatitis or pancreatitis induced by hypothermia. Hyperamylasemia correlates with the severity of hypothermia. Variable elevation in creatine phosphokinase levels may reflect underlying rhabdomyolysis.

Electrocardiography Changes

All intervals—PR, QRS, and QT—are prolonged secondary to hypothermia-induced slowed impulse conduction through potassium channels. When body temperature decreases below 33°C (91.4°F), the J (Osborn) wave may be noted as a positive deflection in the left ventricular leads at the junction of the QRS complex and ST segment in 25% to 30% of patients. The presence of this wave is not pathognomonic and has no prognostic implication. The magnitude of the Osborn wave is associated with the degree of severity of hypothermia.[12,21]

Management (See Fig. 66.2)

The lack of a standardized hypothermia treatment protocol among hospitals is still a challenge. The severity of hypothermia, clinical findings, and comorbid conditions of the patient are important factors for determining the aggressiveness of resuscitation techniques. Once hypothermia is confirmed, assessment and treatment of the critically ill patient should take place simultaneously. Some patients with hypothermia and cardiac arrest achieved an almost complete recovery despite prolonged resuscitation with a temperature as low as 13.7°C. Patients with moderate or severe hypothermia should be resuscitated until adequate rewarming is achieved before declaring efforts as unsuccessful.[33–35]

Initial Stabilization

Removal of wet clothing and moving the patient to a warm environment for protection against continued heat loss are essential. Rough movements of the patient's body during physical assessment should be avoided as it could precipitate serious cardiac arrhythmias. Continuous monitoring of cardiac status and core temperature should be established without delay. Similar to any emergency situation, airway, breathing, and circulation should be evaluated promptly in the hypothermic patient.

Airway/Breathing Support

Chest rigidity and decreased diaphragmatic movement impede adequate ventilation. Oxygenation may be insufficient secondary to underlying aspiration or pulmonary edema. Supplemental oxygen should be provided to alert patients with intact airway reflexes pending full assessment of oxygenation status. Hypothermic patients with apnea, deteriorating mental status, or loss of protective reflexes should undergo endotracheal intubation. The oropharyngeal route is preferred. Jaw maneuvering could be difficult in this category of patients secondary to muscle rigidity. Neuromuscular blocking agents do not have a role as they are ineffective at temperatures below 30°C. Intubation with a smaller endotracheal tube may be attempted. Intubation is unlikely to induce dysrhythmias in hypothermic patients.[8]

Cardiocirculatory Support

Volume Resuscitation

Most patients with moderate to severe hypothermia have volume depletion. Continuous warmed IV fluids (40°C–42°C) should be administered. Peripheral large-gauge catheters are the preferred route of administration. The femoral vein is the preferred site if a central line is anticipated. Volume status should be monitored continuously during rewarming, as peripheral vasodilation and hypotension are likely to occur.[36] Most patients with moderate to severe hypothermia suffer from volume depletion. Continuous warmed intravenous (IV) fluids (40°C–42°C) should be administered. Peripheral large-gauge catheters are the preferred route of administration. The femoral vein is the preferred site if a central line is anticipated. Volume status should be monitored continuously during rewarming, as peripheral vasodilation and hypotension are likely to occur.[36]

Cardiac Resuscitation

Patients with moderate to severe hypothermia should undergo a thorough evaluation, looking for signs of cardiac output or peripheral blood flow. Echocardiography and Doppler ultrasound can be used for this purpose. Cardiopulmonary resuscitation should be performed immediately if no pulse or a nonperfusing rhythm (ventricular fibrillation or asystole) is established.[37–39]

Defibrillation. The hypothermic heart may be unresponsive to cardioactive drugs, attempted electric pacing, and defibrillation. Most arrhythmias other than ventricular fibrillation tend to convert spontaneously with rewarming. Sinus bradycardia does not require pacing or pharmacologic intervention. Ventricular fibrillation or

tachycardia without a pulse requires initial defibrillation with maximum energy.

The European Resuscitation Council 2015 guidelines recommend limiting defibrillation to three attempts until the core temperature reaches above 30°C. Defibrillation is reattempted after every 1°C- to 2°C-increase in core temperature or when temperature rises above 30°C to 32°C.[37–39]

Cardioactive Drugs. The antiarrhythmic and vasoactive drug efficacy in moderate to severe hypothermia is not well determined. It is mainly based on animal studies. Both the American Heart Association and the European Resuscitation Council continue to recommend not to use adrenergic drugs for temperatures below 30°C. According to the American Heart Association 2010 guidelines, it may be reasonable to consider administration of a vasopressor during cardiac arrest according to the standard Advanced Cardiac Life Support algorithm concurrent with rewarming strategies. Isolated use of antiarrhythmics does not appear to be beneficial. Caution should be exercised not to administer these drugs repeatedly, as toxic accumulation can occur secondary to decreased metabolism. As normothermia is approached (>35°C), standard drug protocols are used.[37–39]

Additional Support

A nasogastric or orogastric tube should be placed in patients with moderate to severe hypothermia to relieve gastric distention, which might help reduce vomiting and aspiration secondary to gastric dysmotility. A urinary catheter is also essential to monitor urine output and assess volume resuscitation efforts. Intraarterial catheters for pressure monitoring should be used selectively. A Doppler ultrasound device may be necessary. Pulse oximetry is unlikely to be accurate given the poor perfusion to the extremities.

Rewarming Methods

There are several methods of rewarming. Selection depends on the severity of hypothermia and the clinical condition of the patient. Controlled clinical studies and interventional studies are limited, and evidence-based protocols are lacking. Absence of a developed protocol led to the use of a wide variety of treatment strategies, depending on the expertise and previous exposure of the clinical teams and hospital resources.[40]

Passive External Rewarming

Passive external rewarming is the method of choice for hemodynamically stable patients with mild hypothermia (>32°C), adequate physiologic reserve, and intact mechanism of shivering. Treatment includes placement of patients in a warm environment, removal of wet clothing, and application of insulating materials, such as blankets, to prevent heat loss. This method is expected to raise core temperature by 0.5°C to 2.0°C per hour.[6] If unsuccessful, active rewarming is initiated.

Active Rewarming

Active External Rewarming. Active external rewarming (AER) is applied to patients with a core temperature between 86°F and 92°F (30°C–34°C) without potential compromise of airway or hemodynamic status. It involves one or a combination of techniques, including warming blankets, heating pads, radiant energy, and forced heated air systems. Few complications (such as thermal injuries in the form of skin burns) have been reported using these methods. "After drop" is a phenomenon that was reported as a complication of AER. When the extremities and the trunk are warmed simultaneously, cold acidemic blood returns to the central circulation from the periphery secondary to vasodilation, causing a paradoxical decrease in core temperature. This drop worsens acidemia, precipitating hypotension and arrhythmias that can be fatal. Therefore it is advised to apply rewarming strategies to the trunk before the extremities.[41,42]

Estimated rates of rewarming using this method ranges from 0.8°C with heating blankets up to 2.5°C per hour with the forced air rewarming systems. This forced air system is the most widely used by clinicians because it is easy and effective.[41,42]

Active Internal Rewarming. Active internal rewarming is used for patients with moderate to severe hypothermia (<86°F or 30°C) with adequate hemodynamics, in conjunction with AER.[43] Methods include administration of warmed IV fluids (40°C–42°C) and warmed humidified air (40°C–45°C) through a mask or endotracheal tube. IV fluids alone are not adequate but prevent further heat loss. It is estimated that an average 1 L crystalloid (40°C–42°C) infusion for a 70-kg person will increase the temperature by 0.3°C. Rewarming by heated oxygen by endotracheal tube is more effective than a face mask. A total rate of 1°C to 2.5°C per hour is anticipated by this method.[15,43,44] Gastric bladder and colonic irrigation are of limited value secondary to their small surface area.

If rewarming is inadequate, more aggressive methods include peritoneal and pleural lavage. In pleural irrigation, two large-bore (≥36F) thoracotomy tubes are used. One tube is placed at the midclavicular line and is connected to saline solution at 42°C (107.2°F). The other tube is placed at the posterior axillary line and is connected to a chest tube drainage.[45]

Peritoneal lavage and dialysis are achieved by placement of a peritoneal catheter (8F) into the peritoneum and infusing 10 to 20 mL/kg of warmed 42°C isotonic fluid. The fluid is kept in the peritoneal cavity before it is removed.[15]

Extracorporeal Methods of Rewarming

This approach is the most effective method in raising core body temperature.

Hemodialysis. Hemodialysis is appropriate for patients with severe hypothermia and accompanying hyperkalemia and renal failure. The benefit is that hemodialysis is widely available and practical. It is portable and efficient. The rewarming rate ranges between 2°C and 4°C per hour, but it requires the absence of circulatory collapse.[46,47]

Continuous Arteriovenous Rewarming. Continuous arteriovenous rewarming has the ability to maintain circulation, correct hypoxia, and replenish intravascular volume without the need for systemic anticoagulation. The rate of rewarming ranges between 3°C and 4°C per hour and requires a systolic blood pressure of at least 60 mm Hg to be performed.

Continuous Venovenous Hemofiltration. Continuous venovenous hemofiltration (CVVH) has also been reported to achieve successful rewarming. It is widely available, can be performed with lower blood pressure, but provides slow rewarming rates (1°C–3°C per hour). It does not provide full circulatory support, and volume resuscitation is necessary when cardiac output is inadequate. Chest compressions and ventilation must be continued until the return of spontaneous circulation. However, it may prove to be an alternative to continuous arteriovenous rewarming when limited by profound hypotension.

Cardiopulmonary Bypass. Cardiopulmonary bypass (CPB) is the standard of care for patients with severe hypothermia, apnea, and cardiac arrest or hemodynamic instability. It provides rapid rewarming rates (8°C–12°C per hour) while maintaining oxygenation, circulation, and rapid correction of metabolic derangements.

However, the need for CPB in hypothermic trauma patients may be limited secondary to the need for systemic anticoagulation. In addition, the expert teams required for CPB make the implementation somewhat challenging.[6,15,38] Portable CPB systems are available.

Venoarterial Extracorporeal Membrane Oxygenation. Venoarterial extracorporeal membrane oxygenation (VA-ECMO) has become the preferred method of rewarming for hypothermia less than 28°C with cardiac arrest.[48,49] The advantages of VA-ECMO over CPB include increasing availability, the ability to be continued for several days for cardiopulmonary support even after rewarming, and a lower heparinization requirement. The lower anticoagulation requirement makes VA-ECMO preferable for trauma patients. The VA-ECMO system can provide the same rate of rewarming as CPB (8°C–12°C per hour) and does not require a sternotomy.[35,38]

Endovascular Temperature Control Device. Endovascular temperature control device has been reported in recent years as another tool for rewarming in patients with severe hypothermia. It is generally placed in the emergency department for out-of-hospital survivors of cardiac arrest with return of spontaneous circulation to induce therapeutic hypothermia. It can also be used to warm patients with accidental hypothermia. Because the same device is used in both sets of patients, the operation of the equipment is familiar to both the emergency department and ICU staff. The only procedure required to place this device is a central venous catheter, which is less invasive than CPB or ECMO.[35]

Prognosis

The results of different reports on the outcome of patients with moderate to severe hypothermia have varied. Multiple confounding factors exist that make it difficult to predict survival. Older age, lower core body temperature, indoor exposure, submersion, trauma, toxin ingestion, prehospital hemodynamic status, BUN and potassium levels, the need for intubation, and presence or absence of asphyxiation are significant predictors of outcome. For patients undergoing CPB for hypothermia and hemodynamic instability, favorable factors for survival are associated with younger age, higher arterial pH, lower $PaCO_2$, lower serum potassium levels, and the absence of asphyxia and suffocation.[18] Many patients die even after achieving adequate rewarming secondary to multiorgan failure. Recognizing its detrimental outcome, an important approach should pursue prevention. In general, hypothermia is a preventable condition. Public health education and preparedness should be directed toward populations at risk.

Hyperthermia

History and Incidence

Innumerable military campaigns throughout history were lost as a result of heat illness, long before the enemy ever raised a weapon. In modern times, the Israeli Six-Day War during the late 1960s provides the best example of the ravages of heat illness. The Israeli army had forced water consumption policies, by the clock, including strict disciplinary measures for evidence of heat injury due to negligence. By contrast, the Egyptian army did not have well-enforced policies. In the end, the Israeli army's heat injury statistics were negligible, but more than 50% of the Egyptian soldiers in the same locale had heat illnesses that rendered them unable to effectively perform their expected tasks.

Heatstroke and hyperthermia have been identified as the environmental diseases least frequently monitored by epidemiology systems in the United States. Serious heat illness has received considerable recent attention owing to catastrophic heat waves in the United States and Europe, the deaths of high-profile athletes, and military deployments. The exact incidence of heatstroke in the United States is unknown. The Centers for Disease Control and Prevention reported that between the years 1987 and 1988, 1092 death certificates listed excessive heat as either a primary or a secondary cause.[50] It is suspected that a number of other heat-related severe illnesses and deaths occur each year that are attributed to other causes. Guidelines from the National Association of Medical Examiners suggest that in cases in which the measured antemortem body temperature at the time of collapse was 105°F (40.6°C) or higher, the cause of death should be certified as heatstroke or hyperthermia. Deaths also may be certified as heatstroke or hyperthermia with lower body temperatures when cooling has been attempted before arrival at the hospital or when the clinical history includes mental status changes and elevated liver and muscle enzymes.[51]

Pathogenesis

Heatstroke is a complex syndrome of end-organ dysfunction initiated by hyperthermia that occurs when heat accumulation in the body overwhelms heat-dissipating mechanisms. The diagnosis of heatstroke should be considered in patients with core body temperatures greater than 41°C, or in patients with a core temperature of 40.6°C and concomitant mental status changes. Because anhidrosis is a late finding and sweating may be observed in severely hyperthermic patients, diaphoresis should not be considered a discriminatory finding. Heatstroke traditionally is subdivided into exertional and nonexertional causes. Box 66.1 outlines examples of diseases and conditions within each of these categories. To understand the pathogenesis of heatstroke, the systemic and cellular responses to heat stress must be appreciated. These responses include thermoregulation (with acclimatization), an acute-phase response, and a response that involves the production of heat shock proteins.

Thermoregulation

At basal metabolic levels, less than 100 kcal of metabolic heat is generated per hour. However, when physical activity increases, heat production may rise as high as 900 kcal/hr. This level of heat production is capable of raising the core body temperature by 1°C every 5 to 8 minutes. Heat is dissipated via evaporation, conduction

• BOX 66.1 Conditions and Diseases Associated With Heatstroke

Exertional Causes

Environmental: high ambient temperatures/humidity

Physiologic: lack of physical conditioning, inadequate acclimatization, or overexertion

Nonexertional Causes

Environmental: high ambient temperatures/humidity, lack of air conditioning, lack of shrubbery/trees around dwelling, height of home above ground level

Physiologic: age older than 65 years, alcoholism, congestive heart failure, renal failure, diabetes mellitus, chronic obstructive pulmonary disease, dementia, schizophrenia, cystic fibrosis, thyrotoxicosis, hypokalemia, dehydration

Drugs: alcohol, antidopaminergics, anticholinergics, amphetamines, β-blockers, butyrophenones, cocaine, diuretics, hallucinogens, tricyclic antidepressants

or radiation, and convectional losses. Cutaneous vasodilation results in heat loss through all of these physical mechanisms except evaporation. Unfortunately, when the ambient temperature exceeds body temperature, only evaporative losses associated with perspiration actually dissipate heat. Perspiration can produce a maximum rate of heat loss of approximately 400 to 650 kcal/hr in acclimatized persons. When heat production exceeds this threshold, body temperature quickly begins to rise.

Acclimatization

Acclimatization is a physiologic term that collectively describes various adaptive responses to repeated heat stress. Many of these responses are directed at conserving plasma volume. They include decreased total sweat sodium concentration and nonreflexively increased aldosterone secretion. In addition, acclimatized people tend to drink greater volumes of water and have measurable increases in extracellular fluid volume beyond that of nonacclimatized persons. Ultimately, maximum cardiac output and stroke volume increase, while maximum heart rate and oxygen consumption decrease (improved efficiency per unit of metabolic work expended).[52] Similarly, the net amount of heat generated per unit of work expended also decreases.

Acute-Phase Response

The acute-phase response, involving endothelial cells, leukocytes, and epithelial cells, protects body tissues from heat-induced tissue injury. A variety of immunomodulatory and inflammatory cytokines are released in response to increased endogenous or environmental heat, including interleukin (IL) 6 (IL-6), tumor necrosis factor α (TNF-α), IL-10, IL-12, and interferon.

Heat Shock Response

Cells respond to heat by production of inducible heat shock proteins that help induce a state of tolerance to heat stress. These proteins function as molecular chaperones that bind to partially folded or misfolded proteins and thereby prevent their irreversible denaturation. Heat shock proteins also may help regulate the baroreceptor reflex response during heat stress, abating hypotension and bradycardia.

Predisposing Factors

The epidemiology of heatstroke parallels that of hypothermia—nonexertional heatstroke is seen in elderly, alcoholic, or otherwise debilitated patients in urban areas. By contrast, exertional heatstroke develops in otherwise healthy people who overexert themselves in exceedingly hot or humid conditions. Like hypothermia, heatstroke most often develops in patients with impaired thermoregulation. Antidopaminergic drugs, alcohol, and primary central nervous system (CNS) disorders are common denominators in many patients.[52] A number of environmental and socioeconomic conditions have been associated with heatstroke in recent years.[53,54] A lack of air conditioning and a lack of trees or shrubbery around homes are commonly observed in patients presenting with heatstroke. People who are apartment bound, particularly those on higher floors, also appear to be at higher risk during summer heat waves. Finally, elderly patients not only have diminished temperature perception but also do not produce the same volume of sweat, placing them at higher risk for the development of heatstroke.

Many drugs—"recreational" and prescription—are associated with an increased risk of hyperthermia and deserve further emphasis. Cocaine causes generalized sympathetic activation and loss of response to environmental cues. It is rapidly becoming a leading cause of heatstroke in many urban emergency departments. β-Blockers, on the other hand, have been implicated in heatstroke through a drug-mediated direct decrease in sweat gland production. Diuretics decrease baseline circulating plasma volume, leading to decreased sweat production. Hypokalemia decreases sweat gland output as well, and barbiturates can even cause sweat gland necrosis. When a heat wave arrives in an urban area, any one or several of the foregoing factors combined can lead to outbreaks of heat injury.

Presentation and Clinical Manifestations

Nonexertional heatstroke may manifest insidiously.[55] An urban setting and the recognized presence of a heat wave may be the best available diagnostic clues. Some form of CNS dysfunction is nearly universal in patients with nonexertional heatstroke. The spectrum of dysfunction ranges from increased irritability and confusion to stupor and coma. Hyperpyrexia often is the most specific physical finding. In many cases, the presentation of an elderly patient with an altered mental status, irritability, and a high fever suggests sepsis. However, epidemiologic associations, concurrent debilitating disease, and the impact of medications that limit thermoregulation should be considered before limiting therapy to empiric antibiotics and antipyretic medications.

Exertional heatstroke typically occurs more suddenly and with a more self-evident clinical history.[56] Severe dehydration, anhidrosis, and extreme hyperpyrexia are common in external heatstroke. Affected persons appear hyperdynamic, with tachycardia, increased cardiac output, and peripheral arterial vasodilation. CNS dysfunction is somewhat less common in this patient subset. Initially, thermoregulation is intact in patients with exertional hyperthermia. At high core body temperatures, however, metabolic activity overwhelms normal heat dissipation mechanisms, and clear-cut disruption of normal thermoregulation may then appear. Hyperthermia is further accelerated by the loss of effective sweating for evaporative heat dissipation. Myocardial dysfunction with depression of left ventricular ejection fraction also has been described after heatstroke, which resolves with treatment.[57]

In addition to alterations of consciousness, hallucinations, focal neurologic deficits, various cranial nerve abnormalities, and opisthotonos are well described. Seizures occur in more than half of these patients and may be related strictly to core body temperature or to concomitant disorders of free water–electrolyte balance. Decerebrate posturing also is rarely observed in some patients without other known mechanisms of acute brain injury. Many patients may have residual defects, such as dementia, personality changes, focal deficits, cerebellar changes, or pyramidal findings. Nevertheless, many patients also proceed to complete recovery, suggesting that early findings should not deter acute management.[54]

Diagnostic Approach

In addition to CNS dysfunction, rhabdomyolysis is a frequent feature of exertional hyperthermia. Manifestations sometimes include tender, edematous muscles and "cola-colored" urine, but the condition more commonly is defined by elevation in total creatine kinase (CK), serum aldolase, uric acid, or serum potassium (alone or in combination). Hyperkalemia in this situation may be life-threatening.

Acute renal failure occurs in up to one-third of patients with heatstroke.[58] It is considerably more common in patients in whom rhabdomyolysis is a feature (i.e., with myoglobinuria or urate

nephropathy). However, direct heat injury and renal hypoperfusion also may contribute. Acute tubular necrosis in heatstroke typically manifests with oliguria, nonnephrotic range proteinuria, and abundant granular cast formation.

Evidence of hepatocellular injury is present to some degree in essentially all patients with heatstroke and is attributed principally to a direct toxic effect of hyperthermia on hepatocytes.[59] Elevation of serum transaminases is a cardinal feature of this toxicity and often is observed within 30 minutes of syndrome onset. So prevalent is this finding that the absence of transaminitis should cast serious doubt on the diagnosis of heatstroke. Histologic changes including centrilobular necrosis have been observed within 24 hours of heat injury and evolve over the ensuing days. Transaminase and lactate dehydrogenase levels typically peak on the third or fourth hospital day, and depending on the extent of injury, these changes may be accompanied by increased alkaline phosphatase levels, hyperbilirubinemia, and a prolonged prothrombin time. Overall, fulminant hepatic necrosis is rare; however, hepatic insufficiency contributes to late morbidity and death in patients who survive the initial resuscitation.[60] Prolongation of coagulation times also may be due to disseminated intravascular coagulation (DIC). Although clinical DIC also is rare, it is a marker of poor prognosis when present. Clinical manifestations of DIC range from isolated laboratory abnormalities to generalized bleeding. In patients with heatstroke, DIC may exacerbate hepatic injury and is associated with the development of acute respiratory distress syndrome (ARDS). In fact, the codevelopment of DIC and ARDS in patients with heatstroke is predictive of a high mortality rate (>75%). Qualitative coagulation function (including platelet function) also may be impaired by heat injury. The clinical effects of these impairments are variable.

A range of electrolyte abnormalities related to renal failure and dehydration in heatstroke victims has been well described and includes hyponatremia, hypocalcemia, hypokalemia (hyperkalemia in patients with acute tubular necrosis or rhabdomyolysis), hypophosphatemia, and hypomagnesemia. Of these, hyponatremia and free water excess may produce severe neurologic effects including central pontine myelinolysis, which has been reported in patients with heatstroke who receive aggressive prehospital resuscitation with hypotonic solutions. Serum osmolality should be carefully monitored during volume resuscitation, and IV solutions should be modified accordingly. Severe lactic acidosis is especially common in patients with exertional heat injury.[61] Finally, arterial blood gas results are influenced by temperature in a fashion opposite that described with hypothermia (Box 66.2).

• BOX 66.2 Temperature Correction Factors for Arterial Blood Gas Specimens[a]

ABG Component Correction Factor

$pH + 0.015 (37 - T_c)$
$Pao_2 - 0.072 (37 - T_c) \times Pao_2$
$Paco_2 - 0.044 (37 - T_c) \times Paco_2$

Example

A patient presents with a core temperature of 32°C with the following ABG values: pH 7.12, $Paco_2$ 52 mm Hg, and Pao_2 52 mm Hg. Corrections for temperature are as follows:

$pH = 7.12 + [0.015 (37 - 32)] = 7.195$
$Pao_2 = 52 - [0.072 (37 —32) \times 52] = 33.28$ mm Hg
$Paco_2 = 52 - [0.044 (37 - 32) \times 52] = 40.56$ mm Hg

These corrections also may be used for hyperthermia.

[a]*Arterial blood gas values not corrected for temperature in significantly hypothermic patients yield falsely low pH and falsely elevated $Paco_2$ and Pao_2 values.*
Pao_2, *Partial pressure of oxygen;* $Paco_2$, *partial pressure of arterial carbon dioxide;* T_c, *core temperature.*

Approach to Management

Duration of extreme hyperpyrexia is the single most important determinant of morbidity and fatality in all patients with heatstroke (both exertional and nonexertional). Therefore expeditious cooling should be initiated simultaneously with other basic and advanced life support modalities. Indeed, a review of outcome data for heatstroke victims during the Chicago heat wave of 1995 suggested that computed tomography imaging of the brain contributed little to patient management and simply delayed efforts to rapidly cool the patient.[62]

On-site cooling offers an attractive potential advantage in large sporting events where a significant number of exertional heat strokes can be anticipated. Data from the Indianapolis half marathon would support the feasibility of such a plan.[63] Between 2005 and 2012, 22 of 32 (69%) patients who developed heat stroke were initially treated on-site. For those treated on-site core temperatures ranged from 102.4°F to108.5°F, and 41% had hypotension with none below a systolic blood pressure of 70 mm Hg. The majority were treated with cold water immersion and the remainder with ice packs, cooled IV solutions, and cold towels. Of these patients, 9% were released home, 6 were referred to a local emergency department and released, and 3 were admitted to the hospital (1 to the intensive care unit [ICU]).

The same can be said for leveraging emergency medical services teams for earlier initiation of cooling. There is wide variation in prehospital medicine practices in the treatment of exertional heatstroke, leading to creation of a consensus statement on prehospital care.[64] A similar approach has been taken by the National Athletic Trainers' Association with release of a portion statement on external heat illnesses.[65]

Supportive Measures

Intravascular volume restoration must be individualized. In general, patients with exertional hypothermia are severely hypovolemic. Hemodynamic monitoring has demonstrated that patients may manifest two distinct responses to heatstroke: (1) a hyperdynamic response with an elevated cardiac index and depressed systemic vascular resistance and (2) a hypodynamic response with depressed cardiac index and elevated systemic vascular resistance.[58] Although the hypodynamic response may be more common in older patients with preexisting medical conditions and classic heatstroke, severe hyperthermia can lead to myocardial dysfunction even in young, healthy adults without preexisting cardiac disease. Overzealous volume resuscitation in this setting can produce significant pulmonary congestion. The rapid restoration of an adequate perfusion pressure without pressor support is a reasonable goal, and if this is achieved, further volume resuscitation should proceed at a more measured pace. Pulmonary artery catheterization is recommended early in the clinical course for patients with unclear cardiovascular physiology. Finally, isoproterenol traditionally has been considered the inotrope of choice for patients with severely depressed myocardial performance. Its lack of α-activity ensures that heat dissipation is not impeded. Dobutamine may be a more rational choice, however, because it has considerably fewer myocardial irritant and arrhythmogenic properties.

Seizures are treated according to standard guidelines. Benzodiazepines are used for acute, ongoing convulsive activity. Dilantin

is useful for added control or prophylaxis; however, hypotension with rapid IV infusion should be anticipated. Barbiturates also are effective antiseizure drugs but should be reserved as second-line therapeutic agents because of their theoretical impediment to sweat formation and heat dissipation.

Acute renal failure should be approached aggressively in patients with rhabdomyolysis. Intravascular volume repletion should be promptly accomplished, with continued infusion of volume to produce forced diuresis. Mannitol or loop diuretics may be of value to maintain appropriate urine output. Hyperkalemia management may be challenging. The clinician should not hesitate to administer glucose, insulin, and calcium in patients with electrocardiogram changes. Subsequent sodium polystyrene sulfonate (Kayexalate) dosing may also be required.

Cooling Measures

Effective heat dissipation depends on the rapid transfer of heat from the core to the skin and from the skin to the external environment. In persons with hyperthermia, transfer of heat from the core to the skin is facilitated by active cutaneous vasodilation. Therapeutic cooling techniques are therefore aimed at accelerating the transfer of heat from the skin to the environment without compromising the flow of blood to the skin, which can be accomplished by increasing the temperature gradient between the skin and the environment (for cooling by conduction) or by increasing the gradient of water vapor pressure between the skin and the environment (for cooling by evaporation), as well as by increasing the velocity of air adjacent to the skin (for cooling by convection).

Core body temperature should be rapidly cooled to a goal of 38°C to 39°C. The most effective approaches to lowering the core temperature are immersion and evaporative methods. Of these, efficacy data related to ice water immersion modalities historically have been better defined, with observed cooling rates of up to 0.13°C per minute. Similar efficacy has been noted with cool water immersion as well, which should be less uncomfortable for both patient and staff members. Unfortunately, water immersion is not practical for many critically ill patients. Monitoring and treatment for arrhythmias, seizures, and other sequelae are problematic while the patient is immersed in a tub.

Evaporative techniques are quite effective and allow the ICU patient to be placed on a bed or other supportive surface and treated accordingly. The patient is repeatedly wetted with tepid water (not alcohol) or sprayed with water mist while warm air from a fan is blown across the body surface. Evaporative cooling by this method has shown a faster cooling rate in a canine model that is as effective as aggressive peritoneal lavage cooling, reaching rates as high as 0.32°C per minute.[66] An aggressive approach to cooling the heatstroke victim, whatever the approach, is most important. Other adjuncts to cooling include rectal, intraperitoneal, and gastric lavage with iced saline solution. These techniques are effective at rapidly lowering core temperature but are cumbersome and generally unnecessary and may lead to unwanted iatrogenesis.

Efforts to cool a patient should be discontinued when the core temperature falls to 38°C to 39°C. At that point, a continued fall by 1°C or 2°C is expected. Dantrolene sodium has been used in some patients but was found to be ineffective in a double-blinded randomized study.[67,68] Chlorpromazine may be useful in patients in whom shivering develops during active cooling efforts; however, if neuroleptic malignant syndrome (NMS) is in the differential diagnosis (and it often is), meperidine may be a better option than an antidopaminergic agent in patients with normal renal function.

Specific Hyperthermic Syndromes

Malignant hyperthermia (MH) and NMS deserve special emphasis because of their potentially catastrophic impact on critically ill patients, particularly when they are not promptly recognized. MH is associated with use of certain anesthetic agents and can lead to profound skeletal muscle contraction and the subsequent development of life-threatening hyperthermia and other complications. NMS is caused by a variety of antipsychotic drugs and also leads to sustained muscular contraction and hyperthermia.

Malignant Hyperthermia

MH develops in approximately 1 of 15,000 patients who undergo surgical procedures requiring general anesthesia. The vast majority of cases are associated with either halothane or succinylcholine use; however, a variety of other drugs also have been implicated. Box 66.3 outlines these agents by type. Unlike in heatstroke, endogenous heat production is solely responsible for the observed hyperpyrexia. MH constitutes a true medical emergency because of the rapid tempo at which severe sequelae evolve. Better recognition of this syndrome and modern treatment techniques, however, have reduced mortality rates from 70% to approximately 10% in recent years.

Pathogenesis

MH results from a rapid, sustained increase in myoplasmic calcium ion (Ca^{2+}) levels in response to halogenated anesthetics and depolarizing neuromuscular blocking agents. Susceptibility to MH results from mutations in calcium channel proteins that mediate excitation-contraction coupling, with the ryanodine receptor calcium release channel representing the major locus. The mode of inheritance appears to be autosomal dominant, with variable penetrance. The phenomenon occurs in persons who have

Dopaminergic Agent Withdrawal

Levodopa-carbidopa, amantadine

a mutation in the ryanodine type 1 receptor, resulting in a defective protein in the skeletal muscle sarcoplasmic reticulum membrane.[69] The uncontrolled rise in the myoplasmic Ca^{2+} concentration disables the troponin inhibition of actin and myosin, resulting in uncontrolled muscle tetany. This surge in muscle metabolic activity causes thermogenesis to increase exponentially and is rapidly followed by total body rigidity and extreme hyperpyrexia.

Numerous familial myopathies (such as Evans myopathy, King-Denborough syndrome, and central core disease) have been associated with the reaction.[70,71] Curiously, this genetic predisposition does not translate into the predictable development of MH. That is, an initial challenge with an anesthetic drug that leads to MH does not consistently predict whether or not MH will occur with future exposures to the same drug. Measured contraction in caffeine or halothane preparations of muscle biopsy specimens is the most reliable predictor of risk for MH.

Presentation

MH is characterized by the triad of (1) severe hyperthermia, (2) muscle rigidity, and (3) metabolic acidosis. MH usually is an acute and rapidly progressive process; however, many reports suggest that the syndrome may vary considerably in severity and rate of progression. In the anesthesia setting, capnography may provide the earliest clue of impending MH, as end-tidal carbon dioxide rises in response to the increased metabolic rate. Clinical harbingers of impending MH include masseter muscle rigidity or trismus and tachycardia, which is reported to occur in more than 95% of patients.[70] Cyanosis, increased blood pressure, and increased respiratory rate all may be observed with the onset of the reaction as the hypermetabolic response is triggered.

Muscle rigidity may explosively progress from localized masseter contraction to diffuse rigidity of skeletal muscle groups. When uninterrupted, this process will lead to progressive, severe hyperthermia. Extreme hyperpyrexia is considered a late finding in MH. Mortality risk has been related to peak core body temperature, reflecting both MH severity and delayed recognition. With progressing rigidity, a mixed metabolic and respiratory acidosis may occur, along with a variety of other electrolyte abnormalities, including hyperkalemia, hypercalcemia, and hypermagnesemia. Severe chest wall rigidity may even prevent adequate mechanical ventilation, leading to life-threatening hypoxemia and hypoventilation. Rhabdomyolysis is reflected in elevated CK levels, usually greater than 1500 units/L and often greater than 10,000 units/L. Myoglobinuria may produce acute tubular necrosis with oliguric renal failure and severe DIC. High fever may result in myocardial dysfunction, pulmonary edema, and cerebral edema.

Diagnosis

Susceptibility to MH can be identified unequivocally only by an in vitro muscle test. Fascicles of muscle obtained from the thigh by biopsy are exposed to halothane and separately to increasing concentrations of caffeine in vitro. The muscle contractures are increased in persons who are susceptible to MH. This test is now widely used to identify susceptibility to MH in patients who have had a reaction to inhaled halogenated anesthetics or suxamethonium that is suggestive of MH. If the test results in the propositus are positive, testing can be offered to first-degree relatives for genetic counseling. Patients whose biopsied muscle demonstrates a contracture to 3% halothane of 0.5 g or more and a contracture to 2 mmol/L caffeine of 0.2 g or more are considered to be susceptible to MH.[72] An in vitro contracture test is the gold standard for diagnosing susceptibility to MH. Two different protocols are used. European laboratories use the protocol devised by Ellis in Leeds with incremental doses of halothane up to 2% and incremental doses of caffeine. In the United States, a single dose of 3% halothane and incremental doses of caffeine are used. The two protocols yield essentially the same results.[73]

Treatment

By far, the most important measure for MH is the immediate cessation of any suspected triggering agents. If anesthesia must be maintained, nontriggering agents should be used. Agents considered safe in MH include barbiturates, narcotics, benzodiazepines, and propofol, to name only a few. Nondepolarizing neuromuscular blockers such as vecuronium or atracurium, although also considered safe in these patients, will do nothing to abort the MH reaction because the primary disease resides within the skeletal muscle cell itself—beyond the neuromuscular junction.

In addition to discontinuing offending agents, sodium dantrolene should be administered. Sodium dantrolene initially was tested as an antimicrobial; however, dantrolene was found to produce muscle weakness by blocking the Ca^{2+} efflux from the sarcoplasmic reticulum. The agent is capable of reversing the MH reaction by lowering myoplasmic Ca^{2+} concentrations. The onset of action usually is within 2 to 3 minutes, with initial responses including muscle relaxation, decreasing heart rate, and decreasing core body temperature. Muscle weakness may follow drug administration, but this should never limit proper therapy. After the initial response, dantrolene may be dosed orally for 24 to 48 hours. Late recurrences of MH have been reported if inadequate dantrolene dosing occurs. IV preparations of dantrolene contain significant amounts of mannitol, which may produce a subsequent osmotic diuresis. Although this reaction may be desirable in patients with rhabdomyolysis, volume and electrolyte management should take this effect into account.

Systemic cooling may be best achieved in these complex patients with evaporative techniques, cooling blankets, cold saline solution infusion, or ice packs. Because of its similar actions on myoplasmic Ca^{2+} concentration, procainamide was the drug of choice for this syndrome before the advent of dantrolene therapy. Cardiac dysrhythmias not responding to electrolyte correction may be safely treated with procainamide or lidocaine. Numerous reports suggest that IV calcium may be safely infused for toxic hyperkalemia. Diltiazem and verapamil may interact with dantrolene to produce hyperkalemia; therefore these agents should be avoided. Although the effects of MH on cardiac muscle remain unclear, some authors advocate that cardiac glycosides also should be avoided because they increase intracellular Ca^{2+} concentration.

Neuroleptic Malignant Syndrome

NMS is an idiosyncratic reaction to neuroleptic drugs and other antidopaminergic agents.[74] A number of drugs that are known to be associated with NMS are listed in Box 66.3. NMS is characterized by muscle rigidity and altered mental status, followed by autonomic instability and hyperthermia. However, temperature elevations generally are less extreme than in MH and are not as life-threatening.

NMS is reported to occur in up to 2% to 3% of all patients receiving neuroleptic medications. The reaction typically develops within a few days of initiating therapy and almost always appears within the first 30 days. Curiously, NMS also occurs rarely in

some patients after many years of a stable dosing regimen. Of importance, NMS also can occur in response to the withdrawal of central dopaminergic agonists such as bromocriptine or levodopa-carbidopa.

Pathophysiology

Some investigators suspect that the genetic predisposition to MH also defines patients at risk for NMS, but most work has failed to demonstrate a relationship between NMS and altered sarcolemmal membrane calcium permeability. Unlike in MH, patients with NMS appear to have both increased heat production and impaired central thermoregulation, compromising heat dissipation. In these patients, a decrease in central dopaminergic tone also results in extrapyramidal signs of skeletal muscle rigidity and tremor and may account for alterations in mental status owing to effects in the mesolimbic system and mesocortical pathways.[75] Finally, even though altered central thermoregulation may contribute to hyperthermia in NMS, rapid resolution of fever after administration of neuromuscular relaxing agents or dantrolene suggests that hyperthermia is due primarily to increased heat generation by skeletal muscle rigidity.

In intubated patients who have sustained multisystem trauma and are supported by mechanical ventilation, fever and tachycardia are not uncommon and mental status changes cannot be adequately evaluated.[76] Rhabdomyolysis is not uncommon in this population. It may be difficult to elucidate a history of neuroleptic medications and heightened vigilance is required.

Presentation

NMS should be considered when fever, muscular rigidity, catatonia, or dystonia occur in the setting of neuroleptic drug administration. Recent reviews have suggested the following criteria for the diagnosis of NMS: treatment with neuroleptics within 7 days; hyperthermia with core temperatures above 38°C; muscle rigidity; exclusion of other systemic or drug-related illness; and any five of the following: altered mental status, tachycardia, hypertension or hypotension, tachypnea or hypoxia, diaphoresis or sialorrhea, tremor, incontinence, CK elevation or myoglobinuria, leukocytosis, or metabolic acidosis.[75,77]

Altered mental status commonly precedes the onset of other symptoms and may manifest as confusion or agitation. More severe cases may progress to obtundation or coma or may manifest as a mute catatonia that is difficult to differentiate from lethal catatonia. Muscle rigidity typically involves the neck, shoulders, and limbs but may compromise ventilation if chest wall involvement is severe. Other neuromuscular findings are diverse and may include dysarthria, dyskinesias, ataxia, or tremors.

Autonomic findings typically include diaphoresis, hypertension, and tachycardia. However, hypotension may develop in some patients. Fever is a late finding and usually occurs in the range of 38°C to 42°C. When fever exceeds 42°C, it may cause end-organ damage like that seen in other hyperthermia syndromes.

Rhabdomyolysis occurs often, though it usually is of a milder caliber than that observed in MH or exertional heatstroke. Elevations in serum transaminases, BUN, and serum Cr often are seen, as well as a leukocytosis.

Treatment

When NMS is suspected, the offending drug should be discontinued immediately and supportive measures initiated. Volume resuscitation, physical measures for cooling, and monitoring of cardiopulmonary and renal parameters should be instituted immediately. Pharmacologic options for the treatment of NMS are more numerous than for other hyperthermia syndromes, because they may be directed toward restoring central dopaminergic tone or reducing peripheral rigidity until the neuroleptic effects subside.

Dopamine agonists such as bromocriptine, amantadine, and levodopa-carbidopa have been successfully used in NMS.[75,78] These agents act to directly increase central dopaminergic tone, thereby antagonizing the various effects of neuroleptic dopamine blockade. Regimens include bromocriptine or amantadine for up to 10 days before tapering. If a levodopa-carbidopa combination is used, it should be dosed four times a day owing to its shorter half-life. Some authors advocate avoiding central dopamine agonists if the diagnosis is unclear or if psychosis remains in the differential diagnosis, to avoid acutely exacerbating the psychotic state or contributing to a lethal catatonia.

Sodium dantrolene has been successfully used in numerous small series. The muscle relaxation that occurs helps to reduce temperature and decrease the sequelae of prolonged rigidity. Neuromuscular blockers also are effective at decreasing skeletal muscle tone, and in patients with high fever and autonomic instability, these agents offer a rapid means of establishing therapeutic effects. Combinations of central dopamine agonists and peripheral-acting agents have not as yet demonstrated a significant advantage over either treatment alone. Electroconvulsive therapy has been used in a number of reports, but its advantages over supportive care alone have not been adequately assessed.[78] Furthermore, the need for anesthesia presents an additional hazard that may complicate management in these patients.

Airway-protective reflexes should be vigilantly assessed because dystonia and impaired bulbar functions increase the risk of gastric aspiration in patients with NMS. Morbidity and mortality risks in these cases often arise from pulmonary complications, such as aspiration, pneumonia, ARDS, or pulmonary embolism. Cardiac complications such as arrhythmias or myocardial infarction in more fulminant cases also contribute to fatality in these patients. As in all of the hyperthermia syndromes, worsening rhabdomyolysis and acute renal failure have been identified as signs of poor prognosis.

Rhabdomyolysis

Rhabdomyolysis is a pathologic state in which the necrosis of muscle cells, through trauma, toxins, medications, or other causes, leads to an excess of intracellular solutes in the extracellular compartments. Target organ damage can range from minimal to severe depending on the degree of necrosis; the main consequences are metabolic abnormalities and acute kidney injury (AKI). Our understanding of the pathophysiology of rhabdomyolysis has evolved with an emphasis on early diagnosis and treatment, often in the setting of major catastrophes. The first report in the English literature, describing four cases of crush injury in Britain during World War II, was recently republished.[79]

Epidemiology

The incidence of rhabdomyolysis is dependent on the population undergoing analysis and the diagnostic criteria being used. It is recognized as a major cause of fatality after severe musculoskeletal injury from trauma.[80] Following the 1999 Marmara earthquake in northwestern Turkey, 8.9% of hospitalized patients required

renal replacement therapy for crush-related injuries.[81] Recently a particular focus has been the ability of the HMG-CoA reductase (3-hydroxy-3-methyl-glutaryl-coenzyme A reductase) inhibitor class of medications to cause rhabdomyolysis. Though likely a class phenomenon and rare overall, the incidence of rhabdomyolysis is not equivalent for all medications and is increased with the addition of other specific agents, particularly gemfibrozil, other fibrates, or cyclosporine.[82,83] Additional causes of rhabdomyolysis are listed in Box 66.4.[84–89] One recent review noted exogenous toxins, both prescribed and illicit, to be responsible for nearly 50% of cases.[90] In particularly, cocaine and 3,4-methylenedioxymethamphetamine, more commonly referred to as ecstasy, can cause muscle injury leading to rhabdomyolysis.[91,92]

Two additional scenarios that have received significant attention include "propofol infusion syndrome" and the potential for patients with sickle cell trait (SCT) to develop rhabdomyolysis. Both of these situations occur in younger patients. Propofol is rarely associated with a syndrome of metabolic acidosis and rhabdomyolysis. Risk factors include high-dose infusions over a prolonged period and a young age.[93–96] SCT with subsequent rhabdomyolysis owing to exertional sickling is now recognized as a cause for sudden deaths in young patients during strenuous workouts, in particular, football.[97–103] SCT was recently noted to be associated with exertional rhabdomyolysis in a population of U.S. Army soldiers.[104] The epidemiology of rhabdomyolysis is limited by a lack of uniformity regarding the critical value in CK elevation needed to make the diagnosis. Threshold values above which rhabdomyolysis may occur vary and have ranged from 1000 to 10,000 units/L, though 5000 to 10,000 units/L are most common.[105] From an intensivist's perspective, CK elevations less than 5000 units/L should not lead to myoglobin-induced renal failure unless clear additive causes such as volume depletion, sepsis, or radiocontrast are also present.

• BOX 66.4 Causes of Rhabdomyolysis[a]

Trauma/crush injuries
Prolonged immobilization
Electrical injury
Excessive muscular activity
- Excessive exertion especially in sickle cell trait patients
- Malignant hyperthermia
- Neuroleptic malignant syndrome

Infections
- Bacterial infections, in particular, those involving organisms causing pneumonia, muscle inflammation (pyomyositis), or sepsis
- Viral infections including those due to human immunodeficiency virus, influenza virus, coxsackievirus, and Epstein-Barr virus

Medications[b]
- 3-Hydroxy-3-methyl-glutaryl-coenzyme A reductase inhibitors
- Gemfibrozil
- Paraphenylenediamine (hair dye)
- Phenothiazines
- Theophylline

Toxins
- Cocaine
- Carbon monoxide
- Amphetamines including *N*-benzylpiperazine-based medications
- Alcohol
- *Tricholoma equestre* (wild mushrooms)
- Hemlock
- Animal venoms

Metabolic myopathies[138]
- Carnitine palmitoyl transferase deficiency
- Mitochondrial respiratory chain deficiencies
- McArdle disease
- Phosphofructokinase deficiency

[a]*In addition to the causes listed here, risk factors include excessive heat, hyponatremia, hypophosphatemia, and hypokalemia.*[139–142]
[b]*Additional medications have been associated with rhabdomyolysis.*[84,143]
HMG-CoA, *3-Hydroxy-3-methyl-glutaryl-coenzyme A.*

Pathophysiology

The primary event in rhabdomyolysis is muscle cell necrosis resulting in the accumulation of sodium and calcium intracellularly; disruption of the cell membrane and excessive requirements for adenosine triphosphate accelerate this insult.[106,107] As muscle cells undergo necrosis, intracellular substances are released and include potassium, uric acid, phosphorus, lactic acid, and myoglobin. Under normal circumstances, haptoglobin binds any free myoglobin, thus prohibiting filtration across the glomerulus. As the haptoglobin binding is overwhelmed, free myoglobin is filtered and injures renal tubular cells. This process involves free radical toxicity. Additional causes include volume depletion, renal vasoconstriction, and tubular obstruction.[84,108,109] Myoglobin and urinary tubular-protein casts are more prone to precipitation at a lower pH in experimental models. As a result, inducing an alkaline diuresis has been thought to be beneficial in cases of rhabdomyolysis.[110]

Research has suggested that it is the reperfusion of ischemic muscle as much as the ischemia itself that produces a high burden of oxygen-derived free radicals with subsequent cellular lipid membrane injury.[111] As renal function worsens, particularly when accompanied by intravascular volume depletion and renal failure, patients cannot excrete the high load of metabolites associated with muscle death, especially potassium.

Myoglobin release occurs across a spectrum of physical injuries from moderate exercise to lethal crush injuries. Myoglobinemia was noted in 39% of a cohort of Marine recruits, illustrating the frequency of mild muscle cell necrosis with strenuous exercise.[112] Obviously, not all such injuries lead to AKI. Beyond the actual amount of muscle necrosis, the development of AKI is most dependent on the degree of volume depletion present during the initial insult and the rapidity with which it is restored. Many of the syndromes that lead to the development of rhabdomyolysis, such as very strenuous exercise, crush injuries, or intoxications, are accompanied by volume depletion.

Clinical Presentation

Patients with rhabdomyolysis present with a variety of symptoms. Often there is a history of injury, weakness, or muscle pain. Dark red or brown urine may or may not be present, depending on the amount of muscle necrosis and delay from injury. Frequently, the history is limited because of altered sensorium; clues include unexplained acidosis, hyperkalemia, hyperuricemia, hypocalcemia, elevations in CK not consistent with myocardial infarction, and unexplained renal failure. Recurrent presentations warrant an evaluation for a metabolic myopathy.[113] Screening for rhabdomyolysis, through serial CK measurements, may be worthwhile in high-risk obese patients (body mass index >56 kg/m^2) undergoing gastric bypass surgery.[114] The obese population is also more at risk for rhabdomyolysis after trauma and aggressive CK monitoring may be helpful in this population.[115]

In most instances, serum CK will increase during the initial 48 hours of hospitalization. In a retrospective review of patients admitted to an ICU with rhabdomyolysis, defined as a CK level greater than 10,000 units/L, significantly higher CK levels were associated with renal failure.[116] In the group with renal failure, the mean CK levels were 47,194 and 55,366 units/L at admission and peak, respectively; in the group without renal failure, the same levels were 17,531 and 28,643 units/L.

Although myoglobin is the most important protein in terms of nephrotoxicity, serum CK is routinely used in clinical practice as a marker of disease severity. This inconsistency is due to the widespread availability of the CK assay. Myoglobin clearance is not dependent on the kidneys and thus levels peak before CK levels.[117] Consequently, the CK levels being monitored for disease activity may not correlate with the timing of the renal injury. AKI owing to peak CK levels less than 5000 units/L should not be attributed to rhabdomyolysis unless the diagnosis was made substantially after the peak period of muscle cell necrosis; in this scenario, the CK levels will have decreased from a previously undocumented level.

The change of serum Cr in nonrhabdomyolysis oliguric AKI is usually not more than 1 mg/dL per 24 hours. In rhabdomyolysis, Cr enters the intravascular compartment at a higher rate as the result cell lysis, yielding an unusually rapid rise in serum Cr. In an early report, Grossman and associates noted a rise in Cr frequently greater than 2.5 mg/dL per day.[118] Speculation exists that this change in Cr may, in part, be due to the larger than average size in patients affected with rhabdomyolysis.[119] These same authors noted the impressive rate of renal recovery from rhabdomyolysis-induced AKI seen in the majority of patients; this high rate of recovery is now well recognized.

Specific Treatment Requirements

The most important intervention to limit renal complications of crush-related injuries is early and aggressive volume resuscitation. Delays in initiation of IV fluid are associated with a higher frequency of patients requiring renal replacement therapy.[120] The damaged muscle cells provide a large reservoir for fluid sequestration; as a result large volumes of IV fluids have to be given and, ideally, should be instituted as early as possible, even on-site before victims of crush injuries are freed.[86,121]

A debate exists in the medical literature regarding the ideal type of volume resuscitation. As previously mentioned, alkaline diuresis has been shown in animal models to decrease the formation of myoglobin casts and subsequent AKI.[110] Similarly, mannitol is an agent favored for its proposed ability to scavenge free radicals and to reduce tissue swelling owing to osmotically induced fluid removal from damaged muscle.[122,123] These treatments have not been validated in well-designed, prospective trials. Retrospective studies suggest variable benefits with the addition of mannitol or alkaline diuresis over normal saline solution alone.[124,125] In addition, there are potential risks to volume expansion with bicarbonate-based solutions or mannitol. They include the increased risk of calcium-phosphate complex formation and hypocalcemia from an increase in pH. A hyperosmolar state may occur if mannitol is used in a state of impaired kidney function. Finally, mannitol may *increase* the risk of renal failure in certain populations.[126] Risk factors for mannitol-induced AKI include kidney dysfunction, high-dose mannitol therapy, and use of cyclosporin A. In summary, volume expansion irrespective of the type of agent is the most important treatment modality. The focus on adequate diuresis is appropriate but presumes myoglobin-induced renal damage is ongoing. Intensivists often encounter patients whose myoglobin load is falling and whose renal insult has already occurred. Although the Cr level may continue to rise, the onset of oliguria suggests limited benefit from further aggressive volume resuscitation, presuming adequate intravascular volume has been restored. In fact, given the good prognosis of AKI, overzealous volume resuscitation risks pulmonary compromise.

Historically, extremely aggressive volume resuscitation was pursued with an initial goal diuresis of up to 12 L/day, presuming intact renal function. Less aggressive volume resuscitation may be equally protective though data are lacking. The focus on diuresis downplays the importance of establishing and maintaining adequate intravascular volume. Central venous pressure or other means to monitor intravascular pressure may be more useful to determine adequate resuscitation. It is also likely that the rapidity with which volume status is restored, irrespective of the type or quantity of diuresis, is the key determinant. Unfortunately, these guidelines are poorly studied in a prospective format.

In the setting of AKI requiring renal replacement therapy, the ideal modality is the one most easily accessible, assuming hemodynamic stability. Options include hemodialysis, peritoneal dialysis, and continuous modalities. Although continuous renal replacement modalities provide the best theoretical protection from ongoing metabolic and volume complications, its superiority has not been verified in rigorous trials. In cases associated with large-scale injuries such as earthquakes, the remaining infrastructure often dictates which dialytic modality can and should be provided.[80,127] Historically, peritoneal dialysis has not been considered adequate in its ability to remove the large solute load present with rhabdomyolysis.[128] Nonetheless, if it is the only available modality, its potential role in managing rhabdomyolysis may be improved with more frequent exchanges. It should be noted that no traditional renal replacement method has the capability to remove myoglobin because of its size. However, considering the rapid extrarenal clearance of myoglobin, it is unclear if therapy focused on myoglobin clearance will provide any superiority over current care. A novel approach recently evaluated the use of super high-flux (SHF) membranes to clear myoglobin during continuous venovenous hemofiltration.[129,130] The authors demonstrated a fivefold increase in myoglobin removal but did acknowledge the potential for the removal of albumin, clotting factors, and protein-bound medications. A randomized study is currently under way to evaluate the potential for an extracorporeal therapy device, coupled to a continuous venovenous hemofiltration machine, to remove myoglobin.[131]

Hypocalcemia is common in rhabdomyolysis and may provide challenging management choices. Calcium entry into necrotic muscle cells often causes profound hypocalcemia. Calcium supplementation should be reserved for those patients with symptomatic hypocalcemia as hypercalcemia is a frequent finding during disease recovery.[132] In addition, rapid increases in serum pH through the administration of IV bicarbonate may worsen hypocalcemia. Rasburicase has been reported to reduce hyperuricemia in young patients with rhabdomyolysis.[133]

Additional issues include close monitoring for limb ischemia owing to compartment syndromes induced by muscle damage and subsequent fluid sequestration. Intracompartmental pressure monitoring may predict the need for intervention, although research has suggested additional factors—most importantly hypotension and the difference between mean arterial pressure and intracompartmental pressures—influence whether compartment syndrome develops.[134] The history, logic, and disappointing results of early and aggressive fasciotomy have recently been described.[135] Mannitol

is postulated to "decompress" intracompartmental edema in acute muscle compartment syndromes. Animal data support an acute reduction in intracompartmental pressures[136]; long-term tissue protection and human outcomes have not been validated. High-dose corticosteroids have been proposed as a treatment option for refractory cases of rhabdomyolysis but prospective studies are lacking.[137]

In summary, rhabdomyolysis is a frequent, treatable disorder. Extensive metabolic research has yielded a number of clues about the cause of AKI during rhabdomyolysis. Therapy should emphasize aggressive and early volume resuscitation. Renal replacement therapy may be necessary to assist in managing the metabolic complications of patients; patients have a good prognosis for recovery of rhabdomyolysis-induced AKI.

Key Points

- Populations at risk for hypothermia include the elderly, people with preexisting chronic medical conditions, and people with alcoholism and drug intoxication. Emerging populations include wilderness enthusiasts and winter sport participants.
- All intervals—PR, QRS, and QT—are prolonged secondary to hypothermia-induced slowed impulse conduction through potassium channels.
- Patients with moderate or severe hypothermia should be resuscitated until adequate rewarming is achieved before declaring efforts as unsuccessful.
- The diagnosis of heatstroke should be considered in patients with core body temperatures greater than 41°C.
- Severe dehydration, anhidrosis, and extreme hyperpyrexia are common in external heatstroke.
- Myocardial dysfunction with depression of left ventricular ejection fraction also has been described after heatstroke that resolves with treatment.
- Acute renal failure occurs in up to one-third of patients with heatstroke.
- Intravascular volume restoration must be individualized. In general, patients with exertional hyperthermia are severely hypovolemic.
- The most effective approaches to lowering the core temperature are immersion and evaporative methods.
- By far, the most important measure for MH is the immediate cessation of any suspected triggering agents.
- NMS is characterized by muscle rigidity and altered mental status, followed by autonomic instability and hyperthermia.
- Dopamine agonists such as bromocriptine, amantadine, and levodopa-carbidopa have been successfully used to treat NMS.
- Rhabdomyolysis is unlikely to lead to renal failure with a creatine kinase level below 5000 units/L unless volume depletion or another kidney insult is present.
- Aggressive volume resuscitation is more important than the type of volume replacement given to reduce the risk of myoglobin-induced AKI in cases of rhabdomyolysis.
- Alkaline-based volume resuscitation may worsen hypocalcemia.
- Rhabdomyolysis-associated AKI, including cases requiring renal replacement therapy, has a good prognosis.

Review Questions

1. Which of the following is the most correct statement regarding heat regulation?
   - **a.** Heat conservation is achieved by peripheral vasodilation.
   - **b.** Heat production is achieved through shivering and continues irrespective of the severity of hypothermia.
   - **c.** No shivering thermogenesis is achieved via increased levels of growth hormone.
   - **d.** The hypothalamus plays a central role in heat regulation upon cold exposure.

   Answer: d. Upon cold exposure, the hypothalamus initiates mechanisms for heat conservation and heat production. Heat conservation is achieved by peripheral vasoconstriction, reducing heat conduction to the skin, and behavioral responses such as wearing more clothes and seeking a warmer environment. Heat production is achieved through stimulation of muscular activity via shivering, which can increase the basal metabolic rate by two to five times. A nonshivering thermogenesis occurs via increased levels of catecholamines and thyroxine. This coordinated physiologic response occurs typically for temperatures between 32°C and 35°C. It only lasts for few hours, after which muscle fatigue and glycogen depletion ensue. As the core temperature drops below 32°C (90°F), shivering thermogenesis abates, and nonshivering thermogenesis slows down. By temperatures below 20°C to 24°C, the different mechanisms of heat production completely fail.
2. Which of the following clinical scenarios describes a patient most likely to be predisposed to hypothermia?
   - **a.** 79-year-old man hospitalized taking haloperidol (Haldol) with acute onset of agitation and muscle rigidity
   - **b.** 45-year-old well-nourished woman running a marathon in June
   - **c.** 28-year-old woman hospitalized in the emergency department with tachycardia, weight loss, and sweating
   - **d.** 75-year-old man with Parkinson disease and psoriasis and taking metoprolol for hypertension walking in the wilderness in January

   Answer: d. The first patient is at a risk of neuroleptic malignant syndrome with is associated with hyperthermia. The second patient could be at risk of heat stroke, which is associated with hyperthermia, although less likely owing to the fact that she is active and can make sound judgment to access water and shelter. The third patient should be evaluated for possible hyperthyroidism, which is associated with hyperthermia. The last patient has multiple risk factors for hypothermia including impaired thermogenesis because of age, Parkinson disease, and use of β-blockers. Increased heat loss occurs as the result of cold weather and psoriasis.
3. Which of the following is the most accurate statement regarding cardiac resuscitation during hypothermia?
   - **a.** The hypothermic heart is adequately responsive to vasoactive medications.
   - **b.** Any heart rate below 50 beats/min should be paced.
   - **c.** Ventricular fibrillation without a pulse requires initial defibrillation with maximum energy.
   - **d.** Adrenergic drugs should be used for temperatures below 30°C according to the usual Advanced Cardiac Life Support protocol.

   Answer: c. See the "Cardiac Resuscitation" section.
4. A 28-year-old athlete who was hit by an avalanche was rescued and brought to the emergency department pulseless with a temperature of 28°C. In addition to the ABCs (airway, breathing, circulation), which is the most correct statement regarding management?
   - **a.** Continue cardiopulmonary resuscitation (CPR) and initiate hemodialysis (HD).
   - **b.** Continue CPR and initiate continuous venovenous hemofiltration (CVVH).
   - **c.** Continue CPR and initiate venoarterial extracorporeal membrane oxygenation (VA-ECMO).
   - **d.** Continue CPR and initiate cardiopulmonary bypass (CPB).

   Answer: c. Choices a. and b. require the absence of circulatory collapse. The advantages of VA-ECMO over CPB include the increasing availability of the technology, the ability to be continued for several days for cardiopulmonary support even after rewarming, and its lower heparinization requirement. The lower anticoagulation requirement makes VA-ECMO preferable for trauma patients. The VA-ECMO system can provide the same rate of rewarming as CPB (8°C–12°C per hour) and does not require a sternotomy.[35,38]
5. A 22-year-old male presents to the emergency department complaining of diffuse cramps and decreased urine output for the past 24 hours. He is a body builder and has been increasing his training regimen over the past week. He has had poor oral intake for 2 days with intermittent vomiting. Vitals signs are as follows: pulse 110 beats/min, blood pressure 112/84 mm Hg, temperature 96.2°F, and respiratory rate 22 breaths/min. He weighs 90 kg. Laboratory test results are notable for creatinine 3.6 mg/dL, potassium 5.8 mmol/L, and bicarbonate 20 mmol/L. His urine shows trace protein, specific gravity of 1020, large blood on dipstick of urine and 0 to 5 red blood cells on microscopy. A creatine kinase (CK) level is 62,000 units/L. Despite 3 L of intravenous fluid (IVF) he remains oliguric. Which of the following statements is the most correct?
   - **a.** Mannitol is appropriate to stimulate urine output.
   - **b.** Hemodialysis will likely be needed to control hyperkalemia.
   - **c.** Calcium infusion for hyperkalemia is contraindicated because of eventual rebound hypercalcemia with rhabdomyolysis.
   - **d.** Adequate initial volume resuscitation in this condition is typically around 30 mL/kg IV crystalloid.

   Answer: b. This case presents a scenario of exertional rhabdomyolysis with oliguric acute kidney injury and hyperkalemia. The case illustrates the potential severity at initial presentation of rhabdomyolysis. In light of the patient's low urine output and the expectation that hyperkalemia from muscle cell injury may worsen, dialysis should be considered as an early intervention in this case. Beyond other forms of volume resuscitation and avoidance of offending agents, limited therapeutic options exist. Mannitol is contraindicated in oliguric AKI because of the risk of consequent hyperosmolality. Calcium may be given for emergent hyperkalemia, but a higher threshold should exist for replacement of calcium owing to hypocalcemia in the setting of rhabdomyolysis. Finally, IVF resuscitation often needs to be much larger than other critical illnesses because damaged muscle cells sequester IVF.
6. A 35-year-old male presents with exertional rhabdomyolysis and despite very evaluation showed no evidence of compartment syndrome. He is hemodynamically stable. Laboratory studies include an arterial blood gas analysis showing a pH of 7.28 and a potassium level of 5.2 mmol/L. His lactate level is 3.2 mmol/L. He is scheduled for an additional dialysis session

this day. After an initial decrease in CK, the level is now rising. Which one of the following is most important at this time?

a. Administration of 1 ampule of bicarbonate for lactic acidosis
b. Repeat evaluation for compartment syndrome
c. Increased IVF administration
d. Administration of mannitol

Answer: b. The patient now shows the possible development of compartment syndrome in part related to fluid sequestration despite an initial negative evaluation. Intracompartmental pressure monitoring should be repeated. In the presence of tissue ischemia with stable hemodynamics, the administration of IVF will not be helpful and may be harmful. Bicarbonate administration may be similarly harmful because of the potential to raise pH excessively, especially as dialysis will raise pH independently. Finally, mannitol is contraindicated in states of oliguric kidney failure.

7. A 64-year-old female is hospitalized for recent falls. Her blood pressure on admission is 80/40 mm Hg, which improves with 2 L of IVF. You are consulted for rhabdomyolysis and acute kidney injury. She has a history of coronary artery disease (prior coronary artery bypass grafting), hypertension while using lisinopril 20 mg/daily, and osteoarthritis. She takes atorvastatin 10 mg/day and ibuprofen 400 mg/day. Laboratory results on admission are as follows: potassium 4.6 mg/dL, creatinine 1.8 mg/dL (baseline 0.8), and CK 1800 units/L. Her urinalysis shows 1+ protein, specific gravity of 1.030, and no blood. Which of the following is the most correct statement?

a. CK levels are not related to the level of muscle trauma.
b. Her acute kidney injury is due to rhabdomyolysis.
c. Atorvastatin should not be continued at discharge.
d. Renal vasoconstriction from volume depletion, use of an angiotensin-converting enzyme (ACE) inhibitor, and use of a nonsteroidal antiinflammatory drug (NSAID) are the likely cause of her acute kidney injury (AKI).

Answer: d. This case shows a female presenting with AKI from volume depletion. Her renal function is impaired by the volume depletion with ACE inhibitor and NSAID use. It is unlikely this level of CK elevation will induce acute kidney injury; typically CK levels less than 5000 units/L should lead one to consider other diagnoses of AKI. The lack of blood in her urine and high urine specific gravity support volume depletion and not rhabdomyolysis as the cause of her AKI. As a result, continuation of her atorvastatin is not contraindicated at discharge. Although the cause of AKI in rhabdomyolysis is myoglobin-induced renal tubular damage, CK levels are routinely used as marker of muscle injury as they are more frequently measured than myoglobin. The one important caveat to this is CK levels may not peak until several days after muscle injury, so levels should continue to be monitored until they decline.

- Overview of Prediction Models
- Organ Dysfunction Scoring Systems
- Scores for Early Detection of Critical Illness
- Scoring Systems for Specific Conditions

Summary and Conclusions

Critical Care Performance Improvement

An intensive care unit (ICU) at the most basic level has an obligation to continuously evaluate the quality of care delivered. Outcomes are primarily used to validate effectiveness and quality. However, another approach is to examine the processes producing those results.[1] Striving to improve quality of care is the foundation for performance improvement (PI). PI includes identifying and remedying deficiencies in processes and implementing new processes to provide better patient care and improved clinical outcomes. Clinicians' drive to provide the best possible care for ICU patients in a safe environment is shaping the standard in critical care delivery. Critical care service programs are evolving to include services beyond the walls of the ICU. Services may be provided in emergency departments, step-down units, and by outreach teams that consult for urgent issues and provide initial support for patients in unstable condition on the hospital wards. An essential component of the health care system, intensive care services require dutiful attention to operations to ensure high-quality care and continuous PI wherever critical care is delivered.

Background

In 1999 the Institute of Medicine (IOM) of the National Academies of Sciences, Engineering, and Medicine published a landmark report, *To Err Is Human: Building a Safer Health System.* The National Academies bring together committees of experts in all areas of scientific and technologic endeavor to address critical national issues and provide advice to the federal government and the public. The IOM report was widely hailed as groundbreaking in view of its documentation of the ways in which the health care system harms patients. Some of the findings about the American health care system included the following: (1) tremendous gaps exist between medical knowledge and practice; (2) adverse events harm patients far too often; (3) too many people do not receive the care they need; and (4) the system propagates waste by permitting fragmentation of care and utilization inefficiencies.[2] In *To Err Is Human*, the IOM also estimated that despite incurring costs that are 40% greater than those for the next most expensive nation in terms of health care, 44,000 to 98,000 Americans die each year as a result of errors in their health care.[2]

In 2003 in an exhaustive review of nearly 7000 patient charts across all regions of the United States, McGlynn and colleagues reported that the average defect rate, defined as the percent of cases in which care consistent with 439 indicators of quality was not delivered, approached 45% nationally.[3] Stated otherwise, patients receive the care indicated slightly more than one-half of the time. These investigators concluded that the deficits identified in adherence to recommended processes for basic care posed a continuing immediate danger to the health of the American public. These findings were unfortunately reaffirmed in 2010 when Landrigan and colleagues found high rates of adverse events even among hospitals that had participated in efforts to reduce patient harm.[4]

Donabedian Framework

Building on work begun by Donabedian, the IOM published *Crossing the Quality Chasm: A New Health System for the 21st Century* in 2001. The report outlined fundamental changes that must be made to improve health care in the United States. Donabedian had described three components of quality care—structure, process, and outcome—each of which must be addressed to effectively control and manage quality in health care settings.[5] He proposed that each overarching concept of control should be monitored using specific tools (Table 67.1). The IOM report also refined Donabedian's seven attributes of high-quality health care,

TABLE 67.1 Relationship Between Quality Areas and Management Tools With Their Relative Importance

	MANAGEMENT TOOLS		
Quality Area	Standards	Guidelines	Indicators
Structures	+++	+	+
Processes	++	+++	++
Results/outcomes	+	++	+++

Reproduced from Frutiger A, Moreno R, Carlet J, et al. A clinician's guide to the use of quality terminology. Working Group on Quality Improvement of the European Society of Intensive Care Medicine. *Intensive Care Med.* 1998;24:860–863.

proposing instead six primary aims: safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity.[6]

Quality Improvement Landscape

Based on formidable critiques of the quality of the U.S. health care system, a variety of organizations either willingly have taken up the challenge to improve health care or, through legislation, have been empowered to improve the delivery of health care in the United States. All of these efforts have led to creation of agencies or activities with relevance to the ICU.

Agency for Healthcare Research and Quality

The mission of the Agency for Healthcare Research and Quality (AHRQ) mission is to provide safe, high-quality, accessible, equitable, and affordable health care in association with the U.S. Department of Health and Human Services (HHS) and other partners to ensure that evidence is understood and used.[7] Funding for health care safety and quality improvement research may be acquired through grant applications to the AHRQ. The Comprehensive Unit-Based Safety Program (CUSP) is an example of quality improvement work, supported by AHRQ, to decrease hospital-acquired infections. CUSP methods reduced central line–associated bloodstream infections by 41%, saving 500 lives and avoiding millions in excess costs.[8]

AHRQ's associated functions have changed over the years. The 2010 Patient Protection and the Affordable Care Act (ACA) assigned comparative effectiveness research to a new independent nonprofit agency, the Patient-Centered Outcomes Research Institute (PCORI). Additionally, delivery and system innovations were moved from AHRQ to the Centers for Medicare and Medicaid Innovation.

Patient-Centered Outcomes Research Institute

Established by Congress through the ACA, the PCORI receives 80% of its funding from the Patient-Centered Outcomes Research (PCOR) Trust Fund to support research and operations. A total of $210 million was provided for years 2010 through 2012.[9] From 2013 through 2019 the PCOR Trust Fund will receive $150 million annually. Research funding began in 2012 with an estimated 1110 project awards provided through 2016.[9]

The PCORI's structure is aimed toward projects that improve patient and caregiver health decisions. Research programs focused on several national priorities, including comparing prevention, diagnosis, and treatment for a variety of people; approaching health care access; and communicating and disseminating information.[10]

Centers for Medicare and Medicaid Innovation

The Innovation Center, established by Congress through the ACA as an agency within the Centers for Medicare and Medicaid Services (CMS), was created to test models that improve care, lower cost, and advance quality payment models.[11] Several of the initiatives of the Centers for Medicare and Medicaid Innovation include accountable care organizations, primary care, and initiatives to accelerate the adoption of best practices.[11] In 2016 CMS announced the Million Hearts: Cardiovascular Disease Risk Reduction Model to improve risk assessment for cardiovascular disease.[12] This model is an example of an initiative to speed the adoption of best practice in preventing 1 million heart attacks and strokes over 5 years.

Another example is the Partnership for Patients initiative that began in 2011, focused on making hospital care safer by decreasing preventable hospital-acquired infections and improving care transitions in a reliable and efficient manner. This effort reduced hospital-acquired conditions by 21% over a 5-year period resulting in $28 billion in cost savings.[13] The success led CMS to award $110 million in ACA funds to continue improvements in patient safety.[14] In 2016 more than 4000 hospitals across 16 Hospital Improvement Innovation Networks (HIINs) organizations were contracted to engage in national initiatives to reduce patient harm and 30-day readmissions.[15] Some focuses of critical care highlighted by HIINs in their work include reducing adverse drug events, improving airway safety, maintaining antibiotic stewardship, promoting a culture of safety, and reducing sepsis mortality.[16]

National Quality Forum

Created in 1999, the National Quality Forum (NQF) is a private, not-for-profit membership organization formed to promote and implement a national strategy for health care quality measurement and reporting.[17] The multistakeholder group seeks to improve American health care through endorsement of consensus-based national standards for the measurement and public reporting of health care performance data. Working with a broad base of health care interests including governmental agencies, insurers, and various medical associations, the NQF has prevailed on hospitals to report compliance rates with their measures.[17] Approximately 300 NQF-endorsed measures are used in both private and state programs. The Pulmonary and Critical Care portfolio includes 13 endorsed measures. Areas of measurement include asthma management, mortality in patients with chronic obstructive pulmonary disease or pneumonia, and more generally, critical care mortality, and length of stay.[18] NQF's Infectious Disease portfolio includes the #0500 Severe Sepsis and Septic Shock: Management Bundle endorsed in 2012 and again in July 2017.[19]

The Joint Commission

The Joint Commission (JC), founded in 1951, evaluates, accredits, and certifies nearly 21,000 health care organizations and programs in the United States.[20] Commonly misunderstood to be a governmental agency, the JC is an independent not-for-profit organization that contracts with CMS to accredit health care organizations. The JC seeks to continuously improve the safety and quality of care not only through enforcing standards that lead to Medicare accreditation, but also by promoting quality improvement initiatives. [21]

In particular, the JC has opened the Center for Transforming Healthcare (CTH) aiming to tackle critical quality and safety

problems in health care. The center aims to achieve "high reliability" in health care, typically described as achieving extraordinarily low error rates as observed in nuclear power plant operations, aircraft carriers, commercial aviation, and so on.[22] To achieve these ends, the CTH has adopted Rapid Process Improvement as a methodology to drive change in health care. The approach emphasizes the importance of both change management as exemplified in Six Sigma process improvement, and Lean production tools aimed at increasing value and eliminating waste.[23] Using this approach, the JC has partnered with hospitals to dramatically reduce harm and improve quality in several critical care areas, including reducing sepsis mortality, hand-off communications, hand hygiene, and venous thromboembolism prevention. The CTH has published toolkits known as Targeted Solutions Tools to help hospitals achieve high reliability in several of these areas.[24]

Quality Improvement Interventions in Critical Care

Devotion to collecting, disclosing, and comparing safety and quality metrics is essential to improve critical care practice. Intervention-specific quality improvement initiatives in critical care have developed with many organizations committing resources to implement such initiatives. Some of the strategies for ICU quality improvement benefit from standardized measures available through the NQF and others; however, as practitioners take notice of the growing imperative to change the way critical care is delivered, many cutting-edge initiatives are moving forward without a consensus on which quality indicators should be applied.

The Society of Critical Care Medicine (SCCM) Task Force report recommends a stepwise approach to quality improvement, along with strong motivation, interdisciplinary team collaboration, and engaged leadership.[25] Clinicians interested in quality should understand the structure-process-outcome model, recognizing that structure, the way we organize care, is often the most difficult to change.[25] Process and outcomes, what we do or fail to do, and results we achieve may be easier measures; both have advantages and disadvantages worthy of evaluation.[25]

In 2012 the European Society of Intensive Care Medicine (ESICM) Task Force on Safety and Quality sought to identify a set of indictors that could be used to measure quality and improvement performance in any ICU around the world.[26] Nine indicators were proposed, including three regarding ICU structure, two process related, and four outcome measures (Box 67.1).[26] These indicators and other critical care quality measures are often aligned with strategies that advance more general goals such as developing a culture of safety and harm prevention.

Shewhart Model for Process Improvement

Critical care quality improvement initiatives, such as those advocated by SCCM or ESICM as already described, have typically been executed in the setting of collaborative efforts among several hospitals. Collaboration among hospitals was initially widely championed by the Institute for Healthcare Improvement (IHI) and adapted later by other groups. The IHI developed shared learning programs to improve care through various ICU collaboratives. The precise mechanisms of implementation for these initiatives vary, but most quality improvement initiatives encourage the use of small-scale experiments to test new ideas. The principle calls for organizations to make the process of scientific prediction a part of routine work and was first advanced in 1931 by Walter Shewhart, a pioneer in industrial quality control. Shewhart advocated the use of iterative "plan-do-check-act" cycles to systematically test new ideas, evaluate their results, and, if successful, implement them.[27] The IHI Model for Improvement has promoted a similar structure to accelerate improvement with the "plan-do-study-act" cycle (Fig. 67.1).[28] Organizational components include forming the team, establishing aims and measures, followed by selecting, testing, implementing, and spreading changes.[29]

• BOX 67.1 Proposed Set of Indicators to Measure Quality and Improvement in Any Intensive Care Unit

Indicator Number	Indicator Description	Indicator Type
1	ICU achieves national requirements to provide intensive care.	Structure
2	Consultant level Intensivist available 24 h a day.	Structure
3	Maintain a system to monitor adverse events for each patient.	Structure
4	Provide routine multidisciplinary clinical ward rounds.	Process
5	Standardize handover procedure (chart documentation) for discharging patients.	Process
6	Reporting and analysis of standardized mortality ratio using a calibrated severity of illness score.	Outcomes
7	Evaluate ICU readmission rates within 48 h of ICU discharge.	Outcomes
8	The rate of central venous catheter–related blood stream infection.	Outcomes
9	The rate of unplanned endotracheal extubations.	Outcomes

Prevention of Health Care–Associated Infections

Health care–associated infections (HAIs) are associated with poor outcomes and increased health care costs, with a large number of these infections acquired in the ICU setting. The risk of developing an HAI includes but is not limited to exposure to venous and urinary catheters and ventilators. National initiatives to reduce HAIs have demonstrated impressive results. Large-scale improvement campaigns such as AHRQ's *On the CUSP: Stop BSI* (bloodstream infections) and *On the CUSP: Stop CAUTI* (catheter-associated urinary tract infection) have attracted attention from policymakers.[30] Insights from these national improvement projects provide steps for future quality improvement programs to be more efficient and effective. Nevertheless, spreading innovation and adoption of best practices nationally remain fraught with delays.

Prevention of Ventilator-Associated Events

Reducing complications in high-risk mechanically ventilated patients requires a multidisciplinary approach and high rates of adherence to recommended evidence-based interventions. Ventilator-associated events include ventilator-associated pneumonia (VAP), peptic ulcer disease, gastrointestinal bleeding, aspiration, venous thromboembolic events, and obstacles to managing secretions. Despite variability in clinical definitions to establish valid criteria to diagnose VAP, institutions have devoted considerable effort to combating VAP rates. The Centers for Disease Control and Prevention (CDC), however, has offered a clinical definition of VAP that requires patients to be mechanically ventilated for more than 48 hours and satisfy a minimum of one radiographic, one systemic, and two pulmonary criteria.[31]

The prototypical collaborative effort to decrease VAP rates has been use of the "ventilator bundle" initially promulgated by the IHI more than a decade ago. The IHI ventilator initiative was initially launched to describe a pattern of best practices for ventilated patients, not to decrease VAP rates. Nevertheless, routine use of the ventilator bundles have been shown to reduce VAP rates.[32] A contemporary version of the ventilator bundle includes standard head of the bed elevation to between 30 and 45 degrees, provision of routine oral care with 0.12% chlorhexidine, implementation of peptic ulcer disease and deep vein thrombosis prophylaxis, as well as inclusion of elements A, B, and C from the "ABCDEF bundle."[33] The ABCDEF bundle is aimed at reducing delirium and improving pain management and outcomes for adult ICU patients.[34] Elements of the ABCDEF bundle include the following:

- **A** Assess, prevent, and manage pain
- **B** Both spontaneous awakening trials and spontaneous breathing trials
- **C** Choice of analgesia and sedation
- **D** Delirium: Assess, prevent, and manage
- **E** Early mobility and exercise
- **F** Family engagement and empowerment

Prevention of Central Line–Associated Bloodstream Infection

Prevention of central line–associated bloodstream infections (CLABSIs) has been a national priority in critical care quality improvement. The CDC has produced a standard measure that defines prevention of these infections as part of the National Healthcare Safety Network's patient safety component protocol.[35]

A typical approach to preventing CLABSIs includes four elements of care: proper hand hygiene, use of chlorhexidine for skin antisepsis, routine application of maximal barrier precautions, and optimal site selection. In a 2014 systematic review, CLABSI prevention quality improvement interventions such as care bundles and checklists were effective in risk reduction.[36] The *On the CUSP: Stop BSI* collaborative study included 1071 ICUs from 792 hospitals to prevent CLABSI rates in adult ICUs, with a unit-level mean goal of less than 1 case per 1000 catheter days.[37] Berenholtz and colleagues demonstrated a decrease in mean CLABSI rates from 1.96 cases per 1000 catheter-days at baseline to 1.15 cases in the 16- to 18-month follow-up period. These results suggest that most U.S. ICUs can achieve CLABSI reductions below the national average.[37]

Prevention of Catheter-Associated Urinary Tract Infections

Urinary tract infections are one of the most common HAIs in the ICU, primarily attributable to indwelling urinary catheters. Before the CDC's Healthcare Infection Control Practices Advisory Committee (HICPAC) catheter-associated urinary tract infection (CAUTI) guideline revision in 2009, data from 1990 to 2007 showed a significant decline in national CAUTI rates among 367 facilities representing 1223 adult ICUs.[38] Depending on the type of ICU evaluated (e.g., medical, surgical, neurological) a 19% to 67% reduction in symptomatic urinary tract infection was noted; with regard to asymptomatic bacteriuria, a reduction of 29% to 72% was observed.[38] The various strategies and interventions that led to this reduction informed the HICPAC guideline revision in 2009. These include appropriate urinary catheter use, consideration of alternatives to indwelling urethral catheterization in selected patients, performing proper aseptic technique during urinary catheter insertion, following proper catheter maintenance techniques, and integration of a formal hospital quality improvement program with necessary surveillance strategies.[39]

Deploying Rapid Response Teams

The rapid response team (RRT)—sometimes referred to in the literature as a medical emergency team (MET)—is a team of nurses and other health care professionals (respiratory therapists, pharmacists, emergency department personnel, and others) who bring critical care expertise to the bedside. The teams may or may not include physicians. The essential concept is intervening to prevent harm when nursing staff and in some institutions a family member is urgently concerned about a patient's well-being. The key goal is to act before "failure to rescue" occurs and a patient has had a cardiac or respiratory arrest.[40] The team provides bedside evaluation, treatment, and if indicated, triage to a higher level of care such as the ICU or operating room.[41]

Increased interest in hospital quality and outcomes has resulted in many hospitals developing and implementing RRTs. Evidence supporting RRT adoption is mixed. Nevertheless, many hospitals have detected the need to have such a team to respond to urgent patient issues when physicians or house staff may not be readily available. In a randomized controlled study of 23 Australian hospitals, 11 hospitals functioned as usual and 12 introduced a MET system. The investigators concluded that although the introduction of the MET system led to an increase in calls to the team, it did not substantially affect the incidence of cardiac arrest, unplanned ICU admissions, or unexpected death.[42] A meta-analysis review of seven RRT studies in adults aimed to reduce cardiopulmonary arrest rates yielded mixed results. Together the seven studies

showed that implementation of an RRT in adults was associated with a 33.8% reduction in cardiopulmonary arrests outside the ICU.[43] Methods to identify deteriorating patients earlier may include an educational program, additional staffing of nurse practitioners or increasing nurse staffing to prevent deterioration, and educating caregivers to recognize the signs of deterioration may be alternatives to RRTs.[44] Additional research to assess the benefits or detrimental effects of using or not using an RRT/MET compared with other preventative designs is needed.

Resuscitation and Treatment for Sepsis or Septic Shock

The Surviving Sepsis Campaign (SSC) has been the principal driver in evidenced-based sepsis quality improvement for nearly 2 decades. The SSC was created in 2002 jointly by the SCCM and ESICM. At its inception, the campaign's aim was to change clinical practice with the development of practice guidelines and an associated PI program. The group published evidence-based guidelines for the treatment of severe sepsis and septic shock first in 2004 and subsequently in 2008, 2013, and 2017.[45–48]

Partnering with the IHI, the SSC became a global PI program after publication of the 2004 guidelines.[49] The program included the development of sepsis bundles, educational materials, recruitment of participating hospitals, and a secure database for data collection and monitoring of process and outcome measures. The initial campaign results from 15,022 subjects at 165 international sites reported a significant increase in bundle compliance and unadjusted mortality rate decrease from 37% to 30.8% over a 2-year period.[50] Subsequent analysis of 29,470 patients from 218 community, academic, and tertiary care hospitals in the United States, South America, and Europe over 7.5 years showed that increased compliance with sepsis bundles (based on the 2004 SSC guidelines) was associated with a 25% relative risk reduction in mortality, and with every 10% increase in bundle compliance, a 4% reduction occurred in hospital and ICU length of stay.[51]

These initial publications led to the development of a sepsis measure submitted to the NQF for evaluation as a validated performance measure. As noted earlier, the NQF endorsed the measure as part of its infectious disease portfolio in 2012 and again in July 2017.[52] After the initial endorsement, the measure was adopted by CMS as the first sepsis quality measure, SEP-1, in the United States. The adoption of the measure by CMS was driven in part by an observed doubling in the number of hospital stays for this diagnosis between 2000 and 2008.[53]

In 2015 the CMS released the Sepsis Bundles Project National Hospital Inpatient Quality Measures (SEP-1) early management bundle for severe sepsis/septic shock. Collection and scoring of these quality metrics were mandated to begin in late 2015. The sepsis metrics in these 3- and 6-hour bundles were essentially the same as the 2012 SSC bundles metrics. However, with the publication of the ProCESS (Protocolized Care for Early Septic Shock) and ARISE (Australasian Resuscitation in Sepsis Evaluation) trials demonstrating that successful resuscitation of septic shock could be accomplished without a central venous catheter, SEP-1 did not require central venous pressure (CVP) and central venous oxygen saturation ($ScvO_2$) measurements.[54,55] Instead a reassessment of intravascular volume and tissue hypoperfusion after initial fluid bolus was required. This reassessment could include either a focused physical examination or any two of the following elements: (1) measuring CVP, (2) measuring $ScvO_2$, (3) performing cardiovascular ultrasound, or (4) ascertaining the effect of fluid bolus or passive leg raise on cardiac output.[56]

Almost coincident with the NQF measure endorsement, hospitals in New York were directed by the New York State Department of Health (NYS DOH) to follow and submit patient level data on evidence-informed protocols for early identification and treatment for patients with sepsis and septic shock. Among 49,331 patients, longer times to complete the 3-hour bundle (obtain blood cultures before initiating antibiotic treatment, measure serum lactate level, and administer broad-spectrum antibiotics) and longer time to antibiotic administration were associated with increased risk-adjusted in-hospital mortality.[57] Conversely, in this study a longer time to complete a required fluid bolus was not associated with lower mortality, although the authors indicated this finding may have resulted from confounding by indication.[57] Overall, sepsis protocols that include early identification and rapid treatment continue to contribute to improvement in patient outcomes and avoidable deaths.

Establishing Multidisciplinary Rounds

Surveys of institutional perceptions of the state of safety in ICUs have led to the establishment of multidisciplinary rounds.[58] Multidisciplinary rounds enable all members of the team caring for critically ill patients to gather formally and offer their expertise as cases in the ICU are reviewed. Multidisciplinary rounds have been established in critical care units with various structures, either nurse-led or physician-led, meeting daily or regularly during the week. Experience implementing multidisciplinary rounds suggests that although initial meetings may be wide-ranging and unstructured, they can become a vital adjunct to patient care. Specifically, these rounds provide an opportunity for disciplines to share their knowledge of patient care needs and focus the entire care team on common goals. These rounds are a mainstay of the effort to change the culture of ICUs from compartmentalized care based on a single discipline's knowledge to a more holistic approach integrating the talents of the many services caring for critically ill patients.[59]

Incorporating a mnemonic—for example FAST HUG—to address essential components of care for the critically ill is a simple method to improve teamwork while addressing quality metrics.[60] FAST HUG includes identification of key aspects of care including *F*eeding, *A*nalgesia, *S*edation, *T*hromboembolic prophylaxis, *H*ead-of-bed elevation, stress *U*lcer prevention, and *G*lucose control.[60] Updates to this mnemonic have been proposed such as FAST HUGS BID, which includes additional components, *S*pontaneous breathing trial, *B*owel function, removal of *I*ndwelling catheters and *D*e-escalation of antimicrobials and other pharmacotherapies.[61] FAST HUGS BID was a further modification aimed at the surgical patient in the ICU.[62] In one of the authors' institutions, the mnemonic FASTER FLAGG (*F*eeding, *A*nalgesia, *S*edation, *T*hromboembolic prophylaxis, *E*xtubation candidate, *R*estraint orders, *F*oley catheter removal, *L*ine removal, *A*ctivity, *G*lucose control, and *G*oals of care) is used by the nursing staff daily during both multidisciplinary rounds and in daily chart documentation. Standardizing a method to discuss routine patient care issues with the multidisciplinary team can help frame daily goals of care, address potential adverse events, and lead to improved patient outcomes.

Daily ICU Patient Goals Assessment–Quality Rounds

Daily goals assessment allows all parties involved in the care of patients to formally keep track of plans established on either patient care rounds or multidisciplinary rounds and to verify their completion. This typically has been achieved in critical

care units by using a daily goals worksheet completed by the rounding team.

As one example, a study conducted in a surgical oncology ICU assessed ICU length of stay and percent of ICU residents and nurses who understood the goals of care for patients in the ICU. Comparing baseline and postimplementation of a daily goals worksheet, less than 10% of residents and nurses understood the goals of care for the day at baseline compared with greater than 95% after implementation.[63] After implementation of the ICU daily goals worksheet, a reduction in ICU length of stay from a mean of 2.2 days to 1.1 days was observed.[63]

Effective quality patient care rounds include a multidisciplinary team with defined roles and a standardized structure with a goal-oriented approach that includes a checklist.[64] Barriers to quality patient rounds include poor information retrieval and documentation, long rounding times, and perceptions of not being valued by rounding physicians.[64] For example, improvements were sustained for 2 years in one trauma ICU using a checklist as part of rounds along with noted improvements in measures of preventative care and assessments of culture change.[65]

Practice Management: Clinician-Family Communication

Protocols, guidelines, and toolkits have improved process and outcomes in numerous areas of critical care. Translation of these techniques to advance communication with family members of the critically ill is dependent on coordination between clinicians and family members. Such coordination is frequently not an explicit goal.[66] Discussions with family members geared toward shared decision making and goal-oriented care plans are important in promoting patient- and family-centered care.

Clinician-family meetings are intended to share information related to the patient's condition and prognosis and to allow the family to discuss care preferences, family concerns, and goals of treatment.[67] Early effective communication with patients and family members is imperative in shared decision making as they are an integral part of the care in the critically ill.

The American College of Critical Care Medicine (ACCM) Task Force 2004–2005 recognized the need for clinicians to develop a care plan and partner with patients and family members to improve outcomes.[68] In a unified policy statement the ACCM and American Thoracic Society define shared decision making as a collaborative process that allows patients, or their surrogates, and clinicians to make health care decisions together, taking into account the best scientific evidence available, in addition to the patient's values, goals, and preferences.[69] Adjustments in the decision-making model may be appropriate to fit the situation, patient, and family.[69]

Family members often act as surrogate decision makers for the critically ill, which reportedly has been linked to anxiety, depression, and fatality. Methods to decrease stress include clinicians adapting to the family preference in decision making using a stepwise approach progressing toward improved decision making for the critically ill patient.[66,70]

Ideally clinician-family conferences should be conducted within 72 hours of ICU admission. A brief meeting prior to the conference has been suggested to improve the family experience with future conferences. Increased family satisfaction has been reported when clinicians spend more time listening than talking. Clinical-family communication has been summarized in a mnemonic called VALUE and is used as a framework for communication (Box 67.2). Lautrette et al. reported that application of the VALUE conference approach resulted in significant reduction in family symptoms of anxiety, depression, and posttraumatic stress disorder 90 days after the patient's death.[71] Long-term sustainability of the VALUE-grounded communication approach may be facilitated with point-of-care daily reminders, including a family communication item on the daily goals checklist, progress note templates, and maintenance of placards in each patient room.[72] Documentation of the pertinent conference details and treatment goals are essential to assist future clinician-clinician and clinician-family communication throughout the patient's ICU and hospital stay.

Intensive Care Unit Staffing: Intensivist-Led Team Model

A structural change in ICU care that may lead to improvement in the quality outcomes includes the establishment of an intensivist-led ICU service in medical ICUs. Although in other ICUs, such as neurosurgical units or pediatric units, it is commonly expected that the attending physician is an intensivist trained in that specialty, this has not been the rule in medical ICUs. Typically mixed medical-surgical ICUs in the United States are "open" in that any physician on staff may admit patients to the ICU and intensivists are available for consultation. The literature suggests that "closed" ICUs in which only medical intensivists care for medical patients may be associated with decreased morbidity and mortality rates and length of stay.[73] In a before-and-after cohort study, implementation of the Leapfrog ICU physician staffing model resulted in decreased ICU length of stay, lower rates of VAP and CLABSI, and significant cost savings.[74]

Despite early literature supporting "closed" ICUs and more recent ICU physician model results, barriers to implementation exist, including perceived loss of control for some physicians, administrative perceptions of high costs of implementation with few financial benefits, and concern for limited availability of board-certified intensivists.[75] However, many executive and ICU leaders identify quality of patient care as the main motivating factor for implementing an all-intensivist ICU staffing model.[75] Pronovost et al. suggest avoiding the terms "open" versus "closed" when referencing intensivist staffing and suggest adopting a team-based approach whereby the intensivist partners with the primary physician in care delivery.[75] Coupling the team-based approach with a culture of quality, safety, and accountability can improve quality performance and outcomes.

Culture Transformation and Organizational Learning

The ultimate goal of clinical quality improvement work of any sort remains that of creating a culture of enduring change that can absorb new initiatives and sustain gains earned in prior improvement efforts. Underscoring the long-term strategy of ICU culture change in describing improvement initiatives cannot be overestimated. If insufficient attention is paid to the context in which improvement efforts are set into motion, an environment unfamiliar with testing changes and hostile to deviations from routine will hinder the success of the project itself. To this end, as clinical initiatives are advanced, concern must be maintained for executing projects to encourage collaboration and cooperation among the persons who work in the ICU. Typically these strategies involve crafting of change teams, devising and testing protocols to incorporate the concerns of the front-line users of the protocols, and adapting to local cultural needs and traditions while incorporating new ideas. In the course of this work, colleagues cease contemplating their work as discrete projects that can be finalized. Instead, they learn to constantly revise protocols and strategies in response to feedback from the front-line users. If these ideals are maintained in the rollout of key initiatives and structural changes, often a change in mindset from an organization of independent actors to one in which collaborative efforts promote organizational learning can take hold. Unfortunately, no scientific procedure is available to guide the way in making such cultural transformations gracefully. The talents of committed and patient people are essential.

Critical Care Scoring Systems

Severity of Illness Scoring Systems

Severity of illness scores were introduced in critical care in the 1980s to describe and classify critically ill patient populations. The early instruments were developed to stratify patients based on severity and predict outcome based on a set of variables and an equation model. Models primarily included data combinations from three areas: demographics, such as age and gender; chronic health conditions; and acute physiology, such as laboratory values and vital signs obtained within the first 24 hours of ICU admission. Some of the updated prediction models included principal diagnosis, operative status, and origin before ICU admission.

Mortality prediction models are commonly used in clinical trials to measure severity of illness at admission and for stratification of baseline clinical characteristics.[76] In clinical practice, ICU scoring systems are generally used to assess performance. Historically, the three most commonly used scoring systems in adult ICUs included the Acute Physiology and Chronic Health Evaluation (APACHE), the Mortality Probability Model (MPM), and the Simplified Acute Physiology Score (SAPS).[77,78] Updates to these early scoring systems occurred in the 1990s and again in mid-2000s. A comparison of these three major scoring systems is presented in Table 67.2.

Scoring System Use in Performance Improvement

The purpose of severity scoring systems in PI is to evaluate ICU populations and identify opportunities to improve quality of care and efficiency. However, scoring systems are used in only approximately 10% to 15% of ICUs in the United States.[76] Limited use may be partly due to the expense associated with data collection, including cost for software, training, and support and availability of knowledgeable staff. Concern about the accuracy of ICU scoring systems may also contribute to limited clinical application.[76]

Severity scoring models encompass a combination of diagnostic, physiologic, or demographic variables to predict patient outcomes. Scoring models may perform well in mortality predictions yet the role for benchmarking and PI may be somewhat restricted. Without ICU performance data, clinicians and administrators have a narrowed view in their ability to realistically describe, compare, and improve the quality of care for their critically ill patient population. As a matter of accessibility, often administrative data inform committees regarding ICU quality and performance. Data, based on assigned International Classification of Diseases (ICD) coding, can be appropriate to provide an overview of outcomes and resource utilization centered on diagnosis and length of stay. However, administrative data alone may not adequately quantify severity of illness or mortality risk.

Although severity scoring systems and prediction models are worthwhile tools, they too have limitations. Updates are often required because of the ultimate model deterioration that occurs over time. Reasons for model weakening were partially due to variations in patient characteristics at time of presentation, accessibility to treatment, an increase in mean aged and chronically seriously ill patients, and the growing number of immunocompromised patients.[78,79] Furthermore, errors in prediction models caused by differences in patient selection and lead time bias may support the addition of new variables for consideration in future model revisions.

Model Development, Validation, Calibration, and Discrimination

Early severity of illness scoring model development, including the selection of variables and weights, was based on clinical judgment through a panel of experts. Instrument advances ensued among all three scoring systems (APACHE, MPM, and SAPS) with logistic regression techniques for model development and performance validation with measures of calibration and discrimination. Model development is generally achieved using large databases collected from many ICUs. Validation, in a sample other than that used for model development, may be completed with a new cohort or randomly dividing the existing database. Calibration can be evaluated using the formal goodness-of-fit tests, which evaluate the estimated probability of death to actual patient mortality.[80] A well-calibrated model exists when the number of observed and expected patient deaths is similar. Model discrimination uses the area under the receiver operating characteristic (ROC) curve to measure the accuracy of the model to differentiate patients who live or die, based on the mortality probability estimates. A ROC of 0.50 is no better than a flip of a coin. Thus model developers normally seek a ROC area that exceeds 0.70.[80]

Overview of Prediction Models

APACHE

The prototype APACHE system included weighting for 34 potential physiologic measures, using the worst value during the initial 24 hours after ICU admission, which provided an acute physiology

score (APS).[81] The original model was revised in 1985 creating APACHE II. Measures were simplified to include just 12 physiologic variables, the addition of weighted points for age and chronic health conditions, and the major reason for ICU admission based on a list of 50 operative and nonoperative diagnoses.[82] APACHE II scores were used to stratify patients for new therapy and evaluate resource utilization and efficiency.[82] Six years later a third validation was available in APACHE III, which offered options for an APACHE III score and predictive equations that may be linked to disease classification and patient location.[83] A new variable to APACHE III was location before ICU treatment, as patients transferred to the ICU from areas other than the emergency department have a slightly higher increased risk of death.[83] The current version, APACHE IV, was remodeled in 2006, which included the addition of new variables and a different statistical model.[79] APACHE IV offers hospital mortality predictions and is a suggested tool for benchmarking ICU performance in the United States.[79]

MPM

The Mortality Probability Model (MPM_0) was developed as an assessment of acuity and to predict hospital mortality.[84] Data on ICU admission and variables after 24 hours in the ICU were used to create a model to predict hospital mortality. Revisions to MPM occurred in 1993 (MPM II) and again in 2007 (MPM III).[85,86] MPM_0 characterized patients close to the time of admission and was based on age and 15 binary variables measured within 1 hour of ICU admission, whereas MPM_{24} included data within the first 24 hours of the ICU stay. Revised in 1993 using an international sample of patients, MPM_0 II is based on measurements obtained within the first hour of ICU admission.[85] In a 2007 updated model (MPM_0 III), code status was added to the variables captured in MPM_0 II, providing a more accurate comparison of observed versus expected outcomes.[86]

SAPS

Created in 1984, the SAPS used 14 easily identifiable variables, collected during the first 24 hours after ICU admission, to classify patients at risk for death.[87] The 1993 revision to build SAPS II included 17 variables and used logistic regression to assign weights to the variables, rather than clinical judgment as used in the older system.[88] The SAPS III admission score is based on data collected at ICU admission (±1 hour) consisting of 20 variables.[89]

All of the prediction models are subject to deterioration and require recalibration over time. Future use of large national and international data sets along with advances in computer science technology systems may aid in acceleration of this recalibration process. However, proceeding with caution is vital as data management systems capturing frequent changes in physiologic variables may alter the accuracy of the model.[90]

Organ Dysfunction Scoring Systems

Organ dysfunction/failure may be considered a process that can begin as mild dysfunction to progression of complete organ failure.[91] For some critically ill patients, a second or third organ failure may ensue, resulting in multiple-organ failure, a major cause of morbidity and mortality.[91] Several scoring models were developed to evaluate the presence and severity of organ dysfunction and include the Multiple Organ Dysfunction Score (MODS), the Sequential Organ Failure Assessment (SOFA), and the slightly more complex Logistic Organ Dysfunction System Score (LOD) (Table 67.3).

MODS is a scale to measure the severity of organ dysfunction in six organ systems: respiratory, renal, cardiovascular, hematologic, hepatic, and neurologic.[92] Each organ system is scored from 0 to 4 (0 is normal and 4 is the most severe dysfunction). The worst

TABLE 67.3 Organ Dysfunction/Failure Scoring Systems

Organ System	MODS[a]	SOFA[b]	LOD[c]
Respiratory	Pao_2/Fio_2 ratio	Pao_2/Fio_2 ratio Mechanical ventilation	$Paio_2/Fio_2$ ratio Mechanical ventilation
Cardiovascular	Pressure-adjusted HR	MAP Use of vasoactive agents	SAPS HR
Renal	Creatinine	Creatinine Urinary output	Creatinine Urinary output Urea
Hematologic	Platelets	Platelets	Platelets WBCs
Neurologic	GCS	GCS	GCS
Hepatic	Bilirubin	Bilirubin	Bilirubin Prothrombin time

score during the 24-hour period is used to calculate the overall score (0–24). A high MODS correlates to a higher mortality risk.[92]

Similar to MODS, SOFA counted the same six organ systems applying a score of 0 to 4 for each system.[91] One major difference between the two scoring systems is how the cardiovascular score is calculated. For the SOFA score, cardiovascular dysfunction/failure is based on the use of vasoactive agents.[91] MODS requires a calculation for pressure-adjusted heart rate which is the heart rate times the right atrial pressure (CVP) divided by the mean arterial pressure (MAP).[92] Higher SOFA scores and increases over time were associated with worse outcomes.

Unlike the MODS and SOFA scoring systems, the LOD score was designed to be measured only once in the first 24 hours of ICU admission, rather than repeated measures on subsequent ICU days.[93] The maximum LOD score is 22 with an individual organ score of 0 to 5 for renal, neurologic, and cardiovascular; 0 to 3 for pulmonary and hematologic; and 0 or 1 for hepatic.[93]

Organ dysfunction scores provide an objective measure arising from a potentially life-threatening insult. Application of these scores on ICU admission or on sequential ICU days can be used as a valuable prognostic tool. However, as safety and quality move toward early recognition and timely appropriate response to clinical deterioration regardless of location, scoring systems to identify patients at risk for clinical deterioration are becoming more commonplace among hospital care teams.

Scores for Early Detection of Critical Illness

Critical illness preceded by acute deterioration, owing to delayed recognition or suboptimal care, in hospitalized patients can put patients at risk of cardiopulmonary arrest, unplanned ICU admission, and poor outcomes.[94] Acute deterioration is often observed with changes in vital signs or alterations in mental status. Reasons for delays are generally confounded by limited resources, provider availability, and inadequate staff expertise to respond to the observed patient abnormalities. To aid in early recognition, real-time early warning scores (EWS) have been developed and used in health care settings as a means to provide prompt assessment and intervention in patients at risk for deterioration.[95] The easy to use bedside EWS tools have been modified to specific groups such as surgical patients and medical patients.[95,96] The Modified Early Warning Score (MEWS) was designed to identify medical patients at risk for deterioration.[97] Additionally, scores to aid in early detection of critical illness have been implemented in the prehospital setting. Developed by the Royal College of Physicians, the National Early Warning Score (NEWS) is a surveillance system for patients presenting acutely to the hospital, generating a clinician alert to assess and respond to acute illness.[98] NEWS is also recommended for use in the prehospital setting by primary care and ambulance services. EWS systems are convenient in identifying patients at risk or currently experiencing acute illness, alerting the clinical team for timely response and treatment.

Scoring Systems for Specific Conditions

Simple and practical scoring models have been developed using large databases to assess severity in specific conditions such as sepsis. For example, the Sepsis Severity Score was an internationally developed score containing 36 variables from 23,438 patients with severe sepsis whose data were entered into the Surviving Sepsis Campaign database.[99] Model development included 90% of the population with 10% applied to the validation model. Logistic regression was used to create a model to predict mortality specifically for severe sepsis patients. The Sepsis Severity Score is a sum of individual values with a median score of 56.3, median score of 55, with a range of minimum and maximum scores of 0 to 130.[99] The model performed well in regard to discrimination and calibration.[99]

Using analysis from several databases, a task force of 19 members from the ESICM and SCCM set out to update the sepsis and septic shock definitions. The authors proposed new sepsis definitions and use of a simple bedside clinical score termed quickSOFA (qSOFA) to identify adult patients with suspected infection who may require escalation of care and are more likely to have worse outcomes.[100] The qSOFA criteria require the patient to have at least two of the following: respiratory rate of 22 breaths/min or greater, altered mental status, or systolic blood pressure of 100 mm Hg or less.[100] Although large data sets were used to develop the new definitions and bedside score, the authors stress that the systemic inflammatory response syndrome criteria may still be useful for identification of infection. Early sepsis identification is key to PI. Conversely, patients meeting qSOFA criteria would indicate late identification and potentially poor outcomes.

Specific scoring systems may be incorporated into decision making to determine appropriate treatment options. For instance, extracorporeal membrane oxygenation (ECMO) among patients with acute respiratory distress syndrome (ARDS) using the PRedicting dEath for SEvere ARDS on VV-ECMO (PRESERVE) mortality risk score may be used to assess appropriateness for therapeutic options in acute lung injury treatment.[101] Schmidt et al. used eight ECMO parameters to develop a mortality risk score in patients with refractory ARDS treated with ECMO.[101] The PRESERVE score ranged from 0 to 14 points with a higher score indicating increased risk of death within 6 months of ICU disscharge.[101] The authors suggest that the PRESERVE score may be a useful tool for ICU physicians to define appropriate ECMO candidates in patients with severe ARDS.

These scoring systems need validation before they are widely used. Nonetheless, as clinical management and therapies advance, disease-specific scoring tools may inform clinicians about prognosis or offer decision support regarding whether or not to initiate highly specialized treatment modalities.

Summary and Conclusions

In the era of cost-effectiveness and high quality, ICUs seek solutions to objectively evaluate the quality of care delivered. Severity of illness scoring systems provide a valuable framework to characterize ICU patients for research, evaluate quality improvement programs and resource use, and benchmark performance. As critical care practice and therapies progress, the accuracy of prognostic models may not have the same level of exactness and subsequently underestimate mortality. Periodic testing and revisions may be needed, especially in diagnostic categories with significant improvements in early diagnosis, treatment, and advances in technological resources.

When selecting a scoring system, consideration should be given to the feasibility of data collection, particularly time to calculate the score and whether the model is openly available. One should

reflect on the patient population, choosing a scoring system based on general (medical) or specific conditions (cardiac surgery). Integrating PI process measures, severity scoring, and outcome measures that include length of stay, readmission, as well as mortality may reflect a more accurate assessment of the ICU quality of care delivered in the existing ICU environment.

Key Points

- High-quality health care consists of structure, process, and outcomes executed by a collaborative model.
- Governing agency missions embrace a patient-centered approach to provide safe, reliable, and efficient health care with specific prominence in critical care.
- Multiple national quality improvement campaigns, aimed at spreading best practices, led to a significant infection reduction in hospital acquired infections.
- Advancement in sepsis performance improvement has evolved to endorsed National Hospital Inpatient Quality Measures with mandated sepsis measure reporting for all U.S. hospitals.
- Structured multidisciplinary rounds using simple tools such as a checklist or a mnemonic to address key aspects of critical care contribute to better-quality ICU care delivery.
- Severity of illness scoring systems are commonly used in critical care research and less frequently in clinical practice to predict outcomes, whereas organ dysfunction scores provide a value to evaluate failure of organs owing to a life-threatening insult.
- Optimizing early warning scores to identify patients at risk for deterioration of their conditions or needed escalation of care has been used both in hospital and prehospital settings as a means of improving outcomes in the acutely critically ill patient.

Review Questions

1. According to the available literature, which of the following outcomes is most likely true concerning rapid response team (RRT) implementation?
   - **a.** A decrease in intensive care unit (ICU) admissions in some but not all studies
   - **b.** A decrease in incidence of severe sepsis in some but not all studies
   - **c.** A decrease in ST-segment elevation myocardial infarction (STEMI) mortality
   - **d.** RRT does not require education of the bedside providers outside the critical care environment.

   Answer: a. RRTs have been developed as a means to provide and deploy health care providers with critical care expertise to areas of the hospital during the early phase of potential deterioration in a patient's condition. The impact of RRTs, per clinical trials, has yielded mixed results, including a decrease in cardiac arrest and unplanned ICU admissions in some but not all studies (choice a correct). There has not been an impact of RRTs on the incidence of severe sepsis (choice b) or STEMI (choice c). Education for the bedside providers outside the ICU is essential to implement a rapid response team as RRT calls are commonly generated in medical and surgical areas of the hospital (choice d).
2. Which one of the following is most correct concerning prevention of ventilator-associated events (VAEs)?
   - **a.** Ventilator-associated pneumonia (VAP) requires mechanical ventilation for longer than 24 hours.
   - **b.** Bacteremia is a VAE.
   - **c.** Routine oral care is part of the ventilator bundle.
   - **d.** Choice of antibiotic for surgical prophylaxis of the postoperative mechanically ventilated patient is part of the ABCDEF bundle.

   Answer: c. Reducing VAEs in high-risk mechanically ventilated patients includes adherence to evidence-based interventions. The clinical definition of VAP requires patients be supported by mechanical ventilation for more than 48 hours (choice a). VAEs include VAP, peptic ulcer disease, gastrointestinal bleeding, aspiration, venous thromboembolic events, and obstacles to managing secretions (choice b). Routine oral care with 0.12% chlorhexidine is included in the ventilator bundle as an element to prevent VAEs (choice c correct). Antibiotic administration is not an element of the ABCDEF bundle. The A in the ABCDEF bundle is linked to Assess, prevent, and manage pain (answer d).
3. Which one of the following is true concerning prevention of catheter-associated urinary tract infections?
   - **a.** Consideration of alternatives to indwelling bladder catheter use in selected patients
   - **b.** Daily bladder antibiotic irrigation
   - **c.** Changing bladder catheters every 3 days
   - **d.** Aggressive hydration to increase urine flow

   Answer: a. (CAUTI)
   The Healthcare Infection Control Practices Advisory Committee guidelines include appropriate urinary catheter use, consideration of alternatives to indwelling urethral catheterization in selected patients, performing aseptic technique during catheter insertion, following proper catheter maintenance techniques, and integration of a formal hospital quality improvement program with necessary surveillance strategies (choice a correct). Choices b, c, and d have not been shown to prevent catheter-associated urinary tract infections.

Ethical Considerations in Managing Critically Ill Patients

JEFFREY P. BURNS AND ROBERT D. TRUOG

CHAPTER OUTLINE

Informed Consent and Decision Making in Critical Care
- What Is the Distinction Between Competency and Decisional Capacity?
- Who Gives Consent?
- Who Obtains Consent and, Ideally, When?
- Is the Physician an Advocate or Neutral Party in the Informed Consent/Decision-Making Process?
- What Treatments May Be Withheld or Withdrawn?
- Who Ultimately Decides When There Are Conflicts About the Goals of Care?

Practical Aspects of Withdrawing Life-Sustaining Treatments in the ICU
- Team Preparation
- Family Preparation
- What Is the Most Compassionate Means of Withdrawing Mechanical Ventilation With the Intention of Allowing the Patient to Die?
- How Should Signs of Apparent Patient Suffering Be Treated After Mechanical Ventilation Is Withdrawn?
- How Much Is Too Much Sedation and Analgesia for the Dying Patient in the ICU After the Withdrawal of Mechanical Ventilation?

Managing critically ill patients raises ethical considerations of some kind in nearly every case. The goal of this chapter is to present a focused review of select essential ethical concepts frequently confronted in the practice of critical care medicine, with a special emphasis on how to address these concerns in daily practice. There are many other helpful resources for those wishing a deeper review of the ethical, philosophical, and legal literature underpinning the concerns raised in this chapter.[1]

Informed Consent and Decision Making in Critical Care

The conceptual foundation of informed consent is that patients have the sole right to determine what will be done with their bodies. This includes a firm constitutional right, at least in the United States, that a competent adult patient has the right to accept or refuse any medical or surgical treatment, even if it is potentially lifesaving. From a long history of famous legal cases in the United States on informed consent for medical procedures, patient in effect give their permission "to be touched" after the informed exercise of a choice, and that entails an opportunity to evaluate knowledgeably the options available and the risks and benefits associated with each.[2]

Ideally, informed consent is an ongoing process inherent in patient care that builds trust and reduces disappointment if the intended outcome does not result. By this formulation, informed consent is an ongoing discussion about the general issues of managing an illness as well as specific procedures being proposed.

What Is the Distinction Between Competency and Decisional Capacity?

The essential criteria for informed consent are that it is given voluntarily, without coercion; it may be withdrawn at any time; and it is given by a patient who is competent to understand the nature, and carefully evaluate the consequences of the proposed therapy, in light of his or her life preferences and values.

Although "competent" is the term used most commonly to convey the ability of the patient to reason adequately in this context, in fact only a court of law can determine whether a patient remains competent to make medical decisions. As a practical matter for clinicians in the intensive care setting, the question is framed in terms of whether the patient has "decisional capacity" to give informed consent. One usually does not need a lawyer or a psychiatrist to determine that a patient has or does not have decisional capacity; in most cases this is a determination that experienced, board-certified intensivists can make on their own.

The legally relevant criteria for assessing decision-making capacity involve whether the patient is able do the following:

1. Communicate a choice, as in clearly indicating a preferred treatment option
2. Understand the relevant information, as in grasping the fundamental meaning of the information communicated by the physician
3. Appreciate the situation and its consequences, as in acknowledging the medical condition and the likely consequences of treatment options
4. Reason about treatment options, as in engaging in a rational process of manipulating the relevant information[3]

Who Gives Consent?

In the intensive care setting the ability of critically ill patients to participate in decision making often fluctuates over the course of their illness trajectory. When patients lack the decisional capacity necessary for informed consent, decisions must be made by a surrogate. Ideally, the patient will have completed an advance directive, indicating the individual that he or she has entrusted with making these decisions. This document is also known as a health care proxy or durable power of attorney for health care decisions. In many states, this document is often supplemented by a living will, which provides that surrogate decision maker with specific information about the values and preferences of the patient with regard to the use of resuscitation and other forms of life-sustaining interventions.

If the patient has not designated a durable power of attorney for health care, then states vary on the procedure to be followed. Some stipulate a specific hierarchy for determining the surrogate, beginning with the spouse, followed by adult children, siblings, and so on. Others allow more flexibility and permit the clinicians to choose a surrogate who knows the patient well and who is invested in promoting the patient's well-being, even if that person is not legally related to the patient. When no surrogates are available, the hospital may seek to have a legal guardian appointed by the court, or in some cases the clinicians may make decisions based on their perceptions of the patient's best interests, often assisted by hospital chaplains or the hospital ethics committee.

Who Obtains Consent and, Ideally, When?

The patient's attending physician is responsible for obtaining the patient's informed consent. Other physicians may assist in this process (i.e., residents, or "house staff"), but it is the responsibility of the attending physician to ensure that those involved in obtaining consent are sufficiently knowledgeable about the procedure to adequately communicate the risks, benefits, and alternatives.

All patients provide a general consent for treatment at the time they are admitted to a hospital, and some hospitals consider this sufficient for all of the diagnostic and therapeutic procedures performed in the intensive care unit (ICU). However, both The Joint Commission and the Centers for Medicare and Medicaid Services now stipulate that best practices are associated with each institution having a written policy on what procedures require a separate and specific informed consent.

What Information Must Be Conveyed in the Informed Consent Process?

The classic formulation of the information that should be conveyed in the informed consent discussion includes the following:

1. Risks and benefits of the proposed procedure
2. Alternatives to the proposed procedure
3. Risks and benefits of alternatives to the proposed procedure
4. Risks and benefits of doing nothing

The Joint Commission emphasizes that the informed consent process is far more than obtaining a signature on the way to the procedure. Ideally, the signature should be merely the final step or culmination of a process during which the patient and the physician have the time to ask and answer questions over a period of time that may involve several conversations.[4]

Research suggests that when informed consent is obtained, the information provided by health care professionals is often unclear or insufficient, leading to misunderstanding, a worse treatment response, and even litigation. Studies in the literature also demonstrate that asking the patient to recount ("teach-back") what they have been told in the informed consent discussion adds to comprehension.[5] Importantly, the teach-back method not only helps to determine whether patients understand the risks, benefits, and alternatives to treatment, but it also helps to focus patients on what's important to them in a given context.

Is the Physician an Advocate or Neutral Party in the Informed Consent/ Decision-Making Process?

Stated another way, what is the ideal physician-patient decision-making relationship in critical care?[6] The surrogate decides independently? The surrogate decides after considering the physician's recommendation? There is "shared" responsibility for decision making? The physician decides after considering the surrogate's opinion? The physician decides independently?

A joint statement by the American College of Critical Care Medicine and American Thoracic Society Ethics Committees recently addressed this issue and endorsed the following recommendations, among several others[6,7]:

1. Shared decision-making is a collaborative process that allows patients, or their surrogates, and clinicians to make health care decisions together, taking into account the best scientific evidence available, as well as the patient's values, goals, and preferences.
2. Clinicians should engage in a shared decision-making process to define overall goals of care (including decisions regarding limiting or withdrawing life-prolonging interventions) and when making major treatment decisions that may be affected by personal values, goals, and preferences.
3. Clinicians should use as their "default" approach a shared decision-making process that includes three main elements: information exchange, deliberation, and making a treatment decision.
4. A wide range of decision-making approaches are ethically supportable, including patient- or surrogate-directed and clinician-directed models. Clinicians should tailor the decision-making process based on the preferences of the patient or surrogate.

What Treatments May Be Withheld or Withdrawn?

It is ethical and legal to withhold or withdraw any medical treatment when the patient's family, as informed by a recommendation from the clinical team, determines that the burdens of such treatments outweigh the benefits.

Any medical intervention, from extracorporeal membrane oxygenation and pacemakers to the use of physiologic monitors, may be withheld or withdrawn from the dying patient in the ICU.

Who Ultimately Decides When There Are Conflicts About the Goals of Care?

In the United States there is a firmly established and well-defined legal and ethical consensus that an adult patient with decisional capacity, or the adult patient's legal surrogate if the patient lacks decisional capacity, has the right to refuse any medical and/or surgical intervention, even if his or her physician believes the proposed therapy to be potentially lifesaving treatment. That is, patients have a strong "negative" right to refuse even life-sustaining

treatment—which again in legal parlance is the "right to be free from unwanted bodily touching."

But do patients' or their legal surrogates have an equally strong right to demand any therapy, up to and including potentially life-sustaining treatment? There is no consensus on this point, and the management of requests by patients or surrogates for treatments that clinicians believe should not be administered is controversial.

A joint statement by the American Thoracic Society, American Association for Critical Care Nurses, American College of Chest Physicians, European Society for Intensive Care Medicine, and Society of Critical Care recently addressed this issue and endorsed the following recommendations, among others[6]:

1. Institutions should implement strategies to prevent intractable treatment conflicts, including proactive communication and early involvement of expert consultants.
2. The term "potentially inappropriate" should be used, rather than futile, to describe treatments that have at least some chance of accomplishing the effect sought by the patient, but clinicians believe that competing ethical considerations justify not providing them. Clinicians should explain and advocate for the treatment plan they believe is appropriate. Conflicts regarding potentially inappropriate treatments that remain intractable despite intensive communication and negotiation should be managed by a fair process of conflict resolution; this process should include hospital review, attempts to find a willing provider at another institution, and opportunity for external review of decisions. When time pressures make it infeasible to complete all steps of the conflict resolution process and clinicians have a high degree of certainty that the requested treatment is outside accepted practice, they should seek procedural oversight to the extent allowed by the clinical situation and need not provide the requested treatment.
3. Use of the term "futile" should be restricted to the rare situations in which surrogates request interventions that simply cannot accomplish their intended physiologic goal. Clinicians should not provide futile interventions.

Practical Aspects of Withdrawing Life-Sustaining Treatments in the ICU

Observational studies over the past 2 decades of death in the ICU reveal a strikingly similar pattern; nearly two-thirds of all deaths in adult, pediatric, and neonatal ICUs in North America and Europe follow the withholding or withdrawal of life-sustaining treatments.[8]

The withdrawal of life-sustaining treatment in the ICU with the intention of allowing the patient to die raises difficult and rapidly evolving clinical and ethical decision making more profoundly than nearly any other context. This is especially the case with the abrupt and unpredictable change in patient symptoms as assisted ventilation is withdrawn. Failure of the clinical team to anticipate many different possible patient responses to the cessation of life-sustaining treatment, and especially assisted ventilation, and have in place a flexible and effective plan of care to address changes as they arise, can lead to abrupt decisions that leave both the patient's family and clinicians with lasting emotional distress that optimal and ethical end-of-life care was not provided. How can intensive care clinicians provide care that effectively responds to the evolving physiologic, emotional, and spiritual needs of the patient and their family members in a timely manner, and within an ethical framework consistent with the values of the medical profession and society in which we live?

Many detailed articles in the literature well document comprehensive palliative care for the dying patient. However, the peculiar practical issues in providing palliative care to critically ill patients in the ICU are often not well detailed. The guideline for the withdrawal of mechanical ventilation presented here is adapted from the consensus statement by the American College of Critical Care Medicine.[9]

Team Preparation

Before the withholding or withdrawal of life-sustaining treatments, the attending physician, bedside nurse, and other members of the care team such as clergy and psychosocial experts, should meet to anticipate, plan, and coordinate their efforts during the withdrawal of life-sustaining treatments just as a good resuscitation requires a coordinated team effort.

A guiding concept in determining which treatments to continue and which treatments to withhold or withdraw in this process is that any intervention that appears to promote the patient's comfort or dignity (as well as ameliorate emotional, psychological, or spiritual concerns) should be continued. Those that do not appear to promote the patient's comfort or dignity should be withdrawn.

Family Preparation

Next, anticipatory guidance to prepare the family before the withdrawal of life-sustaining treatments is essential. The attending physician and bedside nurse should meet with the family to provide a brief but clear overview about the process before the withdrawal of life-sustaining treatments, and assurance that symptoms of patient suffering will be treated. Although guiding the family about what to expect cannot alleviate all of their anxiety around the process, failure to guide them at all will surely only increase anxiety and anguish.

Predictions about the patient's clinical course after withdrawal of mechanical ventilation or other forms of life-sustaining treatment are best avoided, as these predictions are often inaccurate and may result in a substantial loss of credibility when expectations about death or the timing of death are in error. The overarching objective at this time is to assure the family that although certain life-sustaining treatments will be withdrawn, care of the patient will never be withdrawn. Thus, in answer to questions about how long the patient might live, for example, it is important to refocus and reassure the family by comments such as "We think it is unlikely that your loved one will survive after the ventilator is withdrawn, but whether he breathes only for a short time or for a very long time we can assure you that we will treat symptoms that appear to be causing him discomfort."

At times it will be necessary for the clinicians to anticipate, ask, and answer concerns or questions that the family appears to be afraid or unable to verbalize. For example, it may be helpful for the attending physician to volunteer, even if not explicitly asked, the comment, "Sometimes after the ventilator is withdrawn patients experience a change in skin color, or unusual breathing noises, and this is to be expected and our job is make sure that your loved one does not experience symptoms of suffering or discomfort. If we see signs of discomfort, we will treat them."

Families should be invited to participate in activities to relieve their loved one's discomfort, such as repositioning, or mouth care, or bathing. They should be encouraged to participate in assessment

of the patient's pain or discomfort, and they should also be encouraged to provide other means of comfort that may have special meaning for them or the patient, such as holding hands, playing favorite music, or wrapping their loved one in a special blanket.

What Is the Most Compassionate Means of Withdrawing Mechanical Ventilation With the Intention of Allowing the Patient to Die?

An artificial airway may be removed (extubation), or the patient may have supplemental oxygen and/or positive-pressure ventilation gradually reduced at some rate determined by the physician when the artificial airway will remain in the trachea through the dying process (a procedure known as "terminal wean").

The method of withdrawal should be guided by the specific circumstances of the patient. For example, a patient likely to experience significant hemoptysis may benefit from a terminal wean with the gradual reduction in the fraction of inspired oxygen and/or ventilator rate at a pace not faster than pharmacologic sedation is administered to treat objective signs of distress from the effects of hypoventilation and hypoxia.

Notably, prior research on alveolar anoxia determined that the most rapid descent into unconsciousness with the least agitation occurs when hypoxia is allowed to progress in the face of normocarbia. On the other hand, when the plan is to extubate the trachea as the mode of mechanical ventilation withdrawal, then it will most commonly be necessary to administer additional analgesia and sedation before extubation in anticipation of respiratory distress that may result from the abrupt removal of assisted ventilation.

How Should Signs of Apparent Patient Suffering Be Treated After Mechanical Ventilation Is Withdrawn?

The abrupt onset of respiratory distress as mechanical ventilation is withdrawn, coupled with the uncertainty on how effectively and how long the patient may be able to breathe without mechanical ventilation, makes dosing medications for symptom relief especially difficult for clinicians. Administering too much sedation will likely compromise effective respirations even further and thus hasten death, whereas administering too little sedation will abandon a dying patient to untreated suffering, often making it difficult to find an appropriate middle ground.

First, palliative measures should be comprehensive and not rely only on medications. Frequent repositioning, mouth care, or massage may be far more effective in providing symptom relief to the dying patient than exclusive reliance on analgesics and sedatives as the foundation of the palliative care plan.

Second, the clinician's obligation is to treat objective signs of discomfort as experienced by the patient. The distress of the family should be addressed by continued reassurance and emotional support. This situation often arises during the evolving and typically unpredictable changes in the breathing pattern of the dying patient. These changes in breathing pattern are not necessarily either easily treated or uncomfortable for the patient. For example, all gasping does not need to be treated with escalating does of sedatives or narcotics; ideally the decision should be determined by a consensus between the family and clinicians at the bedside on whether the patient's activity appears to be causing, or is a manifestation of, suffering.

Third, the current ethical and legal guidelines place importance on the intentions of clinicians in administering analgesics and sedatives at the end of life. Specifically, clinicians should administer doses that are intended to relieve pain and suffering but not intended to directly cause death. One should not, however, give more sedation than what the patient needs to be comfortable (be prepared for the request, "Please, can't we just get this over with?").

How Much Is Too Much Sedation and Analgesia for the Dying Patient in the ICU After the Withdrawal of Mechanical Ventilation?

Although it is not universally accepted, the doctrine of double effect is a common framework to guide clinicians in determining how much is too much sedation and analgesia for the dying patient. The doctrine of double effect states that five conditions must hold for an action to be considered morally acceptable, even if it should hasten the death of another. Those five conditions, in the case of administering sedation or analgesia in the ICU to a dying patient following the withdrawal of mechanical ventilation, are as follows:

1. The action must be morally good or neutral. Most would agree that assuring that a dying patient is treated for pain or suffering is a morally good or neutral action.
2. The good effect is intended. That is, the clinician intends to relieve pain and suffering by administering sedation and analgesia in this context.
3. The bad effect is merely foreseen, but not intended. The clinicians foresee that by administering sedation and analgesia in this context the patient's death may be hastened, but their intention is, or should only be, the relief of pain and suffering and not the patient's death.
4. The bad effect cannot be the means to the good effect. The clinician must not commit an action that is clearly intended to cause the patient's death as the means to stopping or relieving the patient's pain and suffering. For example, by the doctrine of double effect one would not be allowed to administer a neuromuscular blocking agent or a potassium bolus in this context because these agents have no sedative or analgesic properties and thus the only mechanism by which they relieve the patient's suffering is by causing the death of the patient.
5. Proportionality—the good must outweigh the evil permitted. Here the doctrine stipulates it must be better, all things considered, to allow the good effect (action) to be permitted even though some bad consequences (hastening of death) also occur.

What, Then, Is—or Should Be—the Goal of Using Sedatives and Analgesics in This Context?

If one adheres to the doctrine of double effect as a guiding framework in titrating sedatives and analgesics to the dying patient, the goal is only to treat objective signs of discomfort that evolve; it is not to bring about a certain outcome. Stated another way, the target is to make the patient comfortable; the target is not some arbitrary maximum dose and the target is not the death of the patient.

Thus if there are no objective signs of discomfort and the patient breathes effectively after extubation, despite anticipation that death would immediately follow withdrawal of ventilation, there should be no panic among the clinicians that something is wrong or that further sedatives or analgesics must be administered. If the patient is unexpectedly breathing comfortably after extubation, continue all other nonmedication measures of palliative care and provide ongoing and comprehensive support for the family. On the other hand, it may take multiple boluses of escalating doses of sedatives and analgesics to treat clear signs of discomfort after extubation to keep the patient comfortable.

By the doctrine of double effect framework, the frame of mind of the family and of the clinicians before the withdrawal of life-sustaining treatments is that the process of dying will proceed at its own time and place. The response of the clinicians should be based solely on how the patient evolves, and it is not the intention in administering sedatives and analgesics to ensure that a certain outcome evolves.

Intentions are, of course, essentially subjective and private, and thus not easily externally validated. As such, the only way to infer the nature of a clinician's intentions are by self-report and an analysis of his or her actions. Accordingly, documentation of the clinician's intentions in the patient's chart is an important part of providing end-of-life care. Correspondingly, sedation and/or analgesia should be titrated to effect (importantly, some objective sign or symptom suggestive of pain or suffering), and the dose should not be limited solely on the basis of "recommended" or "suggested" doses and the care provided should be clearly documented as such.

The concept of "anticipatory dosing" (as opposed to reactive dosing) should also guide clinicians in the use of sedation and analgesia at the end of life. The rapid withdrawal of mechanical ventilation is an example of the need for anticipatory dosing. At the time of ventilator withdrawal, the clinician can anticipate that there will be a sudden increase in dyspnea. It is not sufficient simply to respond to this distress with titrated doses of an opioid (reactive dosing). Rather, clinicians should anticipate that the abrupt withdrawal of assisted breathing will trigger increased respiratory distress and therefore they should provide adequate sedation or analgesia beforehand (anticipatory dosing). As a general rule, the doses of medication that the patient has been receiving hourly should be increased by twofold or threefold and administered acutely before withdrawing mechanical ventilation.

What Basic Documentation Is Essential?

- A brief description must be placed in the patient's medical record of the decision-making process that led to the withholding or withdrawal of life-sustaining treatment, and the palliative care provided.
- For example, when describing the decision-making process, one should note the date and time of the family meeting, those present, and some statement that conveys that there is "agreement between the family members and the clinician team that the burdens of life-sustaining treatments outweigh any remaining benefit and that the decision has been made to withdraw life-sustaining treatments at this time."
- In describing the palliative care measures provided, it is important to briefly document the rationale used to titrate sedation and analgesia, if administered. For example, "Signs of suffering were noted with the onset of gasping respirations and increased work of breathing after the patient was extubated. Morphine and versed were ordered by Dr. JB and administered by LP RN and titrated to treat these signs of patient suffering. The patient's signs of suffering were relieved after three boluses over 20 minutes and the patient expired at 9:00 a.m."

Key Points

- The conceptual foundation of informed consent is that patients have the sole right to determine what will be done with their bodies. This includes an established constitutional right, at least in the United States, that a competent adult patient has the right to accept or refuse any medical or surgical treatment, even if it is potentially lifesaving.
- Ideally, informed consent is an ongoing process inherent in patient care that builds trust and reduces disappointment if the intended outcome does not result. By this formulation, informed consent is an ongoing discussion about the general issues of managing an illness as well as specific procedures being proposed.
- The legally relevant criteria for assessing decision-making capacity involve whether the patient is able to (1) communicate a choice, as in clearly indicating a preferred treatment option; (2) understand the relevant information, as in grasping the fundamental meaning of the information communicated by the physician; (3) appreciate the situation and its consequences, as in acknowledging the medical condition and the likely consequences of treatment options; and (4) reason about treatment options, as in engaging in a rational process of manipulating the relevant information.
- The classic formulation of the information that should be conveyed in the informed consent discussion are the risks and benefits of the proposed procedure; alternatives to the proposed procedure; risks and benefits of alternatives to the proposed procedure; and risks and benefits of doing nothing.
- It is ethical and legal to withhold or withdraw any medical treatment when the patient, or the patient's legal health care surrogate, as informed by a recommendation from the clinical team, determines that the burdens of such treatments outweigh the benefits. Any medical intervention, from extracorporeal membrane oxygenation and pacemakers to the use of physiologic monitors, may be withheld or withdrawn from the dying patient in the ICU.
- A 2016 joint statement by the American Thoracic Society, American Association for Critical Care Nurses, American College of Chest Physicians, European Society for Intensive Care Medicine, and Society of Critical Care recently addressed the issue of how clinicians should respond to requests for "potentially inappropriate care."[10]
- The practical issues in providing palliative care to critically ill patients in the ICU are comprehensively well outlined in a 2008 consensus statement by the American College of Critical Care Medicine.

Review Questions

1. Who decides?

A 70-year-old man has a prosthetic aortic valve placed and subsequently requires a pacemaker for third-degree heart block. He is poorly compliant with anticoagulation regimen and has multiple embolic strokes over the next decade, leaving him unresponsive. His wife requests disabling of the pacemaker on the grounds that the patient would not choose to continue living in this condition. The patient's only child has been vigilant at the patient's bedside and he advocates that all life-sustaining treatments be continued. The patient appointed his wife the durable power of attorney for his health care several years before his current neurologic decline.

Which answer is correct?

a. The pacemaker must be continued because "internal" treatments cannot be legally withdrawn.
b. The pacemaker must be continued because stopping it would be euthanasia (illegal).
c. The pacemaker cannot be discontinued without a court order.
d. The pacemaker may be discontinued, as the wife is the patient's legal surrogate.
e. The pacemaker must be continued, but the batteries can be allowed to expire without replacement.

Answer: d. When patients lack the decisional capacity necessary for informed consent, decisions must be made by a surrogate. Ideally, the patient will have completed an advance directive, indicating the individual that he or she has entrusted with making these decisions. This document is also known as a health care proxy or durable power of attorney for health care decisions.

2. Which answer is correct regarding the right to refuse life-sustaining treatment?

a. Patients, or their legally authorized surrogates, have a virtually unlimited right to refuse unwanted life-sustaining treatments.
b. There is a difference between withholding and withdrawing treatment.
c. All treatments may be withheld or withdrawn except extracorporeal membrane oxygenation.
d. All treatments may be withheld or withdrawn except pacemakers.

Answer: a. In the United States there is a firmly established and well-defined legal and ethical consensus that an adult patient with decisional capacity, or the adult patient's legal surrogate if the patient lacks decisional capacity, has the right to refuse any medical and/or surgical intervention, even if the patient's physician believes the proposed therapy to be potentially lifesaving treatment.

3. Which, if any, of the following choices represents excellent end-of-life care?

a. No morphine
b. Morphine followed by potassium chloride
c. Large bolus of morphine before extubation
d. Neuromuscular blocking agent before extubation
e. Titrated administration of morphine

Answer: e. Correspondingly, sedation and/or analgesia should be titrated to effect (importantly, some objective sign or symptom suggestive of pain or suffering), and the dose should not be limited solely on the basis of "recommended" or "suggested" doses and the care provided should be clearly documented as such.

Concluding Thoughts

Overview

An admission to the intensive care unit (ICU) is recognized by both the lay public and medical professionals to be a life-threatening event in most circumstances that is immediately made more distressing and sinister by the onset of delirium and severe sleep derangements during the ICU stay. Upon survival, however, these worries are often replaced over the ensuing months and years by mental health disturbances that can be crippling to survivors. We are now aware of the sometimes life-changing ramifications of brain and behavioral disorders sustained by ICU survivors. In the past 15 or so years, data have been published that clearly illustrate a spectrum of acquired or exacerbated "neck-up" disorders that often dismantle the lives of these patients and seriously delay their recovery. Most notable among these disorders is a potentially life-altering "dementia-like" brain injury that occurs in 60% to 80% of ICU survivors that is most often characterized by memory deficits and executive dysfunction. These problems have real-world implications because they diminish patients' ability to work, drive, shop, monitor finances, and remember the names of their friends, relatives, and coworkers. These extremely troublesome neuropsychological deficits are compounded by mood disorders such as major depression and posttraumatic stress disorder (PTSD). These two diagnoses (depression and PTSD) are underdiagnosed despite their occurrence in 20% to 30% and 10% to 20% of ICU survivors, respectively. As a profession, we are just beginning to address the risk factors for these newly acquired diseases.

Having acknowledged the preceding realities of the states of survival of critical illness, it is also true that advances in clinical medicine have resulted in dramatic improvements in survival in a host of medical conditions, such as acute respiratory distress syndrome (ARDS) and sepsis. In general, 1- to 3-month mortality rates for both of these common ICU admission diagnoses in most cohorts are now in the 20% to 35% range, whereas in the 1990s these mortality rates were in the 40% to 60% range. As a result of the increased confidence in survival, both the lay public and health care professionals are now increasingly focused on preservation of cognitive abilities, prevention of functional decline, and the quality of life among patients who survive critical illness.[1–5] The potential of being left cognitively impaired is a major determinant of patients' treatment preferences at the end of life, with 9 of every 10 patients preferring death to severe cognitive impairment.[6] In support of this reality, in a report from the international "Surviving Intensive Care" 2002 Roundtable Conference held in Brussels,[7] the need for future investigations in neurocognitive abnormalities among survivors of intensive care received the strongest recommendation from the international panel of experts. Physicians and health care providers in ICUs are accustomed to recognizing multiple-organ dysfunction syndrome (MODS),[8–11] with therapy focused on the causes and treatment of respiratory, cardiovascular, renal, and hepatic dysfunction. There are increasing data on the syndrome of brain dysfunction during and after the ICU.[12] This chapter focuses on the cognitive and mental health disturbances of critical illness, with emphasis on delirium and sleep disturbances during critical illness, as well as a brief discussion of PTSD, long-term cognitive impairment (LTCI), and depression after critical illness.

Acute Brain Dysfunction or Delirium

Definition

Delirium is defined by American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 5th revised edition (DSM-V),[13] as a disturbance in attention and awareness that develops over a short period of time and tends to fluctuate in severity during the course of a day.

The new DSM-5 criteria shift the core feature of delirium from awareness to attention owing to the recognition that consciousness was difficult to assess objectively. The European Delirium Association and American Delirium Society proposed a more inclusive interpretation of the DSM-5 criteria, suggesting that patients who are not comatose but have impaired arousal, resulting in an inability to engage in cognitive testing or interview, must be understood as effectively having inattention to increase patient safety through broader delirium prevention and identification.[14]

Many different terms have been used to describe this spectrum of cognitive impairment in critically ill patients, including ICU psychosis, ICU syndrome, acute confusional state, septic encephalopathy, and acute brain failure.[15–18] The current consensus of many authorities is to use the unifying term *delirium* and subcategorize according to the level of alertness (hyperactive, hypoactive, or mixed).[19] We take this approach in this chapter.

Prevalence and Subtypes

Although the prevalence of delirium in medical ICU cohort studies has been reported to be between 20% and 80%,[20–22] more general ranges are practical depending on the severity of illness and the delirium detection instrument used, such as 40% to 60% in nonventilated and 60% to 80% in ventilated ICU patients.[23] Unfortunately, because delirium is usually "quietly" manifested by negative symptoms, it remains unrecognized by the clinician in a majority of the patients experiencing this complication,[24,25] and it may be incorrectly attributed to dementia, depression, or just an "expected" occurrence in the critically ill, elderly patient.[24] Peterson and associates reported on delirium subtypes from a cohort of ventilated and nonventilated ICU patients in whom delirium was monitored. They found the rates of these subtypes in the ICU to be 1.6% for hyperactive, 43.5% for hypoactive, and 54.1% for mixed.[26] Pandharipande et al. showed similar results in surgical and trauma patients, in whom hypoactive delirium (64% and 60%, respectively) was significantly more prevalent than the mixed (9% and 6%) or the pure hyperactive delirium (0% and 1%).[27]

Hyperactive delirium, which is rare in the pure form and associated with a better overall prognosis,[28] is characterized by agitation, restlessness, attempting to remove catheters or tubes, hitting, biting, and emotional lability.[19,29] This subtype was in the past referred to by the misnomer "ICU psychosis." Hypoactive delirium, on the other hand, is very common and in many circumstances actually more deleterious for the patient in the long run.[28,30] Unfortunately, it remains unrecognized in 66% to 84% of patients, whether being treated in the ICU, hospital ward, or emergency department.[25,31–33] This delirium subtype is characterized by withdrawal, flat affect, apathy, lethargy, and decreased responsiveness.[28,34,35] Because of the fluctuating nature of delirium, patients may present with a mixed clinical picture or may sequentially experience both of these subtypes. Many critical care providers would have the incorrect impression that hyperactive delirium is far more common, perhaps because affected patients attract attention because of their immediate threat to self and others. Unless routine monitoring for delirium is implemented,[36,37] the majority of delirium episodes, especially the "quiet" (hypoactive) form, will be missed. Another categorization scheme was proposed by Ouimet and colleagues,[38] who evaluated 600 ICU patients for symptoms of delirium and categorized them according to the number of symptoms present. Patients with no symptoms were considered to have "no delirium," those with four or more symptoms to have "clinical delirium," and those with one to three symptoms, to have "subsyndromal delirium.'[39] Subsyndromal delirium has also been associated with worse post-ICU outcomes.[40]

Prognostic Significance

The consequences of this brain dysfunction are important. Delirium itself is a strong predictor of increased length of mechanical ventilation, longer ICU and hospital stays, increased cost, long-term cognitive impairment, and mortality.[41–45] In non-ICU populations, the development of delirium in the hospital is associated with an in-hospital mortality rate of 25% to 33%, prolonged hospital stay, and three times greater likelihood of discharge to a nursing home. It is also an independent predictor of the combined outcome of death or nursing home placement.[42,46–48] Among medical ICU patients, delirium has been shown to be a strong predictor of increased duration of mechanical ventilation, longer length of ICU stay, higher costs, prolonged neuropsychological dysfunction, and even death.[41,42,45,49,50] Ely et al. showed that the majority of ICU delirium cases occurred soon after admission, with an average time of onset between the second and the third day with a mean duration of 3.4 ± 1.9 days. In this study, delirium was the strongest predictor of hospital length of stay, even after adjusting for severity of illness, age, gender, race, and days of psychoactive drug use.[41]

Delirium has been a strong risk factor for mortality.[42,51] Three separate cohort studies have shown that the duration of delirium (in a dose-dependent sort of relationship) is an independent predictor of increased subsequent death, with the most commonly cited finding being that every day a patient spends in ICU delirium portends a 10% higher risk of death even after adjusting for relevant covariates, such as severity of illness, age, psychoactive medication use, and coma.[42,45,51] The relationship between the duration of delirium and mortality was nonlinear, with a greater effect observed earlier in the course of delirium. These data suggest that the harm of delirium may occur early in the course of brain dysfunction for ICU patients.[45] Conversely, Klein Klouwenberg et al. speculated that the increased mortality could be mediated through a prolonged ICU length of stay, rather than a direct effect on the daily risk of death, although longer duration of delirium (>2 days) still had some attributable mortality risk.[52] Nonetheless, a meta-analysis of 28 studies with ICU patients consistently demonstrated a higher a risk of in-hospital death associated with delirium (risk ratio 2.19, 95% confidence interval [CI] 1.78–2.70, $P < 0.001$).[53] In addition, it is now shown that the duration of delirium is an independent predictor of LTCI in general medical and surgical ICU patients who in the past were not suspected of having long-term dementia-like abnormalities.[54]

Pathophysiology

The mechanisms of delirium remain a very promising area of neuroscientific study[55] and likely relate to those factors leading to LTCI, as noted in the following text.

Neurotransmitter Hypothesis

From a neuroscience perspective, delirium is thought to be related to imbalances in the synthesis, release, and inactivation of neurotransmitters modulating the control of cognitive function, behavior, and mood.[28,35] Three of the neurotransmitter systems involved in the pathophysiology of delirium are dopamine, gamma-aminobutyric acid (GABA), and acetylcholine.[17,56,57] Whereas dopamine increases excitability of neurons, GABA and acetylcholine decrease neuronal excitability.[17] An imbalance in one or more of these neurotransmitters results in neuronal instability and unpredictable neurotransmission. In general, an excess of dopamine and depletion of acetylcholine are two major physiologic problems believed to be central to delirium.[58] Other neurotransmitter systems thought to be involved in the development of delirium are serotonin imbalance, endorphin hyperfunction, and increased central noradrenergic activity.[28,56]

Neuroinflammatory Hypothesis

Other factors thought to be mechanistically deliriogenic in ICU patients are inflammatory abnormalities induced by endotoxins and cytokines.[59,60] The inflammatory mediators produced in sepsis, such as tumor necrosis factor α (TNF-α), interleukin (IL)-1, and other cytokines and chemokines, initiate a cascade that leads to endothelial damage, thrombin formation, and microvascular compromise.[61] Animal models show that these inflammatory mediators cross the blood-brain barrier,[62] increase vascular permeability in the brain,[63] and result in electroencephalography (EEG) changes consistent with those seen in septic patients with delirium.[64,65] Release of inflammatory mediators may occur from (1) decreased cerebral blood flow, a result of the formation of microaggregates of fibrin, platelets, neutrophils, and erythrocytes in the cerebral microvasculature; (2) cerebral vasoconstriction occurring in response to α_1-adrenergic receptor activity[66]; or (3) interference with neurotransmitter synthesis and neurotransmission.[67]

Impaired Oxidative Metabolism Hypothesis

One hypothesis attempts to explain acute delirium as a behavioral manifestation of a "widespread reduction of cerebral oxidative metabolism resulting in an imbalance of neurotransmission."[68] On the basis of a series of investigations in which they evaluated delirious patients using EEG, Engel and Romano[69] postulated that delirium is a state of "cerebral insufficiency"—that is, a global failure of cerebral oxidative metabolism. Their work showed that delirium is associated with diffuse slowing on EEG, a finding believed to represent a reduction in brain metabolism.

Cholinergic Deficiency Hypothesis

Blass and colleagues[70] offered a possible link between the state of cerebral insufficiency proposed by Engel and Romano[69] and the hypothesis of cholinergic blockade by suggesting that impaired oxidative metabolism in the brain results in a cholinergic deficiency. The finding that hypoxia impairs acetylcholine synthesis supports this hypothesis.[71] This reduction in cholinergic function leads to an increase in the level of glutamate, dopamine, and norepinephrine in the brain. In addition, serotonin and GABA levels are reduced; all of these changes contribute to delirium.

Large Neutral Amino Acid Hypothesis

Changes in the plasma levels of various amino acid precursors of cerebral neurotransmitters may affect their function, thus contributing to the development of delirium.[72] The amino acid entry into the brain is regulated by a sodium-independent large neutral amino acid transporter type 1.[73] The essential amino acid tryptophan, which is the precursor for serotonin, competes with several large neutral amino acids (LNAAs), such as tyrosine, phenylalanine, valine, leucine, and isoleucine, for transport across the blood-brain barrier via the large neutral amino acid transporter type 1 transporter.[73] This competition determines its uptake into the brain.[73] Recently alterations in plasma tryptophan and tyrosine levels were identified as independent risk factors for the transition to clinical delirium.[74] Increased activation of the kynurenine pathway, which is involved in the metabolism of tryptophan and the formation of neurotoxins, has also been linked to fewer days alive and without acute brain dysfunction in critically ill patients.[75] Another amino acid that may play an important role in the pathogenesis of delirium is phenylalanine.[68] Like tryptophan, phenylalanine competes with the other LNAAs (tyrosine, tryptophan, valine, leucine, and isoleucine) for transport across the blood-brain barrier. An increase in the cerebral uptake of tyrosine and phenylalanine compared with the other LNAAs leads to greater availability of precursors for both dopamine and norepinephrine, two neurotransmitters that have been implicated in the pathogenesis of delirium.[68]

Inflammation Hypothesis

It is important to realize that although delirium may occur as a result of perturbations in other organ systems, the brain responds to systemic infections and injury with an inflammatory response of its own that also involves cytokine production, cell infiltration, and tissue damage.[76,77] Reports indicate that local inflammation in the brain and subsequent activation of these central nervous system immune responses are accompanied by manifestations of systemic inflammation,[57,78,79] including production of large amounts of peripherally produced tumor necrosis factor α, IL-10, and interferon-γ.[76,80–82] Thus it is postulated that the brain can become an engine of inflammation, driving the development, resolution, or both, of MODS. Van Gool and associates propose that this self-propelling inflammation, in the context of microglial activation, could help explain the association between delirium and LTCI.[83] Surprisingly, van Gool points out that animal models have shown activated microglia can remain primed for months after injury, allowing ample time for ongoing injury long beyond the period of an ICU stay. These factors should be considered when designing neuroimaging studies in ICU survivors and will serve as fascinating topics for future study.

Neuroaging Hypothesis

Aging is associated with age-related cerebral changes in stress-regulating neurotransmitters, brain-blood flow decline, decreased vascular density, neuron loss, and intracellular signal transduction systems that may render the brain more susceptible to exogenous insults such as acute inflammatory states in the body.[84–87] In addition, the aging brain may mount a more exuberant central nervous system inflammatory response when stimulated by peripheral inflammatory states.[88]

Neuroendocrine Hypothesis

Delirium represents a reaction to acute stress mediated by abnormally high glucocorticoid levels that induce a general vulnerability in brain neurons by impairing the ability of neurons to survive after various metabolic insults.[89] Chronically high levels of physiologic stress are also associated with increased levels of inflammation in the body, connecting the neuroinflammatory and neuroendocrine theories of delirium.[55]

Diurnal Dysregulation Hypothesis

This hypothesis suggests that disruptions to the 24-hour circadian cycle and the usual stages of sleep may lead to the development of delirium.[90] Derangements in melatonin levels may cause delirium owing to its central role in the regulation of the circadian rhythm and sleep-wake cycles.[91,92] Sleep deprivation has been associated with increased levels of inflammatory substances, connecting this hypothesis to the neuroinflammatory theory of delirium.[55]

Network Disconnectivity Hypothesis

According to this hypothesis delirium could represent a variable failure in the integration and appropriate processing of sensory information and motor responses. The clinical forms of delirium, hypoactive versus hyperactive, may be determined by which neural networks break down in response to stressors such as aging, sleep deprivation, infection/inflammation, or medication exposure.[93] How they break down in the face of a particular stressor is thought to be related to the degree of baseline network connectivity and the level of inhibitory tone, mediated by GABA levels in that particular neural network.

None of these theories by themselves explains the full phenomenon of delirium. Rather, it is thought that two or more of these, if not all, act together to lead to the biochemical derangement we know as delirium.[90]

Risk Factors for Delirium

Although non-ICU cohort studies have identified numerous risk factors for the development of delirium,[48] only a few studies have examined these factors in the ICU population. Numerous risk factors for delirium have been identified, including preexisting cognitive impairment, advanced age, use of psychoactive drugs, mechanical ventilation, untreated pain, and a variety of medical conditions, such as heart failure, prolonged immobilization, abnormal blood pressure, anemia, sleep deprivation, and sepsis.[31,42,94–96] Baseline risk factors that predispose patients to a greater degree of vulnerability for delirium include Alzheimer disease, chronic illness, advanced age, and depression.[17,97,98] Dubois and coworkers[95] found that preexisting hypertension and smoking (presumably because of relative hypoperfusion and nicotine withdrawal, respectively) were significantly associated with the development of ICU delirium.[21] A new area of investigation is genetic predisposition to delirium, as the apolipoprotein (Apo) E4 polymorphism. The relationship between ApoE polymorphism and brain dysfunction is still unclear. Some studies found that the ApoE genotype was able to predict delirium that lasted nearly twice as long as patients without the polymorphism.[99,100] On the other hand, a study of older surgical patients who were free of dementia did not find a relationship between the ApoE genotype and either increased risk or protection in postoperative delirium incidence, severity, or duration.[101]

Precipitating and iatrogenic risk factors represent areas of potential modification and, thus, intervention for delirium prevention and treatment. Precipitating factors are hypoxia, metabolic disturbances, electrolyte imbalances, withdrawal syndromes, acute infection (systemic and intracranial), seizures, dehydration, hyperthermia, sleep deprivation, head trauma, vascular disorders, and intracranial space-occupying lesions.[17,97,98]

The average medical ICU patient has 11 or more risk factors for developing delirium. These risk factors can be divided into predisposing baseline (as with underlying characteristics and comorbidities) and hospital-related, or precipitating factors (such as acute illness, its treatment and ICU management) (Table 69.1).[102] Although delirium may be a function of a patient's specific underlying illness, it may also be due to medical management issues and thus may have preventable causes. Of these risk factors, sedative and analgesic medications and sleep deprivation appear to be the leading iatrogenic, and hence possibly preventable, risk factors for delirium. There are conflicting data on the association of anticholinergics, corticosteroids, histamine H_2 antagonists, and anticonvulsants with the development of delirium in ICU patients.[24,103–105]

TABLE 69.1 Selected Risk Factors for Delirium in the Intensive Care Unit

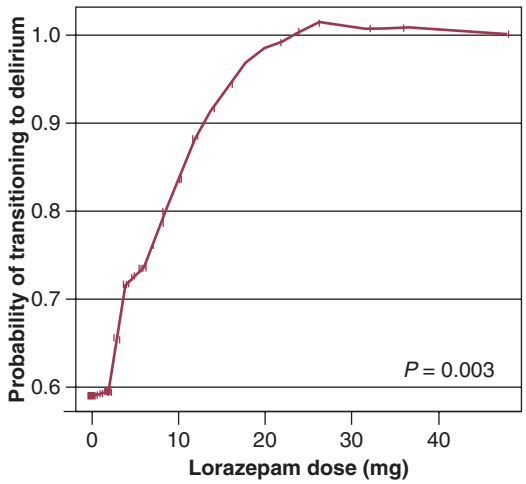
Type of Factor	Risk Factors
Patient Factors	• Age • Baseline comorbid conditions • Baseline cognitive impairment • Genetic predisposition (?) • Acute illness • Sepsis • Hypoxemia[a] • Global severity of illness score • Metabolic disturbances
Iatrogenic or Environmental Factors	• Metabolic disturbances[a] • Anticholinergic medications[a] • Sedative and analgesic medications[a] • Sleep disturbances[a]

[a]Potentially modifiable factor.

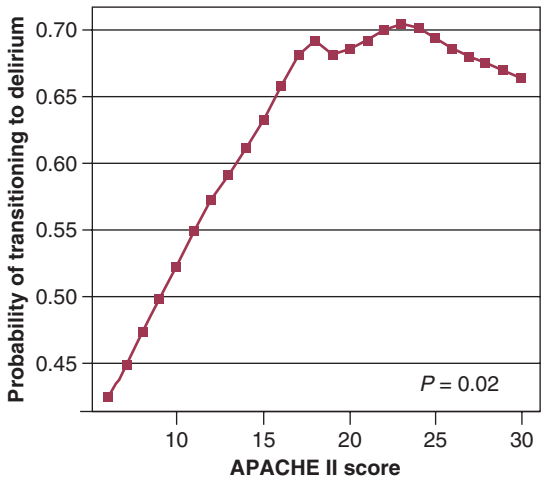
Sedatives and Analgesic Agents Contributing to Delirium

Sedative and analgesic medications are routinely administered to patients undergoing mechanical ventilation, in accordance with widely recognized clinical practice guidelines by the Society of Critical Care Medicine (SCCM),[105,106] to reduce pain and anxiety. Investigations have shown that continuous intravenous sedation is associated with prolonged mechanical ventilation and greater morbidity.[107] Similarly, associations between psychoactive medications and worsening cognitive outcomes have been reported in postoperative patients. Marcantonio and colleagues,[108] studying postoperative patients in whom delirium developed, found an association between use of benzodiazepines and meperidine and the occurrence of delirium. Dubois and coworkers[95] have shown that opiates (morphine and meperidine) administered either intravenously or via an epidural catheter may be associated with the development of delirium in medical/surgical ICU patients. Further comparative research is needed to better understand the role of different type, timing, and dose of opioids in the development of delirium.[109] Studies such as these have generated concern about whether such drugs were actually responsible for the development of delirium or were given as a result of delirium.

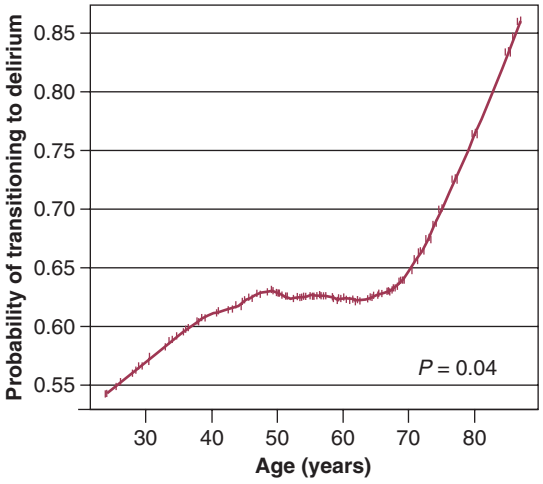
Our group has studied this temporal relationship between the administration of sedatives and analgesics and delirium.[110] To do so, one must make repeated cognitive assessments and must be able to assess the risk factors to which a patient is exposed in between these assessments to study which of these factors is associated with a transition or a change in cognitive status to or from normal, delirium, or coma. In our study, lorazepam was found to



• **Fig. 69.1** Lorazepam dose versus probability of transitioning to delirium. The probability of transitioning to delirium increased with the dose of lorazepam administered in the previous 24 hours. This incremental risk was large at low doses and plateaued at around 20 mg/day. (From Pandharipande P, Shintani A, Truman P, et al. Lorazepam is an independent risk factor for transitioning to delirium in intensive care unit patients. *Anesthesiology.* 2006;104:21–26.)



• **Fig. 69.3** Severity of illness versus the probability of transitioning to delirium. The probability of transitioning to delirium increased dramatically for each additional point in APACHE II (Acute Physiology and Chronic Health Evaluation II) severity of illness score until it reached a plateau score of 18. (From Pandharipande P, Shintani A, Truman P, et al. Lorazepam is an independent risk factor for transitioning to delirium in intensive care unit patients. *Anesthesiology.* 2006;104:21–26.)



• **Fig. 69.2** Age versus the probability of transitioning to delirium. The most notable finding related to age was that the probability of transitioning to delirium increased dramatically for each year of life after 65 years. (From Pandharipande P, Shintani A, Truman P, et al. Lorazepam is an independent risk factor for transitioning to delirium in intensive care unit patients. *Anesthesiology.* 2006;104:21–26.)

be an independent risk factor for daily transition to delirium, and fentanyl, morphine, and propofol were associated with higher but not statistically significant odds ratios for such transition (Fig. 69.1).[110] Increasing age and APACHE II (Acute Physiology and Chronic Health Evaluation II) scores were also independent predictors of transitioning to delirium (Figs. 69.2 and 69.3).[110] Similar associations between another benzodiazepine, midazolam, and transition to delirium have been found in another study conducted in our trauma and surgical ICU patients.[23] In addition, Seymour et al. confirmed that benzodiazepines are an independent risk factor for development of delirium during critical illness even when given more than 8 hours before a delirium assessment.[111]

The class of benzodiazepines does not seem to change the risk profile, with both lorazepam and midazolam being significant risk factors for delirium. Because of this, the SCCM ICU Pain Agitation Delirium (PAD) guidelines recommend that nonbenzodiazepine sedative options may be preferred over benzodiazepine-based sedative regimens.[106,112] The GABA-mimetic effect of benzodiazepines and propofol can alter the levels of numerous neurotransmitters believed to be deliriogenic.[67,113] Novel sedative agents that are GABA receptor-sparing (such as the α_2-agonists) may help reduce some of the cognitive dysfunction seen in ICU patients. Data for opioids and delirium are not as consistent as those for the benzodiazepines. Although meperidine has been associated with delirium in most of the published studies, evidence for both fentanyl and morphine has been less convincing.[95,108,114] Morrison and colleagues[114] conducted a prospective observational trial in patients who had undergone hip surgery and found that patients whose pain was well controlled with morphine were less likely to demonstrate delirium than those who received other opioids. These investigations point to the importance of the judicious use of psychoactive medications, with a focus on adequate analgesia.[115] One hopes that ongoing randomized controlled trials will pave the way to the development of sedation and analgesic guidelines for the prevention or reduction of the occurrence of delirium as the result of administration of these psychoactive drugs.

Diagnosis

The development of tools such as the Intensive Care Delirium Screening Checklist (ICDSC)[20] and the Confusion Assessment Method for the ICU (CAM-ICU)[22] has allowed for the rapid diagnosis of delirium in patients by nonpsychiatrists and other health care personnel even while such patients are mechanically ventilated. Several other scales have been developed and validated to diagnose delirium in ICU patients[116] (Delirium Detection Score [DDS], Cognitive Test for Delirium [CTD], Abbreviated Cognitive Test for Delirium, Neelson and Champagne Confusion Scale

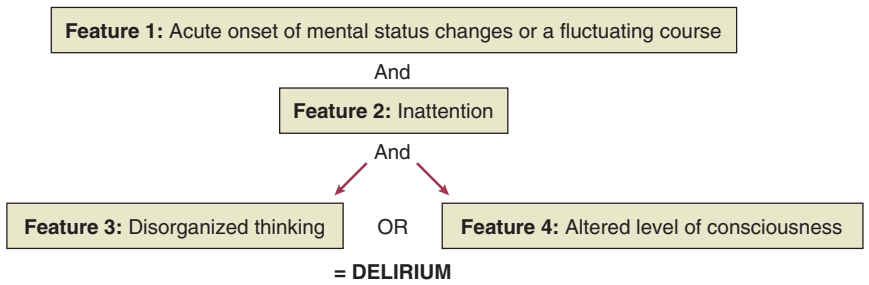
Linking Sedation and Delirium Monitoring:
A Two-Step Approach to Assess Consciousness

Step One: Sedation Assessment
The Richmond Agitation and Sedation Scale: The RASS

Score	Term	Description	
+4	Combative	Overly combative, violent, immediate danger to staff	
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive	
+2	Agitated	Frequent nonpurposeful movement, fights ventilator	
+1	Restless	Anxious but movements not aggressive vigorous	
0	Alert and calm		
–1	Drowsy	Not fully alert, but has sustained awakening (eye-opening/eye contact) to *voice* **(≥10 seconds)**	Verbal Stimulation
–2	Light sedation	Briefly awakens with eye contact to *voice* **(<10 seconds)**	
–3	Moderate sedation	Movement or eye opening to *voice* **(but no eye contact)**	
–4	Deep sedation	No response to voice, but movement or eye opening to *physical* stimulation	Physical Stimulation
–5	Unarousable	No response to *voice or physical* stimulation	

If RASS is –4 or –5, then **Stop** and **Reassess** patient at later time.
If RASS is above –4 (–3 through +4), then **Proceed to Step Two.**

Step Two: Delirium Assessment



• **Fig. 69.4** Richmond Agitation-Sedation Scale (RASS) and the Confusion Assessment Method for the ICU (CAM-ICU). This sedation scale and delirium instrument can be used together as a two-step approach to assess consciousness and diagnose delirium. Patients are considered to have delirium if they have RASS scores of –3 and higher and are assessed by CAM-ICU as "positive" by having both features 1 and 2 and either feature 3 or feature 4. (Data from references 22, 117, and 118 [available online].)

[NEECHAM], Nursing Delirium Screening Scale [NuDESC]). However, the ICDSC[20] and the CAM-ICU[22] are the tools recommended by the SCCM PAD guidelines for this purpose.[106]

Diagnosis of delirium is a two-step process. The level of arousal is first measured with the use of a standardized sedation scale, like the Richmond Agitation-Sedation Scale (RASS) (Fig. 69.4).[117,118] This is a 10-point scale with scores ranging from +4 to −5, with a score of 0 denoting a calm and alert patient. Positive RASS scores denote positive or aggressive symptomatology ranging from +1 (mild restlessness) to +4 (dangerous agitation). The negative RASS scores differentiate between response to verbal commands (scores −1 to −3) and physical stimulus (scores −4 and −5). If the patient's RASS score is −4 or −5 or the patient is not arousable by verbal commands, no further evaluation for delirium is performed, because the patient is comatose and is unable to be assessed for delirium. For patients who are arousable (RASS scores of −3 and higher), delirium can be assessed by the ICDSC that assesses eight features of delirium: altered level of consciousness, inattention, disorientation, hallucinations, psychomotor agitation/retardation, inappropriate mood/speech, sleep/wake cycle disturbance, and symptom fluctuation. The sensitivity and specificity of this tool are 99% and 64%, respectively.[20] The CAM-ICU, which can be performed in about 60 to 90 seconds,[119] consists of four features that assess the following: acute change or fluctuation of mental status (feature 1), inattention (feature 2), disorganized thinking (feature 3), and an altered level of consciousness (feature 4).

To be diagnosed as delirious, a patient must have a RASS score of −3 or higher, with an acute change or fluctuation in mental status (feature 1), accompanied by inattention (feature 2) and either disorganized thinking (feature 3) or an altered level of consciousness (feature 4). A complete description of the CAM-ICU as well as training materials, including translations and clinical vignettes, can be found at our website (www.icudelirium.org).

Recently a meta-analysis evaluated the accuracy of the CAM-ICU and the ICDSC for the diagnosis of ICU delirium.[116] This investigation included nine studies evaluating the CAM-ICU ($N = 969$ total patients) and four studies evaluating the ICDSC ($N = 361$). The authors calculated the pooled sensitivity of the CAM-ICU to be 80% (95% CI 77.1%–82.6%) and specificity of 95.9% (95% CI 94.8%–96.8%). The pooled sensitivity and specificity of the ICDSC were 74% (95% CI 65.3%–81.5%) and 81.9% (95% CI 76.7%–86.4%). They concluded that both delirium scales can be used as a screening tool, and that the CAM-ICU was an excellent diagnostic tool and the ICDSC had moderate sensitivity and good specificity.[116]

Prevention and Management

Primary Prevention and Nonpharmacologic Approaches

In a trial of 852 general medical patients older than 70 years,[94] implementation of strategies for primary prevention of delirium resulted in a 40% reduction in the odds for development of delirium

(15% in control subjects vs. 9.9% in the intervention patients). The protocol focused on optimization of risk factors via the following methods: repeated reorientation of the patient by trained volunteers and nurses, provision of cognitively stimulating activities for the patient three times per day, nonpharmacologic sleep protocol to enhance normalization of sleep/wake cycles, early mobilization activities and range-of-motion exercises, timely removal of catheters and physical restraints, institution of the use of eyeglasses and magnifying lenses, use of hearing aids and earwax disimpaction, and early correction of dehydration.[94] Unfortunately, this intervention did not show sustained benefit during the 6 months of follow-up.[120] Later studies of delirium were unable to reproduce this success in reducing the incidence of delirium.[121,122]

Milisen and associates[123] and Lundstrom and coworkers[124] studied the impact of the implementation of multifactorial and multidisciplinary educational strategies on duration and severity of delirium in patients cared for by staff who had received delirium-specific education.[129,130] In these studies the implemented programs reduced duration of delirium,[123,124] hospital stay, and mortality rate.[123,124] Cole and colleagues[122] found no difference in delirium rates between patients cared for by an intervention nurse and patients who received standard care. All of these nonpharmacologic "protocolization of care" studies focused on non-ICU patient populations. Clearly such investigations must be designed and conducted in the ICU (rather than simply extrapolated from non-ICU studies).

Although primary prevention of delirium is preferred, some delirium is inevitable in the ICU. In patients exhibiting delirium, the basic tenets of patient management, such as restoration of sleep/wake cycles, timely removal of catheters, early mobilization, minimization of unnecessary noise/stimuli, and frequent reorientation, should be applied liberally. Additionally, it should be emphasized that although sedative and analgesic agents have a very important role in patient comfort, health care professionals must also strive to achieve the right balance of administering these drugs through greater focus on reducing unnecessary or overzealous use. Instituting daily interruption of sedatives and analgesics, protocolizing their delivery, and instituting target-based sedation have all been shown to improve patient outcomes, although the studies reporting these results have not specifically looked at delirium rate or duration.[107,125,126] Studies have also shown a benefit for pain control in the prevention of delirium, because pain itself can be a risk factor for the development of delirium.[114,121,123] Family involvement can also be very helpful in reorienting and soothing some patients with delirium. It is important to teach family members about the fluctuating course of delirium as well as how they can detect it. All of these strategies are nicely summarized and operationalized in the evidence-based ABCDEFs of ICU care, which stands for spontaneous Awakening trials, spontaneous Breathing trials, Coordination of care and Choice of sedative, Delirium monitoring and management, Early mobility, and Family engagement. The ICU Liberation Collaborative is a real-world quality improvement initiative being implemented across 76 ICUs designed to strategically engage the ABCDEF bundle through team- and evidence-based care[127] (www.iculiberation.org) (Fig. 69.5). Recently Barnes-Daly et al. showed that, in 6064 patients admitted to 7 community hospitals, higher ABCDEF bundle compliance was independently associated with improved survival and more days free of delirium and coma after adjusting for age, severity of illness, and presence of mechanical ventilation (Fig. 69.6).[128]

Pharmacologic Therapy

Medications should be used for delirium only after adequate attention has been given to correction of modifiable contributing factors (e.g., sleep disturbance, restraints), as discussed previously.

Symptoms Pain, Agitation, Delirium Guidelines	**Monitoring** Tools	**Care** ABCDEF Bundle	**Done**
Pain	Critical Care Pain Observation Tool (CPOT) NRS Numeric Rating Scale BPS Behavioral Pain Scale	**A:** Assess, prevent and manage pain	☐

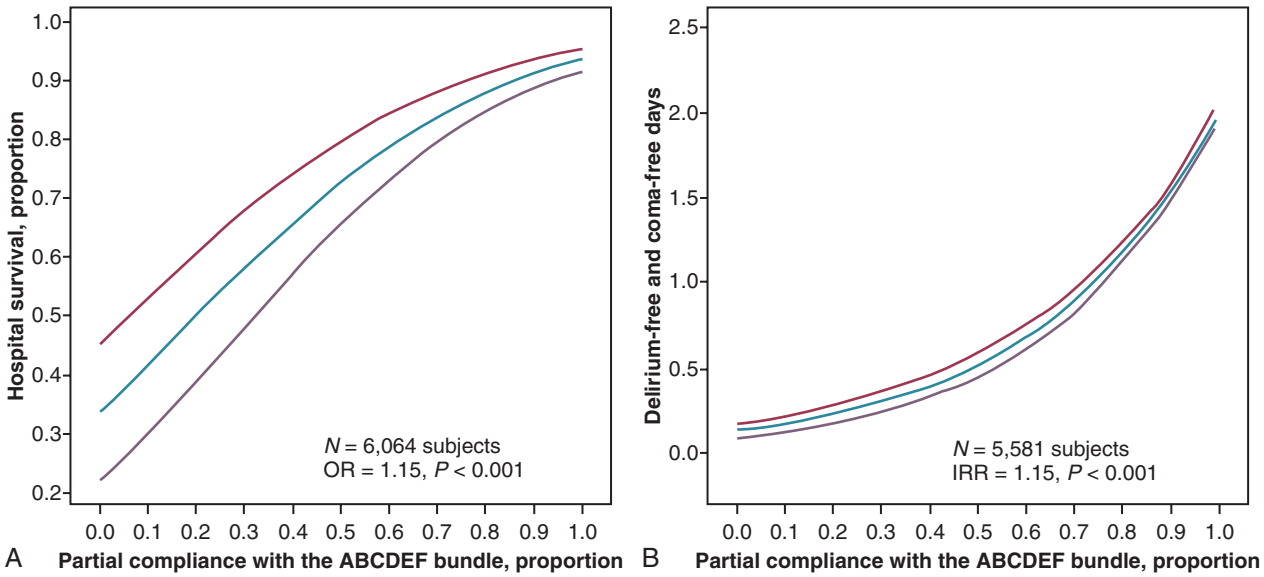
Delirium	Confusion Assessment Method for the Intensive Care Unit (CAM-ICU) Intensive Care Delirium Screening Checklist (ICDSC)	**D:** Delirium: Assess, prevent and manage **E:** Early mobility and exercise **F:** Family engagement and empowerment	☐ ☐ ☐

• **Fig. 69.5** ICU Liberation bundle chart. Intensive care unit (ICU) liberation is a quality improvement program geared toward reducing symptoms of pain, agitation, and delirium that threaten patients' sense of self-worth and dignity. These symptoms are monitored using valid and reliable tools, and the culture is shaped using the evidence-based ABCDEF (Awakening and Breathing Coordination, Choice of drugs, Delirium monitoring and management, Early mobility, and Family engagement) bundle as a rounding checklist.



• **Fig. 69.6** The figure shows the data demonstrating the effect of the ABCDEF bundle on survival (*A*) and delirium and coma-free days (*DFCFDs*) (*B*)—that is, a day during which the patient was alive and both not delirious (CAM-ICU negative) and not in a coma (Richmond Agitation-Sedation Scale [RASS] score of –3 or higher), analyzed by partial compliance (dose response). *A,* Hospital survival plotted in relationship to partial compliance with the ABCDEF bundle after adjusting for patient age, Acute Physiology and Chronic Health Evaluation III (APACHE III), and the proportion of days a patient was mechanically ventilated. With each 10% increase in partial bundle compliance, the odds of hospital survival increase to 15% (odd ratio 1.15; 95% confidence interval 1.09–1.22; $P < 0.001$). *B,* DFCFDs plotted in relationship to partial compliance with the ABCDEF (Awakening and Breathing Coordination, Choice of drugs, Delirium monitoring and management, Early mobility, and Family) ABCDEF bundle after adjusting for patient age, APACHE III, and the proportion of days a patient was mechanically ventilated. For every 10% increase in partial bundle compliance, there was a 15% increase in DFCFDs. (Adapted from Barnes-Daly MA, Phillips G, Ely WE. Improving hospital survival and reducing brain dysfunction at seven California community hospitals: implementing PAD guidelines via the ABCDEF bundle in 6,064 patients. *Crit Care Med.* 2017;45:171–178.)

It is important to remember that delirium could be a manifestation of an acute, life-threatening problem that requires immediate attention (such as hypoxia, hypercarbia, hypoglycemia, metabolic derangement, or shock). After such concerns have been addressed, pharmacologic management should be considered. It should be recognized that although agents used to treat delirium are intended to improve cognition, they all have psychoactive effects that may further cloud the sensorium and promote a longer overall duration of cognitive impairment. Therefore until we have outcomes data that confirm beneficial effects of treatment, these drugs should be used judiciously in the smallest possible dose and for the shortest time necessary, a practice infrequently adhered to in most ICUs. Indeed, some cases prove refractory to all "cocktail" approaches to sedation and delirium therapy, and in these cases, a trial of complete cessation of all psychoactive drugs should be considered. Some reports have described the utility of dexmedetomidine (an α_2-agonist) as an adjunct to assist with weaning patients from all psychoactive medications.[129] Preliminary results from a prospective, randomized, yet unblinded trial in postoperative patients who had undergone cardiac surgery showed that sedation with dexmedetomidine at sternal closure was associated with an 8% incidence of postoperative delirium compared with 50% for either propofol or benzodiazepines.[130]

Benzodiazepines are not recommended for the management of delirium because of the likelihood of oversedation, exacerbation of confusion, and respiratory suppression. However, they remain the drugs of choice for the treatment of delirium tremens (and other withdrawal syndromes) and seizures. Current evidence suggests a possible role of dexmedetomidine as adjunctive therapy for management of withdrawal syndromes for its effects in reducing hypertension, tachycardia, and benzodiazepine requirements.[131–135]

The amnestic qualities of benzodiazepines make these agents especially useful when noxious or unpleasant procedures are required. It is likely, however, that residual accumulation of these drugs may lead to prolonged delirium long after they have been discontinued. In certain populations, particularly elderly patients with underlying dementia, benzodiazepines may increase confusion and agitation. In such cases, one may try to take advantage of the sedative effects of haloperidol in lieu of continuing the benzodiazepine therapy.

Currently no drugs are approved by the U.S. Food and Drug Administration (FDA) for the treatment of delirium. Antipsychotics, especially haloperidol, are commonly administered for the treatment of delirium in critically ill patients.[136] However, evidence for the safety and efficacy of antipsychotics in this patient population is lacking.[105] The 2013 PAD Guidelines include no specific recommendations for using any particular medication to treat delirium.[106] Haloperidol is a "typical" butyrophenone antipsychotic,[137] which does not suppress the respiratory drive and works as a dopamine receptor antagonist by blocking the δ_2-opioid receptor, resulting in treatment of positive symptoms (hallucinations, unstructured thought patterns, and so on) and producing a variable sedative effect. There are data to suggest that haloperidol may have some

antiinflammatory properties,[138,139] although this is theoretical in terms of a helpful pharmacologic effect on disease (such as septic delirium) at this point and requires further study.

In the non-ICU setting, the recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, with repeated doses every 20 to 30 minutes until the desired effect is achieved. In the ICU, a recommended starting dose would be 2 to 5 mg every 6 to 12 hours (intravenous, intramuscular, or oral), with maximal effective doses usually in the neighborhood of 20 mg/day. This dose range will usually be adequate to achieve the "theoretically optimal" 60% δ_2-receptor blockage[140] while avoiding complete δ_2-receptor saturation associated with the adverse effects cited later. Because of the urgency of the situation in many ICU patients—owing to the potential for inadvertent removal of central lines, endotracheal tubes, or even aortic balloon pumps—much higher doses of haloperidol or a sedative are often used. Unfortunately, there are few data from formal pharmacologic investigations to guide dosage recommendations in the ICU. Once calm, the patient can usually be managed with much lower maintenance doses of haloperidol.

Newer "atypical" antipsychotic agents (e.g., risperidone, ziprasidone, quetiapine, and olanzapine) may also prove helpful for delirium.[141] The rationale behind use of the atypical antipsychotics rather than haloperidol (especially in hypoactive/mixed subtypes of delirium) is theoretical and centers on the fact that they affect not only dopamine but also other potentially key neurotransmitters, such as serotonin, acetylcholine, and norepinephrine.[141–143] There are prospective studies that examined the safety and efficacy of antipsychotics such as amisulpride,[144] quetiapine,[144–146] and risperidone.[147,148] These are generally small and quite heterogeneous in design, population studied, dosing regimens, and the use of delirium assessment tools. The use of haloperidol has been reported to have a mortality benefit in a retrospective analysis of critically ill, mechanically ventilated patients.[138] Skrobik and colleagues[141] reported that olanzapine and haloperidol were equally efficacious in treating ICU delirium in both medical and surgical patients but that olanzapine had fewer side effects (again, findings from a moderately ill group that must be confirmed and tested against placebo).The Modifying the Incidence of Delirium (MIND) study showed no difference in the duration of delirium between haloperidol, ziprasidone, or placebo when used for prophylaxis and treatment.[149] A small, prospective, randomized, double-blind, multicenter, placebo-controlled study randomly assigned 18 patients to receive scheduled quetiapine and 18 patients to receive placebo.[146] The quetiapine group had a faster resolution of delirium compared with the placebo group (1 day vs. 4.5 days, $P = 0.001$) and a shorter duration of delirium (36 days vs. 120 days, $P = 0.006$). The quetiapine group required fewer days of as-needed haloperidol (3 vs. 4 days). Kato and coworkers[150] reported a case study that suggests that genotyping may affect the choice of antipsychotic drugs. They showed that a patient with the cytochrome P450 (CYP) 2D6 genotype had persistent delirium and demonstrated severe extrapyramidal symptoms when treated with risperidone. When quetiapine (metabolized by CYP 3A4) was used instead, the patient's delirium cleared within 2 days without side effects. This case report is not proof of a positive effect of antipsychotics, yet it is interesting and suggests that pharmacogenetics may play an important role in medication choices in the near future. Ely et al. are conducting the MIND-USA (Modifying the Impact of ICU-Induced Neurological Dysfunction-USA) Study to define the role of antipsychotics in the management of delirium in vulnerable critically ill patients.[150a,151–153]

Adverse effects of typical and atypical antipsychotics include hypotension, acute dystonias, extrapyramidal effects, laryngeal spasm, malignant hyperthermia, glucose and lipid dysregulation, and anticholinergic effects, such as dry mouth, constipation, and urinary retention. Perhaps the most immediately life-threatening adverse effect of antipsychotics is torsades de pointes, and these agents should not be given to patients with prolonged QT intervals unless absolutely necessary. Patients who receive substantial quantities of typical or atypical antipsychotics or are coadministered arrhythmogenic drugs should be monitored closely with electrocardiography. In 2005, the FDA issued an alert that atypical antipsychotic medications are associated with a mortality risk among elderly patients. This warning was supported by a meta-analysis of a large volume of data from outpatient treatment of patients with dementia who were experiencing psychotic symptoms that resulted in their receiving antipsychotic medications.[154] Similar associations with higher stroke risk and fatality have been reported by other investigators.[155,156] Subsequently, other studies have suggested that this higher risk of death in non-ICU elderly patients treated with antipsychotics may not be limited to the atypical antipsychotic agents. Schneider and colleagues[155] found that the conventional antipsychotic haloperidol had an even higher mortality risk.

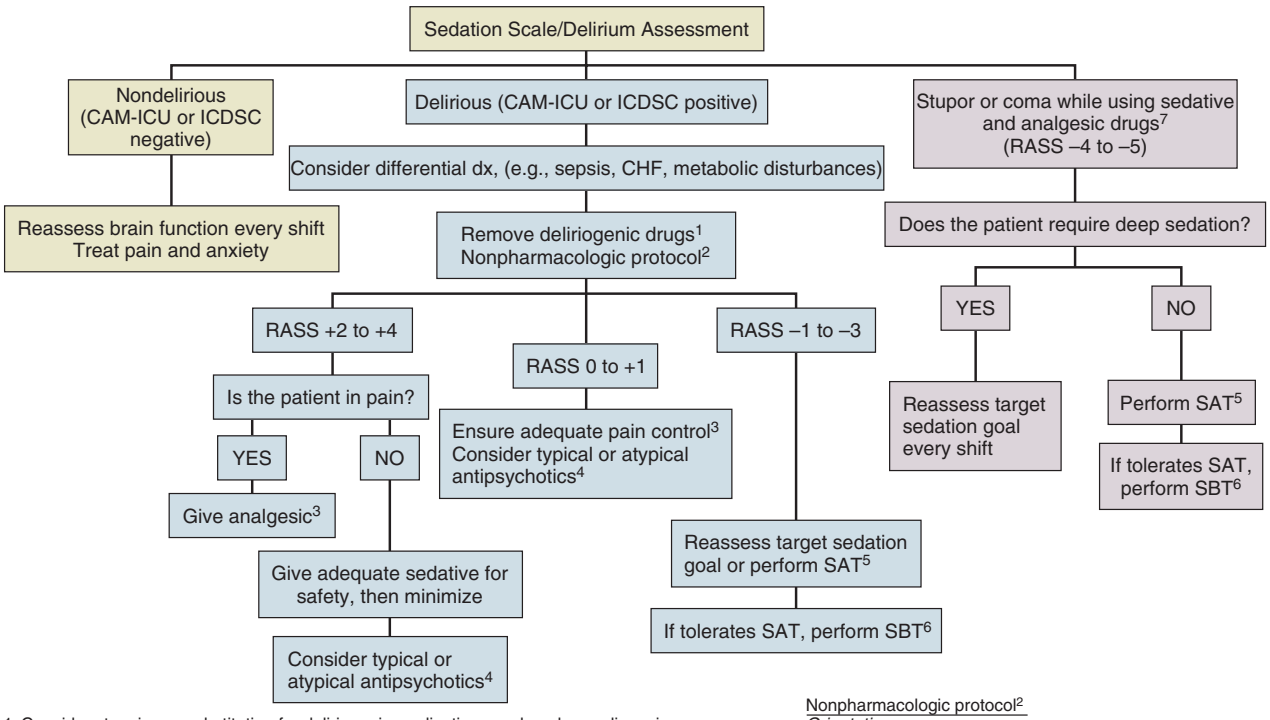
Along with haloperidol and the atypical antipsychotics for the treatment of acute brain dysfunction, a growing body of literature suggests a role for sedatives such as the α_2-agonist dexmedetomidine in the pharmacologic management of delirium. The MENDS (Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction) trial[157] compared dexmedetomidine with lorazepam for targeted sedation greater than 24 hours in 106 mechanically ventilated patients. Sedation with dexmedetomidine resulted in more days alive without coma or delirium and lower prevalence of coma compared with sedation with lorazepam. Subgroup analysis also demonstrated that sedation with dexmedetomidine reduced the daily risk of delirium, particularly in patients with sepsis.[158] The SEDCOM (Safety and Efficacy of Dexmedetomidine Compared with Midazolam) trial[159] compared dexmedetomidine to midazolam, another commonly used benzodiazepine in the ICU. This large prospective trial showed significantly lower prevalence of delirium in patients receiving dexmedetomidine compared with midazolam, an effect observed within 1 day of initiating sedation and sustained throughout the week of study drug administration.[159] In 2012, the MIDEX and PRODEX trials compared midazolam to dexmedetomidine (MIDEX) and propofol (preferred usual care) to dexmedetomidine (PRODEX) in mechanically ventilated patients requiring long-term sedation. These large trials, which together enrolled nearly 1000 patients, showed that dexmedetomidine was not inferior to midazolam or propofol for targeted light to moderate sedation and was found to be associated with improved communication between the patients and others involved in their care. Dexmedetomidine also reduced time to extubation and was associated with fewer neurocognitive disorders (including delirium) than propofol.[160] In each trial, the reproducible significant adverse effect associated with dexmedetomidine was bradycardia, which typically resolved without event and infrequently required adjunctive treatment beyond discontinuation of the drug.[160] Djaiani et al. recently showed that dexmedetomidine reduced delirium incidence in cardiac surgical patients in the ICU as compared to propofol,[161] while Su et al. showed a reduction in patients treated with dexmedetomidine in noncardiac surgical patients admitted to the ICU.[162] There is an ongoing trial (MENDS II study) to determine the best sedative medication to reduce delirium and improve

survival and long-term brain function in the ventilated septic patient.[162a]

Other agents such as the cholinesterase inhibitors have proved unsuccessful in the management of ICU delirium.[163–166] Given the hypothesis that delirium was associated with excess dopamine and a central cholinergic deficiency, it was logical to test the cholinesterase inhibitors such as rivastigmine, used in treating dementia, for the management of ICU delirium. However, in 2010, a large placebo-controlled trial evaluating rivastigmine as an adjunct to usual care with haloperidol was halted early owing to increased mortality risk and longer duration of delirium in patients receiving rivastigmine.[164] In 2011, another study tested the use of donepezil hydrochloride to reduce the prevalence and severity of delirium in older adults undergoing hip fracture repair without showing improvement in delirium presence or severity.[167] Other agents such as ondansetron[168,169] and melatonin[170–172] are being considered for the treatment of ICU delirium but thus far have little support in the literature.

Protocols and evidence-based strategies for prevention and treatment of delirium will no doubt emerge as more evidence becomes available from ongoing randomized clinical trials of both nonpharmacologic and pharmacologic strategies. To assist readers in developing a delirium management algorithm in their respective clinical arenas, we have provided an empiric protocol largely based on SCCM clinical practice guidelines (Fig. 69.7).

At this time, there are few data regarding which antipsychotic medications are most suitable for delirium. The nonpharmacologic interventions recommended in Fig. 69.7 have shown beneficial



1. Consider stopping or substituting for deliriogenic medications such as benzodiazepines, anticholinergic medications (metoclopramide, H_2-blockers, promethazine, diphenhydramine), steroids, etc.
2. See nonpharmacologic protocol—On the right
3. Analgesia—Adequate pain control may decrease delirium. Consider intermittent narcotics if feasible. Assess with objective tool.
4. Typical or atypical antipsychotics—While tapering or discontinuing sedatives, consider haloperidol 2 to 5 mg IV initially (0.5–2 mg in elderly) and then q6h. Guideline for max haloperidol dose is 20 mg/day due to ~60% D2-receptor saturation. May also consider using any of the atypicals (e.g., olanzapine, quetiapine, risperidone, ziprasidone, or aripiprazole). Discontinue if high fever, QTc prolongation, or drug-induced rigidity.
5. Spontaneous Awakening Trial (SAT)—Stop sedation or decrease infusion (especially benzodiazepines) to awaken patient as tolerated.
6. Spontaneous Breathing Trial (SBT)—CPAP trial if on ≤50% and ≤8 PEEP and Sats 90%
7. Sedatives and analgesics may include benzodiazepines, propofol, dexmedetomidine, fentanyl, or morphine.

Nonpharmacologic protocol[2]

Orientation
- Provide visual and hearing aids
- Encourage communication and reorient patient repetitively
- Have familiar objects from patient's home in the room
- Attempt consistency in nursing staff
- Allow television during day with daily news
- Nonverbal music

Environment
- Sleep hygiene: Lights off at night, on during day. Sleep aids (zolpidem, mirtazapine)?
- Control excess noise (staff, equipment, visitors) at night
- Ambulate or mobilize patient early and often

Clinical parameters
- Maintain systolic blood pressure >90 mm Hg
- Maintain oxygen saturations >90%
- Treat underlying metabolic derangements and infections

• **Fig. 69.7** Delirium protocol. This empiric protocol, which is based largely on the current Society of Critical Care Medicine's clinical practice guidelines, is the algorithm we use to treat delirium in our intensive care units (ICUs). We wish to emphasize that such protocols need to be updated regularly with new data and also individualized at each medical center. Specific recommendations about the choice of antipsychotics to treat delirium have not been described, because limited data are available regarding the appropriate drug to use in ICU patients. The nonpharmacologic interventions recommended in this protocol have been shown to have beneficial results in non-ICU patients, but the extrapolation to ICU populations is speculative. *CAM-ICU,* Confusion Assessment Method for the ICU; *CHF,* congestive heart failure; *CPAP,* continuous positive airway pressure; *dx,* diagnosis; ICDSC, Intensive Care Delirium Screening Checklist; *PEEP,* positive end-expiratory pressure; *q,* every; *RASS,* Richmond Agitation-Sedation Scale; *Sats,* saturations.

results in non-ICU patients, but the extrapolation to ICU populations is speculative. Nevertheless, such data emphasize the need for more research in this area and underscore the importance of exercising caution in the treatment of delirium. We emphasize that protocols such as the ABCDEs of critical care[36,37] (Awakening, Breathing, Coordination, Delirium monitoring and management, and Early mobility) must be updated regularly with new data and individualized at each medical center to form an integrated approach to delirium monitoring, sedation targeting, and delirium management in critically ill ICU patients.

By way of summary regarding delirium management, the main thrust of our approach as health care professionals must begin with treatment of the underlying disease processes that are leading to brain dysfunction, then drug removal, and then modification of the environmental factors (hearing and vision aids, removal of restraints and early mobility, and sleep hygiene), which can be summarized via the mnemonic Dr. DRE (Diseases, Drug Removal, Environment). Only after all of these issues are addressed is it appropriate to add another medication such as an antipsychotic into the mix of the individual pharmacopeia for any patient.

Sleep Disruption in the Critically Ill

The sleep cycle is divided into rapid eye movement (REM) sleep and non-REM (NREM) sleep.[173] NREM sleep is further divided into four stages according to an increasing depth of sleep.[130] A normal sleep cycle lasts approximately 90 minutes, cycling continuously between REM and NREM sleep. Stages 3 and 4 of the NREM sleep represent slow-wave or more restful sleep.[173]

Among critically ill patients, 61% report sleep deprivation, placing it among the most common stressors experienced during critical illness.[174–176] The typical sleep pattern of a critically ill patient is characterized predominantly by wakefulness and light sleep (sleep stages 1 and 2), a relative lack of REM sleep, and deep sleep (non-REM sleep stages 3/4).[177] The average amount of sleep in the ICU has been measured to be about 2 hours out of 24 hours, with less than 6% of it spent in REM sleep. In a study by Cooper and associates,[177] the causes of sleep deprivation in the ICU have been extensively reported. They consist of excessive noise and lighting, patient care activities such as procedures and baths, metabolic consequences of critical illness, mechanical ventilation, and the sedative and analgesic medications administered to these patients.[178] This disturbance in duration and quality of sleep has detrimental effects on protein synthesis, cellular and humoral immunity, and energy expenditure, resulting in respiratory and hemodynamic effects as well as cognitive function.[178,179] Studies of sleep disturbances related to noise, patient activities, and light have found that only about 30% of the sleep arousals were a result of these environmental factors, suggesting that other patient factors or management issues play an important role.[180] Of these, it is interesting that the psychoactive medications are common risk factors for both delirium and sleep disturbances, whereas sleep deprivation can itself lead to delirium.

Neurotransmission in Sleep

The ventrolateral preoptic (VLPO) nucleus in the anterior hypothalamus plays a critical role in sleep regulation.[181] Its major neurotransmitter is GABA, and during the awake state, the GABA release from the VLPO nucleus is inhibited by norepinephrine from the locus coeruleus.[181] With the inhibition of the release of GABA, neurotransmitters such as orexin, serotonin, histamine, and acetylcholine are released, resulting in a state of wakefulness (Fig. 69.8). During NREM sleep, norepinephrine release diminishes, thus removing the inhibitory effect on release of GABA from the VLPO nucleus. The firing of GABA neurons inhibits the neurotransmitters of wakefulness (orexin, serotonin, histamine, and acetylcholine), resulting in NREM sleep (Fig. 69.8). REM sleep, on the other hand, is facilitated by neurons in the pons that release acetylcholine. Studies show that serotonin and norepinephrine inhibit these neurons, suppressing REM sleep.

Sedative and analgesic medications are routinely administered to critically ill patients to promote sleep. However, although patients appear sedated, their sleep architecture is often adversely affected.[173] Benzodiazepines and propofol prolong stage 2 NREM sleep while decreasing slow-wave sleep and REM sleep. Opioids, on the other hand, increase stage 1 NREM sleep while decreasing slow-wave and REM sleep. An investigation of the use of dexmedetomidine (an α_2-agonist) in rats shows that it mimics and increases NREM sleep[181] but decreases REM sleep. By acting on the locus coeruleus, dexmedetomidine inhibits the release of norepinephrine, thus causing GABA output from the VLPO nucleus and inhibition of the neurotransmitters of wakefulness to produce an NREM sleep pattern. In contrast, benzodiazepines and propofol exert their sedative action on the VLPO nucleus to increase GABA and decrease the neurotransmitters, such as orexin, histamine, and serotonin, but without affecting norepinephrine release from the locus coeruleus. Further clinical trials are required to ascertain the role of these medications in improving the quality and quantity of sleep in critically ill patients and to determine whether such improvement may better the cognitive outcomes in ICU patients.

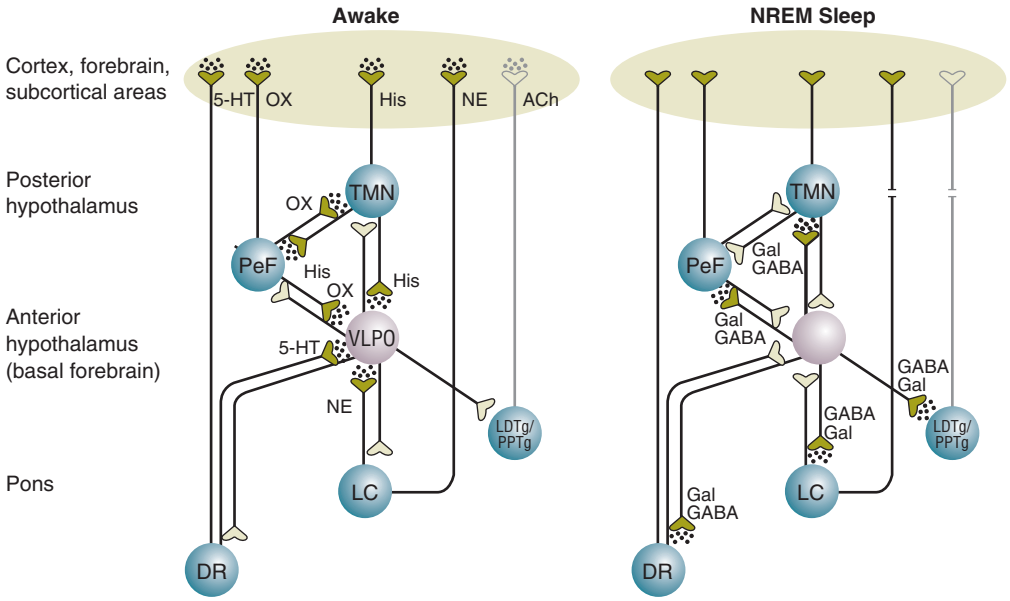
Although they lack anxiolytic properties, ω_1-receptor agonists, such as zolpidem, may preserve REM as well as slow-wave sleep.[182] Similarly, mirtazapine, a noradrenergic and specific serotonergic antidepressant, has been studied in healthy volunteers and has been shown to improve sleep efficiency, reducing the number and duration of awakenings.[183] The slow-wave sleep time was also increased, whereas stage 1 sleep time was reduced significantly. This agent had no significant effect on REM sleep variables.[184]

Numerous other medications routinely administered to critically ill patients affect sleep architecture. These include antiarrhythmic agents, inotropes and vasopressors, antibiotics, antidepressants, steroids, anticonvulsants, and bronchodilators.[173] The effects of some of these compounds on sleep patterns are summarized in Table 69.2.

Posttraumatic Stress Disorder

Definition and Diagnostic Criteria

The DSM-V[13] defines PTSD as a potentially debilitating psychiatric condition that develops as the result of exposure to a traumatic occurrence, in which the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others and that generates intense feelings of fear, helplessness, or horror in the person exposed to the trauma. Symptoms of PTSD fall into four categories: intrusive thoughts (such as repeated, involuntary memories; distressing dreams; or flashbacks of the traumatic event); avoiding reminders of the traumatic event (avoiding people, places, activities, objects, and situations that bring on distressing memories); negative thoughts and feelings (ongoing and distorted beliefs about oneself or others, fear, horror, anger,



• **Fig. 69.8** Neurotransmitter mechanism for wakefulness and non–rapid eye movement *(NREM)* sleep. The ventrolateral preoptic *(VLPO)* nucleus in the anterior hypothalamus is the major area of the brain that controls sleep induction and maintenance. Its major neurotransmitter is gamma-aminobutyric acid *(GABA),* and during the awake state, GABA release from the VLPO nucleus is inhibited by norepinephrine *(NE)* from the locus coeruleus *(LC).* With the inhibition of GABA, neurotransmitters such as orexin *(OX),* serotonin *(5-HT),* histamine *(His),* and acetylcholine *(ACh)* are released, resulting in a state of wakefulness. During NREM sleep, there is a hierarchical sequence of changes in which inhibition of the LC disinhibits the VLPO nucleus to release GABA and galanin *(Gal)* at the projections that terminate at the tuberomamillary nucleus *(TMN).* These inhibitory neurotransmitters inhibit firing of the TMN projections to the cortical and subcortical regions. *5-HT,* 5-Hydroxytryptamine (serotonin); *DR,* dorsal raphe; *LDTg*, laterodorsal tegmental nucleus; *PPTg,* pedunculopontine tegmental nucleus. (From Analgesics: receptor ligands: alpha 2 adrenergic receptor agonists. In Evers AS, Maze M [eds]. *Anesthetic Pharmacology: Physiologic Principles and Clinical Practice.* St. Louis: Churchill Livingstone; 2004. Used with permission from Dr. Mervyn Maze and Elsevier, Inc.)

guilt, or shame); arousal and reactive symptoms (being irritable and having angry outbursts; behaving recklessly or in a self-destructive way; being easily startled; or having problems concentrating or sleeping).

These symptoms must meet the following two criteria to be diagnosed as PTSD:

1. Symptoms must cause significant impairment in social, occupational, or other important functional domains.
2. Symptoms must be present for at least 1 month after exposure to the traumatic event or events.

Prevalence of ICU-Related Posttraumatic Stress Disorder

The incidence of PTSD anchored to the ICU experience and unrelated to past stressful experiences has been consistently around 10% in the first year after hospital discharge[185–188] in the most rigorous studies, despite historically reported higher rates in many other studies.[189,190] It is critically important to recognize that despite these reports of higher epidemiologic occurrences of PTSD after critical illness,[190] many studies have not distinguished pre-existing PTSD from ICU-related PTSD, nor have they used DSM criteria, or accounted for the ICU course. Using a multicenter ICU population of U.S. civilians and veterans, the most recent study to clearly identify ICU-related PTSD demonstrated an occurrence in 1 of 10 ICU survivors.[186]

Risk Factors for Posttraumatic Stress Disorder

A number of subject characteristics appear to raise the risk of PTSD symptoms or an actual diagnosis of PTSD, although consensus among the studies reviewed is limited. Reported risk factors include delusional memories of the ICU, a greater number of traumatic memories of the ICU, longer ICU length of stay, duration of mechanical ventilation, younger age, preexisting psychiatric history, female gender, and higher levels of sedation and neuromuscular blockade and delirium.[187,191–195]

Conceptual Explanations for Posttraumatic Stress Disorder After Critical Illness

Although the stresses associated with ICU hospitalization may differ from events typically described as "traumatic experiences," there are a variety of conceptual explanations for the development of PTSD after critical illness. They include (1) profound feelings of helplessness associated with the experience of critical illness, (2) high rates of preexisting psychiatric morbidity that may characterize ICU patients,[196] (3) cognitive impairment, including decreased working memory, which may limit individual abilities to suppress intrusive thoughts,[196] and (4) multiple traumatic episodes associated with anxiety, panic, or pain that occur during ICU hospitalization, such as intubations, extubations, nightmares, and respiratory distress.[197,198]

TABLE 69.2 Drugs Commonly Used in the Intensive Care Unit and Their Effects on Sleep Patterns

Drug Class/Individual Drug	Sleep Disorder Induced/Reported	Possible Mechanism
Benzodiazepines	↓ REM, ↓ SWS	γ-Aminobutyric acid type A ($GABA_A$) receptor stimulation
Opioids	↓ REM, ↓ SWS	μ-Opioid receptor stimulation
Clonidine	↓ REM	α_2-Adrenergic receptor stimulation
Nonsteroidal antiinflammatory drugs	↓ TST, ↓ SE	Prostaglandin synthesis inhibition
Norepinephrine/epinephrine	Insomnia, ↓ REM, ↓ SWS	α_1-Adrenergic receptor stimulation
Dopamine	Insomnia, ↓REM, ↓ SWS	δ_2-Opioid receptor stimulation/α_1-adrenergic receptor stimulation
β-Blockers	Insomnia, ↓ REM, nightmares	Central nervous system β-blockade by lipophilic agents

Attention has been focused on the quality and duration of sedation provided to ICU patients in relation to the risk of post-ICU PTSD. Particular interest has been placed on the role of benzodiazepines.[110,193] Both receipt of midazolam[199] and total dose of lorazepam[193] administered in the ICU have been found to be associated with greater risk of post-ICU PTSD. Also, higher doses of opiates have been associated with an increased risk of experiencing PTSD symptoms.[194] Conversely, from another study, Patel and coworkers did not find any association between PTSD risk and duration of delirium, benzodiazepine dose, or opiate dose.[186]

For many patients, extreme agitation is a significant component of the ICU experience and higher levels of agitation in the ICU have been identified as a predictor of PTSD-related symptoms.[199] Brewin and Holmes[200] suggest that immobilization with incomplete sedation promotes a dissociative experience that may be a PTSD risk factor.

A significant percentage of patients treated in the ICU have chronic medical illnesses,[201,202] which may increase anxiety or susceptibility to anxiety reactions. The presence of such stressors may have a cumulative effect on an individual's coping resources, leading to a greater vulnerability to PTSD. This concept is bolstered by evidence from numerous studies as well as the theoretical work of Turner and Lloyd,[203] which supports the notion that healthy coping responses are impeded by the "accumulated burden of adversity" associated with illness or disease.[204–206] Although the contribution of cumulative illness to the development of PTSD has not been assessed in ICU populations, investigations support an association between accumulated medical burden and higher risk of PTSD. For example, accident victims (without chronic medical illnesses) who are admitted to the trauma ICU have a lower prevalence of PTSD than their medical ICU counterparts (with multiple chronic diseases).[207] Alternatively, patients with chronic cardiovascular disease who have undergone cardiac surgery have relatively high rates of PTSD, which correlate positively with preoperative disease severity.[197]

The relationship between cognitive function and PTSD is a subject of ongoing debate, particularly as it relates to the role of memory in mediating the development of PTSD.[208] The importance of specific, explicit memories (memories pertaining to facts and events that are accessible to consciousness)[209,210] in the generation and maintenance of PTSD is difficult to estimate because they are the basis for nightmares, flashbacks, and intrusive thoughts and contribute to symptoms of avoidance and reexperiencing. Although a detailed treatment of these issues is beyond the scope of this chapter, we briefly discuss several key findings from the literature as they relate to ICU populations.

The preponderance of evidence suggests that the absence of episodic memory for a traumatic event is protective against the development of PTSD and that the risk of PTSD is markedly lower in individuals unable to recall a traumatic event than in those with explicit memory of it.[211–215] The literature is not unanimous and is narrow in scope, with virtually all relevant studies having been conducted on victims of motor vehicle accidents or other traumas with concomitant traumatic brain injury.[216] Theories of information processing suggest that traumatic memories can be encoded implicitly during periods of impaired consciousness and may provide the basis for the generation of PTSD symptoms, even if patients are not consciously aware of the memories.[217–220]

Additionally, during periods of impaired consciousness, the encoding of emotional experiences such as panic and severe pain appears to be sufficient for the generation of PTSD symptoms.[221]

Many ICU patients report little if any conscious awareness of their critical illness, although as Jones and associates[222] have reported, delusional memories, often with violent and paranoid themes, are pervasive among such patients. Distorted and fragmentary memories may be vestiges of the nightmares, hallucinations, or delusions induced by critical illness, a variety of medications, or other causes, and may be particularly likely to occur during delirium, which is ubiquitous in critically ill, mechanically ventilated patients.[208,223] Sedative medications may constitute one factor that mediates the development of delusional memories.[224] Delusional memories may exist in the absence of factual memories, which provide markers of reality and may serve to orient the patient. For example, daily sedative interruption has been found to be associated with fewer symptoms of PTSD,[225] suggesting that even limited factual memories from brief awakening may reduce PTSD. In addition, delusional memories tend to be stable over time and are significantly more persistent than factual memories.[226] Delusional memories may be more refractory to the normal cognitive processes of habituation and reappraisal because they are not well integrated into the long-term memory. Although research is limited, the presence of delusional memories of the ICU is associated with higher levels of anxiety and PTSD.[227,228]

Jones et al. evaluated the influence of ICU diaries on symptoms of post-ICU posttraumatic stress, among both patients and their family members, after 3 months from ICU discharge. Patients in the intervention arm received their ICU diary at 1 month after critical care discharge and the final assessment of the development of acute PTSD was made at 3 months. The incidence of new cases of PTSD was reduced in the intervention group compared with the control patients (5% vs. 13%, $P = 0.02$).[188] Diaries can probably help patients to change how they think about their illness as they reread the story and build an autobiographic memory. Families may also be helped because the diaries help to facilitate communication with the patient about their treatment and writing in the diary may allow them to express some of their feelings. A strong relation has been found between high levels of PTSD-related symptoms in family members and those in patients. So a therapy, such as a diary, that is shared between the patient and the family may be more effective than one that concentrates just on the patient.[188]

Similarly, Garrouste-Orgeas et al. assessed the influence of ICU diaries written by family members, nurses, and physicians on ICU survivors.[229] At the time of ICU discharge the diaries were provided to survivors and to relatives. For both patients and relatives, levels of posttraumatic symptoms measured by the Impact of Scale Event-Revised score were lower at 12-month follow-up compared with prediary and postdiary controls.[229] ICU diaries have also been associated with a reduction in related post-ICU psychiatric morbidities, including depressive and anxiety symptoms.[230] As with diaries/journals, a single counseling session has been shown to increase both patient and family coping ability after an ICU stay.[227] Both may also prevent, reduce, or help treat PTSD.

Other studies suggest that music, nature sounds, and various forms of massage and reflexology could all be used to reduce acute stress among ICU patients, including mechanically ventilated patients.[231] As acute stress is an important precursor of long-term psychological morbidity such as PTSD, these short-term practices could also have an impact on long-term outcomes. The risk of harm from such therapies is not generally high, but protocols and training for staff are needed.[231]

Long-Term Cognitive Impairment After Critical Illness

Medical and surgical management of critical illnesses can, and frequently does, result in de novo neurocognitive impairments. Approximately one-third or more of ICU survivors have LTCI.[232] It is difficult to make comparisons among studies owing to differences in definitions of neurocognitive sequelae, administered neuropsychological tests, time to follow-up, patient population, study design (prospective vs. retrospective), and inclusion of a control group. Nevertheless, current data suggest that neurocognitive impairments are extremely common in survivors of critical illness. Post-ICU long-term cognitive impairment involves memory, attention, and executive function problems and leads to inability to return to work, impaired activities of daily living, increased risk of hospitalization, and decreased quality of life.

Over the past decade and a half, cohort studies have conducted assessments of the cognitive function among survivors of critical illness and reported significant notable impairments sustained by those who survive a critical illness.[12,232–242] These studies have given rise to the concept of the post–intensive care syndrome, defined as new or worsened symptoms of cognitive impairment, disabilities in activities of daily living, and mental health impairment that arise after critical illness and persist beyond acute care hospitalization.[243,244] The populations of the patient cohorts in studies of LTCI include patients with ARDS, acute lung injury, sepsis, and respiratory failure in the ICU,[12,232,233,236,238–242] as well as two studies in general ICU patients.[234,237] The time to neurocognitive assessments was variable, with the majority occurring during the first year after hospital discharge. Three studies assessed patients more than 1 year later. A prospective longitudinal study monitored patients at hospital discharge and then at 1 and 2 years after hospital discharge,[245] and two retrospective studies assessed the patients at approximately 6 years after hospital discharge.[236,240]

The evidence from the 10 cohorts suggests that 25% to 78% of ICU survivors experience neurocognitive impairments.[232–241] Among specific populations, such as patients with ARDS, the prevalence of LTCI is even greater; it may be as high as 78% at hospital discharge, 46% at 1 year,[233] and 25% at 6 years.[240] Hopkins and colleagues[233] assessed the premorbid estimated intelligence quotient (IQ) of ARDS patients and found it was significantly higher than their measured IQ at hospital discharge. However, the patients' measured IQ improved to their premorbid level by 1-year follow-up, with no additional improvement at 2 years. The finding that patients recovered over time with regard to intelligence does not necessarily suggest a comparable recovery in all cognitive domains, because data from traumatic and anoxic brain injury literature suggest that some neurocognitive abilities are more likely to improve than others.[246]

A 2004 study found that neurocognitive impairments occur in 70% of ARDS patients at hospital discharge, 45% at 1 year, and 47% at 2 years.[245] The neurocognitive test scores of the ARDS survivors with neurocognitive sequelae (≈50% of survivors) fell below the sixth percentile of the normal distribution of cognitive function. These ARDS survivors had marked difficulty with tasks that require executive function, memory, attention, or quick mental processing. The neurocognitive impairments in critically patients are similar to those reported in medical ICU survivors[233] after carbon monoxide poisoning[247] and several years after elective coronary artery bypass graft surgery.[248]

In addition to ARDS survivors, neurocognitive impairments have been reported in the general population of critically ill patients. Jackson and colleagues,[232] evaluating 34 medical ICU survivors at 6 months, found that 33% had LTCI (using a very conservative definition of impairment as two test scores 2 standard deviations below the mean or three test scores 1.5 standard deviations below the mean). The neurocognitive impairments were similar to those reported in ARDS survivors; they included mental processing speed, memory, language, and visuospatial abilities. Additional support for cognitive impairment in the general critically ill population comes from a prospective cohort of 32 critically ill patients who underwent long-term mechanical ventilation (>5 days). The patients were evaluated at hospital discharge and 6 months later.[235] Of the patients who received long-term mechanical ventilation, 91% at hospital discharge and 41% at 6 months had impairments in attention, memory, mental processing speed, and executive function.[235]

Girard and colleagues showed that the duration of delirium was an independent predictor of LTCI at 1-year follow-up even after adjusting for relevant covariates.[54] It is hoped that other ongoing investigations will provide information about the risk factors for the development of LTCI and help guide interventions for prevention of the rather debilitating sequelae of critical illness that affect a person's quality of life. In one of the largest multicenter prospective ICU cohorts to date, a longer duration of ICU delirium has been found to be the major independent risk factor for long-term cognitive impairment up to 12 months after surviving a critical illness. In this population one of four ICU patients had cognitive impairment after 12 months following critical illness that was similar in severity to that of patients with mild Alzheimer disease and moderate traumatic brain injury.[12] This association was found to be independent of severity of illness, sedative or analgesic medication use, age, preexisting cognitive impairment, and comorbid conditions.[12] In this landmark study, the impairment was persistent and no different among medical or surgical ICU populations.[249]

Although the mechanisms by which delirium may predispose patients to long-term cognitive impairment after critical illness have not yet been elucidated, delirium is associated with inflammation and neuronal apoptosis, which may lead to brain atrophy[83,250] and white-matter disruption that are associated with cognitive impairment.[251,252]

Depression

Many ICU survivors experience significant affective symptoms, such as depression and anxiety.[192,253,254] The prevalence and severity of affective disorders, including symptoms of depression and anxiety in ICU survivors, range from less than 10% to 58%.[184,232,233,239,255] Depression has been reported to occur in up to 30% of ICU survivors,[232] and it is estimated that 47% have clinically significant anxiety.[192] Indeed, the high rates of depression among ICU survivors may be related to the cognitive impairment they experience, although this issue has not been evaluated in ICU cohorts. Affective disorders such as depression, PTSD, and anxiety may adversely affect test performance, especially if severe.[256,257] Moderate to severe depression may result in decreased effort and low motivation, which may in turn lower neuropsychological test scores in cognitive domains such as psychomotor speed and attention.[258,259] Moderate to severe anxiety, however, may lead to increased distractibility and blocked thoughts or words.[260,261] In some cases, severe depression may mimic symptoms of cognitive impairment, although there are important differences between these conditions. In general, individuals with depression retain the ability to learn and do not forget as rapidly, do not display significant decrements in language, are inconsistent with regard to orientation to time and date, and are typically more self-aware than their cognitively impaired counterparts.[262–266] A recent study showed that depression was five times more common than is posttraumatic distress disorder after critical illness and is driven by somatic symptoms, suggesting therapeutic approaches targeting physical rather than cognitive causes could benefit patients leaving critical care.[185]

A variety of instruments are available for use in the assessment of affective function. Tools such as the Geriatric Depression Scale-Short Form (GDS-SF),[265] the Beck Depression Inventory (BDI),[266] the Center for Epidemiologic Studies Depression Scale (CES-D),[267] and the Hospital Anxiety-Depression Scale (HADS)[268] assess depression. Anxiety can be assessed with the HADS[268] or the Beck Anxiety Inventory (BAI).[269] Discussion of these tools is beyond the scope of this chapter.

Concluding Thoughts

How might we incorporate these issues into our life as a health care professional? It is important as you encounter patients being newly admitted to the ICU with diseases such as severe sepsis or an exacerbation of chronic obstructive pulmonary disease to remind yourself that during subsequent days under your care, these patients will acquire new "neck-up" and "neck-down" (brain plus neuromuscular) diseases. It is imperative that these two new elements of disease burden become a major focus of medical attention during and after these patients' ICU stays. It is also important to recognize that these two categories of disability are inextricably linked. As we work to identify methods of intervention to prevent and treat these disabilities, it may be helpful to focus on modifiable aspects of care, such as reducing total exposure to psychoactive medications, reducing duration of delirium, mitigating sleep deficits and derangements, and minimizing periods of immobilization.

Key Points

- Delirium is a disturbance in attention, accompanied by a change in cognition or perceptual disturbance that develops over a short period of time and has a fluctuating course with a prevalence in medical and surgical ICU studies between 60% and 80% in cohorts restricted to those receiving mechanical ventilation and around 40% to 60% in ICU cohorts of nonventilated patients.
- Delirium is an independent predictor of longer duration of mechanical ventilation, longer ICU stays, higher costs, and a threefold higher risk of dying within 6 months or an increase of 10% risk of death per day of delirium.
- The development of tools such as the ICDSC and the CAM-ICU has allowed for the rapid diagnosis of delirium in patients by nonpsychiatrists and health care personnel even during mechanical ventilation.
- Sedative and analgesic medications and sleep disturbances in the ICU may be modifiable risk factors of delirium.

- The main thrust of delirium management must begin with treatment of the underlying disease processes that are leading to brain dysfunction, then drug removal (not addition), and then modification of the environmental factors (hearing and vision aids, removal of restraints, early mobility, and sleep hygiene). Summarize these via the mnemonic Dr. DRE. These are nicely summarized and operationalized in the evidence-based ABCDEFs of ICU care.
- Only after these issues are addressed is it appropriate to add another medication such as an antipsychotic into the mix of the individual pharmacopeia for any patient. Which medication to add (e.g., antipsychotic) is a point of ongoing investigation.
- Critically ill patients often have severe sleep deprivation with disruption of sleep architecture that is worsened by most sedative medications. The average amount of sleep in ICU patients has been measured to be about 2 hours in a 24-hour period, less than 6% of which is REM sleep often because of REM suppression from medications such as benzodiazepines and propofol.
- PTSD is a potentially debilitating psychiatric condition that develops in around 10% of ICU survivors as the result of exposure to a traumatic occurrence that generates intense feelings of fear, helplessness, or horror. Using ICU diaries in routine clinical care may alter PTSD outcomes among both patients and families.
- Medical and surgical management of critical illnesses is associated with long-term neurocognitive impairments in approximately two-thirds of ICU survivors. This form of cognitive impairment mimics dementia in many patients as they have moderate to severe deficits in memory, executive dysfunction, and other domains with profound ecologic validity.
- Between one-third and two-thirds of ICU survivors experience significant affective symptoms, such as depression and anxiety, which serve as another ongoing condition that all too often remains undiagnosed and therefore unaddressed by the medical teams caring for ICU survivors.

Review Questions

1. Which one of the following statements is most correct for the treatment of delirium?

a. Medications should be considered for delirium only after failure of restoration of sleep/wake cycles and frequent reorientation.

b. Antipsychotics are approved by the U.S. Food and Drug Administration (FDA) and recommended by the 2013 Pain Agitation Delirium (PAD) Guidelines for the treatment of delirium.

c. Delirium prophylaxis with medications is encouraged in the PAD guidelines.

d. Recent studies found no role in the pharmacologic management of delirium with the α2-agonist sedative, dexmedetomidine.

Answer: a. Delirium could be a manifestation of an acute, life-threatening problem that requires immediate attention (such as hypoxia, hypercarbia, hypoglycemia, metabolic derangement, or shock). After such concerns have been addressed, pharmacologic management may be considered. It should be recognized that although agents used to treat delirium are intended to improve cognition and safety, they all have psychoactive effects that may further cloud the sensorium and promote a longer overall duration of cognitive impairment. The main thrust of our approach as health care professionals must begin with treatment of the underlying disease processes that are leading to brain dysfunction, followed by drug removal, and then modification of the environmental factors (hearing and vision aids, removal of restraints, early mobility, and sleep hygiene), which can be summarized via the mnemonic Dr. DRE (Diseases, Drug Removal, Environment). Medications should be reserved for extremely distressing symptoms, behaviors that threaten the safety of patients or staff, or alcohol or benzodiazepine withdrawal.

2. Which of the following is most accurate for diagnosis of delirium in the ICU?

a. The Folstein Mini Mental State Examination.

b. For patients arousable to voice, Richmond Agitation-Sedation Scale [RASS] scores of −3 and higher), the Confusion Assessment Method for the Intensive Care Unit (ICU) (CAM-ICU).

c. For unarousable patients, (RASS score −4 or −5), the Intensive Care Delirium Screening Checklist (ICDSC).

d. No bedside tools have been validated to diagnose delirium in ICU patients.

Answer: b. The diagnosis of delirium is a two-step process. Level of arousal is first measured with the use of a standardized sedation scale, like the RASS. This is a 10-point scale with scores ranging from −5 to +4, with a score of 0 denoting a calm and alert patient. Positive RASS scores denote positive or aggressive symptomatology ranging from +1 (mild restlessness) to +4 (dangerous agitation). The negative RASS scores differentiate between response to verbal commands (scores −1 to −3) and physical stimulus (scores −4 and −5). If the patient's RASS score is −4 or −5 or the patient is not arousable by verbal commands, no further evaluation for delirium is performed, because the patient is comatose and is unable to be assessed for delirium. For patients who are arousable (RASS scores of −3 and higher), delirium can be assessed by the ICDSC or the CAM-ICU. The ICDSC assesses eight features of delirium: altered level of consciousness, inattention, disorientation, hallucinations, psychomotor agitation/retardation, inappropriate mood/speech, sleep/wake cycle disturbance, and symptom fluctuation. The sensitivity and specificity of this tool are 99% and 64%, respectively. The CAM-ICU, which can be performed in about 60 to 90 seconds, consists of four features that assess the following: acute change or fluctuation of mental status (feature 1), inattention (feature 2), disorganized thinking (feature 3), and an altered level of consciousness (feature 4).

To be diagnosed as delirious, a patient must have a RASS score of −3 or higher, with an acute change or fluctuation in mental status (CAM-ICU feature 1), accompanied by inattention (feature 2) and either disorganized thinking (feature 3), or an altered level of consciousness (feature 4).

3. Which one of the following statements about long-term cognitive impairment (LTCI) after critical illness is most correct?

a. Approximately one of four of ICU survivors has LTCI that persists 12 months after the ICU.

b. Neurocognitive impairments occur in less than 15% of survivors of critical illness without preexisting dementia.

c. Duration of ICU delirium is not a risk factor for LTCI in survivors of critical illness.

d. Neurocognitive impairments have been reported only in survivors of acute respiratory distress syndrome.

Answer: a. Over the last decade and a half, cohort studies have conducted assessments of the cognitive function among survivors of critical illness and reported significant impairments sustained by those who survive a critical illness. These studies have given rise to the concept of the post–intensive care syndrome (PICS), defined as new or worsened symptoms of cognitive impairment, disabilities in activities of daily living (ADLs), and mental health impairment that arise after critical illness and persist beyond acute care hospitalization. Post-ICU long-term cognitive impairment may involve memory and attention and/or executive function problems and leads to inability to return to work, impaired ADLs, increased risk of hospitalization, and decreased quality of life. In one of the largest multicenter prospective ICU cohorts to date, longer duration of ICU delirium was found to be the major independent risk factor for long-term cognitive impairment up to 12 months after surviving a critical illness. In this population, one of four ICU patients had cognitive impairment after 12 months following critical illness that was similar in severity to that of patients with mild Alzheimer disease and moderate traumatic brain injury.

Education in Critical Care: An Administrator's Perspective
- Pathways to Degrees, Licensure, Certification, and Credentialing
- Specific Education Issues

Summary

The missions of critical care units typically include clinical care, discovery, education, and administration. All must be addressed. Moreover, that address must be coordinated to advance all missions. All too often, education is an assumed by-product of clinical work and discovery. All too often, administrative tasks are initially ignored and hastily performed. Without intentional development, education and administration involute. The consequences of such neglect can be devastating, often leaving the critical care unit itself on life support. In this chapter, we emphasize the importance of all four missions, offering guidance to intensive care unit (ICU) leaders with an emphasis on administration and education. Much of this comes from experience. Appropriate references are cited where available.

ICU Administration

Attributes of an Effective ICU

What are the attributes of a high-performing unit? Integrity and vision. Although integrity and vision alone do not guarantee success (resources and leadership are necessary), we have never seen a high-performing unit absent either or both of those attributes.

By integrity, we mean that the unit functions as a cohesive whole toward mutually embraced principles. On our teams, we aim for quality, value (meaning that the quality must be affordable by patients, payers, and the health care system), and access (meaning that every patient in need must be accommodated). These constitute a classic business triad, meaning that any pair can be readily improved, but at the expense of the third. This requires a constant rebalancing of priorities, all within the human, physical, and financial resources available. This is achieved in part by "doing things right"—including hewing to standards and promoting all of the professions that bear on care of the critically ill. This is also achieved by "doing the right things"—hewing to ethical principles, embracing service as a form of leadership, blending toughness with mercy.

By vision, we mean that the practice of critical care and those who practice critical care coevolve. Administrators and educators must work together to craft a vision, lead toward that vision, and engage others toward that vision. Our discipline is scarcely a century old, yet many tools we bring to bear (capnography, bedside ultrasound, magnetic resonance imaging, and assessment of lactate and of troponin are just a few that come to mind) were unavailable, unknown, or unimaginable 3 decades ago. Health care is transforming rapidly in the face of new technology, health care consumerism, and heightened attention to costs. Hospital operating margins are continually shrinking while inefficient or unsafe care is increasingly being denied payment in the United States. This pattern will continue to grow as new pay-for-performance, pay-for-value, and pay-for-quality programs emerge. It is a truism that what we learned as students, what we practice as clinicians, and what we teach the next generation as instructors must all be different if the field is to progress. Those who administer and those who educate must not only anticipate change, they must also catalyze those changes. Further, they must adapt to change. Transformation always comes with costs, and it is the responsibility of leaders to manage both. The introduction or conversion of an electronic health record system is a familiar example of coevolution and the need for leadership to manage people, technology, and the processes of care to ensure that patients are made safer.

We emphasize that the most important word in the phrase "intensive care unit" is "unit." Care of the most vulnerable patients requires not only the colocation of caregivers, technology, patients, and families, but also a strategy that promotes consistency even in the face of forces that lead to disorder. The physical space that

encloses the ICU serves the same purposes as a cell membrane: containing the activity while selectively permitting the influx and efflux of resources and products. Energy is consumed not only in the tasks but also in the constant struggle to create order in the face of chaos. Stocking the clean utility room or the electronic medication dispenser serves as a convenient example: items that are outmoded, expired, or have fallen into disuse must be identified, evaluated and, where appropriate, superseded. Decisions about "what stays" and "what goes" are clinical decisions. Ensuring that those decisions are made regularly is an administrative responsibility.

Collaboration

The administration (and administrators) of larger health care organizations face challenges homologous to those faced by every ICU—for example, "do more with less." Ongoing dialogue with system leaders requires ICU administrative leaders to not only find a way to "have their voices heard" but also to "listen to what is being spoken" and adapt. Hostility manifested as silence, pejorative remarks, backbiting, and so on are profoundly destructive. It is worth the investment of time to develop and assert a code of conduct equally applicable to those inside and outside the ICU. This does not mean that the priorities of hospital leaders and the ICU will perfectly align, but it provides some guarantees that misalignments will be exposed, negotiated, and resolved insofar as possible. Conflict is inevitable in the chief administrative suite and at the bedside; promoting expeditious, honorable, and reasonable resolutions through collective adherence to a code of conduct is, in our view, essential to maintaining integrity.

The importance of collaborative coinvestment cannot be overstated. This is not strictly a matter of money, although budgets often need to be merged. Rather, it is a commitment that there should be a plan and an accounting of financial, physical, and human investment to achieve a desired goal. For example, requests to fund additional positions within the ICU should clearly state why those personnel are necessary and how their presence will measurably and favorably affect patient-centered outcomes for the unit and the health care system as a whole. If the new personnel are assigned tasks currently absorbed by others, what new activities and what improved outcomes can be expected of those shedding tasks? These are tough but realistic questions that illuminate shared expectations.

Health care system administrators demand strategy, and strategy nearly always involves sacrifice. This is true in business, in games, and in the allocation of health care resources. Sacrifice is not the same as "saying no." It most often involves using marginal time and dollars to achieve a desired end. For example, delaying replacement of a piece of equipment may free up funds to perform a study to show that there is a reason to make a different investment that results in better equipment. The sacrifice here will likely be investment of time and effort to conduct the study, write the report, and make the presentation.

We hasten to add that whereas strategy is important, logistics and execution are more important. Nearly every decision in ICU administration and education will be regarded as strategic owing to limitations on resources: "we have chosen to do this, not that; allocate here, not there; retain this, relinquish that." The effectiveness and impact of those decisions are utterly dependent on how the leadership team executes a decision. That execution nearly always requires engagement of and communication with key stakeholders.

Coordination of Critical Care Within Health Care Systems

Larger hospitals often have several ICUs that are specialized into service lines (e.g., general surgery, transplant, cardiothoracic, neurocritical care). Critical care fellowship training is aligned in a similar manner. Surgical critical care fellows were traditionally trained in surgical ICUs, anesthesia critical care fellows were assigned to cardiothoracic units, pulmonary/critical care fellows to medical ICUs, and so on. These specializations often lead to "siloed" ICUs run by different medical disciplines—either under medical school departments or private practice groups. In many cases, these ICUs function independent of other ICUs in their staffing (nurse practitioners, physician assistants, residents, fellows), budgets, and performance. This variation makes it difficult for hospital leaders to measure the value of any unit and attempts at comparing units often create tension among unit leaders, compounding and concealing inefficiencies.

What, then, are the coordinating characteristics that predict system-level success of critical care? The Academic Leaders of Critical Care Medicine (an ad hoc task force of the Society of Critical Care Medicine), studied existing critical care organizations (CCOs) and recently disseminated the results. Generally, CCOs collect two or more ICUs into a group and appoint CCO leaders who are held responsible for the success of the collective. The benefits and challenges of creating and sustaining CCOs are discussed in two recent reports. (For transparency, the authors of this chapter are leaders of a CCO composed of 14 ICUs with a total of 251 beds across 4 hospitals, 48 physician intensivists [only 25 full-time equivalents], 120 advanced practice providers, and tele-ICU monitoring center.)

Key findings of the Academic Leaders of Critical Care Medicine task force included the following. As of 2015, there are 27 identified CCOs across Canada and North America.[1] Two-thirds of the CCOs are in large urban health systems (>500 beds). Hospital administration initiated the transition to a CCO in 46% of the organizations; 50% are still gradually transitioning and 25% are completely established. Ideally, CCOs should be tasked with aligning all ICUs horizontally across the system to optimize performance, improve quality, reduce waste, and standardize policies and protocols. Horizontal integration is challenging in and of itself, and commonly there are units reluctant to integrate into the CCO, choosing to remain completely aligned with a parent department such as medicine or surgery. Stepwise component integration (e.g., initially pooling advanced practice provider training or clinician scheduling tasks) is a strategy to demonstrate both usefulness as well as good faith.

CCOs can also benefit from vertical integration of care.[2] Payors continue to implement value-based payment models. In these models, health systems and their partners will be required to take responsibility for a patient's entire care continuum and reimbursement will be bundled into episodes of care. The financial stability of health care organizations will hinge on how well they can manage population health. A CCO that is vertically integrated would coordinate downstream providers and organizations to ensure patients do not "fall through the cracks" on their way to recovery.

Slonim and Mariccini have pointed out weaknesses in the assertions that CCOs—and more specifically patients cared for in CCOs—benefit from such horizontal and vertical integration.[3,3a] Regarding horizontal integration, it is true that no prospective studies have been reported comparing horizontal integration with

the conventional isolated (siloed) approach. It is difficult to imagine a controlled trial because the process of horizontal integration takes time and before-and-after studies are subject to legitimate critique about the confounding effect of that time. Nevertheless, there are abundant data to suggest that horizontal integration provides for meaningful interunit comparative data as well as mechanisms to drive improvement (such as competitive incentive plans).

Regarding the weakness of vertical integration, the challenge is that vertical integration can never be complete unless there is a parent accountable care organization. A more limited vertical integration (perhaps from the emergency department through palliative care, but excluding preventative health and primary care) could be duplicative and wasteful in the setting of an accountable care organization. This is true, but ignores the reality that accountable care organizations are rarely complete. Indeed, vertical integration of a CCO could just as easily catalyze extension into a fully integrated accountable care organization. Given the widely recognized and reported costs of communication and handoff errors across services, the delays commonly encountered in transfers into and out of the ICU, and the financial consequences of inappropriate care being delivered in inefficient locations, we believe that even in the absence of direct comparative evidence a bias toward vertical collaboration and integration is justified and justifiable.

The Finances of Critical Care

Leaders of CCOs commonly remark that they have three tasks: (1) keep the peace; (2) "unload the trucks" (meaning keep the patient care going and keep the patients flowing); and (3) don't break the bank. The first task requires diplomacy and equanimity. The second requires the application of clinical acumen and logistical skills, all of which is commonly learned and practiced during training and participation in the ICU. The third imperative—fiscal responsibility—requires skills that are typically neither taught nor learned until ascent to a leadership position.

Nonclinical administrators typically introduce that third imperative into the conversation with allusions of "building value" and "improving performance." The central problem is cost: in the United States, it is estimated that critical care costs more than $100 billion annually. Payors are consistently reducing reimbursements. Thus the expectation is that the CCO leader will "do more" and likely have to do more "with less." Viewed through the lens of the hospital finance officer, the aggregate costs assigned to critical care outweigh the aggregate revenues that are accrued, with the result that CCO leaders are asked to become "more efficient." The initial response to such conversations can safely begin with the observations that acute care hospitals require ICUs to care for the most physiologically vulnerable patients, and further that many other parts of the hospital enjoy utilization benefits that are driven by critically ill patients. (Laboratory and imaging studies are revenue generators.)

Such initial responses only serve to remind administrators and others outside the ICU that critical care is an essential hospital-based service, and that the creation of value is different than unit-based profitability. (A thought experiment may serve to clarify the difference: spending a little extra money in the ICU [reducing profits] may make sense if more patients are sent home in better health and with reduced use of long-term care facilities and reduced unit and hospital readmissions [creating value].)

Fiscal negotiation therefore depends on being able to calculate attributable costs, attributable revenues, and attributable benefit to patients, families, and the health care institution. Understanding the financial model of the hospital (and, if applicable, the parent health care organization) usually rests with the CCO administrator.

Augmenting Value

CCO leaders have at least three core strategies by which they can augment value: economies of scale, standardization, and task reallocation.

Scale offers economies in at least three ways: with the total number of ICU beds, with the size distribution of the ICUs within the organization, and with the purchase of equipment and supplies.

With regard to the total number of ICU beds, there are administrative infrastructure and clinical staffing costs that are incurred when the first patient occupies the first bed: staff, unit equipment (such as a dedicated defibrillator), supplies (central line kits, for example), and other resources must be available to that initial patient. Each succeeding bed offers additional operational efficiency. For example, one ICU nurse can typically care for two patients, so addition of the second bed adds only minimal nursing cost. An ICU physician can care for dozens of patients. A bronchoscopy cart might serve adjacent units. The number of beds and volume of patients served generally leads to economies of scale, with the understanding that the economies are punctuated with the need to increment resources when thresholds are reached (step fixed costs).

The size distribution of ICUs yields both efficiencies and inefficiencies. Whereas traditional recommendations held that the ideal size of a physical ICU was 12 beds, contemporary models that feature new teams of professionals (advanced practice providers, respiratory therapists, pharmacists, dietitians, and so on) suggest that 18 to 24 beds can be efficiently managed by a single primary team. Professional "coverage" can often be aggregated during off-hours to provide essential services. The efficiency here relates to labor cost. Many health care organizations report around 54% of their budget to labor; in the ICU, labor costs are higher owing to staffing ratios and often approach 70% of total costs. Unfortunately, CCOs often inherit legacy units and their physical sizes. CCO leaders therefore must demand design efficiencies when new ICUs are proposed. It should be remembered that size can also create inefficiencies; the usual problem relates to communication barriers as the unit increases in size.

Regarding economies of scale, most health care organizations have supply chains that operate on the principles of bulk purchasing, local warehousing, and just-in-time delivery. The cost models are complex, including not just the purchase prices but the logistical cost of maintaining local and warehouse inventory. Thus the decision (for example) to use a particular brand of mattress pad different from the health system standard can result in many thousands of dollars of hidden costs. This problem expands quickly with complex equipment. Imagine having a single type of ventilator; it means one type of spare parts, one type of accessories, one reservoir of clean machines on standby for use, and one type of training cost. These savings quickly add up. This should not suggest slavish dependence on a single source for essentials, but it does suggest that purchasing in bulk consistently provides unique leverage at many points in the care continuum, which is only partially reflected in the purchase contract price.

Standardization

Standardization—better thought of as removing unnecessary variation—can apply to people, processes, equipment, and supplies. Standardization has benefits and risks. Regardless, standardization

is rarely embraced owing to beliefs about what is best for a particular patient. We consider the issues in turn.

Critical care professionals are trained more to competencies and less to standards. A history and physical examination, for example, can be completed in many ways. There are neither expectations nor restrictions on specific sequences provided that the key findings are gleaned and reported. Although most practitioners develop a consistent routine, there is no agreed-upon "one best way." This general attitude is not only pervasive but is in fact reinforced by the appointment of preceptors and teachers who view themselves as guides more than "instructors." (In contrast, flight instructors are expected to teach from a common syllabus, instruct the performance of specific maneuvers, and grade the learner's performance against written completion standards.) Although licensure, board certification, and hospital credentials are often asserted to verify standards, only observation and audits can evaluate the translation of professional standards to clinical practice.

Processes are easier to observe, audit, evaluate, and change. The range of processes available to standardize is vast and far exceeds the time and effort available. Prioritization is necessary. The assignment of priority rests on two types of questions. The first type relates to difficulty. Is standardization feasible? How difficult will it be to standardize this or that process? How much training, monitoring, and evaluation will be required? The second type relates to impact. Is the standardization essential to patient safety or critical outcomes? If the outcome is not critical, will standardization reduce costs or improve satisfaction? None of this is easy—witness the difficulty in standardizing a process that should be easy and has great impact on safety—namely, handwashing. Although cash incentives are effective, even small tokens like coffee cards and candy bars are powerful tools to change behaviors.

ICUs develop equipment and supply preferences that become enshrined as necessities. With rare exception, "different" represents a cost. If there are several types of ventilators, spares and repairs and skills must be maintained for all types. Similar to all durable equipment, from beds, to defibrillators, to monitors, to ultrasound machines, the consumables add up as well. A tour through the "clean utility room" often reveals near-identical kits and, worse, items that expire through lack of regular use. Equipment and supplies often represent the first and easiest targets for standardization.

Task Reallocation

Critical care can be viewed as a series of decisions and actions. Each depends on completion of a set of tasks. The tasks can be further divided into those that must be performed at the bedside (e.g., inserting a bladder catheter) and those that could be performed remotely. An alternate division of tasks relates to the profession(s) qualified to complete the task. The aforementioned bladder catheter could be inserted by a physician, an advanced practice provider, a nurse, or a specialized catheter insertion "team."

Although a class of professionals is typically recognized as having the best expertise and qualifications to perform a task, it often emerges that some tasks are better performed by different professionals or different groupings. Insertion of peripherally inserted central venous catheter line teams is one example of a task where constant repetition seems to improve outcomes. Yet there are many tasks that are often inefficiently performed. The process of charting, for example, can be accelerated with voice recognition transcription or use of a scribe.

Monitoring of vital signs, laboratory data, and medication interactions can be performed remotely. The expansion of tele-ICU services suggests that many cognitive aspects of patient care can be distributed to members of the care team quite distant from the bedside, including the evaluation of patients and the prescription of diagnostics and therapeutics.

Some tasks have "sunsetted" owing to technological advancements, such as the filing of laboratory data and imaging reports into physical charts. Others are candidates for simplification and automation, such as the recording of intravenous fluid administration that can be automated via device integration. We do not mean to suggest a wholesale revision of workflows, but rather a critical examination of the value stream and the assignment of each team member to the specific tasks.

Administrative Principles That Appear Reliable and Effective

1. Within the ICU, keep the hierarchies flat. This does not mean there should not be leaders. Quite the opposite—there should be a leadership team that visibly embodies the behaviors expected of the workforce. At a minimum, this demands a partnership between the nurse unit director and the physician unit director. In our practice, we include the lead advanced practice provider (APP) and the designated unit educator. Together, they set the tone and the expectations for the unit. Together, they guide conversation and deliberation about unit practice. Together, they evaluate outcomes and address opportunities. Extending this concept to CCOs, leadership should feature the professions that define critical care.
2. Set standards high and goals higher; demand the former and incentivize the latter. The standards should be as general and as widely applicable as possible. For example, there should be standards of family visitation, hand hygiene, use of universal precautions, and timely administration of antibiotics when sepsis is suspected. Such general standards do not preclude local additions that are necessarily focused in particular units—for example, adherence to practices regarding extraventricular drains in neurology units and intraaortic balloon pumps in cardiac units. Rather, the mechanisms by which those general standards are communicated, compliance evaluated, and corrected provide a foundation for unit-specific behaviors.
3. Reward performance. We believe that incentives are important to bring groups together toward common achievements; it is important that the challenge as well as the incentive engage more than one profession in the ICU. Anything that can be measured can potentially be used to drive behaviors. One of our early initiatives was to create an incentive plan for providers. By deploying incentives, Murphy et al. significantly reduced red blood cell transfusions, chest x-ray, and arterial blood gas utilization, resulting in an estimated cost savings of $1.5 million.[3] Mortality also decreased during their study period. Albumin utilization was also decreased over a 2-year intervention with an estimated savings of $2.5 million.[4]

   Carpenter et al. incentivized providers to merely account for their patient care time—both billable time and nonbillable services. Over the 6-month period, billable time increased from 53% to 63% of APP shifts. Interestingly, although the physicians were ineligible for this incentive, their billable time increased from 4.7 hours per day to 6.3 hours per day.[5] Although improvement can be achieved in simply reporting data without setting expectations or using incentives, in our opinion, incentives are more effective.

   We annually examine existing processes and engage all ICU leadership teams in identifying and selecting two to four metrics

TABLE 70.1 Incentive Domains and Metrics

Domain	Sample Metrics
Patient-/family-centered care	• Family satisfaction survey (FS-ICU 24) • Pain/agitation/delirium management • Advance directives
Finance	• Chest x-ray utilization • Arterial blood gas utilization • Red blood cell transfusions • Pharmacy or laboratory costs • Meeting or exceeding budget
Productivity	• Patient care time accounting • Documentation lag
Quality	• Hemoglobin A1c Testing • Nutrition implementation • Central line insertion protocols and timely removal • Vancomycin utilization • Early mobility • Ultrasound training • Low tidal volumes

FS-ICU 24, Family Satisfaction in the Intensive Care Unit questionnaire, revised, shortened form.

for which improvement is feasible (quality, value, and/or access) and improvement would have meaningful impact. A list of domains that have formed the bases for recent incentives is included in Table 70.1. Note that many of the metrics cross several domains.

4. Administration must care for staff if staff members are to care for patients. We will neither review nor dwell on "burnout," a construct that is increasingly applied to critical care among the many medical professions. We simply remark that critical care is hard work. Although most critical care professionals find their work deeply satisfying, they are no different than the general population in being susceptible to depression, fatigue, isolation, and other common threats to mental health. One area in which critical care professionals may differ from the general population is their chronic and repeated professional exposure to emotionally stressful situations.

We hasten to add that critical care professionals knowingly choose such exposures when they join the professions, yet only a fraction experience burnout syndrome. Others are energized by the continuing challenges. The challenge for CCO leaders is thus to ensure that the ICU remains an attractive and rewarding place to work for all. Although compensation is important, a sense of teamness and of a "work family" sharing the joys and burdens may play heavily into decisions by an employee to remain or depart. Those who report burnout emphasize isolation, depersonalization, and emotional exhaustion. Thus attention to well-being cannot be a response to crises but rather must be engineered into the fabric of daily work.

ICU Workforce Planning: Models, Strategies, and Retention

This chapter would be lacking if we did not mention the shrinking critical care workforce. The second imperative for CCO leaders—namely, to sustain the clinical processes of care—is threatened by the lack of qualified personnel.

By 2030, nursing shortage ratios will be largest in the Western portion of the United States, followed by the South, Midwest, and Northeast regions. The total national deficit could range from 725,000 to 1.1 million nurses.[6] In 2004 nurses were surveyed about the shortage. Ninety-eight percent of nurses believed that the shortage would increase stress on nurses, 93% indicated it would lower quality of care, 93% reported it would cause nurses to leave the profession, and only one-fifth believed that their working conditions would improve or that respect for nurses would increase.[7]

Physician intensivists are also becoming scarce. The COMPACCS (Committee on Manpower for Pulmonary and Critical Care Societies) study predicted an intensivist shortfall of 35% by 2030.[8] Rather than focusing on increasing the number of intensivists, Kahn and Rubenfeld suggest several alternatives: staffing ICUs with nurse practitioners and physician assistants, using telemedicine to monitor several units, and regionalization of care, transferring only the highest-acuity patients to tertiary or quaternary hospitals.[8a]

Complementary to the physician and nurse shortages is a relative abundance of nurse practitioners and physician assistants: APPs.[9] APPs are trained to provide medical care under the supervision of attending physicians and have been used in ICUs since the late 1970s.[10] In the ICU, APPs round on patients, conduct histories and physicals, admit and discharge patients, and perform procedures such as central venous line insertions, arterial lines, and intubations. APP-to-patient ratios vary greatly across the United States and Canada from 1 APP to 3 patients to 1:8 patients.[11] Our own data suggest that day shift APPs are most efficient with 6 patients, whereas nighttime APPs can care for 10 to 12 patients. Specific ratios aside, a method for providing counsel for these APPs when physicians are not physically present should be considered. We have deployed tele-critical care to leverage our scarce experienced physicians and critical care nurses, thereby enabling guidance on demand. The conversation is not about independent practice of APPs, but rather how to support their more complex decision making.

The Challenge of Clinical Research

Clinical research comes to the ICU in two ways. The patient may be enrolled in a protocol related to the primary illness for which critical care is incidental. An example would be a patient with cancer receiving experimental therapy in whom sepsis develops with the patient requiring ICU management. Alternatively, the ICU may have its own experimental protocols. For example, patients with sepsis might be randomly assigned to receive a placebo or a study drug in addition to standard care. In either case, professional staff members in the ICU providing care to a patient participating in a research protocol are expected to know (1) their general responsibilities to a patient participating in a research protocol and (2) sufficient specifics about the study, device, and/or drug to promote subject safety while ensuring protocol adherence. Although the medical unit director, nurse unit director, educator, study coordinator, and study investigator are jointly responsible for ensuring that training sufficient for safe conduct of the study in the ICU has occurred, the administrator is expected to know which studies are ongoing and, moreover, to verify that staff educational needs are met. Failure to do so may result in protocol violation, patient injury, and study interruption.

Education in Critical Care: An Administrator's Perspective

Care of the critically ill patient demands synchronized application of knowledge, technical skills, and attitudes from multiple professions. The need for specialized training is self-evident. This section briefly reviews the convergent training pathways and the role of the administrator in facilitating effective learning toward practice. This section omits consideration of formal training in critical care research, except where such training is needed to prepare bedside professionals to participate in clinical research trials.

Pathways to Degrees, Licensure, Certification, and Credentialing

Although the professions of critical care are diverse, there are homologies among the paths to competency. Nurses, APPs, physicians, pharmacists, and other allied health personnel generally must complete undergraduate medical education toward a degree in the health professions. (As used here, undergraduate education denotes training that includes classroom and patient-facing experiences that serve as a foundation for the profession before focus in critical care medicine and lead to initial degrees in the profession: BSN, MS [for PAs and NPs], MD or DO, PharmD, and so on.)

Such undergraduate programs typically require some limited exposure to acute and critical care medicine. For this largest cohort of learners, administrators must ensure that learners are constantly accompanied by teacher/supervisors; that appropriate confidentiality agreements are in place; and that the role of the learner is appropriately restricted (often to observation and unofficial "student" entries into the medical record). As the demand for ICU exposure is high, the central challenge faced by administrators is titrating the flow.

Completion of the foundational degree fulfills a key component toward licensure. In general, licensure is sufficient to qualify for some care privileges, although there are nuances. For example, a newly graduated physician may qualify for limited licensure as a trainee provided he or she is supervised in an accredited postgraduate training program. A newly graduated physician assistant will have one or more supervising physicians.

In the critical care environment, licensure is tantamount to obtaining a "learner's permit," and newly licensed professionals typically require some form of mentorship. Such mentorship may be complex and structured as in postgraduate training programs (residencies) for physicians and APPs. It may consist of mentored on-the-job-training, which is the norm for new nurses coming to the ICU. The administrator has three typical tasks associated with mentorship of the newly licensed professional: (1) verifying the existence of a training plan; (2) verifying the assignment of one or more supervising mentors, including clarification of the roles and responsibilities of trainee and mentor; and (3) monitoring completion, including an objective determination from the responsible individuals that training is satisfactory and complete and further an attestation that the trainee can practice independently.

Certification (typically board certification) complements licensure. Whereas licensing is a regulatory and legal matter, certification by a board representing that profession validates not only that the individual has completed a prescribed course of training but also that certain advanced competencies have been evaluated and found satisfactory, typically by an examination that may be written, oral, simulated, or a combination thereof. The administrator's primary role in certification is often as custodian of records verifying that the necessary training has been completed, qualifying the trainee to enter the certification pipeline and complete the evaluation process. Of note, certification by a board occurs not only at different stages across professions but also can occur at different experience levels within a profession. For example, board-certified internal medicine physicians require 2 to 3 years of postgraduate training to complete critical care medicine training and enter the examination process, whereas board-certified surgeons and anesthesiologists require a single additional year of critical care medicine training. Progress to completion is typically profession and discipline specific. The administrator must understand the pipeline, including how trainees in all the professions are actually funded for their training. This is crucial to annual budgeting.

Credentialing to one or more hospitals is required before independent practice of critical care medicine within a profession. Privileges are granted to the professional permitting services within a scope of practice. For example, a pharmacist can dispense drugs and consult on selection and dosing; a nurse can administer drugs; and a provider (physician or APP) must prescribe a drug but typically cannot dispense and only in some cases may administer the drug. Although each profession is associated with a set of core competencies (e.g., airway management), the granting of privileges is individual, based not only on training, licensure, certification, and self-reported experience but also on contemporary peer evaluation. The administrator's role in credentialing is generally to ensure that staff in all professions maintain the credentials necessary for critical care practice, which typically includes scheduled recurring professional practice evaluations and completion of required continuing professional education.

Specific Education Issues

The previous section outlined educational processes and milestones with homologies among the critical care professions. The administrator is often called on to offer solutions to three related challenges.

1. The number of learners exceeds the capacity of the trainers and/or training sites. Although this may be perceived as a challenge confined to academic health science centers, it affects every hospital and critical care site because critical care staffs predictably have turnover. There is a need, even with the most experienced professional joining a new hospital or ICU, to ensure that the new hire knows the scope of practice, is familiar with the local emergency procedures, and achieves minimal competency with the electronic medical record. All of this takes professional time and it is rarely (if ever) accounted for in the budget. The administrator is therefore required to verify training assignments while ensuring that patient care needs are met. This invariably requires prioritization of needs, balancing most requests, and declining requests when they would cause hardship to the unit or danger to the patients.
2. Initial learning typically occurs within professional silos, yet care invariably requires rapid communication and collegial interaction among the different professions. The challenge can emerge in several forms, most often surfacing after an adverse outcome or a complaint about professional behavior. More often than not, the root of the problem can be traced to failure to transition from a "parallel play" to a "team effort" mindset. The challenge, then, is to create educational experiences that catalyze the transition. One approach involves shared educational experiences, such

as setting requirements that all staff must train toward certain certificates (e.g., Fundamental Critical Care Support, Advanced Cardiac Life Support). Another approach involves simulation of common emergencies at a simulation center or within the ICU. Yet another approach involves multiprofessional educational conferences, including morbidity and mortality.

3. Continuing education is required of all professions and professionals who practice in the ICU to maintain licensure and credentialing. Although this requirement might seem a challenge for the professional more than the administrator, failure to plan for continuing education incurs substantial cost. Some requirements are intramural, such as completion of annual infection prevention education. Staff members who fail to complete the intramural education are summarily suspended. Other requirements are extramural, including a set number of hours of continuing education to maintain licensure. In the absence of planning to meet the licensing requirements, there is typically a hurried effort to gain credits. There may even be a temporary lapse of privileges (and the need for expensive replacement staff) while necessary continuing education credits are acquired. Such problems are best prevented by planned intramural continuing education appropriate to many of the critical care professions complemented by planned attendance at regional and national professional meetings.

Summary

This chapter has covered some of the broader aspects of critical care administration and education. Performance improvement strategies, burnout, and workforce shortages were also briefly discussed.

To be effective, critical care leaders must develop a vision and a practical plan to achieve it. Regardless of vision, an operational plan needs to be able to quickly demonstrate value to an organization. This could come in the form of lowering costs, improving quality, patient satisfaction, and so on. This value proposition is particularly important to the successful formation of CCOs. CCOs can integrate both horizontally and vertically, which provides opportunities for economies of scale, standardization, and task reallocation. In an accountable care organization, vertical integration could also improve care coordination for critically ill patients.

Health care in the United States is rapidly evolving and leaders must embrace change to survive. Reimbursement models are shifting toward episodes of care rather than paying for each patient visit as a separate transaction. These "value-based" care models represent significant financial risks for health care organizations. Critical care leaders will need to adapt to these changes and find ways to thrive in increasingly difficult landscapes.

Education is threaded through training pathways, ICU operations, and research protocols. Although the administrator is neither expected to design nor approve content, nor to determine whether a professional has met training completion standards, the administrator must be sufficiently familiar with the activities to ensure that education meets the needs of patients and professionals alike. The need for close collaboration with clinical leaders is self-evident.

Review Questions

1. Which of the following is most true about conflict in critical care?
   - **a.** Conflict should be confined to the administrative suite ("C-suite")
   - **b.** Conflict is inherently destructive
   - **c.** Conflict resolution is an essential skill for providers and administrators
   - **d.** Conflict is the underlying cause of burnout in the ICU

   Answer: c. Conflict, which is defined as the existence of alternate perspectives on a situation or alternate approaches to solving a problem, is inherent to all aspects of critical care. Conflict resolution is therefore an essential skill for providers at the bedside and administrators at all levels. There is no evidence that conflict is the underlying cause for ICU burnout
2. The priorities of critical care leaders universally include each of the following EXCEPT:
   - **a.** Balancing revenue and expense
   - **b.** Managing interpersonal conflicts
   - **c.** Ensuring reliable and qualified staffing
   - **d.** Enhancing discovery and innovation

   Answer: d. While research (discovery and innovation) is a common good, it is not an essential priority. Leaders must ensure continuous patient care, manage schedules, and ensure that interpersonal conflicts do not interfere with safety and effectiveness as their top priorities.
3. Which of the following is most correct concerning the comparison of integrated critical care organizations (CCO) with historically isolated ("silo'ed") ICUs?
   - **a.** No direct comparison between the performance of the two models has been presented in the peer-reviewed literature as of mid-2018
   - **b.** CCO offer a more flexible and reliable staffing model
   - **c.** CCO offer a more cost-efficient approach to critical care
   - **d.** CCO enhance discovery and innovation

   Answer: a. Despite conventional wisdom, the hypothesis that CCO outperform traditional models has never been directly and prospectively tested.
4. Regarding the use of incentives to change performance in ICUs
   - **a.** Pay-for-performance incentives are inherently inimical to team performance
   - **b.** Incentives are inherently bad because they encourage slavish adherence to a protocol
   - **c.** Incentives have been shown to change behaviors and improve outcomes in critical care
   - **d.** Incentives are best directed at managers and supervisors in ICUs

   Answer: c. Incentives have been shown to change behaviors and improve outcomes. Incentives are typically directed at outcomes and not method; teams are invited to be creative in their approach. For optimal effect, group incentives that include all team members are preferred to those that simply reward managers and supervisors.

Diagnosis and Management of Liver Failure in the Adult

CONSTANTINE J. KARVELLAS AND NICHOLAS MURPHY

CHAPTER OUTLINE

Decompensation of Chronic Liver Disease
- Precipitating Factors of ACLF
- Supportive Management of ACLF in the ICU

Acute (Fulminant) Liver Failure
- Etiology
- Clinical Course
- Management
- Artificial Liver Support
- Liver Transplantation

Liver failure is most often encountered as result of decompensation of chronic liver disease but can also occur de novo in patients with normal hepatic function. These patients are often described as having fulminant or acute liver failure, depending on the definition used.

Liver failure is characterized by a constellation of physical signs and symptoms including jaundice, coagulopathy, and encephalopathy. Not all of these need be present for a diagnosis to be made, but as the syndrome progresses they are usually present to varying degrees. Liver failure progresses to multiple-organ failure and ultimately death in a large proportion of patients, and supportive care plus removal of the primary cause is the mainstay of treatment. Liver transplantation may be indicated in a small group. Liver support systems are being actively investigated and may, in the future, have the ability to bridge a patient to recovery or transplantation.

Decompensation of Chronic Liver Disease

"Decompensation" in cirrhosis of the liver is a term used to describe the onset of visible signs of portal hypertension such as the development of ascites and variceal bleeding. These signs and symptoms can also be described as "symptomatic" cirrhosis, with the onset of liver failure in symptomatic cirrhosis described as "decompensation." One often leads to the other, but for the purposes of this chapter decompensation refers to the onset of liver failure.

The pathologic basis of acute decompensation in chronic liver disease or acute on chronic liver failure (ACLF) is incompletely understood but is thought to be precipitated by systemic inflammation, and if looked for hard enough, some signs or symptoms of infection will be seen in most patients.[1,2] Patients with well-compensated cirrhosis often decompensate following a defined event. The precipitants can be split into two types: (1) those related to direct liver insult, such as ischemia, a toxic insult such as alcohol, or a superimposed viral infection; and (2) those in which the liver is affected as a bystander in a systemic inflammatory process, such as after an episode of sepsis or a gastrointestinal bleed. This can be contrasted to the progressive liver failure of end-stage cirrhosis. Both present with similar clinical pictures, but in ACLF there remains the possibility of improvement and reversibility, and if these patients do recover, they return again to the previous mortality trajectory.[1,2]

Differentiating between the two is difficult but the presence of a precipitating factor and history can be useful. In patients with end-stage liver cirrhosis, there is often a history of gradual deterioration in biochemical parameters, clinical status, and other organ function, whereas in ACLF there is often an acute deterioration. Organ support in the former setting is of dubious utility as it is almost always futile (Fig. 71.1).

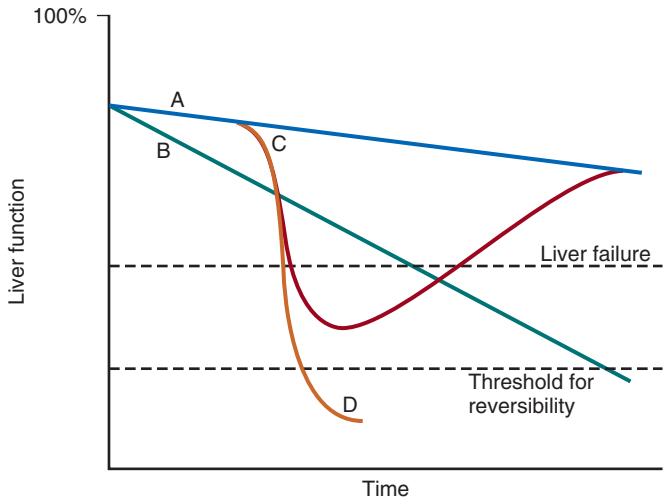
The European Association for the Study of the Liver-Chronic Liver Failure (EASL-CLIF) consortium proposed a working definition for ACLF as "acute deterioration in liver function over a period of 2–4 weeks, usually associated with a precipitating event, leading to severe deterioration in clinical status with a high risk of short term mortality."[1]

ACLF often occurs with multiple-organ dysfunction. This may be because of the underlying precipitating event, such as pneumonia or bacterial peritonitis, or as a result of the severe deterioration in liver function. Often it is difficult to distinguish which came first. Renal failure is the most common organ failure associated with ACLF, and it is the severity of organ dysfunction that dictates the outcome.[3]

Precipitating Factors of ACLF

Alcoholic Hepatitis

Alcoholic hepatitis is a common manifestation of alcohol abuse. Between 20% and 30% of heavy drinkers present with it at some time. The clinical picture is variable and ranges from a relatively mild syndrome associated with loss of appetite, nausea, and vomiting with right upper quadrant pain to severe life-threatening liver



• **Fig. 71.1** Graphs A and B represent the trajectory of liver function in cirrhosis. B is indicative of a patient with progressive end-stage disease. A has a more shallow trajectory until there is a precipitating event, at which time either graphs C or D can be followed. C recovers with intervention back to the previous trajectory, but D does not.

decompensation, but the most obvious sign is the sudden onset of jaundice, which this can be the first indication of liver disease in a heavy drinker. Overall, after first presentation, 35% to 50% of patients will die within the first month of diagnosis.[4] It usually presents after a bout of heavy drinking and often occurs on a background of cirrhosis. Patients' conditions frequently deteriorate after stopping alcohol. This may be due to the immunosuppressive effects of alcohol. In patients without cirrhosis, abstinence and nutritional support can lead to a marked improvement in liver function over time.

See the online supplement for additional text on alcoholic hepatitis.

Portal Hypertensive Bleeding

Portal hypertension is a significant complication of chronic liver disease, leading to the formation of portosystemic collateral vessels. Of these vessels, the most significant clinically are those that occur in the wall of the stomach and esophagus. In patients with portal hypertension as a result of cirrhosis, the development of gastrointestinal varices occurs in approximately 60% at the time of diagnosis.[11] The incidence of the first acute bleed in an unselected patient is relatively low at about 5% per year, but it can be catastrophic when it occurs.[12] The mortality rate associated with the event has fallen over the past 20 years from approximately 30% to 50% to about 20%, and control of the initial bleeding episode is achieved in about 90% of patients.[13] Half of all fatalities occur in the first 5 days after an acute bleed; about half of them are due to uncontrolled bleeding and the rest are due to multiple-organ failure. This pattern remains the same when mortality rate in the first 6 weeks after the first bleed is examined.[13]

See the online supplement for additional text on portal hypertension.

The use of antibiotic prophylaxis has been shown to reduce the incidence of infection in this group of patients and to improve the short-term mortality rate.[20,21] It has been proposed that infection is the precipitant to an acute increase in portal pressure that may trigger bleeding.[22]

Bacterial Peritonitis

Patients with chronic liver disease are at increased risk of infection. The immunosuppression associated with chronic liver disease is incompletely understood but relates to a range of factors, including an impaired innate and adaptive immune response.[23,24]

In cirrhotic patients with ascites, decompensation to liver failure is often precipitated by infection. Bacterial peritonitis is a common and severe complication. It can be completely asymptomatic but can present with a range of symptoms and signs, including local signs of peritonitis, abdominal pain, diarrhea, and signs of systemic inflammation, such as fever, rigors, elevated white blood cell count, hypotension, and tachycardia.[25]

Bacterial peritonitis is often spontaneous, without any obvious source, although it can be secondary to other intraabdominal disease. It is generally caused by aerobic gram-negative bacteria, although gram-positive bacteria including methicillin-resistant Staphylococcus aureus (MRSA) should be suspected if there is treatment failure, especially if the patient has been taking prophylactic antibiotics.[26] In any patient with ascites and decompensation of liver disease, spontaneous bacterial peritonitis (SBP) should be suspected. Diagnosis is demonstrated by sampling of the ascitic fluid. An absolute leukocyte count in ascitic fluid of greater than 250/μL is diagnostic. Antibiotics should be started as soon as SBP is suspected, following blood culture and a diagnostic ascitic tap. Empiric broad-spectrum antibiotic coverage for gram-negative and MRSA organisms (depending on local prevalence) should be started until culture results are available.

Renal failure is a significant complication of SBP in patients with cirrhosis and is discussed later. The use of human albumin solution in SBP has been shown to reduce the incidence of progression to renal failure and should be considered in this setting.[25]

Supportive Management of ACLF in the ICU

The presentation of ACLF depends on the precipitating event or events but the clinical picture and pattern of organ failure overall look very similar. Hyperbilirubinemia and the resulting jaundice are almost universal, as are other biochemical manifestations of poor liver function. Plasma protein production is deranged, leading to a prolongation of prothrombin time and hypoalbuminemia. Thrombocytopenia resulting from hypersplenism and sepsis is also characteristic. The effects on the coagulation system are complex, however, as there is a concurrent reduction in the production of endogenous anticoagulant proteins in the liver, resulting in a relative rebalancing. Infection leads to consumption of factors and platelets and so the use of thromboelastography is recommended in bleeding patients. Lower levels of factors can result in difficulties maintaining coagulation during times of stress, particularly during infections, and evidence of a heparin-like effect has been shown.[27] It is also interesting to note that the incidence of thromboembolism is not lower in patients with cirrhosis even in the setting of a prolonged international normalization ratio (INR), suggesting that standard measures of coagulation are unreliable.[28]

The pattern of circulatory changes associated with cirrhosis is distinctive. Hypotension and an increase in cardiac output are typical, resulting in a hyperdynamic circulation. Peripheral vasodilatation, however, is not distributed evenly and occurs mainly in the splanchnic circulation as a result of sinusoidal portal hypertension. Splanchnic vasodilatation results in effective arterial

Features suggestive of malnutrition, such as muscle wasting and vitamin deficiency, are seen commonly. In severe decompensation, other intercurrent illnesses such as pneumonia or urinary tract infection or a gastrointestinal bleed are often present. Systemic inflammation may be the precipitant of decompensation in these patients.[5]

In alcoholic hepatitis, liver enzymes are moderately raised with an aspartate aminotransferase (AST) level rarely greater than 300 IU. The ratio of AST to alanine aminotransferase (ALT) is usually raised to greater than 2.[6] A high white blood cell count and bilirubin are also typical. The liver is usually enlarged and fatty on ultrasound. Portal hypertension often complicates the clinical picture, presenting as worsening of ascites. Assessment of filling pressures can be difficult if ascites is tense. Further hemodynamic monitoring is recommended if there is any doubt regarding filling status or if cardiac output is thought to be compromised.

Strictly speaking, liver biopsy is required to make the diagnosis of alcoholic hepatitis and is often performed to assess the extent of fibrosis, although it is not required for acute management. Demonstrated under light microscopy, the Mallory hyaline and a neutrophil infiltration (the amount of which is a marker of severity and prognosis), necrosis of hepatocytes, collagen deposition, and fatty change establish the diagnosis.

The prognosis of patients with alcoholic hepatitis depends on the severity of the disease. Risk stratification is important, both in defining the indications for the use of specific pharmacologic agents aimed at the interruption of progression and in clinical research. Serum markers and liver histologic findings provide the best means for risk stratification, with the presence of cirrhosis a poor marker.[7] In many cases, however, biopsy is precluded because of the risks of bleeding. Serum bilirubin, coagulation parameters, and creatinine levels have been shown to predict outcome and have been combined into several scoring systems: the discriminative function; Child, Turcotte, Pugh; the Mayo end-stage liver disease (MELD) score; and the Glasgow Alcoholic Hepatitis score have been used to evaluate outcome. Of these, the MELD score appears to offer the best prediction of mortality risk because of the inclusion of renal function (creatinine) as well as liver function; renal deterioration in this setting has a particularly poor prognosis.[8] Standard critical care prognostic scores have also been used to assess the prognosis of patients with decompensated chronic liver disease of any cause. The Sequential Organ Failure Assessment (SOFA) score has been shown to provide useful prognostic information.[1,9]

In early disease, abstinence and good nutrition, including supplementation with B vitamins, is the mainstay of management. In severe disease, progression to hepatic encephalopathy and organ failure can be rapid. In addition to general supportive care, specific therapies have been used in an attempt to halt and reverse the hepatic inflammation, but none other than corticosteroids have been demonstrated to prevent the fall into multiple-organ failure and ultimately death.[10]

Control of bleeding episodes is via direct endoscopic therapy, usually in the form of band ligation in the case of esophageal varices.[14] Terlipressin, a synthetic analog of vasopressin, can be used as an adjunct to band ligation. Terlipressin induces splanchnic vasoconstriction and reduces portal pressure and has been shown to reduce mortality rate.[15] There is some evidence that somatostatin may reduce the amount of blood transfused but the evidence is weak.[16] Uncontrolled bleeding owing to either failed endoscopic or pharmacologic therapy or when resources do not allow immediate endoscopic therapy may be managed with balloon tamponade of the stomach or esophageal varices. Primary control of esophageal varices is usually successful, but balloons should not be inflated for more than 12 hours because of the risks of mucosal necrosis. Care should be exercised when inserting and inflating a Sengstaken-Blakemore or Minnesota tube because perforation of the esophagus is usually fatal in this setting. After control with the insertion of a balloon tamponade device, further endoscopic therapy, surgical shunting, or transjugular intrahepatic portosystemic stent shunts (TIPS) may be attempted. Of the shunt procedures used TIPS is the most commonly attempted where personnel with technical skills are available. The procedure involves decompressing the portal circulation into the hepatic vein via a stent inserted percutaneously through the liver via the internal jugular vein. The procedure is a very successful salvage therapy for controlling bleeding but can induce certain complications, including (1) volume overload as a result of portal shunting into the right atrium, which can induce heart failure; (2) bypassing the portal circulation, resulting in ischemic liver injury and, rarely, liver failure; and (3) worsening of encephalopathy grade (the most common complication), resulting in failure to awaken from the procedure, the need for extended ventilation, and the risk of hospital-acquired infection. There have not yet been any controlled trials of TIPS as salvage therapy in this setting, and it is unclear what role TIPS has in the management of acute bleeding varices as it may result in just prolonging the dying process. Despite better prevention of rebleeding when compared with endoscopic therapy in patients with bleeding varices, a mortality benefit cannot be shown with TIPS.[17] Garcia-Pagan and colleagues have shown that TIPS, performed not as salvage therapy but used as a primary form of therapy once the initial bleed has been controlled, results in a dramatic reduction in rebleeding rates and mortality rates.[18] Coagulation abnormalities are commonly present in patients with acutely bleeding varices, and abnormalities in clotting factors have been shown to be independent prognostic factors in patients with esophageal varices. Attempts to treat coagulation abnormalities with clotting components should be undertaken during an acute bleed to include fresh frozen plasma and platelets targeted to correct abnormal partial thromboplastin time and platelet count. Activated factor VII has not demonstrated significant benefit in this setting.[19]

Bleeding from varices is associated with infection. Between 35% and 60% of cirrhotic patients with bleeding varices have documented infection over the following 2 weeks.[20]

underfilling with the resulting activation of compensatory mechanisms.[29] During decompensation circulatory changes become more pronounced with an increase in portal pressure; systemic vasodilatation worsens and blood pressure drops further and becomes less responsive to vasopressor support. Recent work shows that cardiac output may fall in those who develop acute kidney injury (AKI)/hepatorenal syndrome, as do cardiac filling pressures and pulmonary artery pressure. These changes point toward some form of cardiac depressant factor associated with decompensation.[29] There is a reduction in intrarenal blood flow owing to the activation of compensatory mechanisms designed to maintain arterial volume, such as the renin-angiotensin system and sympathetic nervous system. This results in a further reduction in glomerular filtration rate and urine output. Cardiac function may be further compromised by liver failure–associated cardiomyopathy, which is manifested by a low or normal cardiac output in the setting of reduced afterload.[30] There may also be a relative hypovolemia in the setting of a normal or raised central venous pressure because of raised intraabdominal pressure caused by ascites. Echocardiography is very helpful in the delineation of any cardiac dysfunction and can help assess pulmonary artery pressure to assess if the patient has portopulmonary hypertension.[31] A pulmonary artery catheter should be used if there is any doubt.

AKI is the most common form of organ dysfunction seen in patients with ACLF and has significant attributable mortality risk.[32] There are four main causes; those associated with bacterial infection are the most common, followed by hypovolemia and parenchymal disease, with hepatorenal failure the least common.[3] However, hepatorenal failure has a particularly poor outcome. The diagnosis of AKI in the setting of liver disease is problematic, as conventional measures of renal function are less indicative of renal function.

Hepatorenal syndrome (HRS) is a severe complication of advanced cirrhosis. Its clinical manifestations are related to changes in renal, hepatic, and the systemic circulation. HRS is a consequence of intense renal vasoconstriction, leading to a reduction in renal perfusion and glomerular filtration. The ability of the kidney to excrete sodium and free water is also severely impaired without histologic changes accounting for this renal impairment. Traditionally, HRS has been described in two different clinical patterns, according to intensity and onset of renal failure: Type 1 HRS increasingly represents the severe end of the spectrum of renal failure in cirrhosis. It is characterized by rapidly progressive renal failure with oliguria. It is defined as a doubling of the serum creatinine level to more than 2.5 mg/dL or a 50% reduction in 24-hour creatinine clearance to a level less than 20 mL/min in less than 2 weeks. Type 2 HRS progresses slowly and represents a less severe deterioration in renal function that may remain stable for extended periods of time. The dominant clinical feature of a patient with type 2 HRS is refractory ascites. This is the result of intense sodium retention, reduced glomerular filtration, and marked stimulation of the renin-angiotensin system. More recently, the International Club of Ascites (ICA) in 2011 revised traditional criteria to define HRS-type AKI (HRS-AKI) as including diagnosis of cirrhosis with ascites, increase in serum creatine (SCr) by 50% with final SCr value greater than 133 µmol/L (1.5 mg/dl), no response to diuretic withdrawal/plasma expansion with albumin 1 g/kg per body weight, absence of shock, absence of nephrotoxins (nonsteroidal antiinflammatory drugs, iodinated contrast) and an absence of macroscopic signs of structural kidney disease.[33]

Until recently there was no effective treatment for patients with HRS other than liver transplantation, but over the past 15 years observational and interventional studies have shown that countering the compensatory circulatory changes that promote intrarenal vasoconstriction with use of systemic and selective vasoconstrictors plus plasma volume expansion with albumin can lead to significant improvement in renal function.[34] The aim of therapy is to focus vasoconstriction on the dilated splanchnic vessels, resulting in a redistribution of the blood volume back into the systemic arterial circulation. Over time this results in suppression of the compensatory mechanisms; a reduction in plasma renin activity, sympathetic activity, and circulating catecholamines; and an associated increase in glomerular filtration rate, sodium excretion, and urine output.[35] Many different vasoconstrictors have been tried in this setting. The drug most commonly studied is terlipressin, and it is often given with 20% human albumin solution. This approach has been subjected to a randomized controlled clinical trial in which the addition of albumin was associated with an improvement in renal function.[36] Evidence suggests that vasoconstrictor therapy, with or without plasma volume expansion, results in an improvement in renal function in about a third of patients with type 1 HRS. The best predictor of response to therapy is the baseline serum creatinine level, and those who do respond have a significant rise in their arterial pressure.[34,37]

Hepatic encephalopathy (HE) is almost universal during decompensation cirrhosis and is characterized by loss of normal day/night differentiation, confusion, somnolence, asterixis, hyperreflexia, and progression to coma. It is reversible in the event of recovery of liver function or removal of the precipitating event. The etiology of hepatic encephalopathy is incompletely understood but relates to the inability of the failing liver to clear circulating toxins, most notably ammonia. There are other important factors, including minor degrees of cerebral edema and systemic inflammation. Interaction of these components leads to the profound levels of encephalopathy seen in ACLF.

Ammonia production in the gut is important in the pathogenesis. Ammonia is usually cleared from the portal circulation in the liver. The mainstays of treatment are colonic cleansing with enemas and enteral disaccharides such as lactulose. Both of these procedures have been shown to improve encephalopathy grades. The restriction of protein, once fashionable in patients with liver disease, is contraindicated. The majority of these patients are malnourished/sarcopenic, and adequate enteral nutrition is essential.[38]

Patients with ACLF and high grades of HE require intubation and ventilation, if not because of hypoxia, then to allow airway protection. Airway protection is most frequently needed in patients with bleeding esophageal or gastric varices requiring endoscopic therapy for large-volume hematemesis in the presence of HE and a difficult or prolonged endoscopic procedure. Patients with ACLF are usually exquisitely sensitive to sedative and anesthetic agents, particularly benzodiazepines, which can prolong coma. Care should be exercised in their use and shorter-acting agents such as propofol are preferred.

Large-volume paracentesis should be considered in any patient with tense ascites. There is evidence that large-volume paracentesis improves lung mechanics and oxygenation in nonventilated patients but data in ventilated patients are lacking.[39–41] Hepatic hydrothorax is a persistent pleural effusion, almost always associated with ascites, usually on the right side of the chest. It can be massive in size, containing many liters of fluid, and is thought to be caused by communication from the peritoneum. Management can be difficult. Direct drainage with thoracocentesis is usually inadvisable, as the fluid accumulation is persistent, leading to continued need for chest tube placement, which carries the risk of infection. Management should be directed at the ascites and includes diuretics, salt

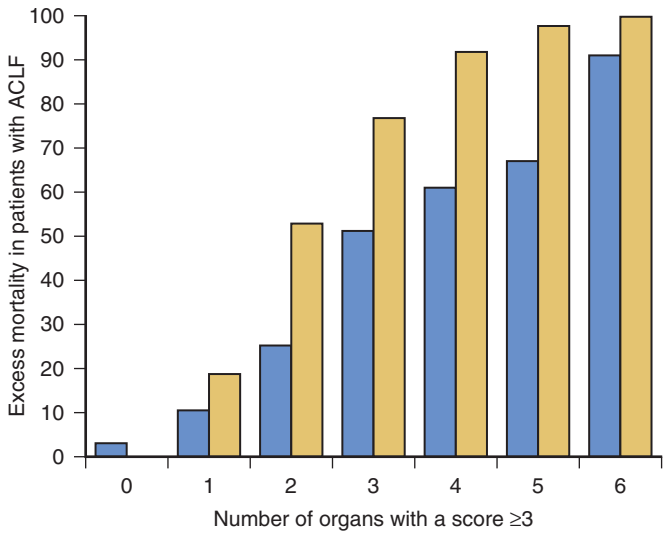
restriction, and paracentesis. TIPS can be used to control both ascites and hydrothorax, but is associated with worsening encephalopathy grade in some patients.[42]

Adrenal dysfunction in patients with critical illness, particularly patients with septic shock, has been documented extensively.[43] Studies have suggested an improvement in outcome with steroid use but subsequent investigations have been less clear. Current recommendations suggest steroid treatment should not be based on adrenal stimulation and should be reserved for those with vasopressor-resistant septic shock or early acute respiratory distress syndrome within 14 days of onset.[43] Patients with ACLF have also been shown to have a high incidence of adrenal suppression, although it is not clear if this has a different etiology from other critically ill patients. Patients with adrenal suppression have worse hepatic and renal function, more organ failure, and a higher intensive care unit (ICU) and hospital mortality rate.[44] There remains, however, a lack of consensus regarding definitions of adrenal dysfunction and appropriate testing in patients with liver disease and in which patients require treatment.[45] However, in patients with cirrhosis and septic shock admitted to the ICU with adrenal insufficiency, as defined by a suboptimal response to adrenocorticotropic hormone stimulation, replacement of hydrocortisone (50 mg every 6 hours) results in a higher incidence of shock resolution and hospital survival when compared with historical control subjects.[46]

Outcome and Data on ICU Use in Decompensated Cirrhosis

Despite ICU care, the outcome in patients with decompensated cirrhosis is poor. In one study overall cumulative mortality rates were 36% in the critical care unit, 46% in the hospital, and 56% at 6-month follow-up.[47]

In patients who require organ support within the critical care environment a number of observations can be made. Derangement of acute physiology at admission is a predictor of outcome, as it is for unselected patients admitted to the ICU.[48] In addition, the number of organs requiring support also is predictive of outcome, as it is in unselected patients.[47,49] If you compare the number of organs failing (defined as an organ-specific SOFA score >3), there is an excess mortality rate associated with cirrhosis when compared with an unselected group (Fig. 71.2).[50] The CLIF consortium has developed the CLIF-ACLF score (based on SOFA but evaluated in patients with ACLF), which demonstrates a mortality of more than 80% with failure of more than three organs.[51]



• **Fig. 71.2** This graph shows the relative mortality rates associated with the number of failing organs as defined by a SOFA (sequential organ failure) score of greater than 3. In patients with cirrhosis *(yellow bars)* there is an excess mortality rate at each position. *Blue bars*, Unselected group.

Acute (Fulminant) Liver Failure

Acute liver failure (ALF) is a syndrome manifested by the rapid cessation of normal function in individuals with previously normal hepatic function. The rate of decline in function dictates the manner in which the syndrome manifests and influences the outcome. The cause is the main influence on the rate of progression and the likelihood of spontaneous recovery.[52]

The pathologic basis of the massive hepatic necrosis was described in detail by Lucké and Mallory after the Second World War in 1946.[53] The presence of the American army in East Asia and Africa resulted in exposure to both epidemic and serum hepatitis, and data regarding the clinical course of the syndrome and its pathologic features were collated via the army medical services.

In 1970 Trey and Davidson introduced the term fulminant hepatic failure to encompass the current clinicopathologic understanding of the syndrome.[54] This definition was an attempt to encapsulate the clinical course and to differentiate it from decompensation of chronic liver disease. They described a syndrome of rapidly progressing liver failure (within 8 weeks) in which the defining point was the onset of hepatic encephalopathy following the onset of symptoms in someone without previous liver disease. They make the point that the syndrome is potentially reversible in some patients. This definition is still used today; however, it has become clear that this definition is too narrow and that subgroups exist. This point is important as these subgroups predict the likely prognosis and potential for survival without a liver transplant.[52]

The rate of progression from the onset of jaundice or other initial symptoms (such as fatigue or acute viral illness) to development of encephalopathy is used to define subgroups. This in part relates to the cause of liver failure and to the way the pathologic expression of the pattern of organ failure presents. For example, patients with significant acetaminophen-induced hepatotoxicity generally present with liver failure within 7 days of ingestion, unless ingestion was staggered over a period of time when the timing of liver insult is difficult to define. In contrast, patients presenting with seronegative hepatitis (unknown cause) can have a very variable presentation, some with a prolonged illness over a period of months, resulting in a patient who is deeply jaundiced with evidence of portal hypertension, such as ascites, at the onset of encephalopathy, and others with a relatively short presentation period. These two extreme ends of the syndrome split the group into hyperacute and subacute, with ALF in the middle. Interestingly, it is the hyperacute group that has the best chance for spontaneous recovery, although this group has the highest risk of cerebral edema. The subacute group has the worse prognosis with medical management alone.[52]

ALF is rare, with about 1 to 6 cases per 1 million of the population in the developed world.[55] The incidence in the rest of the world is less clear because of the paucity of data (Box 71.1).

Etiology

Worldwide, and in the developing world in particular, approximately 95% to 100% of patients presenting with ALF have viral hepatitis.[56]

Within the United Kingdom and as recently reported in the United States, paracetamol (acetaminophen) hepatotoxicity is the leading cause of ALF. This is followed by liver failure of unknown cause or seronegative hepatitis.[57,58]

The pattern of ALF within the United Kingdom and United States has been changing over the past 30 years.[57,58] Up until the late 1990s, the rate of hospital admission owing to acetaminophen ingestion had risen year by year. In the United Kingdom acetaminophen overdose is usually due to deliberate self-harm. In contrast, the U.S. data suggest that over half of all patients with ALF owing to acetaminophen were due to therapeutic misadventure. Some doubts have been expressed regarding this interpretation as misadventure in some cases that appear to be occult suicide attempts.[58,59]

In 1998 legislation was introduced in the United Kingdom to restrict the over-the-counter sale of paracetamol to 16 tablets from most retail outlets and 32 from pharmacies in the form of blister packs. Interpretation of the effects of the legislation has proved to be complex, in large part because there were no prospective audits initiated at the time to study it. Early interpretation suggested that admissions to hospital, severe liver toxicity, and transplantation for acetaminophen fell.[60] The picture is more complex, though. Death rates have fallen; however, much of this reduction can be related to the withdrawal of co-proxamol during the mid-2000s. Co-proxamol, a combination of paracetamol and dextropropoxyphene (a mild opioid), was a prescription-only medication associated with a high degree of fatality if taken in overdose; most of these cases occurred out of hospital and were attributed to the effects of dextropropoxyphene on respiratory depression.[61] Admission to the hospital because of acetaminophen has continued to rise year by year, but the number of pills taken on average has fallen and so the case fatality rate is lower. The numbers of patients referred to transplant centers is also lower than before the legislation, but the number of patients who received transplants has remained about the same, indicating the small number of determined overdoses and misadventure cases has remained relatively stable.

In the United Kingdom and the United States, the incidence of acute hepatitis A virus and hepatitis B virus (HBV) infection has fallen dramatically since the 1980s[57,58] (Figs. 71.3 and 71.4).

Less than 1% of acute hepatitis A or B progress to ALF. In the United States and United Kingdom, as a proportion of the total, the number of admissions with ALF owing to viral hepatitis has fallen steadily and is currently responsible for less than 5% of all admissions in the United Kingdom and 11% in the United States.[57,58]

Indeterminate hepatitis (non-A to -E hepatitis, seronegative ALF, indeterminate) is often presumed to be viral in origin and is the most common presentation, excluding acetaminophen in the United Kingdom and United States along with viral hepatitis in the developing world. It is a diagnosis of exclusion and, as diagnostic capabilities improve, is falling in incidence in some centers.[57]

• BOX 71.1 Hyperacute, Acute, and Subacute Liver Failure

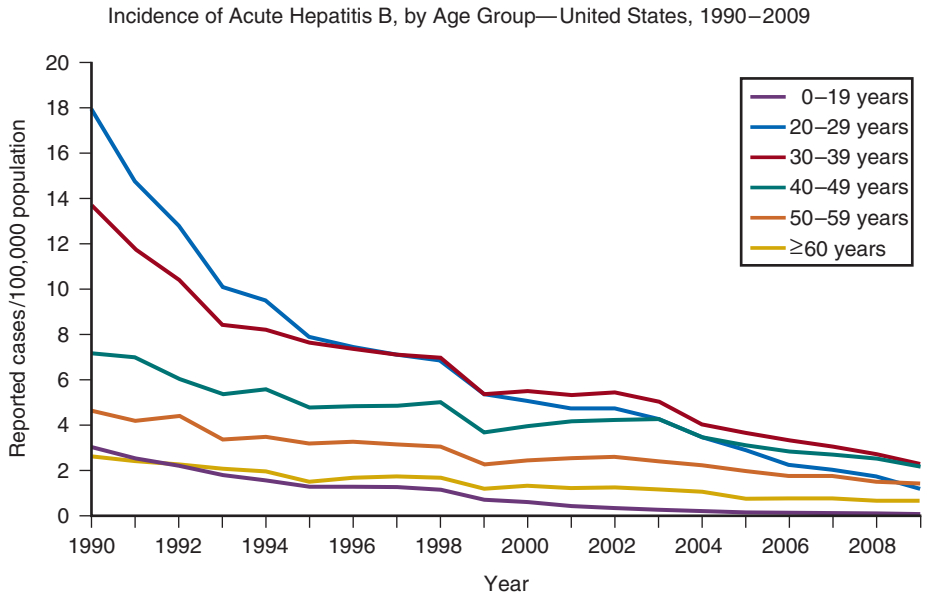
Hyperacute liver failure
- Jaundice to encephalopathy within 7 days—usually secondary to acetaminophen hepatotoxicity

Acute liver failure
- Jaundice to encephalopathy in 8–28 days

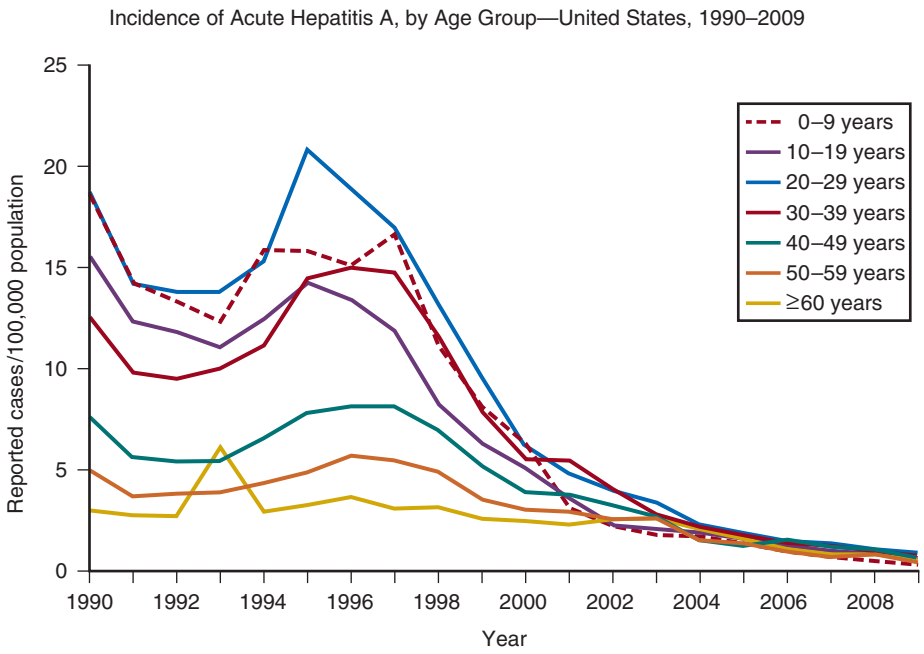
Subacute liver failure
- Jaundice to encephalopathy in 29 days to 6 months

Acetaminophen (Paracetamol)

Acetaminophen-induced liver failure is the cause of the majority of hyperacute liver failure. Acetaminophen poisoning is a common cause of presentation to acute and emergency departments in the United Kingdom and United States; however, the case progression to ALF after acetaminophen ingestion is rare, at just 0.6% of all presentations in the United Kingdom.[62]



• Fig. 71.3 The incidence of acute hepatitis B in the United States by age group 1990–2009. The incidence has fallen in all age groups over this time. (From National Notifiable Diseases Surveillance System.)



• **Fig. 71.4** The incidence of acute hepatitis A in the United States by age group, 1990–2009. The incidence has fallen in all age groups in recent years. (From National Notifiable Diseases Surveillance System.)

It was in the mid-1960s that the main mechanisms of acetaminophen-induced liver injury were elucidated. The scheme outline by various groups revealed the production of electrophilic quinone imine (N-acetyl-p-benzoquinone imine [NAPQI]), which covalently binds to hepatic proteins, was central to the resultant centrilobular necrosis seen after poisoning. The two major pathways for metabolism are the glucuronidation and sulfation of the phenolic group, with the metabolites produced excreted in the urine. In therapeutic doses approximately 80% of the drug is metabolized via these two pathways and 5% to 10% is excreted unchanged in the urine. The remainder is metabolized via the hepatic mixed function oxidase, cytochrome P450, to produce NAPQI.

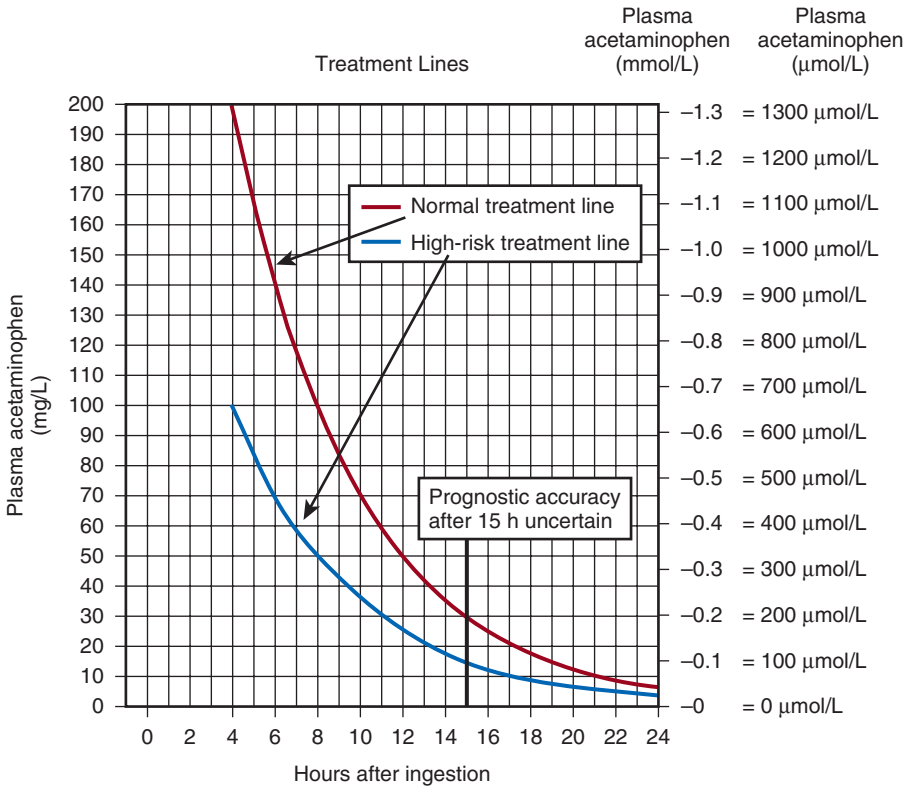
After poisoning the half-life of acetaminophen is greatly prolonged because of the saturation of glucuronidation and sulfate conjugation. As a result, there is an increase in the quantity of NAPQI produced. NAPQI is extremely reactive in biologic systems and has a short half-life. After poisoning, reaction of NAPQI occurs within the centrilobular portions of the liver and leads to necrosis in experimental models. It reacts with cellular constituents in a covalent and noncovalent manner. The exact mechanisms by which NAPQI induces cell death are incompletely understood but include the deactivation of critical cellular proteins, the induction of reactive oxygen species, and the activation of Kupffer cells.[63] The loss of regulatory protein function results in abnormal calcium homeostasis and resultant energy failure within the cell and mitochondria.[63] Other events such as noncovalent interaction with intracellular signaling and lipid peroxidation also contribute to the toxicity of this molecule. After this primary toxic phase there is a secondary or extrinsic phase. This extrinsic phase is equated with the recruitment of immune cells to the liver. The liver is one of the major immune organs of the body. Up to 35% of the liver is made up of nonparenchymal cells, including endothelium, Kupffer cells, and resident lymphocytes. These cells, together with macrophages within the liver, perform a major role in immune regulation and in the filtering of antigens from the gut contents via the portal circulation. They are also implicated in the pathologic processes that occur after liver insult. Massive activation of immune cells in response to the intrinsic cellular damage induces the release of cytokines and chemokines both locally and into the systemic circulation.[64,65]

The pathophysiologic consequences of severe liver injury result from a combination of factors, including the release of cytokines and other inflammatory molecules resulting from the necrosis of hepatocytes and activation of local and systemic immune cells, and from the loss of metabolic activity related to a critical reduction in liver cell mass. The relative contribution of these factors is not completely clear but is debated and has led to attempts at therapy, including temporizing hepatectomy and nonbiologic liver assist devices.

The minimum dose that can induce hepatic damage appears to be about 125 mg/kg. This represents 15 × 500-mg tablets in a 60-kg individual, although hepatic necrosis has been recorded at much lower doses, especially if associated with hepatic enzyme induction. Doses above 250 mg/kg (30 × 500-mg tablets in a 60-kg individual) will often produce damage, and doses in excess of 350 mg/kg invariably produce significant damage.[66]

The symptoms over the first 24 hours after a significant intake of acetaminophen, irrespective of amount ingested, are usually nausea and vomiting. During the next 4 to 5 days, if liver failure ensues, there is a gradual worsening of the patient's general condition. Those with significant overdose should be admitted to the hospital and monitored closely.

The antidote for acetaminophen poisoning is N-acetylcysteine (NAC). It provides complete protection against hepatotoxicity if given within 12 hours of nonstaggered ingestion.[67] Within 12 hours, if the time from ingestion is known with certainty and a plasma acetaminophen level is obtained, reference can be made to the nomogram to determine if the potential for hepatotoxicity



• **Fig. 71.5** Normal treatment line and high-risk treatment line for the initiation of N-acetylcysteine (NAC) treatment based on serum acetaminophen levels and hours after ingestion. The high-risk line has been adopted as the standard and only treatment line in the United Kingdom. This is done to avoid confusion and to reduce the risk of undertreatment in patients with chronically induced hepatic enzymes, such as those receiving antiepileptic medication, chronic ethanol abusers, or smokers. If there is any doubt about the number of hours since ingestion, or if there is any suggestion of a staggered overdose or chronic overingestion, NAC should be administered. (From Paracetamol overdose: new guidance on treatment with intravenous acetylcysteine. *Drug Safety Update*. September 2012;6[2]: A1.)

is present. The nomograms are unreliable if the time from ingestion is uncertain or if there was staggered ingestion over a period of time, as often occurs with therapeutic misadventure or repeated overdose. The use of alcohol often accompanies ingestion, making timing unreliable. Situations that alter normal cytochrome P450 function such as drug induction, (chronic ethanol use, phenytoin, and isoniazid) again render the information unreliable.[68] The use of the nomogram as the only basis for the decision to withhold NAC therapy is to be discouraged because of the uncertainty associated with this timing and the catastrophic potential if NAC is erroneously withheld (Fig. 71.5).

The main effect of NAC is to increase hepatic glutathione production. This promotes the conjugation of NAPQI and its subsequent excretion. In addition, NAC may act as an antioxidant within and outside the liver. It is most effective if given within the first 8 hours after overdose but is still effective after this time, although less so. There is some evidence that NAC is effective when administered to the patient up to 72 hours after poisoning, although the mechanism of action is unclear and probably relates to antioxidant effects rather than to any effect on acetaminophen metabolism.[69] The role of NAC in established ALF from any cause is more controversial despite widespread use, but data have lent support to its use certainly at lower coma grades. However, the mechanism of action is unclear.[70,71]

Viral Hepatitis

Both epidemic and serum hepatitis were recognized well before the viral form was discovered. In the seminal work of Lucké and Mallory in 1946, they describe 196 patients who died of ALF after both epidemic hepatitis and serum hepatitis, related to the administration of blood products during World War II.[53]

ALF after acute viral hepatitis is uncommon, with a reported incidence of 0.2% to 4% depending on the underlying cause.[72] Liver failure after viral hepatitis tends to run an acute or hyperacute course with the onset of encephalopathy occurring within days or weeks of the first symptoms.[73]

Hepatitis A is now rare in the United States and Western Europe but is still a common form of acute enterally transmitted hepatitis in the underdeveloped world where it is mainly a mild and self-limiting illness of children.[73,74] Infection with hepatitis A carries the lowest risk of conversion to acute hepatic failure of all the hepatotropic viruses. In the West the incidence of ALF after hepatitis A appears to be higher than in the endemic areas. It occurs more commonly in adults and is more severe. Persistent infection with hepatitis A has also been reported[75] and even recurring after liver transplantation.[76] Diagnosis is made on the basis of immunoglobulin (Ig) M antibodies at the time of hospitalization, although false-negative results can occur.[77]

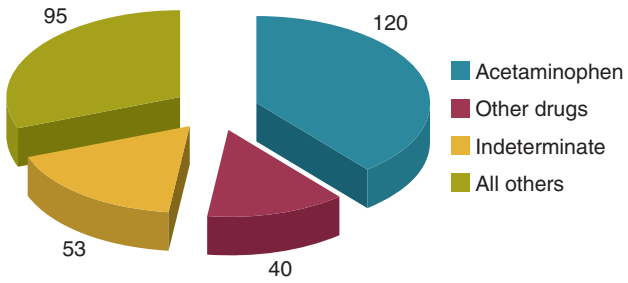
Hepatitis B may lead to ALF is several settings. It occurs most commonly after acute infection but can occur after an acute increase in viral replication following immunosuppressive therapy such as cancer chemotherapy or steroids, as well as with coinfection with other viral agents such as hepatitis delta virus. The host immune response is thought to be responsible for the severity of reaction to the virus, subsequent clearance, and the induction of ALF. This can be seen after the withdrawal of immunosuppressive therapy when there is a very active immune response to the increased viral load. In acute infection the surface antigen of hepatitis B (HBsAg) is often negative but IgM antibodies to the viral core (HBcAb) are usually positive. Mutations to the precore stop codon or the core promoter region of the viral genome may be associated with a higher incidence of ALF.[78] These particular genes code for hepatitis B e antigen (HBeAg), and lack of this antigen is associated with a more profound immune response. There have been reports of a very high incidence of ALF associated with outbreaks of acute hepatitis B in the setting of intravenous drug use and chronic hepatitis C infection.[79] Lamivudine antiviral therapy for acute HBV-induced hepatitis has been tried, but because of the lack of controlled trials, it is difficult to know if it or other drugs like it help.[80]

Hepatitis C, as a cause of ALF, is rare in northern Europe and the United States but has been described.[81] There is a wide spectrum of clinical presentation associated with acute infection with the more florid presentation associated with a more rapid clearance rate, suggesting that the magnitude of the initial immune response is important.[82] Liver failure associated with acute infection appears to be more common in India and the Far East.[83] Acute infection may contribute to decompensation in patients with preexisting liver disease, and hepatitis C seropositivity may predispose to liver failure when coinfection with another hepatotropic virus is present.[83]

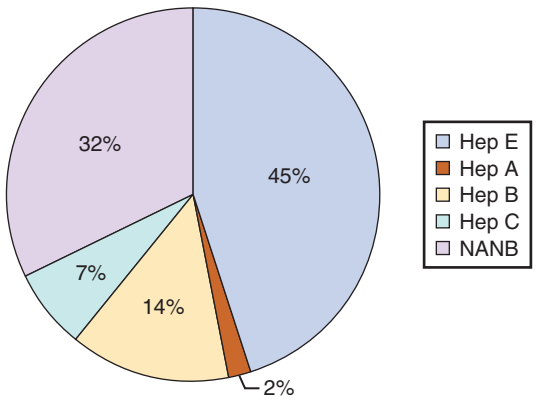
Hepatitis E is likely the most common cause of ALF worldwide and certainly for the Indian subcontinent.[83] In the Far East acute HBV infection is the most common cause of ALF owing to the high levels of endemicity.[84]

The existence of hepatitis E was inferred before serologic evidence was available by a process of exclusion. It was long assumed that most if not all epidemic enteric hepatitis was due to the A virus. When serologic markers for hepatitis A became available in the early 1980s, it was apparent that the majority of waterborne epidemic hepatitis were due to other agents, producing a syndrome similar clinically to hepatitis A.[85] Hepatitis E does not produce a chronic infection and in the vast majority is a self-limiting infection that occurs most commonly in young adults, in contrast to hepatitis A, which is primarily an infection of children. The incidence of hepatitis E associated with ALF is low, with a case-related mortality rate reported at about 0.5% to 4% in the general population but with a much higher mortality rate in pregnancy, as high as 20% in the third trimester. Pregnancy itself appears to be a risk factor for ALF, with a quarter of all infected female patients reported as pregnant in one series. However, this may not be particular to hepatitis E but rather due to the high incidence of epidemic hepatitis E in a relatively immunosuppressed state and pregnant patients do not have a worse prognosis compared to nonpregnant patients with ALF owing to hepatitis E.[83,86]

Five genotypes have been described, with genotypes 1 to 4 infecting humans and genotype 5 infecting only birds. Genotype 1 is the most common in Asia, with genotype 2 more common in Africa and South America. Genotype 3 can infect both human and animals, whereas genotype 1 and 2 have been described only in humans.[87] In the West, travel to endemic areas is a risk factor, but sporadic cases are now being seen more commonly in the developed world. Some of these cases have been associated with contact with animals.[87]



• **Fig. 71.6** Etiology of acute liver failure in the United States 1998–2001 based on 17 centers (n = 308). (From Ostapowicz G, Fontana RJ, Schiodt FV, et al. Results of a prospective study of acute liver failure at 17 tertiary care centers in the United States. *Ann Intern Med.* 2002;137:947–954.)



• **Fig. 71.7** Causes of acute liver failure in an Indian center 1989–1996. (From Khuroo MS, Kamili S. Aetiology and prognostic factors in acute liver failure in India. *J Viral Hepat*. 2003;10:224–231.)

Seronegative hepatitis is the second most common cause of ALF worldwide in most published series. In northern Europe and the United States it ranks behind acetaminophen toxicity, and in the developing world it is second to acute viral hepatitis (Figs. 71.6 and 71.7).

Seronegative hepatitis can be conveniently thought of as a single entity. In reality it is probably an amalgam of various causes that have defied definition or characterization, including acute presentations of autoimmune hepatitis, idiosyncratic drug reactions, and viruses.[88,89] Seronegative hepatitis has a variable clinical presentation, including a slow insidious onset of general malaise, jaundice, and ascites, followed by progressive signs and symptoms of liver failure. At presentation the patient may be deeply jaundiced and may already have ascites and splenomegaly. It can also present with a hyperacute picture. The pattern of signs, symptoms, and organ failure is dictated by the rate of progression. In subacute seronegative hepatitis, the presenting clinical picture can be similar to that of decompensated chronic liver disease, causing occasional diagnostic difficulty. A liver biopsy is sometimes needed to differentiate between the two.

Acute Presentation of Autoimmune Hepatitis

Autoimmune hepatitis can occur at any time of life from childhood until old age. It is more common in women with a male/female ratio of 1:3. Presentation can be asymptomatic, discovered after

routine laboratory testing, or more commonly, the infection may present with jaundice and general malaise. In rare cases autoimmune hepatitis can present as ALF.[90] Unfortunately, there are no serologic tests with sufficient sensitivity or specificity to make the diagnosis certain. Patterns of markers in the right clinical setting and in the absence of other causes may be useful.[91] The diagnosis of autoimmune hepatitis in the setting of ALF is difficult and a degree of uncertainty often lasts. Classically there is a combination of elevated immunoglobulin levels, autoantibodies, and confirmatory histologic evidence of hepatitis in the absence of active viral markers. Elevation of autoantibodies is often seen in patients with ALF owing to other causes such as drug-induced liver disease.[90] Liver failure should be assessed in the same way as for other causes, and once signs of encephalopathy become apparent, standard prognostic criteria apply. The role of steroids is unproved but should be considered in patients before the onset of encephalopathy. Once the patient is listed for transplantation, steroid use is controversial because of increased risk of infection.

Drug-Induced Liver Disease

The liver is a major site for drug metabolism in the body. Metabolism of xenobiotics (a chemical found in an organism but which is not normally produced or expected to be present in it) takes place in a series of specialized enzyme reactions that increase the water solubility of lipophilic molecules by the incorporation of polar groups. Drug metabolism often involves a number of processes. Intermediates produced during the process are sometimes more toxic than the parent drug and can cause liver damage by a number of mechanisms.

Drug-induced liver disease may be due to a known dose-dependent toxicity, as with acetaminophen. Alternatively, unpredictable, rare, idiosyncratic reactions can occur with any drug with a frequency of about 1 in 1000 to 1 in 100,000 patient prescriptions.[68] Drug-induced liver failure can mimic all forms of acute and chronic liver disease. However, the predominant clinical presentation consists of either acute hepatitis or cholestatic liver disease. The former has a reported mortality rate of 10% irrespective of the drug.

The patterns of injury associated with these idiosyncratic reactions relate to the mechanism of damage and the cells involved.[92] Many patterns have been described but it is massive hepatic necrosis that most often presents as ALF. Liver failure associated with severe cholestasis and veno-occlusive disease is also seen.[92]

Liver injury usually is seen within 6 months after the initiation of therapy. Even if the diagnosis of drug-induced liver failure is considered, a search for other possible causes should be performed. Although any drug is capable of inducing liver injury, more common causes include herbal remedies and recreationally used drugs such as "ecstasy" and cocaine. If suspected, a comprehensive history with a timetable of drug initiation should be constructed. Management includes stopping the offending drug and supportive care. Transplantation should be considered once liver failure occurs as the outcome from drug-induced liver failure, other than that induced by acetaminophen, can be poor.[93] Presentation profiles for various drugs causing ALF are shown in Table 71.1.[68]

Pregnancy-Induced Liver Disease

In general, pregnancy-associated liver failure has the best prognosis when compared to all other causes of ALF, and prompt recovery can be expected with delivery of the fetus in most cases, if recognized early enough. Pregnancy-associated liver failure can present in several ways, including the syndromes of preeclampsia and the HELLP syndrome (hemolysis, elevated liver function tests, and

TABLE 71.1 Idiosyncratic Drug Reactions and Effects on Cells

Type of Reaction	Effect on Cells	Examples of Drugs
Hepatocellular	Direct effect or production by enzyme-drug adduct leads to cell dysfunction, membrane dysfunction, cytotoxic T-cell response	Isoniazid, trazodone, diclofenac, nefazodone, venlafaxine, lovastatin
Cholestasis	Injury to canalicular membrane and transporters	Chlorpromazine, estrogen, erythromycin and its derivatives
Immunoallergic	Enzyme-drug adducts on cell surface induce IgE response	Halothane, phenytoin, sulfamethoxazole
Granulomatous	Macrophages, lymphocytes infiltrate hepatic lobule	Diltiazem, sulfa drugs, quinidine
Microvesicular fat	Altered mitochondrial respiration, β-oxidation leads to lactic acidosis and triglyceride accumulation	Didanosine, tetracycline, acetylsalicylic acid, valproic acid
Steatohepatitis	Multifactorial	Amiodarone, tamoxifen
Autoimmune	Cytotoxic lymphocyte response directed at hepatocyte membrane components	Nitrofurantoin, methyldopa, lovastatin, minocycline
Fibrosis	Activation of stellate cells	Methotrexate, excess vitamin A
Vascular collapse	Causes ischemic or hypoxic injury	Nicotinic acid, cocaine, methylenedioxymethamphetamine
Oncogenesis	Encourages tumor formation	Oral contraceptives, androgens
Mixed	*Cytoplasmic and canalicular injury, direct damage to bile ducts*	*Amoxicillin-clavulanate, carbamazepine, herbs, cyclosporine, methimazole, troglitazone*

IgE, Immunoglobulin E.
From Lee WM. Drug-induced hepatotoxicity. *N Engl J Med.* 2003;349:474–485.

low platelets), liver rupture, and acute fatty liver of pregnancy (AFLP).[94] Any cause of ALF can occur during pregnancy, and in particular viral hepatitis can be particularly fulminant in its course. This is especially true for hepatitis E and herpes simplex virus infection.

Although originally thought to be a variant of preeclampsia there is evidence that HELLP syndrome may be a separate entity and in fact more related to AFLP.[95] Both HELLP syndrome and preeclampsia appear to be related to an endothelial injury, possibly immunologically initiated with activation of the coagulation and complement cascades and an imbalance of prostaglandin and thromboxane, resulting in increased vascular tone, microangiopathic hemolytic anemia, and vascular thrombosis.[96] About 2% to 12% of severe preeclampsia is complicated by HELLP.[94] HELLP is thought to occur in approximately 1 in every 1000 live deliveries, and patients usually present in the third trimester with nonspecific signs often seen in preeclampsia such as weight gain as the result of edema and hypertension. In addition, right upper quadrant pain accompanied by nausea and vomiting is commonly seen. Laboratory abnormalities include hyperbilirubinemia owing to liver dysfunction and evidence of hemolysis. Transaminase levels are modestly raised and the platelet count is usually less than 100,000/μL. Liver biopsy, although commonly normal in preeclampsia, shows specific changes of periportal necrosis and fibrin microthrombi. Microvascular steatosis may also be present.[96] The liver failure associated with HELLP syndrome is manifest as a prolonged prothrombin time and ascites. Renal failure is common. Maternal mortality rate is low but fetal mortality rate has been reported to be between 20% and 60%, although some reports suggest this is lower at 7% and associated with twin pregnancies.[96–98] The treatment of choice is delivery of the infant. Conservative therapy is associated with an increase in both maternal and fetal complications.

Spontaneous rupture of the liver can occur in the setting of both preeclampsia and the HELLP syndrome, although it can occur de novo. It often presents with sudden onset of right upper quadrant pain accompanied by signs of hypovolemia or shock and is more common in multiparous women.[96] Spontaneous rupture of the liver has high maternal and fetal mortality rates. Its pathogenesis is unclear, but it appears that periportal hemorrhage associated with HELLP syndrome may occur close to the capsule, resulting in lifting and bleeding into the potential space. These areas of the capsule then coalesce and rupture. Management of this devastating complication includes prompt delivery of the fetus, local surgical control with packs, and aggressive management of the accompanying coagulopathy. Embolization of any feeding vessels in the liver may be of utility if such skills are available. Hepatectomy followed by liver transplantation can be lifesaving and has been performed.

AFLP occurs during the third trimester of pregnancy and should be considered in any patient exhibiting signs of liver dysfunction. It is uncommon with an incidence of approximately 1 in 6659 live births.[99] If left untreated, maternal and fetal mortality rates are high. The treatment of choice is delivery, and prompt recovery can then be expected. There is usually a prodromal illness over a couple of weeks with nonspecific symptoms progressing to jaundice and encephalopathy. Symptoms and signs of preeclampsia or HELLP syndrome are seen in a third of cases, and there is some evidence of a common origin owing to a fetal fatty acid metabolism disorder.[95] Diagnosis is critical and it should be differentiated from viral hepatitis or hepatic failure related to other causes. Liver biopsy can aid in the diagnosis and can be performed via the jugular route if coagulopathy precludes the conventional approach. Characteristic zone 3 microvesicular steatosis is seen. Delivery is the best treatment if diagnosed early. Characteristic features include normoblasts on blood smears and high serum urate levels. Bleeding can be a major problem during operative delivery. On occasion transplantation may be the only viable option. Triggers for transplantation in pregnancy-induced liver failure are not well defined and the King's College Criteria perform poorly. Arterial lactate in the setting of encephalopathy appears to be the best predictor.[98]

Wilson Disease

Wilson disease is a rare autosomal recessive disorder resulting from copper toxicity with primarily brain and liver manifestation. It usually presents in the second or third decade of life, although it can present from early childhood until late middle age.[100] The disease can present with predominantly liver or neurologic symptoms. Neurologic symptoms relate to the distribution of copper to the basal ganglia and result in movement disorders. Patients presenting with liver disease may presents with an active hepatitis, established cirrhosis, or ALF. Other signs such as Kayser-Fleischer rings are associated but not pathognomonic for Wilson disease. These green-brown rings in the cornea result from the deposition of copper.

ALF caused by Wilson disease can present at any age but more commonly presents in the early 20s. High urinary copper excretion is possibly the most predictable laboratory finding, although the patient may be anuric on presentation. A low serum ceruloplasmin is an additional indicator but again is unreliable in ALF. A high serum bilirubin level in combination with modest elevations of transaminases and alkaline phosphatase is often seen, as is intravascular hemolysis, contributing to the raised bilirubin level. Patients with severe liver failure caused by Wilson disease have an almost 100% mortality rate without liver transplantation, which should be considered as soon as the diagnosis is made.[100] There is debate as to whether liver failure secondary to Wilson disease is truly ALF, as cirrhosis is invariably present on liver biopsy at the time of presentation. Nevertheless, many patients present acutely and the presentation is often catastrophic. In this sense the timing of the onset and the lack of previous symptoms place fulminant Wilson disease in the ALF group. In an uncontrolled series the administration of D-penicillamine before the onset of encephalopathy was associated with survival.[101]

Neoplastic Infiltration

Poorly differentiated solid tumors such as breast and lung and hematologic malignancies can sometimes present with a syndrome of liver failure. There is often diagnostic delay and difficulty.

The syndrome can be considered part of the hypoxic hepatitis group as zone 3 necrosis is often seen. The metabolic demand of the neoplastic cells and congestion within the liver sinusoids results in infarction of hepatocytes. Hepatosplenomegaly and a raised alkaline phosphatase are often present. Other stigmata, including palpable lymphadenopathy and marrow or peripheral blood film changes, may be present. Imaging may be diagnostic, especially with massive hepatomegaly, but biopsy may be required.[102]

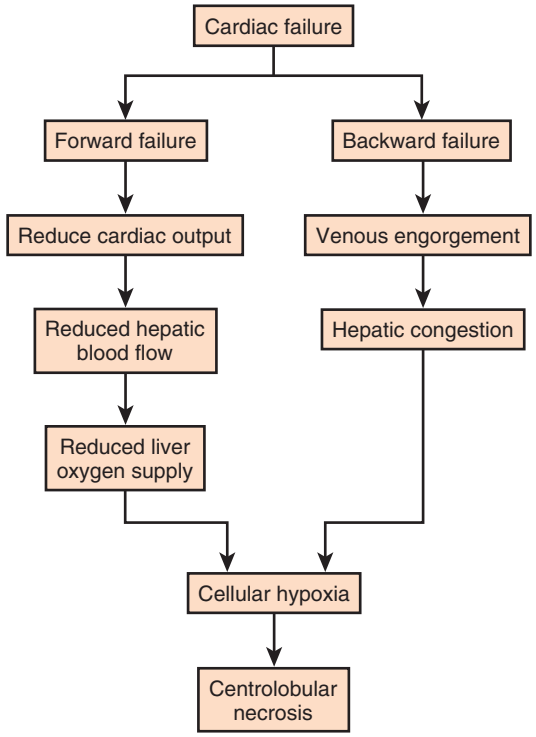
Budd-Chiari Syndrome

ALF secondary to Budd-Chiari syndrome is usually fatal without transplantation. The syndrome is defined as outflow obstruction to the hepatic veins and the underlying pathogenesis is thrombosis in the majority, but tumor invasion or vascular membrane obstruction may be the cause. This is a rare disorder that occurs

predominantly in young adults and affects more women than men. Overall, the 5-year survival rate varies from 50% to 80% in different series.[103] The vast majority of patients with the syndrome have at least one predisposing clotting abnormality, either congenital or acquired, such as a malignancy, myeloproliferative disorders, protein C or S deficiency, polycythemia rubra vera, lupus anticoagulant, antithrombin III deficiency, antiphospholipid syndrome, and so on.[104] The fulminant form of the syndrome in which the patient develops encephalopathy within 8 weeks of the onset of symptoms is rare, and it is much more common for Budd-Chiari syndrome to present in a subacute form over a 3- or 4-month period, characterized by ascites, abdominal pain and hepatomegaly, jaundice, coagulopathy, and raised AST and alkaline phosphatase levels. Others present with signs of portal hypertension, including refractory ascites and variceal bleeding, and relatively intact hepatocellular function. The diagnosis is made with the combination of clinical presentation and imaging, including Doppler ultrasound studies of the hepatic vessels, plus or minus liver histologic examination, usually via the jugular route because of coagulopathy. Management of the syndrome depends on the manner in which it presents and the underlying cause. Medical management of the syndrome involves the use of anticoagulants and diuretics in an attempt to control ascites. Thrombolysis can be attempted in selected patients with recent onset of disease.[105] In patients in whom there is progression to signs and symptoms of liver cell failure, some sort of portosystemic shunting procedure may reduce symptoms and prevent progression of the disease, allowing time for collateral vessels to develop. Transjugular intrahepatic portosystemic shunt (TIPSS) is most often attempted unless there is evidence of a hypertrophied caudate lobe and inferior vena cava compression, making mesoatrial shunting a better option. In patients with signs of liver failure care must be used when considering a TIPSS procedure, as this can precipitate decompensation and rapid progression to ALF.[106] Liver transplantation is ultimately the only option in many patients in whom there is a failure of medical and shunt therapy as well as in the fulminant presentation of the syndrome.[107] Anticoagulation is usually necessary in the immediate postoperative period.

Veno-Occlusive Disease of the Liver

Veno-occlusive disease (VOD) of the liver is a nonthrombotic obstruction of the sinusoids, which may extend to the central veins, in the absence of thrombosis or other underlying disorder of the hepatic veins.[108] As a result of a toxic challenge, there is acute damage to the endothelial cells, followed by their detachment and their embolization in the central area of the lobule, where they cause a postsinusoidal outflow block.[108] The most common cause is myeloablative chemotherapy induction regimens in preparation for bone marrow transplantation (BMT), being seen in up to 54% in some older series.[109] Other toxins are known to cause it and it was first described in children after the ingestion of herbal teas in South Africa; it represents a nonspecific response to certain noxious stimuli. Particular induction regimens such as high-dose cyclophosphamide and total body irradiation are implicated in the pathogenesis. The more aggressive induction regimens appear to result in a higher incidence of VOD. Recent reduction in incidence may be due to a reduction in the use of myeloablative regimens and better monitoring of plasma drug concentrations.[110] The symptoms of VOD usually occur within 2 weeks of BMT. The development of jaundice, hepatomegaly, abdominal pain, and encephalopathy in the setting of recent BMT strongly suggests the diagnosis. Severe cases are characterized by evidence of hepatocellular necrosis and a high AST concentration. In 25% of cases, which are characterized as severe, the syndrome is progressive, leading to ALF.[111] Treatment options in these patients are limited as the outcome is poor with medical management or liver transplantation, although there is hope that newer therapies such as defibrotide (a DNA derivative anticoagulant with multiple modes of action), if initiated early before the onset of multiple-organ failure, may improve the outlook. In addition, the prophylactic use has been tried in several uncontrolled reports.[108]



• **Fig. 71.8** The most common cause of hypoxic hepatitis results from a combination of liver congestion owing to chronic cardiac failure and an acute drop in cardiac output causing liver ischemia.

Hypoxic (Ischemic) Hepatitis

"Shock liver," "ischemic hepatitis," or more recently hypoxic hepatitis is the most common cause of significant rise in serum aminotransferase (S-AT) seen in hospitalized patients (Fig. 71.8).

There is often an underlying chronic reduction in oxygen delivery to the liver owing to comorbid disease states such as congestive cardiac failure or chronic respiratory failure. There is then a subsequent sudden acute drop in oxygen delivery resulting from a decrease in cardiac output or further hypoxia.

Diagnostically, there are three conditions that should be met: the appropriate clinical setting of circulatory, cardiac, or respiratory failure with a massive rise in S-AT and the exclusion of other causes of massive hepatic necrosis, such as viral or drug-induced liver failure.[102]

In patients with chronic congestive heart failure (CCHF), liver congestion is common. This is usually manifest as mild abnormalities of liver function test results, a prolonged prothrombin time, and mild ascites in some. Hepatic congestion is usually clinically unapparent unless jaundice is present, which can occur after multiple bouts of CCHF. Chronic congestion can lead to fibrosis and ultimately cirrhosis in some patients. Acute rises in serum transaminase levels and prolongation in prothrombin time, representing acute hepatic necrosis, most commonly develop in patients with

CCHF when there is a sudden drop in cardiac output resulting from an event such as an arrhythmia or myocardial infarction. It is relatively uncommon for the liver to become involved during shock states because of the huge redundancy in blood supply and the ability of the portal system to compensate for any reduction in hepatic arterial flow. If, however, portal flow is already compromised because of passive congestion, then an acute drop in hepatic blood flow can result in ischemia. It is uncommon for hypoxic hepatitis to occur without a recognizable precipitant, but it can occur as the result of a silent myocardial infarction or arrhythmia, for example. It can occur before the diagnosis of CCHF has been made or be the primary diagnostic event in a younger patient with a cardiomyopathy. Clinically, severe ischemic hepatitis becomes apparent between 24 and 48 hours after an event and is manifest as huge rises in S-AT (up to 10–20 times normal). There is prolongation of the prothrombin time, encephalopathy, hypoglycemia, jaundice, and renal failure. The syndrome is usually self-limiting once the hemodynamic disturbance has receded, and there is a rapid fall in serum transaminase levels (usually 50% in the first 72 hours).[112] Occasionally, progressive liver cellular failure leads rapidly to death. Management should be aimed at investigating and supporting the underlying cause.

Heat Stroke

Liver failure in the setting of heat stroke can be considered to be part of the hypoxic hepatitis group of causes. The argument for its inclusion here is the zone 3 necrosis seen in the liver after autopsy in patients who survive long enough for a reperfusion injury to occur.[102] The pathophysiology is complex but is probably related to dehydration and cardiovascular collapse plus increased oxygen demand and acute cardiac failure.[102] Exertional heat stroke may occur in new recruits to the army or police force engaging in physical initiation programs. It can also occur in unacclimatized athletes in hot conditions or with drug overdoses such as cocaine and hyperpyrexia syndrome such as those induced by MDMA (methylenedioxy-N-methylamphetamine). It is a potentially devastating syndrome that can lead to multiple-organ failure and death. It ranges from mild involvement to ALF and is seen to develop during the first few days after the event. Management is supportive and the majority improves over a period of days to weeks. Liver transplantation has been used in severe cases but the outcome is poor owing to coincident organ failure.[113]

Mushroom Poisoning

A number of fungi are associated with the induction of liver failure after ingestion. Of these, the most common and most deadly are of the genus Amanita. Amanita-associated hepatotoxicity follows a triphasic response after ingestion. The first is a self-limiting, nonspecific gastrointestinal upset that occurs within the first 6 to 24 hours. Nausea and vomiting, abdominal cramps, and diarrhea are often seen and it can mimic food poisoning. This is followed by a period of recovery and a few days later by progressive liver failure.

Management is essentially supportive, although many specific therapies have been tried in the treatment of Amanita toxicity such as high-dose penicillin, silibinin, cimetidine, and NAC, but none has been shown to improve outcome.[114]

Clinical Course

History and Physical Examination

The presentation and clinical course of ALF depends on its cause and the rate of progression of the syndrome. This varies widely from admission via an emergency department after an acetaminophen overdose or acute viral hepatitis versus admission from a hepatology outpatient department in a patient with progressive jaundice and ascites. Owing to its relative rarity, the diagnosis can often be missed during initial contact and this delay may detrimentally influence the outcome.

The history initially focuses on the rate of progression of the illness and any clues to the cause. The first symptoms are often the onset of jaundice (typically noticed by a relative). Any history of foreign travel or high-risk behavioral activity (intravenous drug use or unprotected sex) associated with the contraction of viral hepatitis should be investigated. A thorough drug history should be taken for prescribed and recreational drug use for the preceding 6 to 10 weeks. Drug therapy or recreational use that can induce or inhibit hepatic enzymes should be noted. If the patient is unable to provide this information, the relatives and the patient's primary care physician should be contacted for help.

The history may be self-evident in the case of acetaminophen hepatotoxicity, especially if the patient self-presents after deliberate self-harm. However, therapeutic misadventure, which is a relatively common cause of hepatotoxicity, especially in the United States, may not be obvious unless considered by the physician.[115] Any patient presenting with coma should have a drug screen (including acetaminophen).

Subacute liver failure has, by definition, a more insidious onset. Jaundice is often preceded by nonspecific symptoms of fatigue and general malaise. Abnormal liver enzyme levels are often revealed during the initial workup. Subsequent investigations include viral, iron, copper and genetic studies, in addition to attempting to rule out decompensation of chronic liver disease as a cause the current symptoms and signs. Liver biopsy may be considered in subacute liver failure (Fig. 71.9).

Initial Resuscitation and Emergency Care

Patients presenting with acute or hyperacute liver failure tend to follow a similar course irrespective of cause. Initial therapy and emergency care are dictated by the condition of the patient at presentation. Liver failure is a multisystem disease and can progress very rapidly to multiple-organ failure.

Patients presenting with rapidly progressive hepatic encephalopathy via the emergency care system often are intubated and ventilated at the time of or shortly after admission. Emergency physicians often perform a head computed tomography (CT) scan because of diagnostic uncertainty.

The symptoms and signs of hepatic encephalopathy in ALF are subjectively different from those seen in decompensated chronic liver disease or in patients with stable chronic encephalopathy. Agitation and aggressive behavior are more common in ALF. This may be based on an increased turnover of the excitatory neurotransmitter glutamate in ALF associated with an acute increase in cerebral ammonia uptake.[116]

The West Haven criteria, designed to assess coma grade in patients with cirrhosis, are often applied to patients with ALF and are useful because of familiarity.[117] However, once the patient becomes unconscious at grade IV encephalopathy, the scale does not provide any further information and is too crude to provide a clinically useful description of the level of consciousness. The Glasgow Coma Scale (GCS) score, although not assessed specifically in this setting, is useful in relating clinical information to others.[118] Encephalopathy grade can progress very quickly, especially with hyperacute presentation. Intubation and sedation are recommended once grade III encephalopathy (GCS < 10) is achieved because of

the attendant risks to airway and possibilities of raised intracranial pressure, discussed later. Fig. 71.10 describes encephalopathy grade and GCS score.

Early contact with a regional liver center should be made in any patient with signs of acute severe liver dysfunction as serial blood results and clinical signs can be relayed to the center by phone. Patients who have taken acetaminophen can often be managed by phone but plans for transfer can be made well in advance, if necessary. As liver failure progresses over the next several days, a number of organ systems may become affected.

After the safe and appropriate management of airway and breathing, focus can be directed to the correction of any circulatory dysfunction. Patients with ALF can progress rapidly to circulatory shock. The circulatory changes associated with ALF are predictable, usually associated with systemic vasodilatation and relative hypovolemia. This can be profound and require significant volume resuscitation. Monitoring at this stage should include a central venous catheter and direct arterial access for both blood pressure monitoring and repeated blood tests. Care must be given to monitoring of serum electrolyte levels because they often become deranged during this initial period. In particular, hyponatremia and hypophosphatemia are common.[119–121] This may be due to excess quantities of hypotonic fluid administration. A typical flowsheet of investigations of a patient presenting with acetaminophen poisoning from a referring hospital is shown in Table 71.2.

Regardless of cause, patients with significant liver damage or signs of secondary organ dysfunction should be managed within the ICU. The speed at which patients' conditions deteriorate can

TABLE 71.2 Acetaminophen Overdose Case Example: Laboratory Data

A 20-year-old woman, an intravenous drug user, took a 250-tablet overdose (500 mg of acetaminophen) the day before presentation at the hospital emergency department. She received N-acetylcysteine alanine transaminase 25 h after the ingestion. The patient was then transferred and listed for transplantation. The table shows the results of laboratory testing.

Laboratory Tests				
Dates	7/10/2003	8/10/2003 AM	8/10/2003 PM	9/10/2003 AM
INR	2.08	3.17	3.79	6.2
Bilirubin (mmol/L)	12	37		35
AST/ALT (U/L)	273/223	8,535/4,254		15,734/10,060
Alkaline phosphate (U/L)				100
Albumin (g/L)	52	45		30
Glucose (mmol/L)	4.1		7.5	5.2
Urea (mmol/L)		5.5		3.0

AST/ALT, Aspartate transaminase/alanine transaminase; *INR*, international normalized ratio.

be very rapid and it is not uncommon for hepatic encephalopathy to progress from grade 0 to grade IV over several hours.

For prognostic reasons it is important not to avoid correcting any biochemical coagulopathy at this stage if possible. Despite quite significant prolongation of prothrombin time, bleeding from line sites is uncommon in the initial stages of ALF. In fact, there is evidence that the patients are prothrombotic in vivo.[122]

Investigation in a Patient With Suspected Acute Liver Failure

Initial investigations provide a baseline from which important diagnostic and prognostic information is taken. Serial blood test measurements should be performed as severity and prognosis are assessed over time from initial presentation (Table 71.3). Depending on the manner and speed of presentation, a complete blood cell count, clotting tests, liver function tests, arterial blood gas measurements, and ammonia level testing should be performed twice daily, if not more often, in the early stages to assess progression of the illness. A liver ultrasound scan to assess liver size and blood supply should be performed.

Transfer Criteria Guide

ALF is a sporadic syndrome with a case incidence of about 2000 per year in the United States.[123] Management is complex and liver transplantation is the only effective therapy in severe cases. Transfer to a unit with experience in the management of these patients, preferably one with a liver transplant program, provides optimal care. It is often difficult to decide when or whether to transfer a patient with acute liver dysfunction and this decision varies according to cause and presentation. The best described clinical course is that after severe acetaminophen poisoning after a deliberate overdose.[52] Staggered overdose and therapeutic misadventure are less predictable in their clinical course but often have a poor outcome and can be considered a poor prognostic risk factor.[124]

The following criteria for transfer are based on expert opinion and have not been subjected to rigorous study and err on the side of caution[72] (Fig. 71.11):

- In patients with a subacute presentation it is better to transfer patients before they have progressed to grade II encephalopathy because of the additional complications associated with transferring ventilated patients.
- Patients with acute or hyperacute liver failure showing signs of early encephalopathy should be intubated and ventilated before transfer. This can occasionally result in disagreement between referring hospitals and receiving liver units on how the transfer should be managed. There are many anecdotal stories from liver units around the world describing patients who become unmanageable during transfer in planes, helicopters, and road ambulances, resulting in injury to patients and staff.
- Heroic transfers are almost always inappropriate. Patients should not be considered for transfer if they require rapidly accelerating inotropic support, have severe hypoxemia, or already have fixed dilated pupils. There is little point in a patient dying in an ambulance.

Management

Supportive Care

Airway and Ventilation

Patients with ALF who reach grade II or higher encephalopathy require intubation and ventilation to provide safe management in the setting of increasing agitation, protection of the airway from stomach contents, or transfer from peripheral hospitals. In patients with severe liver failure, it can be expected that encephalopathy grade will progress; therefore waiting until some predefined stage before intubation often delays adequate resuscitation and monitoring.

Controlled ventilation to a normal partial pressure of arterial carbon dioxide ($PaCO_2$) is recommended at this stage. The use of

TABLE 71.3 Initial Investigation and Common Findings

Laboratory Test	Finding(s)
Complete blood cell count	Platelets often low
Urea and electrolytes	Serum sodium often low, especially in acetaminophen hepatotoxicity Urea often low because of reduced production Serum creatinine is useful prognostic marker
Liver enzymes	Serum AST/ALT variable, very high in acetaminophen toxicity Bilirubin is prognostic marker in nonacetaminophen liver failure Also can be high in Wilson disease from hemolysis
Phosphate	Often low, especially in acetaminophen toxicity High level indicative of poor prognosis; suggests lack of regeneration
Magnesium	Often low
Prothrombin time, international normalized ratio (INR)	Very sensitive indicator of liver function Has prognostic significance in all forms of acute liver failure May improve with vitamin K in deficiency states
Viral serology for all known hepatotropic viruses	
Urinary copper, plasma ceruloplasmin if Wilson disease is suspected	Ceruloplasmin level often very low but can be normal Urine copper usually high
Arterial ammonia	Has some prognostic value and may be an indicator of cerebral edema in patients at risk
Arterial whole blood lactate	Very sensitive marker for liver function, particularly in acetaminophen toxicity High level indicative of poor prognosis
Serum glucose	Hypoglycemia common
β-Human chorionic gonadotropin in women	Unwanted pregnancy can be a precipitant of deliberate self-harm

AST/ALT, Aspartate transaminase/alanine transaminase.

Referral to specialist unit after acetaminophen ingestion. Any of these criteria should prompt referral.

Day 2	Day 3	Day 4
Arterial pH < 7.30 INR > 3.0 or PT > 50 s Oliguria Creatinine > 300 μmol/L Hypoglycemia	Arterial pH < 7.30 INR > 3.0 or PT > 50 s Oliguria Creatinine > 300 μmol/L Encephalopathy Severe thrombocytopenia	INR > 6 or PT > 100 s Progressive rise in PT to any level Oliguria Creatinine > 300 μmol/L Encephalopathy Severe thrombocytopenia

INR, International normalized ratio; *PT,* prothrombin time.

Referral to specialist unit in non-acetaminophen ingestion etiologies. The presence of any of these criteria should prompt referral.

Hyperacute	Acute	Subacute
Encephalopathy Hypoglycemia Prothrombin time > 20 s INR > 2.0 Renal failure Hyperpyrexia	Encephalopathy Hypoglycemia Prothrombin time > 20 s INR > 2.0 Renal failure	Encephalopathy Hypoglycemia (less common) Prothrombin time > 20 s INR > 1.5 Renal failure Serum sodium < 130 μmol/L Shrinking liver volume

INR, International normalized ratio.

hyperventilation is not indicated unless in a salvage setting with further monitoring.[125,126]

Circulation

The circulatory changes associated with ALF can be profound.[127] The pathologic bases for these changes are incompletely understood but similar in many ways to changes observed in patients with a systemic inflammatory response owing to sepsis or trauma. The pattern observed depends on the cause and the rate of onset of the syndrome. In hyperacute liver failure as the result of acetaminophen overdose, patients can develop fulminant peripheral cardiovascular collapse that can be an early mode of death.[128] Others with a more subacute onset can develop peripheral vascular changes similar to those with decompensated chronic liver disease.

Fluid resuscitation should be commenced as soon as possible after presentation and should be directed by invasive monitoring. The type of fluid used for resuscitation has not been subjected to controlled trials in this setting, but large volumes of hypotonic fluids should be avoided as this may contribute to cerebral swelling seen in this group, and it has been shown that hypertonic saline solution infusion reduces the incidence of intracranial hypertension (ICH) in patients with ALF.[119]

If mean arterial pressure remains less than 65 mm Hg after adequate fluid resuscitation, a vasopressor should be commenced. Norepinephrine is the vasopressor of choice as it induces vasoconstriction without the induction of lactate production as often seen with the use of epinephrine, although epinephrine has been used in this setting successfully.

Vasopressin and its longer-acting analog terlipressin have been used as vasopressors in septic and cardiogenic shock.[129,130] Terlipressin results in profound systemic vasoconstriction and, if used inappropriately, has the potential to reduce cardiac output and hence oxygen delivery. It has been shown to increase ICH in ALF owing to an increase in cerebral blood volume because of the breakdown in cerebrovascular autoregulation.[131] However, the data are mixed and a more recent study suggests that vasopressin/terlipressin may be a useful adjunct to norepinephrine in ALF.[132]

The majority of patients presenting with ALF are young adults, and as a result, comorbid cardiac dysfunction is usually absent. Cardiac depression has been reported in association with acetaminophen.[128] On occasion cardiac disease can present as ALF in the case of ischemic hepatitis.

Relative adrenal insufficiency has been shown to occur in patients with septic shock and in patients with decompensated chronic liver disease and ALF.[44,133–135] The use of stress doses of corticosteroids in ALF has been shown to reduce norepinephrine requirements in patients with ALF.[136] The effect on survival is uncertain, though.

Renal Support

AKI is common in ALF with a reported incidence of up to 70%.[137] Acetaminophen causes direct renal tubular dysfunction, possibly by affecting membrane protein function, and occasionally renal failure is the predominant organ affected.[138,139] As a result, AKI can be expected in this setting. Although it is most commonly associated with acetaminophen, the incidence in other causes, such as Wilson disease as a result of the direct toxic effects of copper, is also high but it is less prominent in ALF owing to viral hepatitis or seronegative hepatitis.

The Acute Kidney Injury Network (AKIN), proposed a definition of AKI in ICU patients, defined as an absolute increase in serum creatinine of greater than 0.3 mg/dL or higher (26 µmol/L) within 48 hours. Once AKI is established, a staging system then defines the severity of the AKI. These criteria were then adopted by the international multidisciplinary Kidney Disease Improving Global Outcomes (KDIGO) in their 2012 clinical practice guideline.[140] The use of hepatorenal syndrome in ALF is also inappropriate because this term does not adequately describe the often rapid clinical deterioration. This is not to say that altered systemic and renal hemodynamics do not contribute to the pathophysiology of renal failure as they do in critical illness in general. In the subacute presentation of this syndrome, early renal dysfunction can be similar in presentation to that seen in end-stage chronic liver disease with sodium and water retention in the absence of intrinsic renal damage.[141]

Management of AKI is essentially the same as in ALF and other forms of critical illness and consists of maintenance of intravascular volume, cardiac output, and mean arterial pressure.[123,142]

Renal replacement therapy is necessary in most patients with ALF at some time. Continuous venovenous hemofiltration (CVVH) is the most efficient and safest method for renal support and should be started early.[143] Indications for the early use of renal support are not limited just to oliguria. CVVH has been shown to improve hemodynamic stability in patients with critical illness and has been used as salvage therapy in patients receiving high-dose vasopressors.[144] High-volume hemofiltration (4000 mL/h ultrafiltrate exchange) has been studied in ALF and has been shown to reduce serum lactate, base deficit, and norepinephrine requirements when compared with historical control subjects.[145] Evidence for survival benefit for high-dose renal replacement therapy in critical illness is lacking, however, and recent high-quality studies suggest that there is a ceiling of dose above which there is no additional survival benefit.[146,147] Patients with liver failure do not tolerate the lactate load associated with lactate-buffered replacement fluid during CVVH, which can induce a systemic acidosis.[148] Also, the infusion of large quantities of lactate-containing fluid reduce the utility of serum lactate as one of the most important prognostic indicators.[149] As a consequence, the use of bicarbonate hemofiltration is recommended.[150]

CVVH can often be performed successfully without anticoagulation in ALF. If required, a loading dose of 2000 units of heparin and thereafter 500 to 1000 units/h, depending on the activated clotting time, can be used if needed to allow CVVH. If bleeding is a problem or there is severe thrombocytopenia, epoprostenol should be instituted (2.5–5 ng/kg per minute) either alone or in association with low-dose heparin (100 units/h). Blood flow rates of 200 mL/min and above will help with filter life.

Intracranial Hypertension

Etiology

The hallmark of ALF is the development of hepatic encephalopathy, which with severe liver failure progresses to deep coma. In addition to the progressive coma, early reports of patients with signs of raised intracranial pressure (ICP) were noted in the literature.[151] What is less clear is whether they possess a common cause. Certainly patients with subacute liver failure can develop a deep coma without signs of cerebral edema, but patients with signs of ICH always develop high-grade encephalopathy before this.

Cerebral edema was noted and commented on in the seminal clinicopathologic review of servicemen presenting with fulminant epidemic hepatitis during the East Asian campaign of the Second World War.[53] However, the recognition that cerebral edema was a distinct clinical entity and cause of death associated with ALF did not become clear until much later.[151,152]

Management strategies place the risk of ICH at the forefront of care, and prophylactic therapy, monitoring, and treatment are widely debated in the literature.[153,154] The incidence of cerebral edema in ALF is not completely clear and is dependent on the cause of ALF, the severity, and the rate of onset. It is important to distinguish between ICH and cerebral edema. The former requires the measurement of pressure within the cranial vault and results in brain ischemia and signs of tentorial herniation. The latter is difficult to define clinically and depends on how earnestly it is sought. CT and postmortem studies have suggested an incidence between 50% and 80% of those with high-grade encephalopathy.[151,155] The pathologic changes of cerebral edema and ICH in ALF are not completely understood, but in recent years progress has been made in understanding the processes involved.[156]

Ammonia has long been implicated as important in hepatic encephalopathy and, as the evidence mounts, is increasingly recognized as an important factor in the cause of cerebral edema in ALF.[157] Recent work has shown that whole blood ammonia predicts outcome and the chances of cerebral herniation.[158,159] Electron microscopic analysis of postmortem brain biopsy and gravimetric analysis of brain water content, in animal models, have shown that swelling occurs in the gray matter and that astrocytes are the main target.[160,161] Ammonia may induce astrocyte swelling by a number of possible mechanisms. It is detoxified in astrocytes by combining with glutamate to produce glutamine. Astrocytes are the only cell type in the brain that contains glutamine synthetase, and this normal pathway maintains the ratio of glutamate to glutamine within astrocytes and neurons. The raised serum ammonia induces a buildup of glutamine within astrocytes, increasing the osmotic potential, absorption of water, and an increase in volume. Evidence of this effect can be inferred by the fact that inhibition of glutamine synthetase, which catalyzes the reaction, prevents brain swelling in experimental models.[162] An osmotic effect may not be the only mechanism by which glutamine induces cellular swelling, however, but there is circumstantial evidence that it occurs to some extent. In subacute and chronic liver disease there is time for adaptation to the increase in astrocyte osmotic potential by the excretion of intracellular osmolytes such as myoinositol.[163] In ALF there is less time for adaptation because of the rapid increase in intracellular glutamine.

Other possible mechanisms include a breakdown in cellular energy metabolism induced by an increase in intracellular glutamine and ammonia. Impairment of α-ketoglutarate dehydrogenase and pyruvate dehydrogenase induced by oxidative stress and ammonia results in a breakdown in astrocyte energy production and an increase in glycolysis. This is supported by an increase in extracellular lactate and brain lactate flux in clinical studies.[116,125] Mitochondrial dysfunction induced by ammonia may also play a role.[157]

In addition to the cytotoxic edema seen early in ALF, changes in cerebral blood volume may play an important role in the development of ICH. Cerebral blood flow varies widely in patients with ALF, and the normal close relationship between cerebral metabolism and flow appears to be lost.[164] In animal models of liver failure there is a gradual increase in cerebral blood flow but this situation is less clear in human studies.[156,165] Cerebral metabolism is generally reduced with high-grade encephalopathy in patients with ALF, and there is evidence that relative or absolute cerebral hyperemia can contribute to ICH.[131,166]

An increase in cerebral blood flow may induce ICH by a number of mechanisms and induce further cerebral swelling. This could occur owing to an increased flux of potentially toxic metabolites such as ammonia or by an increase in cerebral water content because of an increase in cerebrovascular hydrostatic pressure. The blood-brain barrier has been considered to remain intact in ALF, but recent evidence suggests that there is some impairment, although the degree to which this contributes to cerebral swelling is still being debated.[161,167]

Cerebrovascular autoregulation is lost in ALF.[165,168] The cause is unknown but a gradual cerebral vasoparesis concurs with clinical observation. Autoregulation can be restored by hyperventilation and mild hypothermia but not by the use of indomethacin.[169] It has been suggested that the increase in astrocyte glutamine plays a role in this gradual vasoparalysis and loss of autoregulation by the induction of local nitric oxide or carbon monoxide.[156] It is relatively common to find a patient with a high ICP and jugular venous oxygen saturation above 80%. This suggests a state of luxury perfusion (unregulated blood supply in excess of demand) in which an increase in cerebral blood volume in an already swollen brain accounts for the associated increase in ICP.[170]

Patients with ALF often develop a systemic inflammatory response. Depending on the cause and severity of hepatic necrosis, damage-associated molecular pattern molecules and pathogen-associated molecular pattern molecules are released from the liver. These, in turn, activate the innate and adaptive immune response, culminating in the pathophysiologic picture associated with ALF. The severity of the inflammatory response has been shown to correlate with the degree of encephalopathy and the severity of ICH, and there is evidence that neuroinflammation in response to circulating cytokines exacerbates ICH.[171]

Management

In the management of ICH in ALF it is important to target those at risk. The development of ICH sets the management of ALF apart from other forms of critical illness, and ALF remains a leading cause of death despite advances in the understanding of the etiology of ALF and management of patients with ALF.[172,173] Monitoring the pressure within the cranial vault is difficult and invasive. Despite investigation, a reliable noninvasive method for the evaluation of cerebral blood flow, cerebral oxygenation, and ICP remains elusive.[174]

There are important points that need to be considered when managing a patient with ALF and possible raised ICP:

- Prediction of patients at risk of ICH
- How to monitor the brain
- Prophylactic management
- Treatment of established ICH

Predicting Intracranial Hypertension

In ALF the development of cerebral edema is seen in patients with the shortest time between the development of jaundice and the onset of encephalopathy.[52] A fulminating presentation, lack of time for cerebral adaptation, and systemic burden of a necrotic liver appear to be the likely reasons. Patients with acetaminophen toxicity make up the largest number in this group. Other causes can fall into the hyperacute group, including patients with ALF owing to hepatotropic viruses, particularly HBV. In contrast, patients with subacute liver failure have a smaller risk.

It has been suggested that the incidence of ICH after acetaminophen toxicity has fallen since the mid-1980s.[175] However, it still represents a significant complication in this setting. Recent work from King's College Hospital in London suggests an incidence of 20% to 30% in all patients with ALF. Data from our own unit suggest that ICH is implicated in the death of 25% of all patients with ALF and 35% of those after acetaminophen-induced toxicity.[172,173]

• BOX 71.2 Risk Factors for Brain Swelling in Acute Liver Failure

Are There Risk Factors for Intracranial Hypertension?

- Less than 40 years of age
- Very low or high jugular venous oxygen saturation
- Significant organ dysfunction requiring support
- Severe hyponatremia <130 mmol/L
- Arterial ammonia >150 μmol/L
- Pupillary abnormalities or seizures
- High temperature, tachycardia, hypotension, signs of infection

Young age has consistently been found to be a risk factor.[151,173] Arterial ammonia concentration has been shown to correlate with death and cerebral herniation.[158,159,173,176] Recent commentary suggests that arterial ammonia should be measured serially in all patients with ALF and that ICP monitoring be instituted if the concentration is greater than or equal to 150 μmol/L.[170]

Hyponatremia in patients with ALF is common and is associated with a poor outcome in ALF,[177] and data have shown an inverse relationship between ICP and serum sodium in patients with ALF[178] (Box 71.2). The severity of the inflammatory response and organ failure are positively associated with the risk of developing ICH. Systemic inflammation may exacerbate ICH in a brain primed by ALF.[173]

Monitoring the Brain

A number of monitoring devices and methods can be used to screen for raised ICP or cerebral ischemia or both. Some of these devices are more invasive than others and the possible risks and benefits need to be understood.

CT is a standard investigation in any patient with suspected intracranial disease. Cerebral edema can be recognized in CT scans of patients with ALF and the severity correlates crudely to encephalopathy grade, but the correlation between imaging and severity of ICP measurement is poor.[155,179] As little additional information is gained, very careful consideration should be undertaken before transporting this very sick group of patients to the CT scanner. Occasionally there are diagnostic difficulties or a suspected complication of ICP bolt insertion and CT scanning might be considered.

Functional brain imaging with single positron emission tomography has been used to investigate the distribution of cerebral blood flow in ALF and magnetic resonance imaging scanning has been used to investigate the distribution of intracerebral water, but neither has found a place in clinical practice.[126,180,181]

In patients with suspected ICH the direct monitoring of cerebral oxygenation and blood flow are appealing but current methods have technical and clinical limitations. Tissue partial pressure of oxygen (P_{O_2}) and interstitial metabolites, using intraparenchymal probes, have been investigated in traumatic brain injury (TBI) and to a limited extent in ALF.[116,182] They have the advantage in traumatic injury of providing localized information around the area of injury. The use of cerebral microdialysis (sampling of the cerebral interstitial fluid using a microcoaxial catheter with a semipermeable membrane) remains a research tool in ALF at the present time.

Methods used for the estimation of global cerebral oxygenation include the sampling of jugular venous (JV) blood for oxygen saturation and products of metabolism such as lactate. A JV saturation of less than 55% suggests an ischemic brain. This can be due to a reduction in blood flow in excess of demand because of brain swelling or cerebral vasoconstriction as the result of hypocarbia if the patient is being hyperventilated. An increase in demand because of seizure activity can also manifest as a reduction in JV saturation.[183] High jugular saturation (>80%) may represent a hyperemic brain, and steps can be taken to reduce cerebral blood volume if ICP is raised. Very high JV saturation is often seen as a terminal event and may represent a complete loss of oxygen extraction by the brain (Fig. 71.12).

Near-infrared spectroscopy is a noninvasive technique used to assess the oxygen content of various organs. It can be used to determine cerebral oxygenation and changes in cerebral perfusion in ALF and warrants further investigation.

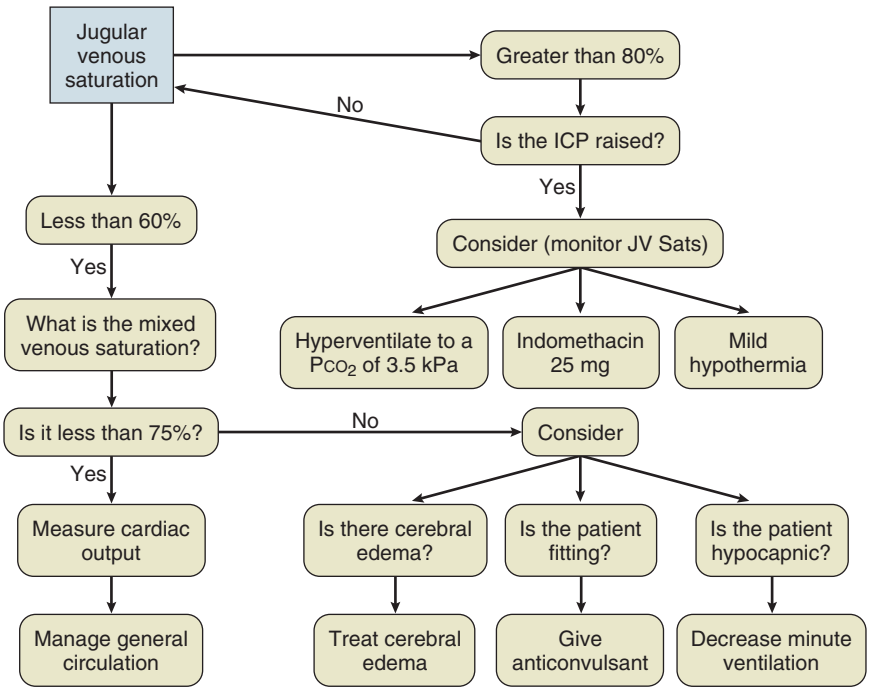
Noninvasive measurement of cerebral blood flow using transcranial Doppler has been investigated in ALF. In one study it was found to be predictive of changes in cerebral blood flow induced by hyperventilation.[184] More recent investigation has shown changes in transcranial Doppler waveform as ICP increases, but it is not clear how reproducible these results are.[185]

The recognition that ICP is raised in a significant proportion of patients with ALF and that this is implicated in significant rates of morbidity and mortality has led to the use of direct measurement of ICP with various forms of monitoring.[151,186] These techniques, although fully supported internationally in TBI, are controversial in the field of ALF, and there remains a dichotomy of opinion in most countries, with some units using them and others not.[153,154,187,188]

Controversy revolves around the lack of evidence of improved outcome with the monitoring of ICP and the risk of intracranial bleeding complicating insertion. The overall reported risk of bleeding is 5% to 20%, the majority of which is not clinically significant. Mortality rate has been reported at between 1% and 3%.[186,188] The risk of bleeding after placement is higher than that seen after TBI. There is no definitive evidence for the role of activated factor VII in this setting.[189]

It has not been possible to prove that ICP monitoring improves survival in ALF, as a randomized controlled clinical trial has not been performed to evaluate it. However, it is generally accepted that medical intervention can reduce ICP and prevent cerebral ischemia and brain herniation in patients with ALF.[170] Published data suggest that in patients with an ICP monitor the intervention rate increases compared with patients without a monitor and the length of survival in the critical care unit, if not overall survival, increases.[188,190] The majority of patients with ALF die of multiple-organ failure caused by sepsis. Intervention to reduce ICP may just prevent early cerebral death.

Although the risks of monitoring are documented, the risks of not monitoring are less clear. Without monitoring ICP, there is a tendency toward therapeutic paralysis because of uncertainty and a tendency to manage all patients as if they had raised ICP. The reassurance of a normal ICP enables a reduction in sedation and paralysis. It enables tracheal suctioning and other nursing care without the uncertainty of worsening an unknown ICP. With ICP monitoring, modest increases in ICP can be treated early before clinical signs suggest impending brain herniation. Monitoring ICP allows the calculation of cerebral perfusion pressure and, together with the monitoring of jugular oxygen saturation, affords a more complete picture of cerebral perfusion and oxygenation. The use of ICP monitoring has been advocated in the setting of liver transplantation for ALF and, of course, enables continued clinical research into the management of cerebral edema.



• **Fig. 71.12** Monitoring cerebral oxygenation with jugular bulb sampling. *ICP,* Intracranial pressure; *JV,* jugular venous; P_{CO_2}, partial pressure of carbon dioxide; *Sats,* saturation.

Prophylactic Measures

In patients at high risk of cerebral edema a number of prophylactic interventions have been shown to reduce the incidence of ICH. Based on retrospective data showing an inverse relationship between ICP and serum sodium in patients with ALF, moderate hypernatremia was investigated as a possible prophylactic intervention.[119,178] Maintaining serum sodium between 145 and 155 mmol/L using hypertonic saline solution was found to reduce ICP from baseline and reduce the incidence of surges in ICP.[119] Hypothermia improves outcome after out-of-hospital cardiac arrest and has been investigated in patients with TBI. Early reports suggest hypothermia can reduce ICP and ammonia production in patients with ALF. However, prophylactic hypothermia has not been shown to reduce the incidence or improve outcome in this setting.[191] Simple measures such as raising the head of the bed to a 30-degree angle and the avoidance of excessive stimulation are also prudent.

Cerebral Perfusion Pressure

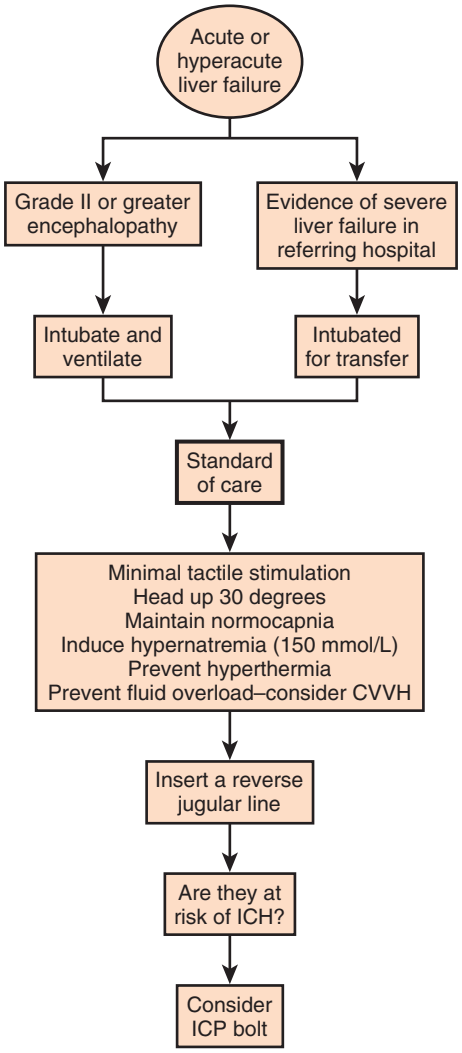
In TBI there is a consensus of opinion supporting the use of cerebral perfusion pressure (CPP) as a treatment goal.[187] In ALF the concept of CPP-directed therapy is less useful. To assume a correlation with cerebral blood flow requires a consistent cerebrovascular resistance, which is not the case in ALF.[170] This is due to the loss of cerebrovascular autoregulation, and attempts to increase cerebral perfusion are often unsuccessful as the use of a vasopressor results in an increase in ICP as brain blood volume increases.[131,192] However, this is not to say that CPP should be ignored entirely but the safe lower limit of CPP has yet to be defined, as there are many reports of patients surviving with normal cerebral function despite a low CCP.[193] The normal lower limit of cerebral autoregulation is reached at a mean arterial blood pressure of about 50 mm Hg, below which flow becomes pressure dependent. In patients with absent autoregulation, such as in ALF, CCP should probably be maintained above 40 mm Hg (the normal lower limit of autoregulation with an ICP ≤10 mm Hg), but no data exist to support this statement. Maintenance of CPP in ALF is best achieved by decreasing ICP and aiming for a mean arterial pressure with fluid and a vasopressor that does not increase ICP above 25 mm Hg. Attempting to improve cerebral oxygen balance is also attractive in this setting. This may be attempted with intravenous indomethacin (which has been shown to improve CPP without compromising cerebral oxygenation), hypothermia, increased sedation, and hyperventilation.[169,194–196] Monitoring cerebral oxygenation is very useful during such a maneuver.

General Management of Patients With Raised Intracranial Pressure

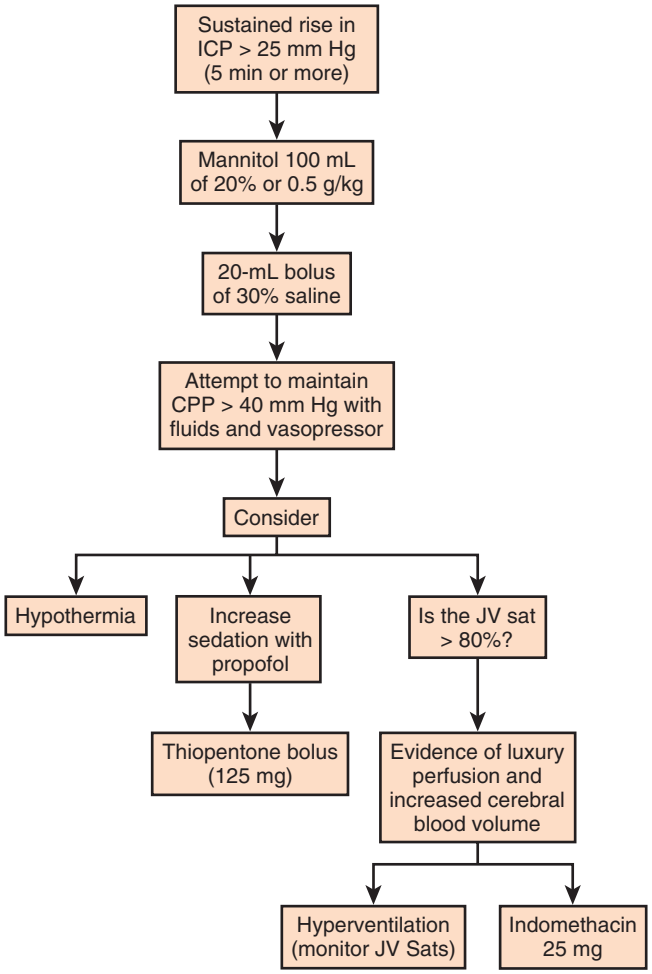
In patients at risk of or with suspected cerebral edema, prophylactic measures should be instituted. The decision whether or not to insert an ICP bolt will have to be made by the clinical team. If a bolt is inserted, there is the potential to manage ICP.

ICP is normally less than 15 mm Hg in an adult. The definition of ICH is not precise and varies among patients. Available data are derived from patients with TBI; observational studies suggest that intervention to reduce pressure should be instituted between 20 and 25 mm Hg, although pupillary abnormalities and brain herniation can occur at lower pressures.[187] There have been no studies investigating a treatment threshold in ALF and so similar thresholds to TBI are used.

The management of ICH is usually escalated along standard algorithms (Figs. 71.13 and 71.14). Elevate the patient to an angle of 30 degrees and avoid tight straps around the neck to encourage venous drainage. ICP tends to increase during nursing intervention. If the ICP rises after nursing intervention and does not resolve after several minutes, it implies poor intracranial compliance. Treatment is usually instituted for a sustained rise in ICP (>10 minutes over the treatment threshold) or clinical signs suggesting cerebral ischemia or impending herniation.



• **Fig. 71.13** Initial management of patient with high-grade encephalopathy. *CVVH,* Continuous venovenous hemofiltration; *ICH,* intracranial hypertension; *ICP,* intracranial pressure.



• **Fig. 71.14** Management of a sustained rise in intracranial pressure. *CPP,* Cerebral perfusion pressure; *ICP,* intracranial pressure; *JV,* jugular venous; Sats, saturation.

- Sedation should be increased. Propofol is probably the agent of choice.[194]
- Osmotherapy is the mainstay of treatment following these simple measures.
  - Mannitol as a rapid infusion (0.5–1.0 g/kg) has been shown to reduce ICP reliably in ALF.[197] The dose can be repeated but care must be used in renal failure owing to accumulation, and multiple administrations can result in a hyperosmolar syndrome. Plasma osmolality should be monitored if multiple doses are used. Current practice is to remove 500 mL of ultrafiltrate via CVVH after each bolus dose of mannitol.
  - Bolus doses of 20 mL hypertonic saline solution (30%) have an effect similar to mannitol in this setting in the authors' experience. Hypertonic saline solution has a higher reflectance coefficient at the blood-brain barrier compared with mannitol and there appears to be less tachyphylaxis to multiple administrations.[119]

In patients with a raised ICP and cerebral hyperemia, suggested by a JV oxygen saturation of 80% or greater (luxury perfusion), short-term hyperventilation induces cerebral vasoconstriction and reduces blood volume. This maneuver has been shown not to impair cerebral oxygenation, but close monitoring of cerebral oxygenation should be used if it is attempted.[195] Short-term hyperventilation has not been shown to improve outcome in ALF but does prolong survival in the ICU.[198] Hyperventilation may be lifesaving and may buy time for definitive treatment (transplantation). Indomethacin induces cerebral vasoconstriction and reduces ICP in patients with both TBI and ALF without impairing cerebral oxygenation, although confirmatory studies are needed.[169]

Seizures

Ammonia toxicity and cerebral edema are associated with seizure activity and it has been recognized that subclinical seizures occur more commonly than previously thought.[183] The use of mechanical ventilation facilitated by sedatives and muscular paralysis can mask clinical signs. Seizures adversely affect cerebral oxygen consumption and may contribute to cerebral edema and are a cause of low jugular oxygen saturation. The use of prophylactic phenytoin has been suggested in all patients with ALF and high-grade encephalopathy. Others have questioned this approach because of the significant side effects and apparent lack of effect on outcome.[199] If confirmed, seizure activity should be managed according standard management guidelines.

Infection and Immunosuppression

Patients with ALF have multiple immune defects and are susceptible to infections.[200] Infection is a common cause of progression and complication in ALF. Antibiotic prophylaxes have not been shown to reduce the incidence of infection or improve survival.[201] Selective decontamination of the digestive tract has not been shown to be superior to intravenous antibiotics alone.[200,202] More recent work has shown how the microbiologic flora of a liver unit has changed over the past 20 years—for example, bacteremia appearing later in the ICU stay and being predominantly gram-negative in nature.[203]

It is current practice to prescribe broad-spectrum antibacterial and antifungal medication to patients with ALF depending on local sensitivities. There is a general trend to the timing of infection with gram-positive infections occurring earlier than with gram-negative infections. Early gram-negative infections tend to be less resistant "endogenous" bacteria followed later by resistant hospital-acquired organisms.[204,205]

Nutrition

Within the general intensive care literature there is a consensus toward enteral nutrition (EN) as the route of choice.[206] There are few additional data on which to base decisions in patients with ALF. There is, however, wide regional variation in the prescribing of parenteral nutrition compared with EN. The reason for this is unclear as EN is associated with a reduction in infectious complications.[206] However, it is clear that some centers prefer parenteral nutrition.[207] Nutritional requirements in ALF are not well understood.

See the online supplement for additional text on nutrition.

Artificial Liver Support

At the present time liver transplantation is the only form of definitive therapy for severe hepatic failure. However, the scarcity of organs and potential for delay in transplantation, together with a proportion of patients who will make a full recovery if supported while the liver regenerates, suggest that there would be a role for some kind of liver support system.

The liver is a complex organ, and to be an ideal liver replacement, any system has to support a wide range of biosynthetic and metabolic functions. Any working system will also have to counter the systemic burden of the necrotic, dying liver.[216]

Artificial liver support can be split into two main approaches. In the first there is an attempt to simulate or replace all or most of the functions of the liver. These systems include hepatocytes either from human or animal sources. Another view of liver failure suggests that toxins either excreted by the dying liver or not metabolized because of an acute reduction in function are responsible for the majority of the signs and symptoms. In this view extracorporeal blood purification with dialysis or adsorption techniques are employed and serum proteins not produced are replaced with plasma (Box 71.3).

Biologic Systems

Biologic systems consist of a bioreactor within which the cellular biomass is contained and a mechanism of containing and separating the biomass from the circulation of the patient. They require an extracorporeal system to deliver blood or plasma to the bioreactor and may also contain an adsorption or dialysis component. Data from liver resection suggest that approximately 250 mL of liver by volume is required to prevent death from liver failure. This typically represents 20% to 30% of liver mass.[217]

See the online supplement for additional text on biologic systems.

• BOX 71.3 Functions of the Liver

Excretion of bilirubin, cholesterol, hormones, and drugs
Metabolism of fats, proteins, and carbohydrates
Enzyme activation
Storage of glycogen, vitamins, and minerals and regulation of glucose levels
Synthesis of plasma proteins such as albumin, clotting factors, and bile production
Blood detoxification and purification
Immune regulation

Nonbiologic Systems

Many of the molecules that accumulate within the blood during ALF are small or middle-sized. These molecules can be targeted by a variety of extracorporeal purification techniques, including dialysis through various types of membranes and adsorption onto carriers such as charcoal, resins, or albumin. Nonbiologic systems are attractive because they are relatively inexpensive (compared with biologic systems) and logistically much easier to implement.[216]

See the online supplement for additional text on nonbiologic systems.

Liver Transplantation

When and Whom to Transplant

Liver transplantation for ALF was used sporadically during the 1980s but gained pace in the late 1980s and now has a huge impact. It remains the only definitive form of therapy for some.

Timing is important, and in those with severe liver injury there is a window of opportunity beyond which transplantation often becomes futile because of deteriorating organ function.[228] It was recognized early in the history of transplantation for ALF that the challenge was to develop robust prognostic indicators. These need to be sensitive, early enough to provide maximum advantage to the patient, and specific enough not to result in unnecessary transplants.

A "super-urgent" designation exists in the national transplant sharing scheme in the United Kingdom with a similar "category 1A" designation in the United States (see http://www.unos.org/ for details). These categories recognize the role of early transplantation in ALF and the detrimental effect of delay in this setting.

In the United Kingdom, the super-urgent designation (Table 71.4) is closely linked to the prognostic score developed in King's College Hospital in the late 1980s using retrospective multivariate analysis with prospective validation.[229] The prognostic criteria have been subsequently validated in other centers and shown to be robust.[230] Other criteria have been developed.[231]

The criteria are not perfect. First, despite their good specificity (i.e., if the patient meets criteria the patient is likely to die), the sensitivity and negative predictive value are not as good, and there is a substantial proportion of patients who will die without ever reaching transplant criteria. In addition, awaiting positive criteria can lead to delay in listing and worsening of organ failure that often then preclude listing. This contributes to the fact that published rates of transplantation in those who reach criteria are

Energy expenditure is raised during ALF. This is surprising considering the normal contribution of the liver, a large metabolically active organ, on the overall energy expenditure, illustrated by the effects of hepatectomy on energy expenditure during elective liver transplantation.[208] There is organ-specific lactate production in both the liver and the lungs and evidence of a systemic inflammatory response in many patients.[201,209,210] The cause of systemic inflammation in ALF is activation of inflammatory cells (leukocytes and endothelium) and the release of systemic cytokines. This may be initiated by infection.[201] Patients in the early stages of ALF are markedly catabolic with insulin resistance despite the frequent presence of a hypoglycemic state.[211] The Harris-Benedict equation is inaccurate in ALF and indirect calorimetry should be used if energy requirements are sought.

Hypoglycemia is common as a result of the failure of both glycogenolysis and gluconeogenesis. Massive hepatic necrosis can result in a precipitous fall in serum glucose concentration. For this reason an infusion of 50% glucose should be used at least until feeding is established. Low-volume, high concentrations of glucose are preferred to reduce the infusion of large quantities of water and the resultant hyponatremia if lower concentrations are used.

Serum amino acids are consistently deranged during liver failure. There is a low or normal concentration of glutamine, branched-chain amino acids, and tryptophan and an increase in others.[212] High brain concentration of ammonia is thought to contribute to cerebral edema and encephalopathy in ALF. Manipulation of ingested amino acids has been investigated in an attempt to reduce ammonia concentration. L-Ornithine and L-arginine (LOLA) infusion encourages alternate pathway metabolism and reduces hepatic encephalopathy in chronic liver disease.[213] LOLA has been investigated in animal models of ALF and resulted in normalization of plasma ammonia concentration, significant delay in the onset of encephalopathy, and a reduction in brain water concentration.[214] LOLA was investigated in 2009 with a randomized controlled clinical trial in ALF. Despite theoretical promise, the investigators were unable to show any reduction in mortality rate or ammonia between the groups.[215]

NAC is primarily used as a glutathione precursor and antidote in acetaminophen poisoning, but it is used widely in patients with ALF induced by other causes and later in its subsequent course. Results of a recent randomized controlled clinical trial have shown efficacy with NAC in patients with low-grade encephalopathy and non–acetaminophen-induced liver failure. The mechanism of action is unknown.[70]

There is little evidence that protein restriction has any role in ALF, and protein requirements based on total calorie ingestion should be used.

Serum electrolytes are often deranged in the early stages of ALF. Hypophosphatemia is common in patients with ALF and is a good prognostic sign. High or normal phosphate may indicate a lack of hepatic regeneration and renal impairment.[120] Hypomagnesemia is also common and should be corrected.

Possible cell types for use as the biomass include animal or human primary hepatocytes or other forms of cell line with hepatocyte phenotype. Primary hepatocytes outperform other cells lines but are of limited availability and tend to have a time-dependent loss of hepatic phenotype. In addition, scaling up production with primary hepatocytes is difficult, as they do not readily undergo cell division under laboratory conditions. Instead, they have to be directly seeded into the bioreactor either immediately after harvest or after a period of storage and cryopreservation. Human cells are limited in availability but can be obtained from unused livers, after donation, and from cut-down grafts. Theoretically, animal cells are readily available but uncertainty about possible cross-infection from animal pathogens to the patient with organisms such as PERV (porcine endogenous retrovirus) and incompatibility of secreted antigens render them far from ideal, and regulatory authorities are often reluctant to sanction their use.

Immortalized cell lines that proliferate in culture, while retaining some liver-specific functionality, can be used in an attempt to overcome the limitations of primary hepatocytes. Many lines have been created by retroviral transfection with regulatory genes that stimulate cell division. The insertion of "terminator" genes that give the cells a limited life or enable switching the immortalizing gene off have also been developed to improve safety.[218] Other sources of immortal and readily cultured cells are tumor derived such as the ubiquitous HepG2/C3A hepatoblastoma line. Finally, stem cell sources appear to offer the most hope in terms of a readily available and functional supply of differentiated hepatocytes.[219]

Clinical trials in the use of bioartificial liver support have been relatively disappointing. The bioartificial liver uses porcine hepatocytes and a charcoal column in series. The largest trial published so far in the field was powered for survival advantage in ALF and primary nonfunction after liver transplantation.[220] The study was terminated early by the data and safety monitoring board because the trial was likely to be futile based on the results at interim analysis.[220] Post hoc analysis suggested some effect in the ALF group alone. The extracorporeal liver assist device system uses the HepG2/C3A hepatoblastoma line and has been investigated in a number of phase I and phase II studies designed to report safety and activity. A randomized controlled study, not powered for mortality, showed a trend for improved survival in the treatment group.[221, 222] Since then, in a more robust study of 203 ACLF patients with alcoholic hepatitis, the extracorporeal liver assist device failed to demonstrate an improvement in outcome.[223,224]

Early work with hemodialysis was unsuccessful and was largely abandoned with the conclusion that the toxemia of ALF was not due solely to small water-soluble molecules. The advent of synthetic membranes in the 1970s rekindled the interest in convective therapy for ALF. These allowed larger molecules to pass through compared with the cuprophane alternatives. Cardoso reported clinical improvement (reduction in ammonia) with the use of hemofiltration in patients with ALF.[225] Hemofiltration, as a form of renal support, is used in most liver critical care units as part of general supportive care and there is some evidence that increased convective exchange, with high-volume hemofiltration (>35 mL/kg per hour), is associated with improved ammonia clearance and mortality in ALF patients.[145,225]

Charcoal hemoperfusion has been extensively investigated. Initial trials were encouraging, but later larger randomized controlled trials were unable to show an improvement in outcome.[137] Large-volume plasma exchange showed some improvement in hemodynamics and other parameters in initial studies.[226] Recently Larsen and colleagues published a large multicenter randomized controlled clinical trial of high-volume plasma exchange (10 L/day for 3 days) in ALF that demonstrated an improvement in transplant-free survival (likely in patients using acetaminophen), and it may become a standard form of therapy.[227]

In an attempt to improve the efficacy of dialysis techniques, adsorbents have been added to the dialysis fluid to widen the range of molecules removed. A number of approaches are used for this. One is dialysis of blood or plasma against albumin solution. This is done via a recycled circulation in the Molecular Adsorbent Recirculating System (MARS; Gambro/Baxter International, Lakewood, CO) machine or via single-pass albumin dialysis. Another is the use of plasma separation, adsorption, and filtration and then recombining the "cleaned" plasma with the patient's blood.[223]

Nonbiologic systems have been shown to improve blood pressure, increase vascular resistance, and improve short-term encephalopathy scores in patients with ACLF. Three large studies have been reported, two in the management of ACLF (the RELIEF study and the HELIOS study) and the FULMAR study in patients with ALF. Unfortunately, none of the studies has shown an improvement in outcome.[223]

TABLE 71.4 Prognostic Indicators for Liver Transplantation

Acetaminophen-Related Acute Liver Failure[a]	Nonacetaminophen-Related Acute Liver Failure[a]	ALFSG Prognostic Index[b]
A. Single criterion • pH <7.30 or lactate >3.0 mmol/L after adequate fluid resuscitation B. Three criteria • Grade III-IV (West Haven) hepatic encephalopathy • INR >6.5 • Creatinine >3.4 mg/dL	A. Single criterion • INR >6.5 B. Three of 5 criteria • Age <10 or >40 years • Time from jaundice to coma >7 days • INR >3.5 • Bilirubin >17 mg/dL • Unfavorable etiology: drug-induced liver injury, Wilson disease, or seronegative liver injury	• Hepatic coma grade 3 or 4 (West Haven) • Favorable etiology • Acetaminophen, ischemia, hepatitis A, pregnancy • Vasopressor use • INR • Bilirubin

only 50% following acetaminophen toxicity.[232] Clinical practice has changed since this designation was first defined. For example, it is rare to see a patient after acetaminophen-induced ALF with a pH below 7.3 or a creatinine above 300 mmol/L because of improved resuscitation and early renal support at the referring hospital. Because of these factors, ongoing efforts continue to establish markers that increase sensitivity and occur even earlier in the course of the syndrome, while maintaining good specificity and not reducing the positive predictive value to unacceptable levels leading to unnecessary transplants.

Serum phosphate levels are higher in nonsurvivors after both acetaminophen toxicity and in other causes of ALF.[120,233] However, there appears to be an unacceptable overlap and others have suggested that the use of serum phosphate does not provide any additional benefit to existing markers.[121,234,235] Other factors investigated include α-fetoprotein levels and nuclear magnetic resonance analysis of peripheral blood.[120,236] Acute physiologic scoring as a basis for prediction has also been used.[237]

The liver plays a central role in lactate metabolism. In fact, in patients with severe liver necrosis the liver changes from being a consumer of lactate to being a net producer.[209] Arterial blood lactate levels have been shown to improve the sensitivity and maintain the specificity if added to the original King's College Hospital criteria and are achieved earlier in the course of the syndrome.[149]

More recently the ALFSG (Acute Liver Failure Study Group) prognostic index has been published from prospectively collected data from 1974 patients with ALF based on five variables (coma grade, etiology, vasopressor use, bilirubin, and INR).[238] Its performance characteristics (C statistic 0.84) significantly improve on KCC (0.55–0.65) and are available as a smartphone app.

Outcome From Transplantation

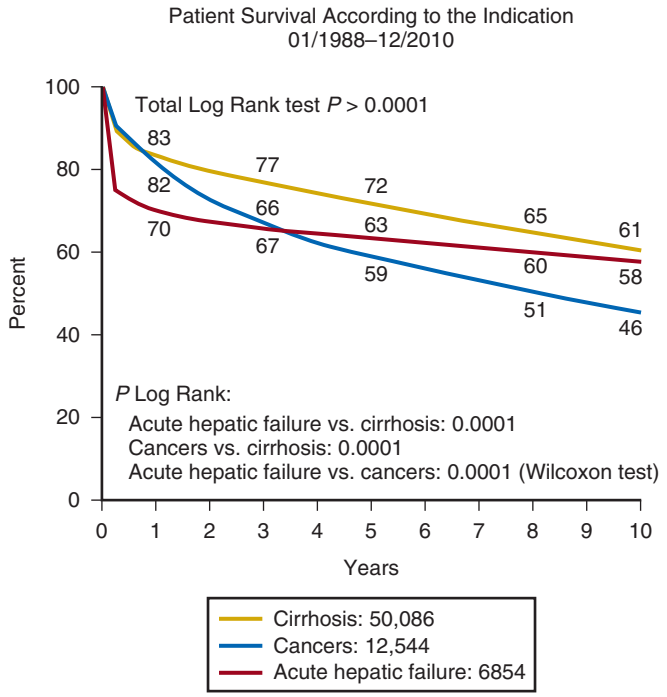
In Europe the 1-year survival rate after transplantation for ALF is worse than that seen in chronic liver disease. The excess mortality rate is seen in the first month or so after transplantation. This represents the severity of organ dysfunction seen before transplantation in ALF. After this initial period, the curve flattens and the survival rate is actually better than that of patients with chronic liver disease (Fig. 71.15). This probably represents a younger age group and less disease recurrence. There is a huge degree of heterogeneity in ALF, and those with seronegative hepatitis who receive transplants display a better survival profile than patients receiving transplants for other causes, although they exhibit a similar early mortality rate while in the ICU.[89]

Tremendous research efforts have gone into the search for prognostic criteria on which to base the decision to perform transplantations in patients with ALF; however, much less information is available about the prediction of fatality after transplantation. This is important, as decisions to withdraw from the waiting list based on severity are difficult.

There appear to be both recipient and donor factors that help predict the outcome from transplantation in ALF.[89,232,239] In theory, the severity of illness and organ dysfunction before transplantation should predict outcome. However, because patients whose conditions are unstable tend to be either not listed or withdrawn from the waiting list, there is inherent bias in retrospective analysis. Age of the recipient is a significant factor, certainly for seronegative ALF, but also in acetaminophen-induced failure, in which age is often used to exclude listing.[232] In non–acetaminophen-induced ALF, serum creatinine at the time of transplantation is a predictor of 2-month survival. After acetaminophen overdose, time from ingestion to transplantation has been shown to be a good predictor of 2-month survival; all patients who receive transplants later than 6 days from ingestion died. The APACHE III score at transplantation and the severity of metabolic acidosis are also predictive.[239]

Donor factors found to be important are the use of reduced size grafts in acetaminophen-induced ALF and evidence of early graft dysfunction as defined by a high AST or INR in the early postoperative period. In addition, a high donor body mass index is a risk factor for death in seronegative hepatitis.[89,232]

In 2012 a review of the European liver transplant database for patients receiving transplants after ALF evaluated 4903 patients. The 1-, 5-, and 10-year patient and graft survival rates were 74%, 68%, and 63%, respectively. Death and graft loss were independently associated with male recipients, recipients older than 50 years, incompatible ABO matching, donors older than 60 years, and reduced size graft. Recipients older than 50 years who received a



• **Fig. 71.15** Patient survival according to the first indication for liver transplant. (From European Liver and Intestine Transplant Association, accessed at http://www.eltr.org.)

graft from a donor older than 60 years had a 57% 1-year mortality rate or graft loss.[240]

The conclusions from this review suggest that older recipients with severe preoperative organ dysfunction are less able to tolerate poor early graft function, often seen with marginal grafts. Therefore to achieve the best graft and patient survival there should be matching of the organ to the recipient, but this is difficult because of time constraints.

Auxiliary Transplantation

Auxiliary partial liver transplantation has many theoretical advantages compared with standard orthotopic transplantation in ALF. It can be performed orthotopically (i.e., in the same place as the original liver) or heterotopically (e.g., in the left iliac fossa). These days it is always performed as a partial orthotopic transplant with a native left lobe in situ in adults and a right lobe in children using an adult left lobe graft, depending on size.

Auxiliary transplantation provides the potential to support the patient during the acute phase of liver failure, enabling regeneration of the native liver. This is attractive because in a number of patients immunosuppressive drugs can be withdrawn, allowing the graft to atrophy or be removed, and eliminating the risks associated with lifelong immunosuppression. Data on this procedure have been accumulating since the mid-1990s. Initial reports suggested that the procedure was associated with a high incidence of technical problems, primary dysfunction, and retransplantation. Later reports, however, suggest that many of these issues are resolving with greater experience in patient and graft selection. The best outcome has been seen in patients aged younger than 40 years with either acute viral hepatitis or acetaminophen hepatotoxicity in whom 1-year graft and patient survival are similar to those for standard transplantation for ALF. Withdrawal of immunosuppression can be achieved in 30% to 70% of patients receiving transplants.[241–243]

Living Related Lobe Donation

In many countries the only chance of transplantation for ALF is a living related donation of a liver lobe. This is most often performed in children when an adult left lobe can be used. In adults, a right lobe is usually required, increasing the risk to the donor. With the worldwide shortage of donor organs, living related transplantation for ALF is widely accepted in many countries but not all. There are significant issues related to living related transplantation in ALF, including a donor mortality rate of 1% and major morbidity rate of 40% to 60%. There are also ethical implications of adequately preparing the donor, medically and psychologically, in a time of acute crisis.[244]

Key Points

- Liver failure can occur with a background of cirrhosis, when it is often termed acute on chronic liver failure (ACLF), or it can occur de novo in a previously healthy individual owing to a toxic, immunologic, hypoxic, or infective cause, when it is termed acute liver failure (ALF) or fulminant liver failure.
- Liver failure, defined by the onset of hepatic encephalopathy and progressive failure in hepatic metabolic activity, progresses to multiple-organ failure and ultimately death in a large proportion of patients, and supportive care is the mainstay of therapy.
- ACLF is seen much more commonly than ALF. It is most often seen in the setting of advanced, decompensated cirrhosis with portal hypertension. It is usually precipitated by some intercurrent event such as sepsis or an upper gastrointestinal bleed. Therapy is aimed at the treatment of sepsis and aggressive management of the circulation.
- Worldwide, particularly in the developing world, approximately 95% to 100% of patients presenting with ALF have viral hepatitis.
- Acetaminophen poisoning is the most common cause of ALF in northern Europe and the United States. It can be treated successfully in the majority of patients with NAC, if given within the first 12 hours after nonstaggered ingestion.
- The presentation and clinical course of ALF depends on its cause and the rate of progression of the syndrome.
- Liver failure after viral hepatitis is rare and tends to run an acute or hyperacute course, with the onset of encephalopathy occurring within days or weeks of the first symptoms.
- The West Haven criteria, designed to assess coma grade in patients with cirrhosis, are often applied to patients with ALF and are useful because of their familiarity.
- Intracranial hypertension secondary to cerebral edema often complicates severe hyperacute liver failure and remains a leading cause of death.
- Management of ALF is complex, and liver transplantation is the only effective therapy in severe cases.

Review Questions

1. A 27-year-old female with a history of depression and anxiety presents to her local emergency department with upper abdominal pain, jaundice, and lethargy. Her laboratories suggest a severe, acute liver injury. Her serologic investigations has been sent to the laboratory, but results are pending. Which of the following treatments has been shown to improve outcome of patients with the corresponding etiology of acute liver failure (ALF)?
   a. Lamivudine: hepatitis B
   b. Hepatitis A immune globulin: hepatitis A
   c. N-acetylcysteine (NAC): idiosyncratic drug-induced liver injury (DILI)
   d. Methylprednisolone: autoimmune acute liver failure
   e. Acyclovir: herpes simplex virus

   Answer: c. Use of NAC in non-acetaminophen ALF may improve transplant-free survival. Very few studies have had the statistical power to make firm conclusions about the efficacy of specific treatments for ALF by etiology. A randomized, controlled study of patients with severe hepatitis B found no improvement in patients who received lamivudine compared to placebo. There are no data to support the use of hepatitis A immune globulin. A retrospective review of corticosteroids for autoimmune ALF found no benefit. Case reports do not suggest benefit from acyclovir in patients with ALF owing to herpes simplex virus. These negative results do not argue against their use because all of the data are flawed to some extent.

   Although NAC has clearly been shown to improve the clinical course of patients with acetaminophen-induced ALF, its use in non–acetaminophen-induced ALF is less well documented. In one multicenter randomized, placebo-controlled study, NAC was found to improve liver transplant–free survival in patients with non–acetaminophen-induced ALF without high-grade hepatic encephalopathy. The two groups with the most benefit were those with hepatitis B and idiosyncratic DILI.
2. A 35-year-old female with a history of previous suicide attempts ingested a "handful" of extra-strength acetaminophen tablets at an unclear point in time and was found unresponsive by her sister. Results for her admission laboratory tests in the local emergency department include the following:

Aspartate aminotransferase (AST)	4567 IU/L
Alanine aminotransferase (ALT)	8459 IU/L
Total bilirubin	1.4 mg/dL
Creatinine	3.8 mg/dL
International normalized ratio (INR)	9.6
Ammonia	105 µmol/L

   Which of the following is the only prophylactic measure to prevent cerebral edema in patients with ALF supported by a randomized, controlled clinical trial?
   a. Mannitol
   b. Lactulose
   c. Hypertonic saline solution
   d. Hypothermia
   e. Renal replacement therapy

   Answer: c. Hypertonic saline has been shown to be effective as prophylaxis against cerebral edema in patients with ALF. Murphy et al. performed the only randomized and controlled clinical trial to prevent cerebral edema and intracranial hypertension. The trial showed that raising the serum sodium to 145 to 155 mEq/L with hypertonic saline solution decreased the mean intracranial pressure of study subjects with ALF and high-grade hepatic encephalopathy compared with patients managed with standard of care without hypertonic saline solution. Hypothermia was recently explored in a randomized, controlled, multicenter trial and was not shown to improve outcome or the development of intracranial hypertension.

   The other prophylactic measures listed have not been systematically studied in clinical trials. However, there are reasonable rationales behind their use and may be considered, particularly the early institution of renal replacement therapy in the presence of significant hyperammonemia (>150 µmol/L), even in the absence of azotemia.
3. A 27-year-old male is admitted with jaundice and altered mentation. There is no history of previous liver disease or acetaminophen ingestion, and the patient takes no over-the-counter or herbal remedies.

   After admission to the intensive care unit, the following data are obtained:

Sodium	147 mEq/L
ALT	3798 IU/L
AST	2857 IU/L
INR	8.5
Venous ammonia	135 µmol/L
Total bilirubin	2 mg/dL
Creatinine	0.8 mg/dL
Platelet count	56 x 10^9/L

   Hepatitis B surface antigen (HBsAg) and IgM anti-hepatitis B core antibodies (HBcAB) are positive.

   The patient has a mean arterial pressure of 70 mm Hg off vasopressors. He is lethargic and oriented only to person.

   You have entered the above data into the ALF Study Group Prognostic Score app on your smartphone, and determine the patient has a predicted transplant-free survival of ~5% at 21 days. An expedited liver transplant evaluation is nearly complete. Which of the following management options should be instituted next?
   a. Administer lactulose via nasogastric tube to effect three bowel movements.
   b. Administer plasma and platelets.
   c. Insert an intracranial pressure monitor.
   d. Intubate the patient.
   e. Administer an intravenous (IV) mannitol 0.5 g/kg bolus

   Answer: d. The progression of hepatic encephalopathy to higher than grade 2 is an absolute indication for endotracheal intubation and thereby airway protection. One of the worst mistakes a clinician can make in managing a patient with ALF is delaying intubation and losing control of the patient's airway long enough to result in aspiration. This patient has grade 3 hepatic encephalopathy, which is an informal, but widely accepted indication for immediate sedation and intubation. Lactulose is very unlikely to result in significant diminution of the ammonia to avoid the need for intubation or lower the risk of intracranial hypertension. Mannitol is given therapeutically after intracranial hypertension is suspected or established by head computed tomography (CT) or intracranial pressure (ICP) monitor criteria. The decision to place an ICP monitor is contentious and center and practitioner dependent, but it is usually reserved to manage

patients with deep coma who are at high risk of intracranial hypertension (i.e., those taking vasopressors, renal replacement therapy, and with severe hyperammonemia).

There is an emerging consensus that the INR should not be corrected unless a patient is actively bleeding. The reasons include that (1) patients with ALF seldom have clinically significant spontaneous (non–procedure-related) bleeding; (2) plasma transfusion obscures the trend in INR, a key prognostic indicator; and (3) plasma transfusion may be harmful. Sources of harm may include exacerbating a relative hypercoagulable state in patients with ALF, volume overload, transfusion-associated lung injury, and others. There are no data to support the transfusion of platelets in patients with ALF. Extrapolating from in vitro data in patients with cirrhosis, a platelet count of more than 60×10^9/L supports thrombin generation at the 90th percentile of normal. Therefore platelet transfusions in patients with ALF should be reserved for patients with significant spontaneous bleeding or in patients with counts below 60×10^9/L before undergoing high-risk procedures such as ICP monitor placement.

4. A patient with ALF as the result of hepatitis B is deeply comatose with no sedation for 48 hours and has received an offer of a liver from a deceased donor. Which of the following should be performed immediately before proceeding to the operating room for liver transplantation?
   a. Placement of an ICP monitor
   b. Electroencephalogram (EEG)
   c. CT scan of the head
   d. Optic nerve sheath diameter
   e. Transcranial Doppler ultrasound

   Answer: c. In a comatose patient with ALF, irreversible brain damage must be ruled out by head CT on the way to the operating room for liver transplantation. Predicting neurologic outcome after liver transplantation is often not possible in deeply comatose patients with ALF. The primary question at the time a patient has received an offer of a liver graft is which patient absolutely should not proceed to transplant. Placement of an ICP monitor remains a contentious management decision in patients with ALF, as several surveys and retrospective studies have failed to show an improvement in outcome or neurologic recovery. Furthermore, they are associated with uncommon but potentially fatal bleeding complications. ICP monitor placement is physician and center dependent, but is usually reserved for liver transplant candidates awaiting the offer of a graft in hopes of improving management of cerebral edema and would not be placed on the way to the operating room. However, patients with prolonged intracranial hypertension or low cerebral perfusion pressures assessed by an indwelling ICP monitor have been shown to have poor neurologic recovery after liver transplantation. Similarly, an EEG might be considered during the waiting period if seizures were considered. Transcranial Doppler and optic nerve sheath diameter are noninvasive procedures to estimate ICP. The single best test to determine whether a patient should absolutely not undergo liver transplantation is to do a head CT scan to look for evidence of irreversible brain damage, such as brainstem herniation.

5. The mental status of a patient with ALF caused by acetaminophen overdose has deteriorated from grade 1/2 hepatic encephalopathy to unresponsiveness over the previous 12 hours. Which of the following must be excluded urgently?
   a. Brainstem herniation
   b. Infection
   c. Acute kidney injury
   d. Acute respiratory distress syndrome and hypoxemia
   e. Hyponatremia.

   Answer: b. Sudden progression from low-grade to high-grade hepatic encephalopathy in a patient with ALF must be considered a sign of infection until proved otherwise. The most common risk factor for sudden, rapid, worsening of hepatic encephalopathy from mild to high-grade is infection. The other complications of ALF listed certainly would be expected to result in an exacerbation of encephalopathy, but they would occur in a patient with preexisting high-grade encephalopathy (brainstem herniation) or more gradually.

Conclusion

Gastrointestinal (GI) bleeding includes a wide range of diagnoses with multiple types of lesions and bleeding that can occur virtually anywhere in the GI tract. Acute GI bleeding is often an emergency that can be alarming to both the patient and physician. Management and the outcome of GI bleeding depend on both the severity of the bleeding and any comorbid conditions present at the time of the bleeding. Acute GI bleeding often requires close monitoring and management in an intensive care unit (ICU). Management of such bleeding relies on a team approach that involves the expertise of an intensivist, gastroenterologist (endoscopist), radiologist, and surgeon.

The annual hospitalization rate for GI bleeding of any cause in the United States is estimated to be at 150 per 100,000.[1] Upper GI bleeding accounts for most of these hospitalizations, with an incidence rate of 100 cases per 100,000,[2] whereas the incidence of lower GI bleeding is estimated at 20 to 27 cases per 100,000.[3,4] In recent years, a significant decline in incidence of all-cause acute upper GI bleeding has been reported in some but not all time-trend studies, especially peptic ulcer bleeding.[5] Mortality rates vary depending on the source of the bleeding, with an annual rate of 2.5% to 3.5% for any type of GI bleeding.[1] Most nonvariceal upper GI bleeding studies document mortality rates approximating 5% to 10%.[5–7] These rates have not changed over the past 2 decades despite the evolution of acid suppression therapy, which is probably explained by an aging population with increased comorbid diseases. Mortality rates for lower GI bleeding are usually in the range of 5%.[8,9]

Clinical Presentation

Initial Evaluation and Resuscitation

The clinical findings in a patient with GI bleeding are crucial in determining the site, cause, and rate of bleeding. The first step in clinical evaluation is to assess the severity of the bleeding. This is done primarily by measuring hemodynamic parameters in an attempt to quantify the amount of blood volume lost (Table 72.1).[10] Because bleeding can represent a dynamic ongoing situation, continuous monitoring of hemodynamics is necessary to guide resuscitation efforts and provide key prognostic information. In patients with GI bleeding, two large-bore intravenous (IV) catheters should be placed immediately on arrival to restore euvolemia.

The hematocrit at initial evaluation may not reflect the severity of the bleeding because very recent loss of both plasma and red blood cells (RBCs) leads to a percentage of RBCs in the remaining blood (which defines the hematocrit) that is close to the same value. The hematocrit drops when hemodilution occurs as extravascular fluid enters the vascular space to restore volume, a process that may take up to 72 hours (Fig. 72.1).[11]

The rapidity of blood and colloid infusion depends in part on the patient's cardiovascular condition. Placement of a central venous pressure catheter can help one base decisions on more objective findings. Several recent studies found that transfusion was associated with a higher risk for nosocomial infection, multiorgan dysfunction, acute respiratory distress syndrome, and death.[12] Current transfusion trends are to administer blood to patients with hemoglobin less than 7 mg/dL and to avoid transfusion when it is above 10 mg/dL. However, the threshold for blood transfusion should take into consideration the patient's underlying condition, hemodynamic status, and markers of tissue hypoxemia.[13] A study evaluating blood transfusion for upper GI bleeding found a significantly higher survival rate and lower rebleeding rate when a restrictive transfusion threshold of 7g/dL was followed compared with a threshold of 9 g/dL.[14] In patients with conditions associated with defects in platelet or coagulation factors, these substances should be replaced. Patients requiring massive transfusion of packed red blood cells require fresh frozen plasma and platelets. Hypocalcemia can develop in these patients because of the large amount of citrate received

TABLE 72.1 Hemodynamics, Vital Signs, and Blood Loss

Hemodynamics and Vital Signs	% Blood Loss (Fraction of Intravascular Volume)	Bleeding Type
Shock (resting hypotension)	20–25	Massive
Postural (orthostatic tachycardia or hypotension)	10–20	Moderate
Normal	<10	Minor

TABLE 72.2 Blatchford Score for Gastrointestinal Bleeding[a]

Admission Parameter	Score Value
Urea (mg/dL)	
≥6.5 to <8.0	2
≥8 to <10	3
≥10 to <25	4
≥25	6
Hemoglobin (g/dL)	
Men	
≥12 to <13	1
≥10 to <12	3
<10	6
Women	
≥10 to <12	1
<10	6
Systolic Blood Pressure (mm Hg)	
100–109	1
90–99	3
<90	3
Other Parameters	
Pulse >100 beats/min	1
Melena at presentation	1
Syncope	2
Hepatic disease	2
Cardiac failure	2

[a]The score is calculated by adding the points from each variable. A score of zero is associated with a low risk of the need for endoscopic intervention.
From Blatchford O, Murray WR, Blatchford M. A risk score to predict need for treatment for upper-gastrointestinal haemorrhage. *Lancet.* 2000;356:1318–1321.

with massive transfusion, and thus calcium replacement should be considered, especially in individuals with end-stage liver disease and heart failure, in whom citrate metabolism may be impaired.[15]

The initial evaluation of patients with nonvariceal upper GI bleeding should include risk stratification of patients into low- and high-risk categories for rebleeding and death based on clinical, laboratory, and when available, endoscopic criteria.[12] This allows appropriate intervention and minimizes morbidity and mortality risks. The most extensively validated scores for risk stratification are the Blatchford and Rockall scores[16,17] (Tables 72.2 and 72.3). Similarly, risk stratification in lower GI bleeding helps in guiding the management of these patients. Hemodynamic instability, ongoing hematochezia, age older than 60 years, history of diverticulosis or angioectasia, and comorbid illnesses have been consistently associated with poor outcome in lower GI bleeding.[18,19]

History and Clinical Findings

After hemodynamic stabilization is achieved, a careful history and clinical examination are imperative to make a preliminary assessment of the location and cause of the bleeding. Important historical features in the evaluation of GI bleeding are shown in Box 72.1.[10]

Hematemesis typically points to an upper source of bleeding, proximal to the ligament of Treitz. In rare cases, hematemesis can be a sign of swallowed blood from oral, pharyngeal, or nasal bleeding. Melena is defined as black tarry stool with a glistering sheen and results from degradation of blood in the GI tract. At least 50 mL of blood in the upper GI tract is required to cause melena, although volumes up to 100 mL may be clinically silent.[20] Melena usually indicates upper GI bleeding, but its source may be the small bowel and sometimes even the proximal part of the colon when the volume of blood is too small to cause hematochezia. Coffee-ground emesis is typically a sign of recent, but currently inactive, upper GI bleeding, and its appearance is caused by the acid's effect on blood in the lumen. Hematochezia is generally associated with colonic bleeding but can also be caused by more proximal bleeding. Proximal bleeding in association with hematochezia is usually more hemodynamically significant.

Other symptoms at initial evaluation can help in narrowing the differential diagnosis. Abdominal pain before or at the time of the bleeding episode can be a sign of underlying peptic ulcer disease (PUD), mesenteric or colonic ischemia, perforation, or even intestinal infarction. Multiple episodes of vomiting and retching preceding the bleeding episode should alert one to the presence of a Mallory-Weiss tear (MWT).

TABLE 72.3 Rockall Scoring System for Risk of Rebleeding and Death in Acute Gastrointestinal Bleeding[a]

	POINTS			
Variable	**0**	**1**	**2**	**3**
Age (years)	<60	60–79	>80	
Shock	No shock (systolic BP >100 mm Hg, pulse <100 beats/min)	Tachycardia (systolic BP >100 mm Hg, pulse >100 beats/min)	Hypotension (systolic BP <100 mm Hg, pulse >100 beats/min)	
Comorbidity	Nil major		Cardiac failure, ischemic heart disease, any major comorbid condition	Renal failure, liver failure, disseminated malignancy
Diagnosis	Mallory-Weiss tear, no lesion, and no SRH	All other diagnoses	Malignancy of upper GI tract	
Major SRH	None or dark spot		Blood in upper GI tract, adherent clot, visible or spurting vessel	

[a]The score is calculated by adding the points from each variable. A score of 2 or less is associated with a low risk of further bleeding or death.

• BOX 72.1 Historical Features in the Assessment of Gastrointestinal Bleeding

Age
Previous bleeding
Previous gastrointestinal disease
Previous surgery
Underlying medical disorder (especially liver disease)
Nonsteroidal anti-inflammatory drugs
Abdominal pain
Change in bowel habits
Weight loss or anorexia
History of oropharyngeal disease

From Rockey DC. Gastrointestinal bleeding. Gastroenterol Clin North Am. *2005;34:581–588.*

A previous history of bleeding from PUD, esophageal or gastric varices, diverticulosis, or vascular ectasia puts these diagnoses high on the differential diagnosis list. A history of abdominal vascular surgery adds aortoenteric fistula to this list. In patients with known liver disease, the possibility of bleeding from conditions associated with portal hypertension, such as esophageal or gastric varices and portal gastropathy, should be raised. One should also look for risk factors for chronic liver disease, such as a history of chronic alcohol abuse and chronic hepatitis.

GI bleeding in elderly patients is usually caused by conditions less commonly encountered in younger patients (i.e., diverticulosis, vascular ectasia, ischemic colitis), whereas in younger patients, bleeding from sources such as varices, ulcer disease, and esophagitis is more common.

Ingestion of aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) increases the risk of bleeding from PUD. In patients taking anticoagulant medications, bleeding most often results from underlying GI disease such as ulcer disease or vascular ectasia, even in the setting of a supratherapeutic international normalized ratio, and should not be attributed to the anticoagulation itself.

Other medical conditions present at the time of the bleeding can have a large impact on the resuscitation efforts and subsequent management. Bleeding patients with a history of coronary artery disease are at increased risk for myocardial infarction, and restoration of volume and oxygenation should be an immediate goal. Patients with pulmonary disease may need airway intubation before sedation when endoscopy is being contemplated.

Physical examination should look for evidence of chronic liver disease, such as spider angiomas, gynecomastia, splenomegaly, and ascites. The presence of these signs suggests the possibility of portal hypertension. Telangiectases of the skin or mucous membranes and lips raise the possibility of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease). Acanthosis nigricans can be a sign of GI malignancy (especially gastric cancer). The presence of purpura suggests vascular diseases such as Henoch-Schönlein purpura or polyarteritis nodosa. Tenderness with or without peritoneal signs on abdominal examination may indicate PUD, ischemia, or perforation. The abdominal examination should include percussion and palpation to look for organomegaly and masses. Bedside examination of the character of the stool is a necessary measure that provides critical information about the source and severity of the bleeding episode. Bright red blood per rectum, maroon-colored stools, and melena suggest active bleeding, whereas brown stools indicate less aggressive bleeding.

The use of a nasogastric tube in patients presenting with GI bleeding is a common practice but at the same time controversial. The presumed benefits of nasogastric lavage include confirmation of an upper GI source of bleeding, better visualization during endoscopy, and prediction of high-risk lesions, such as an oozing or spurting lesion and nonbleeding visible vessel. A bloody aspirate suggests, with some degree of certainty, an upper source of bleeding because false-positive results are rare and generally related to nasogastric trauma.[21] In one study of patients presenting with suspected upper GI bleeding, 45% of cases with a bloody aspirate were associated with a high-risk lesion on endoscopy versus 15% when the aspirate was clear or bilious.[22] Identifying patients with high-risk lesions is important because those patients have the worst outcome and early endoscopic therapy may have the most benefit.

However, the positive and negative predictive values of a bloody aspirate for high-risk lesions are only 45% and 85%, respectively, which makes basing the decision of an early endoscopy on the information obtained by the nasogastric lavage controversial. In a retrospective study of the impact of performance of nasogastric lavage, this practice was associated with earlier time to endoscopy but had no effect on mortality rate, length of hospital stay, surgery, or transfusion requirements.[23] In another recent randomized trial of nasogastric tube placement in patients with acute upper GI bleeding, routine nasogastric placement did not improve physicians' ability to predict the culprit bleeding lesion, did not affect rebleeding rates or mortality, and was complicated with pain and nasal bleeding in more than 25% of patients.[24] In our opinion, if an upper endoscopy is planned in the next 12 to 24 hours after presentation of a patient with suspected upper GI bleeding, nasogastric lavage should be avoided owing to lack of proven benefit and major discomfort and pain inflicted to the patient. In the setting of hematochezia with hemodynamic instability, extremely brisk upper GI bleeding should be suspected, and a positive nasogastric aspirate result can confirm this suspicion.

Diagnostic Tests

The initial laboratory evaluation in patients with GI bleeding should include a complete blood cell count, liver enzymes, prothrombin time, blood urea nitrogen, and creatinine. As mentioned earlier, the first hematocrit level may be falsely reassuring, so management decisions should rely on other parameters such as hemodynamics and the nature of the bleeding. A high white blood cell count should alert one to the presence of ischemia or infarction. Thrombocytopenia can be a sign of portal hypertension, and a critically low platelet count, as well as a high prothrombin time, should be addressed immediately by transfusion of platelets and fresh frozen plasma. An elevation in the blood urea nitrogen level disproportionate to creatinine is compatible with upper GI bleeding but may also be seen with intravascular volume depletion from any source of bleeding. In one study, this ratio was significantly higher in patients with upper GI bleeding than in those with lower GI bleeding (22.5 ± 11.5 vs. 15.9 ± 8.2; $P = 0.001$); however, the degree of overlap shows the poor discriminatory value of this ratio.[25] In another study, a ratio greater than 36 had a specificity of 27% and a sensitivity of 90% for upper GI bleeding.[26]

After initial resuscitation and stabilization, a diagnostic plan should be initiated. Several diagnostic tools are available, including endoscopy, radionuclide imaging, and angiography. These tests are aimed at detecting the location, source, and activity of bleeding. Other tests may be necessary in specific clinical situations, such as computed tomography (CT) scanning when abdominal pain is a prominent complaint to rule out ischemia, infarction, and perforation. Endoscopy and to some extent angiography have the advantage of allowing both diagnosis and therapy.

Therapeutic Options

In addition to controlling the current episode of bleeding, treatment is also aimed at preventing recurrent bleeding. The available forms of therapy are pharmacologic, endoscopic, angiographic, and surgical. They are often complementary and require a multidisciplinary team approach. Use of these different modalities varies with the specific cause and source of bleeding.

Advances in potent acid suppression with the advent of proton pump inhibitors (PPIs) and the progress made in endoscopic technology have revolutionized the management of GI bleeding. Effective acid suppression has an established role in decreasing bleeding recurrence. Different endoscopic treatment modalities can be used alone or in combination during endoscopy and have been shown to decrease bleeding recurrence. Such modalities include injection, cautery, and mechanical therapy.

Detailed approaches to the diagnostic and therapeutic options are highlighted in specific sections of this chapter.

Upper Gastrointestinal Bleeding

Differential Diagnosis

Nonvariceal Bleeding

Nonvariceal upper GI bleeding remains a significant cause of death and morbidity despite recent advances in pharmacologic and endoscopic therapy. The cause of nonvariceal bleeding encompasses a large array of diagnoses involving multiple organs above the ligament of Treitz and at times outside the GI tract. The causes and frequency of nonvariceal bleeding are listed in Table 72.4.[27]

Peptic Ulcer Disease

PUD traditionally refers to gastric and duodenal ulcers, gastritis, and duodenitis. A number of population-based and prospective studies rank PUD as the most common source of acute upper GI bleeding, with PUD representing up to 50% of all such cases.[28] However, analysis from the Clinical Outcomes Research Initiative database reported that the most common endoscopic finding in persons with acute upper GI bleeding was "mucosal abnormality" (40%), and gastric or duodenal ulcers were found in 20.6%.[29] Eradication of *Helicobacter pylori* and extensive use of PPIs are probably responsible for this observed decline in the frequency of PUD.

The most important factors predisposing to ulcer disease include acid, *H. pylori* infection, and NSAIDs; however, the role of some of these risk factors in inducing ulcer bleeding remains unclear. Indirect evidence regarding the role of acid in ulcer bleeding comes from data showing that acid suppression by PPIs in patients with active or recent bleeding reduces the risk for rebleeding.[30] Evidence of the association between NSAIDs and ulcer bleeding is strong and comes from both placebo-controlled and case-control studies.[31,32]

TABLE 72.4 Causes of Nonvariceal Upper Gastrointestinal Bleeding

Diagnosis	Incidence (%)
Peptic ulcer	30–50
Mallory-Weiss tear	15–20
Erosive gastritis or duodenitis	10–15
Esophagitis	5–10
Malignancy	1–2
Angiodysplasia or vascular malformations	5
Other	5

From Ferguson CB, Mitchell RM. Nonvariceal upper gastrointestinal bleeding: standard and new treatment. *Gastroenterol Clin North Am.* 2005;34:607–621.

The pathogenesis of bleeding from an ulcer involves aneurysmal dilation with an intense arteritis associated with a marked inflammatory response.[33] When eroding into large vessels, ulcers can cause catastrophic bleeding. This most commonly occurs in the posterior portion of the duodenal bulb, where ulcers can erode directly into the pancreaticoduodenal artery.

Other Sources of Nonvariceal Upper Gastrointestinal Bleeding

MWTs are mucosal and occasionally submucosal lacerations caused by sudden increases in pressure within the cardia and lower esophagus produced by retching. MWTs are responsible for 5% to 15% of upper GI bleeding.[28] The majority of upper GI bleeding caused by MWTs stops spontaneously and does not require any blood transfusion or endoscopic treatment. However, some cases are severe enough to require endoscopic hemostasis and occasionally angiography with embolization or even surgery. A history of retching on arrival at the emergency department is not always present.[34] Endoscopically, tears are usually 1.5 to 2 cm in length and occur at the gastroesophageal junction or, most commonly, in the proximal part of the stomach (Fig. 72.2).

Angiodysplasia, also referred to as arteriovenous malformation or vascular ectasia, is another source of upper GI bleeding and accounts for approximately 5% to 10% of cases.[28] It occurs in inherited syndromes such as hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) and blue rubber bleb nevus syndrome, but most cases are acquired.[35] The association of angiodysplasia with medical conditions such as renal failure, aortic stenosis, connective tissue disease (scleroderma), and von Willebrand disease has been recognized, but the evidence for these associations is limited.[28,36]

Dieulafoy lesion is an underrecognized cause of upper GI bleeding and is described as a visible vessel protruding from a small mucosal defect without any underlying ulcer.[28] It has also been called "caliber-persistent artery" in submucosal tissue. Bleeding from Dieulafoy lesion represents less than 5% of cases of upper GI bleeding.[37,38] The lesion is generally located on the lesser curvature within 6 cm of the gastroesophageal junction and can be difficult to detect because of its small size and normal surrounding mucosa (Fig. 72.3).[36]

Benign and malignant neoplasms are responsible for less than 5% of upper GI bleeding.[39] Bleeding can be the initial symptom of tumors originating from the esophagus, stomach, or small intestine. These neoplasms can be primary malignancies, such as adenocarcinoma of the esophagus, stomach, or duodenum; squamous cell carcinoma of the esophagus; and gastric or duodenal lymphomas. GI stromal cell tumors, carcinoid tumors, and lipomas are examples of benign tumors that can cause upper GI bleeding.[28]

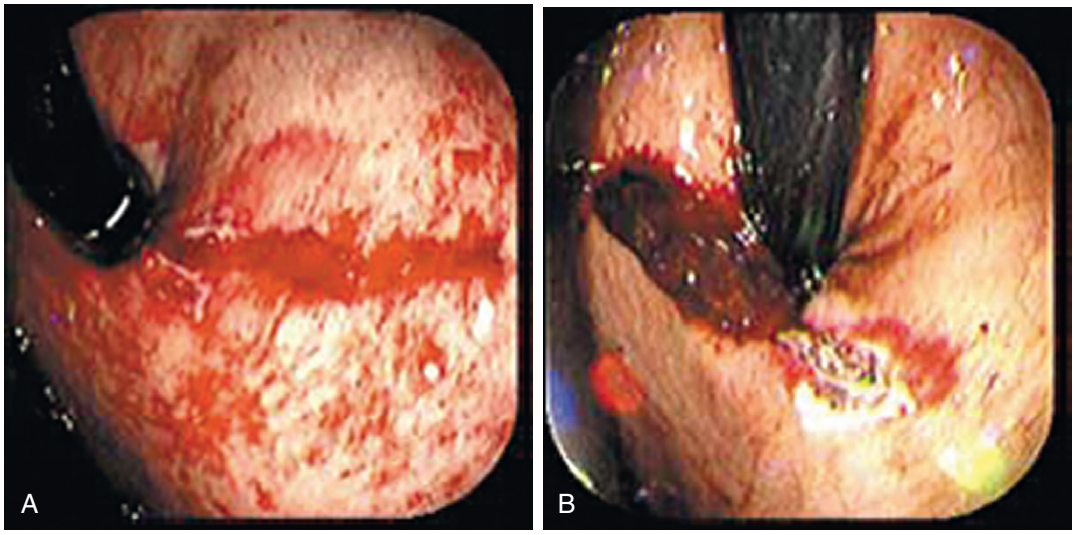
Upper GI bleeding from an aortoenteric fistula is very rare but should be considered in the appropriate clinical setting (such as a patient with a history of aortic aneurysm repair). Fistulas are generally located in the third portion of the duodenum. Patients frequently have a small hemorrhage first, known as a "herald bleed," that occurs before a major hemorrhage.[40]

Another rare cause of upper GI bleeding is hemobilia. It can occur after liver biopsy or hepatobiliary tree instrumentation (such as with endoscopic retrograde cholangiopancreatography) or from biliary tumors.

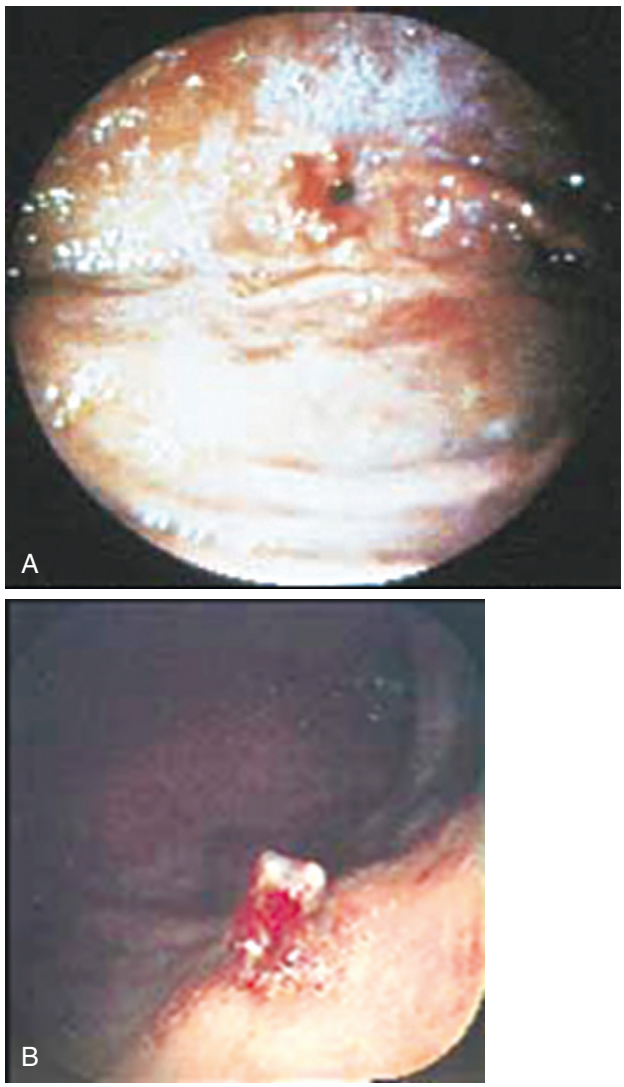
Hemosuccus pancreaticus is an uncommon cause of upper GI bleeding that occurs secondary to pseudoaneurysm formation and rupture into the pancreatic duct as a complication of a pancreatic pseudocyst in patients with chronic pancreatitis.[41]

Bleeding Secondary to Portal Hypertension

Portal hypertension is defined by a hepatic venous pressure gradient (HVPG) greater than 5 mm Hg. HVPG represents the difference between portal vein pressure and free hepatic vein pressure. Portal hypertension is most commonly related to cirrhosis but can be secondary to a variety of other conditions. It has been classified as prehepatic, hepatic, and posthepatic, depending on the location of the obstruction to flow. Examples of noncirrhotic portal hypertension include portal vein thrombosis, Budd-Chiari syndrome, and constrictive pericarditis. In the presence of portal hypertension, the development of portosystemic collateral venous drainage results



• **Fig. 72.2** A, Mallory-Weiss tear in the cardia of the stomach. Active bleeding is seen. B, The same tear seen in A after injection with epinephrine and coagulation. The bleeding is controlled. In: DiMarino AJ, Benjamin S [eds]. *Gastrointestinal Disease: An Endoscopic Approach.* 2nd ed. Thorofare, NJ: Slack; 2002:245–262.)



• **Fig. 72.3** A and B, Endoscopic appearance of Dieulafoy lesion in the proximal part of the stomach. (From Bashir RM, Al-Kawas FH. Vascular lesions of the stomach. In: DiMarino AJ, Benjamin S [eds]. *Gastrointestinal disease: An endoscopic approach*. 2nd ed. Thorofare, NJ: Slack; 2002:535–550.)

in the formation of varices. Varices develop most commonly in the distal portion of the esophagus and the stomach. Ectopic varices can be seen in the duodenum, jejunum, or colon; at the level of stomas (ileostomy and colostomy); and in the anorectal region. Most portal hypertensive bleeding results from ruptured esophageal varices, but clinically significant bleeding can also be secondary to gastric varices, portal gastropathy, and ectopic varices.

Esophageal Varices

The incidence of varices among all patients with cirrhosis is around 50%. However, if monitored long enough, varices eventually develop in most cirrhotics.[42] Variceal hemorrhage occurs in a third of cirrhotic patients with varices. Although portal hypertension is defined by an HVPG greater than 5 mm Hg, Garcia-Tsao and colleagues showed that varices do not develop and hence do not bleed as long as the HVPG is less than 12 mm Hg.[43] However, once this threshold is reached, there is poor correlation between the pressure gradient and the risk for bleeding. Other risk factors associated with variceal bleeding include the degree of liver disease (provided by the Child classification), variceal location and size (higher risk near the gastroesophageal junction and with large varices), and the presence of particular endoscopic signs (red wale markings suggestive of dilated longitudinal venules, cherry-red spots, and hematocystic spots consisting of small red dots or a reddish blister-like formation on the variceal surface and the white or purple nipple sign on a varix) (Fig. 72.4).[42,44]

Gastric Varices

Sarin and colleagues classified gastric varices into two groups: (1) isolated gastric varices and (2) gastroesophageal varices (GEVs) that are continuous with esophageal varices and extending to the cardia (GEV 1) or to the fundus (GEV 2).[45] The authors found that GEV 1 was the most common type of gastric varix but isolated gastric varices were the type that bleeds the most. Although the incidence of bleeding from gastric varices is in the range of 10% to 36%, it is usually massive and associated with high mortality rates.[46]

Diagnostic Evaluation

Endoscopic Examination

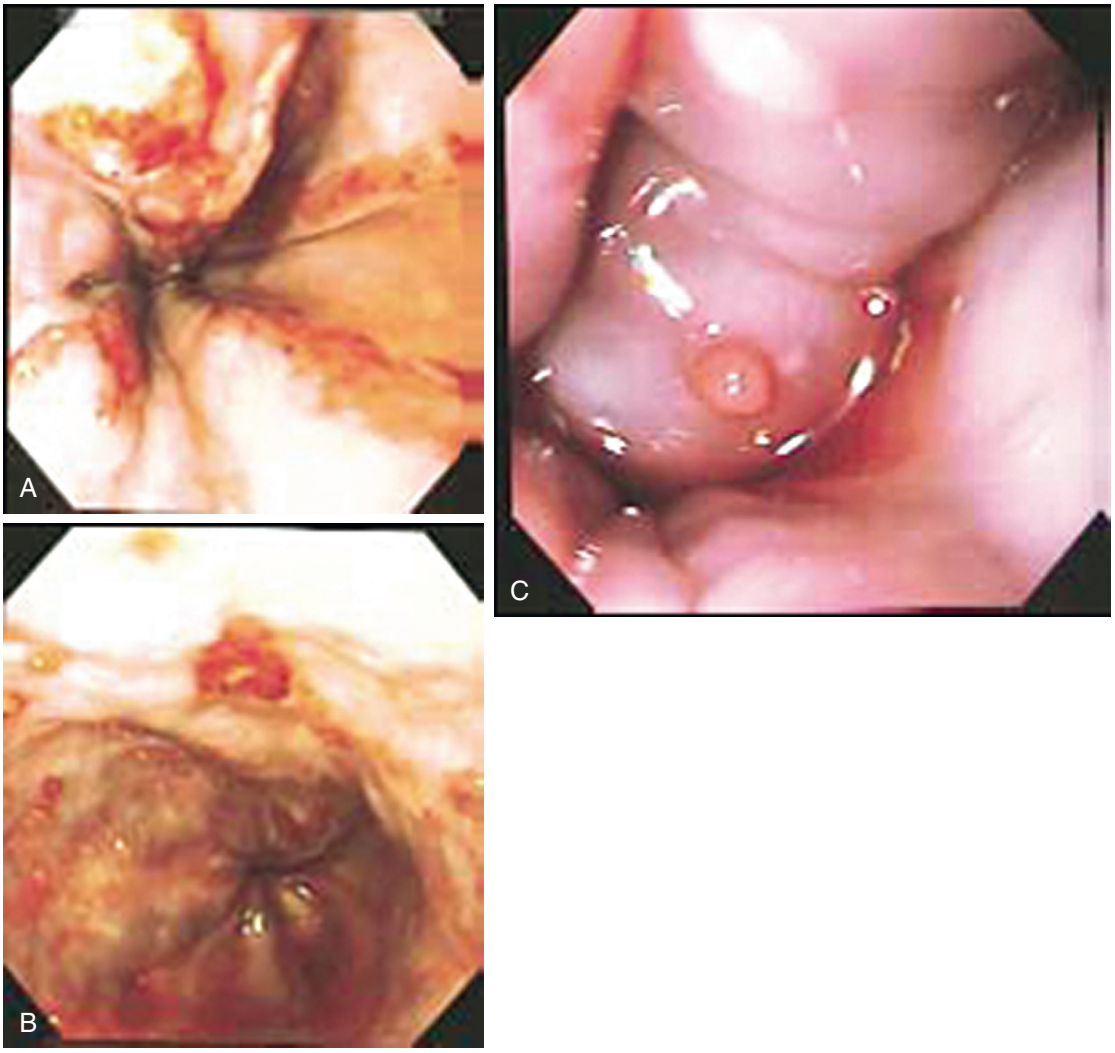
After the initial evaluation, resuscitation, and stabilization of a patient with upper GI bleeding, effort is directed at localization and treatment of the hemorrhage. Endoscopy has become the preferred diagnostic and therapeutic modality for upper GI bleeding because of its accuracy and low complication rate. With its use, a specific diagnosis can be achieved in 95% of patients. The use of promotility agents such as metoclopramide and IV erythromycin (250 mg by IV bolus or 3 mg/kg over a 30-minute period) before the endoscopic examination can significantly improve mucosal visibility by promoting gastric motility and emptying of gastric contents.[47–49] Two meta-analyses of the benefit of prokinetics showed a significant reduction in the need for repeat endoscopy.[50,51] The QT-interval–prolonging effect of erythromycin should be taken into consideration and an electrocardiogram first performed.

The optimal timing of endoscopy remains a balance between clinical need and resources and is still subject to controversy.[27] Endoscopy has to be delayed or deferred in selected high-risk patients such as patients with bowel perforation or acute coronary syndrome. In a meta-analysis of the timing of endoscopy, no significant reduction in rebleeding, surgery, or mortality rate was found with urgent endoscopy (1–12 hours) compared with later endoscopy (>12 hours).[13] In a subset of patients with bloody gastric lavage, length of hospital stay and blood transfusion requirements were significantly lower in the urgent endoscopy group (within 12 hours).[52] Guidelines from American and European societies recommend the performance of upper endoscopy within 24 hours in patients with suspected nonvariceal upper GI bleeding, and within 12 hours in patients with higher-risk clinical features (e.g., tachycardia, hypotension, bloody emesis, or nasogastric aspirate in the hospital).[53,54]

One major role of endoscopy is to identify stigmata of recent hemorrhage known to correlate well with an increased risk for rebleeding and thus a need for endoscopic therapy. Rates of rebleeding with these specific endoscopic findings are summarized in Table 72.5.[55]

Nonendoscopic Assessment

When endoscopy cannot be performed or has not yielded a definitive diagnosis, angiography and radionuclide imaging may be useful



• **Fig. 72.4** A to C, Esophageal varices with red color and white nipple signs. (From Sheikh RA, Prindiville TP, Trudeau W. Gastrointestinal bleeding in portal hypertension. In: DiMarino AJ, Benjamin S [eds]. *Gastrointestinal Disease: An Endoscopic Approach.* 2nd ed. Thorofare, NJ: Slack; 2002:605–644.)

alternatives. Such endoscopic failures are most often related to anatomic situations (i.e., strictures or surgical alterations) preventing full endoscopy. Esophagography and upper GI series are no longer used as part of the diagnostic evaluation of patients with upper GI bleeding.

Therapeutic Alternatives

Nonvariceal Bleeding

Pharmacotherapy

Acid suppression has been shown to play a role in the inactivation of pepsin, optimization of platelet function, and inhibition of fibrinolysis. Subsequently, clot stabilization and ulcer healing may be more effective and rapid within a less acidic environment. This constitutes the rationale for acid suppressive therapy in patients with bleeding peptic ulcers.

Treatment with PPIs before the performance of upper endoscopy has been shown to down-stage the endoscopic lesion and decrease the need for endoscopic intervention.[13] However, a meta-analysis of six randomized trials showed that a PPI given to patients with upper GI bleeding soon after presentation did not significantly reduce the risks of further bleeding, surgery, or death.[56]

Once endoscopy is performed, the role of PPI therapy becomes more obvious. In patients found to have high-risk lesions treated endoscopically, the guidelines recommend an IV bolus followed by continuous-infusion PPI therapy.[13,53,54] The use of a continuous infusion is supported by data showing that maintenance of intragastric pH at greater than 6 after endoscopic hemostasis is associated with the lowest rebleeding rates and that this goal can be achieved only by bolus administration of a PPI followed by a constant infusion.[57] However, a recent meta-analysis showed that intermittent oral or IV PPI therapy resulted in outcomes that were noninferior to those after continuous infusion.[58]

Other agents with different mechanisms of action have been studied in patients with upper GI bleeding. A reduction in splanchnic blood flow with somatostatin and its analogs (such as octreotide) is an attractive measure in patients with upper GI bleeding and has been the subject of several trials, with conflicting results.[59–61] To date, the available data are not convincingly in favor of using these agents in patients with nonvariceal upper GI bleeding,

TABLE 72.5 Stigmata of Ulcer Hemorrhage and Risk for Recurrent Bleeding Without Endoscopic Therapy

Endoscopic Finding	Risk for Recurrent Bleeding Without Therapy
Active arterial (spurting) bleeding	Approaches 100%
Nonbleeding visible vessel ("pigmented protuberance")	Up to 50%
Nonbleeding adherent clot	30%–35%
Ulcer oozing (without other stigmata)	10%–27%
Flat spots	<8%
Clean-based ulcers	<3%

From ASGE Standards of Practice Committee. ASGE guideline: the role of endoscopy in acute nonvariceal upper GI-hemorrhage. *Gastrointest Endosc.* 1999;49:145–152.

even though some authors find them useful in patients who are bleeding uncontrollably while awaiting endoscopy or surgery or in whom surgery is contraindicated.[59]

Endoscopic Therapy

Endoscopic therapy for nonvariceal upper GI bleeding in patients with high-risk lesions has been shown to reduce the rate of rebleeding, need for surgery, and mortality rate.[62] It is indicated in patients with active bleeding, spurting arterial vessels, and nonbleeding visible vessels in an underlying ulcer.[55] When a clot is found in an ulcer bed, targeted irrigation in an attempt at dislodgment with treatment of the underlying lesion is indicated. If the clot remains adherent after irrigation, endoscopic therapy (injection followed by snaring of the clot) may be considered but intensive PPI therapy alone may be sufficient.[13] Different forms of endoscopic therapy include injection technique, thermal technique, mechanical technique, and topical spray. In many cases, a combination of these modalities is used to treat a single bleeding lesion or one at high risk of bleeding.

Injection therapy results in hemostasis, probably from a combination of vascular tamponade and the pharmacologic effect of the injected agent. Agents used for injection include normal saline solution, epinephrine, and sclerosants such as ethanol, ethanolamine, and polidocanol. In addition to the local tamponade effect of normal saline solution and epinephrine, the latter has a vasoconstricting effect. Sclerosant agents work by causing direct tissue injury and thrombosis.[55] Epinephrine at a concentration of 1 : 10,000 or 1 : 20,000 is the most commonly used agent, sometimes in conjunction with other agents or techniques.

Thermal therapy consists of the delivery of heat to the mucosa, which results in edema, coagulation of tissue proteins, and contraction of arteries. When heat is delivered through a contact probe, an additional effect is achieved by mechanical compression of the target artery before delivery of the heat.

Thermal energy can be delivered through noncontact techniques, such as the neodymium-yttrium-aluminum garnet and argon lasers and argon plasma coagulation (APC). The laser technique has been abandoned because of its high cost and the high risk of complications associated with its use. In APC, the argon gas forms a plasma and acts as an electrical conductor of the current, thereby resulting in coagulation of superficial tissues. Despite comparable results with the heater probe technique when used for ulcer bleeding,[63] APC is used primarily for the treatment of superficial lesions such as vascular abnormalities.[55]

Contact thermal techniques refer to the delivery of heat through direct contact of the mucosa with heater probes or electrocautery probes (monopolar and bipolar probes). The heater probe is an aluminum cylinder that delivers a programmed amount of energy (heat) through its end or sides to the tissue. The catheter tip can also be used to apply firm pressure on the bleeding point or the visible vessel. Electrocautery probes use an electrical current that passes from the electrode tip through the patient's body to a grounding plate (monopolar) or flows between two or more electrodes at the probe tip (bipolar or multipolar). The advantage of the bipolar (multipolar) probe is that the concentration of current at the level of the tip results in less depth of tissue injury and lower potential for perforation.

Mechanical therapy refers to the use of a device that causes physical tamponade of a bleeding site. Such devices include metallic clips, sewing devices, rubber band ligation, and endoloops. Metallic clips are the most studied of these devices and have shown variable success, probably because of the difficulty encountered with their placement. Some authors have suggested the use of clips in combination with other endoscopic treatments.[59]

Topical hemostatic sprays have been recently introduced with promising results. They consist of absorbent powder that rapidly concentrates clotting factors at the bleeding site. The advantages of topical therapy include ease of use, access to lesions in difficult areas, and the ability to treat large surfaces. However, the role of this new modality remains ill-defined in the absence of trials comparing it to other traditional hemostasis methods.[64]

The choice of endoscopic therapy depends on the stigmata of ulcer hemorrhage and the experience of the endoscopist. Monotherapy with epinephrine injection has been shown to be more effective than medical therapy in patients with high-risk lesions. However, it is inferior to other monotherapies (thermal or mechanical) or to combination therapy that uses two or more methods.[13] Epinephrine plus a second method significantly reduces rates of rebleeding, surgery and mortality when compared with epinephrine alone.[65]

Angiographic Therapy

Angiography can be useful as a potential diagnostic and therapeutic modality in specific cases of upper GI bleeding when endoscopy cannot be performed or fails to reveal the bleeding site and when endoscopic hemostasis is unsuccessful. It is also considered in patients who are poor surgical candidates.

Angiographic or "transcatheter" intervention in cases of upper GI bleeding involves two techniques: infusion of vasoconstricting medication and mechanical occlusion (embolization) of the arterial supply responsible for the hemorrhage. Vasopressin infusion induces vasoconstriction and results in cessation of bleeding in 70% to 80% of cases initially, but rebleeding occurs in up to 20%. Complications can range from problems related to arterial access to pulmonary edema and myocardial depression.[66] Vasopressin infusion has lost favor with the advent of embolization. Transcatheter embolization has become the mainstay for the radiographic treatment of nonvariceal upper GI bleeding and ranks second after endoscopic therapy in most centers.[67] The embolic material used

can be temporary (such as a gelatin sponge and autologous clot) or permanent (such as coils). Clinical success with embolization ranges from 52% to 91%. Potential complications of embolization include ischemia and perforation.[67]

Surgical Therapy

When endoscopic hemostasis fails to control the bleeding or when hemorrhage recurs after successful control of bleeding, surgical intervention provides an alternative therapeutic option. The main goal of surgery is control of active bleeding and prevention of exsanguination, with a secondary aim to prevent recurrent ulceration. The choice of operation depends on the location of the bleeding lesion and the surgeon's expertise. Truncal vagotomy with antrectomy and vagotomy with pyloroplasty are examples of operations performed in cases of nonvariceal upper GI bleeding. Total gastrectomy is rarely indicated. Because recurrent ulcers can be prevented by avoiding NSAIDs, eliminating *H. pylori* if present, or administering prophylactic PPI therapy, most ulcer operations for acute bleeding focus on oversewing the ulcer rather than performing the more definitive surgeries just listed.

Variceal Bleeding

Pharmacotherapy

Pharmacologic agents used in the treatment of acute variceal bleeding are aimed at reducing portal pressure by either decreasing portal blood flow or reducing intrahepatic resistance. Infusion of vasoactive agents constitutes an adjunct to endoscopic therapy and often precedes endoscopy when suspicion of variceal bleeding is high.

Vasopressin, terlipressin, somatostatin, and somatostatin analogs (octreotide and lanreotide) all induce constriction of the splanchnic vasculature and result in a decrease in portal blood flow. Vasopressin causes systemic vasoconstriction, as well as splanchnic vasoconstriction, and can lead to adverse effects, such as myocardial ischemia and infarction and cerebrovascular accidents.[68] These dangerous side effects led to the combination of vasopressin with other agents and the search for analogs with a better safety profile.

In one study, the combination of vasopressin with nitroglycerin resulted in a reduction in side effects and improved efficacy over vasopressin alone.[68] Nitroglycerin, a potent venous dilator, decreases the hemodynamic side effects of vasopressin and at the same time reduces intrahepatic resistance, thereby resulting in a further reduction in portal pressure.

Terlipressin is a synthetic analog of vasopressin with a longer duration of action and fewer side effects than vasopressin. Unlike other vasoactive agents, terlipressin has been shown to reduce mortality rate when compared with placebo.[69] At present, terlipressin is not available nor approved for use in the United States.

Somatostatin is a naturally occurring peptide that induces splanchnic vasoconstriction without affecting the systemic circulation and thus results in a decrease in portal pressure. When compared with vasopressin, somatostatin was equivalent in bleeding control but had significantly fewer side effects.[70] Further data suggested that somatostatin has the greatest effect when used in conjunction with endoscopic therapy.[71,72] Octreotide, a somatostatin analog, is approved for use in variceal bleeding in the United States. Meta-analyses of the efficacy of octreotide led to controversial results.[70,73] One meta-analysis of trials of somatostatin analogs in general showed a negligible effect.[74] However, octreotide appears to be useful as an adjunct to endoscopic therapy.[75,76] At present, because of its excellent safety profile and easy availability, octreotide (50-µg bolus followed by a 50-µg/h continuous infusion for 3–5 days) is almost always used in conjunction with endoscopic therapy.

The use of prophylactic antibiotics in patients with variceal bleeding has been shown to decrease the mortality rate in several randomized controlled trials.[71] The rationale behind antibiotic prophylaxis derives from the fact that bacterial infection is present in up to 20% of patients with cirrhosis who are admitted with variceal bleeding and that infection develops in as many as 50% of patients while hospitalized.[77] The mortality rate is significantly higher in infected patients with cirrhosis than in those with cirrhosis who are noninfected.[78,79] Furthermore, infected patients with cirrhosis have a higher rate of variceal rebleeding.[80] This is probably due to the presence of cytokines and endotoxins that induce hematologic abnormalities, such as platelet dysfunction and activation of the coagulation and fibrinolytic systems.[71] An updated meta-analysis showed that antibiotic prophylaxis significantly reduced the all-cause mortality rate, bacterial infection mortality rate, rebleeding events, and length of hospital stay.[81] Prophylaxis benefits were observed regardless of the type of antibiotic used. Nonabsorbable antibiotics, quinolones, and more recently cephalosporins have all been used with good success. Recent concerns have been raised about bacterial resistance and potential decreased benefit with quinolones in some geographic areas.[81]

Endoscopic Therapy

Endoscopic sclerotherapy and endoscopic band ligation are the mainstays of therapy for acute variceal bleeding. These procedures are successful in achieving hemostasis in 80% to 90% of patients.[71]

Sclerotherapy consists of intravariceal or paravariceal injection of a sclerosant agent such as sodium tetradecyl sulfate or ethanolamine. These agents provoke a severe inflammatory reaction within or around the varix that leads to variceal thrombosis and obliteration. Despite its high effectiveness in controlling bleeding, the complication rate with sclerotherapy can be as high as 40%.[84] Complications range from local effects, such as deep ulcers causing rebleeding, odynophagia, and in some cases perforation to bacteremia and systemic complications such as pleural and pericardial effusion. Esophageal stricture is the most common long-term side effect of sclerotherapy. Once the acute bleeding is controlled, repeated sessions of sclerotherapy are required to eradicate the varices and prevent rebleeding.

Endoscopic band ligation consists of the placement of a ligating device on the tip of the endoscope, and elastic rings are placed over the targeted varix (Fig. 72.5). With the availability of multiband ligating devices, 5 to 10 bands can be deployed in one session. Band ligation has a lower rate of complication (including the rebleeding rate in some but not all studies[85]) than sclerotherapy does, but it can be difficult to perform during acute bleeding.[71] Superficial mucosal ulceration occurs when the elastic ring and underlying tissue slough off. Transient chest discomfort and dysphagia are common after band ligation. Band ligation also has the advantage of achieving eradication of varices with fewer endoscopic sessions than are typically needed for sclerotherapy.[85]

A meta-analysis of 10 randomized clinical trials showed an almost significant benefit of endoscopic band ligation over sclerotherapy in the initial control of bleeding.[86] A practice guideline by the American Association for the Study of Liver Diseases recommends the use of endoscopic band ligation as the preferred form of endoscopic therapy and the use of sclerotherapy when band ligation is not technically feasible.[76]

The management of gastric varices depends on their location: GEV 1 (gastroesophageal varices extending to the cardia) are managed the same way as esophageal varices, whereas banding is not effective for GEV 2 (varices extending to the fundus) and

• **Fig. 72.5** Esophageal varices immediately after band ligation. (From Bashir RM, Al-Kawas FH. Vascular lesions of the stomach. In: DiMarino AJ, Benjamin S [eds]. *Gastrointestinal Disease: An Endoscopic Approach*. 2nd ed. Thorofare, NJ: Slack; 2002:245–262.)

isolated gastric varices. Fundic varices are usually treated with injection of cyanoacrylate glue. However, although used extensively in Europe and Asia with excellent outcomes, cyanoacrylate glue is not approved by the U.S. Food and Drug Administration.[87]

Balloon Tamponade

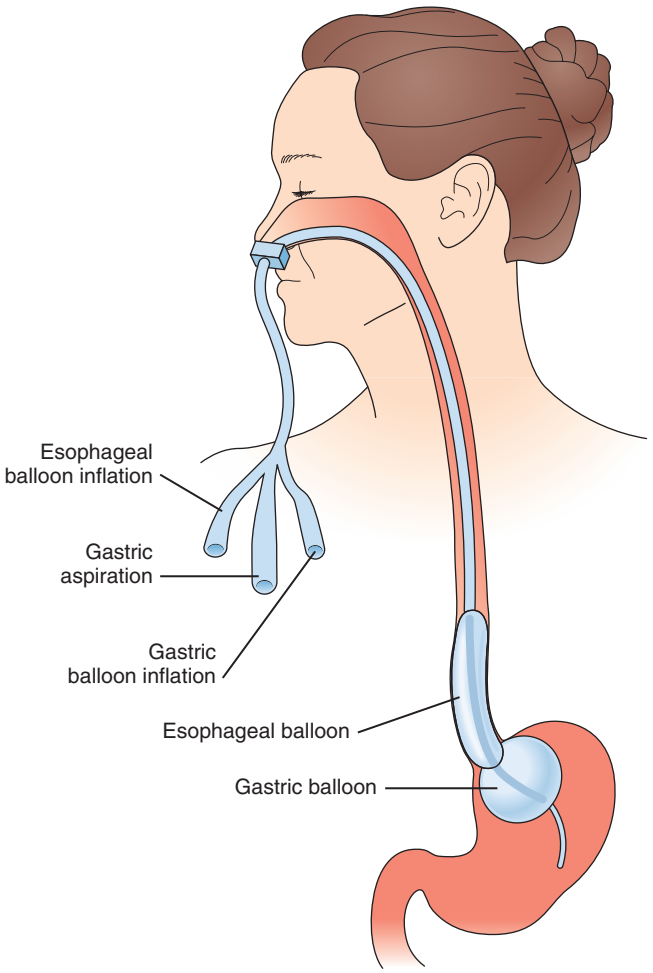
The use of balloon tamponade in the control of active variceal bleeding comes as a last resort when other forms of therapy are not available or fail to achieve hemostasis. Three balloons have been used for this purpose: the Minnesota tube, the Sengstaken-Blakemore tube, and the Linton-Nachlas tube. Control of bleeding with these tubes depends on patient selection, the concomitant use of other therapies, and the experience of the staff using them. With the advent of other therapies and the increasing experience of endoscopists in sclerotherapy and endoscopic banding, experience in the use of tamponade balloons decreased substantially. A major concern with the use of these tubes is the high risk of rebleeding after deflation of the balloon, in addition to the risk of esophageal rupture. Balloon tamponade should be used only as a temporary means of stabilization and as a bridge to a more definitive form of therapy. Fig. 72.6 illustrates the steps used to control bleeding with a balloon.

Esophageal Stenting

A recent randomized controlled trial compared balloon tamponade with the use of esophageal covered metal stent in patients with cirrhosis and acute refractory esophageal variceal hemorrhage. Success of therapy, defined as 15-day survival without serious adverse events or GI bleeding, was significantly more frequent in the esophageal stent group. Moreover, control of bleeding was higher and transfusional requirements and serious adverse events were lower in the esophageal stent group.[88]

Transjugular Intrahepatic Portosystemic Shunt

The transjugular intrahepatic portosystemic shunt (TIPS) procedure involves the creation of a low-resistance channel between the portal vein and the hepatic vein through which blood is shunted from the portal to the systemic circulation. Via an angiographic technique, an expandable metal stent is deployed across this channel and

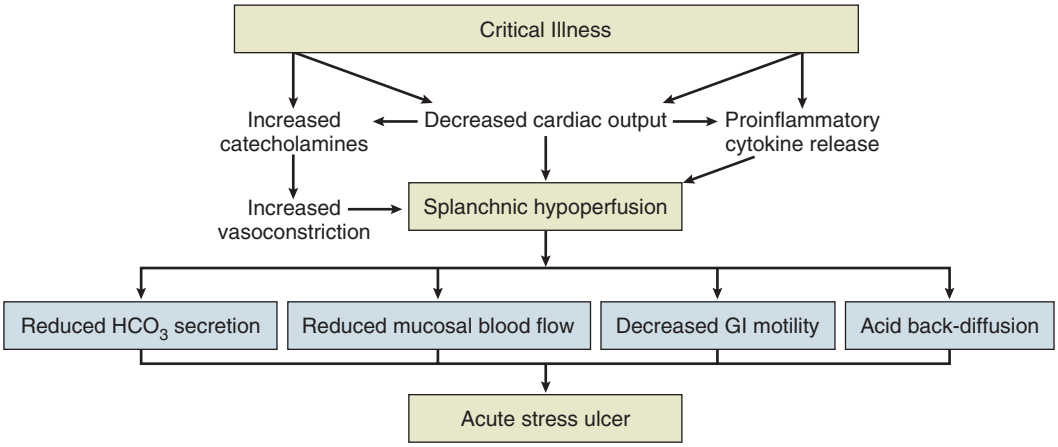


• **Fig. 72.6** Sengstaken-Blakemore tube. The tube is passed to at least the 50-cm mark. The gastric balloon is then inflated with the full recommended volume of air (usually 450–500 mL). A portable chest radiograph should be obtained to check for proper placement. The tube is pulled back gently until resistance is felt against the diaphragm. If bleeding persists from the aspiration port, the esophageal balloon is inflated to the lowest pressure needed to stop bleeding (usually 30–45 mm Hg).

results in a significant decrease in portal pressure. This technique allows the creation of a portosystemic shunt without requiring general anesthesia and major surgery. The TIPS procedure is indicated in situations in which acute variceal bleeding is refractory to endoscopic and pharmacologic therapy. It has been shown to control bleeding in more than 90% of patients, with a rebleeding rate of less than 20%.[89,90] In 2010 Garcia-Tsao and colleagues showed that an early TIPS procedure (within 24–48 hours of admission) was associated with significant decrease in mortality rate in high-risk patients (with HVPG >20 mm Hg or with Child-Pugh class C disease).[91] However, the mortality rate after the TIPS procedure in the setting of acute uncontrollable variceal bleeding is between 30% and 40%.[71] A major complication associated with this procedure is the development of encephalopathy in 10% to 20% of patients. Stenosis and complete occlusion of the shunt occur in 5% to 15% of the cases, requiring revision.

Surgical Therapy

Surgical creation of portosystemic shunts has been used for decompression of the portal system to treat and prevent variceal



• **Fig. 72.7** Pathophysiology of stress ulcers. *HCO_3,* Bicarbonate. (From Mutlu GM, Mutlu EA, Factor P. GI complications in patients receiving mechanical ventilation. *Chest.* 2001;119:1222–1241.)

bleeding. The various forms of surgical shunts include portacaval shunts, distal splenorenal shunts, and partial shunts. Revascularization of the esophagus is another surgical option for the treatment of variceal bleeding. Interest in surgery has declined over the years because of the advent of the less invasive endoscopic and TIPS procedures. At present, surgery is considered only when medical and endoscopic therapy fails to control bleeding and the TIPS procedure is not available.[71]

Stress-Related Mucosal Disease

The term *stress-related mucosal disease* (SRMD) covers a spectrum of conditions ranging from superficial mucosal damage to focal deep mucosal damage (stress ulcers). The terms *stress ulcer, stress gastritis, stress erosions,* and *stress lesions* are used interchangeably in the literature. SRMD is defined as mucosal abnormalities of the upper GI tract that occur with extreme physiologic stress, typically in the ICU.

The incidence of endoscopically documented gastric lesions in patients in the ICU ranges from 74% to 100%.[92] The lesions are typically, but not exclusively, located in the fundus and body of the stomach. However, most of these lesions are of little significance because healing occurs rapidly. Clinically evident bleeding, defined as blood in a nasogastric aspirate, hematemesis, and melena, occurs in 5% to 25% of patients in the ICU. Clinically important bleeding, however, is defined as overt bleeding associated with one of the following within 24 hours of the onset of the bleeding: a drop in systolic blood pressure of greater than 20 mm Hg, an increase in the pulse rate of more than 20 beats/min and a 10-mm Hg drop in systolic blood pressure, or a decrease in hemoglobin of greater than 2 g/dL requiring blood transfusion and failure of hemoglobin to increase by the number of units transfused minus 2 g/dL.[93] Clinically important bleeding affects only 3% to 6% of critically ill patients.[94]

The pathogenesis of SRMD involves a disruption in the balance between aggressive and protective factors that leads to gastric mucosal damage. Adequate microcirculation in the upper GI tract is the most important defense mechanism against luminal aggressors such as acid and enzyme secretion, as well as infection. The role of the microcirculation is to provide nutrients and eliminate toxic oxygen-derived free radicals. In the presence of severe physiologic stress, disruption of intramucosal blood flow leads to a number of events, including the formation of toxic oxygen-derived radicals, a decrease in the synthesis of cytoprotective prostaglandins and mucus production, and a reduction in bicarbonate secretion resulting in an increase in intramural acidity (Fig. 72.7).[92,94] These events create a favorable setting for mucosal injury and ulceration.[95,96] Subsequent reperfusion also plays a major role in the development of lesions.[96]

Identification of critically ill patients at risk for significant bleeding from SRMD has been the subject of several studies. A landmark study by Cook and associates[93] demonstrated a significant increase in the risk for bleeding from SRMD in patients requiring mechanical ventilation for more than 48 hours and in those with coagulopathy (defined as thrombocytopenia [platelet count <50,000/mL^3], an international normalized ratio above 1.5, or a partial thromboplastin time more than 2.0 times the control value). Other risk factors such as shock, sepsis, renal failure, liver failure, and glucocorticoids were identified, but the association with bleeding was not statistically significant. Risk factors associated with the presence of SRMD (not necessarily bleeding) include recent major surgery, major trauma, severe burns (Curling ulcers), head trauma or coma (Cushing ulcers), and multiple organ failure.[97–99] Further understanding of the risk factors associated with bleeding from SRMD will help in directing prophylactic therapy to patients who will benefit most from this therapy.[100]

The reported mortality rates in critically ill patients with bleeding from SRMD ranges from 46% to 77%.[93,101,102] These high rates are most likely due to the underlying disease and not directly related to GI bleeding. However, they reveal the importance of significant bleeding as a sign of the degree of severity of the primary illness.

Prophylaxis

As mentioned earlier, the risk for bleeding from SRMD is significantly increased in patients undergoing prolonged mechanical ventilation and in those with coagulopathy. Such patients should benefit from the different forms of prophylaxis available.

The role of enteral nutrition in prophylaxis for SRMD is controversial.[103,104] The rationale behind the use of enteral nutrition derives from its ability to improve blood flow to the stomach and sustain mucosal immunity and integrity.[105]

When compared with placebo, antacids have been shown to decrease bleeding in patients with SRMD.[106] However, antacids require frequent dosing and monitoring of pH and are not practical

to use, especially with the advent of other effective agents for prophylaxis.

Sucralfate works by coating the gastric mucosa and forming a thin protective layer between the mucosa and the gastric acid in the lumen without affecting acid secretion and intragastric pH. The use of sucralfate for the prevention of bleeding in patients with SRMD gained interest because of theoretical concern about gram-negative bacterial overgrowth when the pH of the stomach is increased by the use of histamine 2 receptor agonists (H_2RAs) or PPIs, which can potentially lead to nosocomial pneumonia. Conflicting results were reported regarding this issue, but a large trial by Cook and colleagues in which ranitidine and sucralfate were compared showed no significant difference in the development of nosocomial pneumonia.[107] In this same trial, the incidence of clinically important bleeding was significantly lower with ranitidine. Other studies demonstrated comparable efficacy between sucralfate and antacids and H_2RAs in terms of prevention of SRMD.[108,109] One drawback to the use of sucralfate is that it may decrease the absorption of other concomitantly administered oral drugs.

IV H_2RAs are the most widely used pharmacologic agents for the prophylaxis of bleeding in patients with SRMD. A meta-analysis of studies looking at the role of H_2RAs in SRMD demonstrated a decrease in the incidence of clinically important bleeding.[106] Furthermore, H_2RAs were more effective than antacids in preventing bleeding.[106,110] Despite better control of gastric pH with continuous infusion of H_2RAs, bolus infusion has been shown to be as effective in preventing bleeding.[106,111] One major concern is the development of tolerance to H_2RAs when administered for a prolonged period.

In recent years PPIs have gained wider use in the prevention of bleeding from SRMD because of their ease of dosing, effective and predictable acid suppression, lack of need for regular gastric pH monitoring, and lack of tolerance as encountered with H_2RAs.[105] A recent meta-analysis compared the efficacy of PPIs versus H_2RAs in the prophylaxis of stress-related mucosal bleeding in critically ill patients at risk of bleeding. It demonstrated that PPI prophylaxis significantly decreased rates of clinically significant bleeding compared with H_2RAs without affecting the development of nosocomial pneumonia or mortality rates.[112]

The development of adverse events owing to acid suppression, including nosocomial pneumonia and *Clostridium difficile* infection, has been the subject of many reports with conflicting but concerning results.[113] Drug interactions, liver and bone marrow toxicity, and hypomagnesemia represent other concerns relevant to patients in ICU. These concerns should alert providers to the importance of discontinuation of acid suppression in the absence of proper indication.

Treatment

Endoscopy is the principal diagnostic and therapeutic procedure used in patients with bleeding from SRMD. The same endoscopic techniques used for hemostasis in peptic ulcer bleeding are used in SRMD when an actively bleeding lesion is found. Surgery is reserved for patients with uncontrolled hemorrhage and usually involves vagotomy, oversewing of bleeding sites, and in rare cases, subtotal or total gastrectomy.[105] In poor surgical candidates with severe uncontrolled hemorrhage, angiography may be a useful diagnostic and therapeutic option.

Lower Gastrointestinal Bleeding

Differential Diagnosis

Lower GI bleeding is defined as bleeding that originates from a source distal to the ligament of Treitz. It is caused by a diverse range of bleeding sources and can range from trivial to life-threatening bleeding. It can also be acute, arbitrarily defined as less than 3 days' duration and possibly resulting in hemodynamic compromise, or chronic, extending over a period of several days or longer and usually less severe in terms of the amount of blood loss.[114] Sources of lower GI bleeding and their incidence from several large studies are listed in Table 72.6.[115–122]

Studies cited in this table may be found in the complete list of references for this chapter provided online.

[a]Includes inflammatory bowel disease, infectious colitis, ischemic colitis, radiation colitis, vasculitis, and inflammation of unknown origin.

[b]Includes hemorrhoids, anal fissure, and idiopathic rectal ulcers.

[c]Includes postpolypectomy bleeding, aortocolonic fistula, trauma from fecal impaction, and anastomotic bleeding.

From Zuckerman GR, Prakash C. Acute lower intestinal bleeding. Part II: etiology, therapy, and outcomes. *Gastrointest Endosc.* 1999;49:228–238.

Diverticular Bleeding

Diverticular bleeding, the most common source of lower GI bleeding, accounts for up to 40% of cases.[114] Diverticular disease is more common in the elderly. It affects up to two-thirds of people older than 80 years. Only 3% to 15% of patients with diverticulosis experience diverticular bleeding.[114]

Patients with diverticular bleeding typically have painless hematochezia. Most patients stop bleeding spontaneously, but the bleeding can recur in 10% to 40% of cases.[123]

The bleeding is thought to occur after repetitive trauma to the vasa recta (nutrient arteries) that stretch over the diverticular dome.[124] NSAIDs have been associated with increased risk for diverticular bleeding.[125]

Ischemic Colitis and Other Forms of Colitis

Ischemic colitis accounts for up to 19% of lower GI bleeding.[114] It results from a sudden reduction in mesenteric blood flow. As opposed to acute mesenteric ischemia, this reduction is transient and reversible. The typical regions affected are the "watershed" areas of the colon: the splenic flexure, the rectosigmoid junction, and the right colon. Ischemia is precipitated by any event that compromises colonic blood flow. Clinically, patients have a sudden onset of abdominal pain, followed by hematochezia within 24 hours. Endoscopically, ischemia is suspected in the presence of bluish hemorrhagic nodules from submucosal bleeding, cyanotic or necrotic mucosa with hemorrhagic ulcerations, or segmental distribution with an abrupt transition between injured and normal mucosa (Fig. 72.8).[114] Most cases of ischemic colitis resolve spontaneously with supportive treatment. Rare cases require surgery (if peritoneal signs are present) or develop chronic ischemic colitis with stricture formation. Ischemic colitis is a common cause of lower GI bleeding in patients in the ICU because of the frequent hemodynamic instability in this setting.[126]

Infectious colitis, radiation colitis, and inflammatory bowel diseases can also result in bloody diarrhea, but the bleeding is rarely severe.

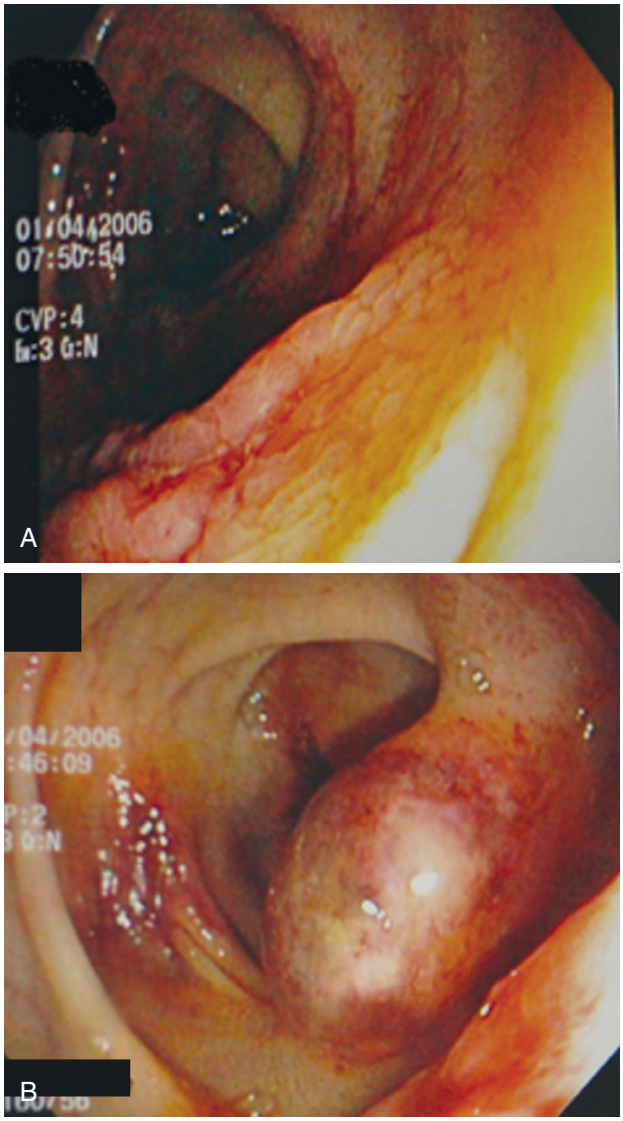
Angiodysplasia

Estimates of angiodysplasia as a source of lower GI bleeding vary widely and reach 37% in some reports.[117] Current data suggest that acute bleeding caused by angiodysplasia is less frequent than previously thought, with most cases demonstrating iron deficiency anemia and occult blood loss.[124] These lesions are seen predominantly in the elderly. They appear endoscopically as red, flat lesions with ectatic blood vessels radiating from a central feeding vessel, usually in the right colon (Fig. 72.9). Overt bleeding from angiodysplasia is usually brisk and painless and cannot be distinguished from diverticular bleeding. Endoscopic treatment is highly effective and safe and prevents bleeding episodes from recurring.

Other Sources of Lower Gastrointestinal Bleeding

Acute significant bleeding from colonic neoplasia and polyps is uncommon despite reports in which it accounts for up to 36% of cases.[121] Cancer and polyps are thought to bleed from erosions on the surface.

Postpolypectomy bleeding occurs in 1% to 6% of patients undergoing colonoscopic polypectomy.[124] Bleeding can be immediate or delayed up to 3 weeks after the procedure. Risk factors for postpolypectomy bleeding include large size, sessile morphologic appearance, and right colonic location.[127]



• **Fig. 72.8** A and B, Ischemic colitis.

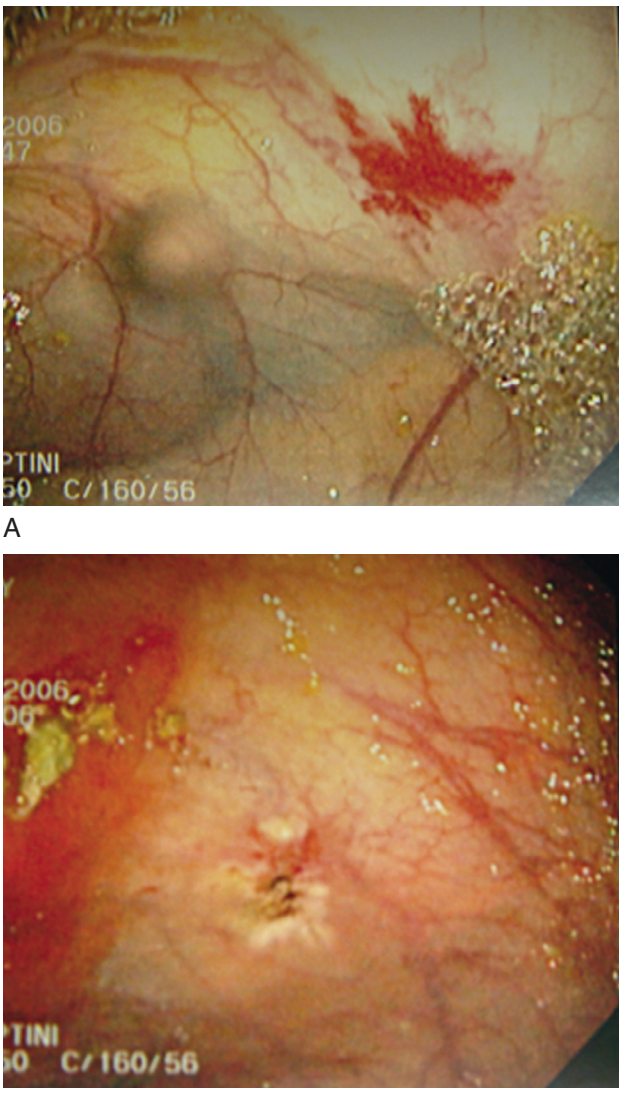
Anorectal sources of lower GI bleeding include hemorrhoids, anorectal fissures, stercoral ulcers, and proctitis. Hemorrhoids can cause significant bleeding and may sometimes require endoscopic or surgical intervention. Bleeding from rectal ulcers is common in elderly bedridden patients and in critically ill patients.[115]

Small bowel sources of lower GI bleeding include angiodysplasia (most frequent), lymphoma, small bowel ulcers, and Crohn disease.[124] Small bowel lesions are typically more difficult to identify and require more diagnostic procedures.[128]

Diagnostic Evaluation

Colonoscopy

After initial evaluation, stabilization, and exclusion of an upper GI source, management shifts to localization of the lower GI bleeding site. Colonoscopy is an attractive choice in this setting because it offers the best opportunity for early diagnosis and subsequent management. In the past, colonoscopy used to be performed in an expectant manner, after cessation of bleeding and



• **Fig. 72.9** A, Angiodysplasia in the cecum. B, Same lesion after thermal therapy (electrocauterization).

colonic preparation. Concern about poor visibility, the potential for complications, and the adverse effects of bowel preparation in the setting of bleeding is behind the reluctance in performing "urgent" colonoscopy. Over the past decade, early colonoscopy has gained interest in the management of lower GI bleeding. Several reports have shown that early (or urgent) colonoscopy is safe and has high diagnostic yield in patients with hematochezia.[129–133] The definition of "urgent" varied in these reports, from within 8 hours to within 24 hours of initial evaluation. This approach was also associated with shorter hospital stay.[134] Bowel preparation is generally recommended before urgent colonoscopy to improve visibility and prevent complications related to poor visibility. Polyethylene glycol lavage solution by mouth or through a nasogastric tube is commonly used in these cases. It can be administered at a rate of approximately 1 L every 30 to 45 minutes.[114] Some authors have proposed the use of colonoscopy without bowel preparation and have shown high diagnostic yield with this approach.[135] Despite the fact that urgent colonoscopy improves the diagnostic yield and leads to more frequent endoscopic therapy, there is still controversy regarding its impact on important outcomes, such as mortality rate, rebleeding, and the need for surgery.[131,133]

Jensen and colleagues[131] showed that urgent colonoscopy with endoscopic treatment in a group of patients with active diverticular bleeding (versus a historical group that did not receive endoscopic treatment) may prevent recurrent bleeding and the need for surgery. Another randomized trial compared urgent colonoscopy with a standard care algorithm in which radionuclide scanning, followed, if positive, by angiography, was used in patients with suspected active bleeding versus expectant colonoscopy in those without active bleeding. This trial showed that a definite source of bleeding was found more often in urgent colonoscopy patients. However, no difference in mortality rate, surgery, and rebleeding was found in the two groups.[133] A more recent trial of the benefit of urgent versus elective colonoscopy (<12 hours vs. 36–60 hours from presentation) showed no evidence of improving clinical outcomes, such as rebleeding, transfusion requirements, and hospital length of stay. A major limitation of this trial was that the study was terminated before reaching the prespecified sample size.[136] A recent guideline on acute lower GI bleeding recommends the performance of colonoscopy within 24 hours of patient presentation in patients with high-risk clinical features and signs or symptoms of ongoing bleeding as this approach can potentially improve diagnostic and therapeutic yields.[19]

Radionuclide Scanning

The use of radionuclide scanning (also known as a technetium-labeled RBC scan) in patients with lower GI bleeding is highly controversial. It has been used for several decades as a method for localization of the bleeding source.[124] A main advantage of radionuclide scanning is its sensitivity for bleeding at a rate as low as 0.05 to 0.1 mL/min, in addition to its noninvasive nature.[124] It also can be repeated in cases of intermittent bleeding. On the other hand, this diagnostic modality lacks therapeutic capability, has variable accuracy, and may delay other diagnostic and therapeutic procedures. A review of data from several studies of radionuclide scanning for lower GI bleeding in which radionuclide scintigraphy findings were confirmed by a different test found the accuracy of a positive test to be 66%.[18] Localization improves when scan results are positive within 2 hours of injection. A common practice in the setting of ongoing lower GI bleeding is to perform radionuclide scanning as a screening test before angiography and in some cases as a guide to surgery. The problem with this approach is the inconsistent and widely variable accuracy and the high rate of false-positive results in different reports.[124,137,138]

Angiography

Angiography is less sensitive than radionuclide scanning in the detection of active bleeding. It can detect bleeding at a rate of 0.5 to 1.0 mL/min. In addition to its role in accurate localization of bleeding lesions, angiography offers therapeutic possibilities. As with radionuclide scanning, the ability of angiography to detect the bleeding source varies widely among studies, from 20% to 70%.[124] This variation is due to several factors, including patient selection (higher diagnostic yield in patients with positive radionuclide scanning results), the severity and intermittent nature of the bleeding, procedural delay, and venous or small vessel bleeding.[124] In one study, a systolic blood pressure of less than 90 mm Hg and a requirement of at least 5 units of blood within a 24-hour period have been shown to predict positive angiography results (85% when both criteria were present).[139] Angiography is usually performed in patients with ongoing lower GI bleeding with or without

a positive radionuclide scan. This sequence in management was the standard approach to ongoing bleeding until recently, when colonoscopy started gaining interest in the setting of acute bleeding (as opposed to expectant elective colonoscopy). When angiographic therapy fails or is not available after localization of the bleeding, the findings are used to guide surgical resection. Angiography can cause serious complications, such as contrast reactions, arterial thrombosis and dissection, and catheter site infection and bleeding. Thus it should be used in carefully selected patients.

Computed Tomography

CT angiography gained interest in the setting of GI bleeding after the recent introduction of multidetector row CT. It enables the accurate acquisition of arterial images, which can show contrast extravasation in areas of active bleeding.[18] It can detect bleeding rates as low as 0.3 to 0.5 mL/min. The yield for lower GI bleeding ranges from 25% to 95% and is highest in severe ongoing bleeding. The advantages of CT are its wide availability and the added diagnostic yield of cross-sectional imaging, but exposure to radiation and contrast and, like radionuclide scanning, the inability to deliver therapy constitute some of the disadvantages of this technique.[18]

In a recent retrospective study comparing CT angiography with radionuclide scanning, the two modalities showed similar diagnostic yields but the site of bleeding was accurately localized with CT angiography in a significantly higher proportion of cases.[140] CT angiography should be considered if a diagnostic test is desired for localization of the bleeding site before angiography.[19]

Therapeutic Alternatives

Endoscopic Therapy

Data on the effectiveness of endoscopic therapy for lesions causing lower GI bleeding are limited. However, the experience from published series suggests that this form of therapy is likely to be beneficial. Methods of endoscopic hemostasis are similar to those used for upper GI bleeding and include injection therapy, thermal therapy (APC and heater and electrocautery probes), and mechanical therapy (hemoclips).[141] Several studies showed that clipping is very effective modality for diverticular bleeding with a low rate of early rebleeding.[18]

Angiographic Therapy

When angiography identifies the bleeding site in cases of lower GI bleeding, hemostasis can be achieved by the intraarterial infusion of vasopressin or superselective embolization. Infusion of vasopressin can control bleeding in up to 91% of cases,[141] but complications develop in 10% to 20% and include arrhythmia, pulmonary edema, and ischemia.[141] Furthermore, rebleeding occurs in as many as 50% of cases.[141] In early studies, transcatheter embolization carried a high risk for bowel infarction, but current superselective techniques using smaller catheters with various agents (gelatin sponge, microcoils, and polyvinyl alcohol particles) appear to be more effective and safer than the old techniques. Review of several studies using superselective techniques showed that immediate hemostasis was achieved in 96% of cases and rebleeding within 30 days occurred in 22%.[18] Since the advent of these new techniques, embolization has become the preferred modality when angiographic therapy is contemplated.

Surgical Therapy

Surgery is indicated in cases of recurrent bleeding (especially diverticular) and massive ongoing bleeding with high transfusion requirements (generally >6 units of packed RBCs in a 24-hour period).[114] Accurate localization of the site of bleeding preoperatively is crucial so that segmental rather than subtotal colectomy can be performed. Unfortunately, the accuracy of radionuclide scanning in localization of the bleeding is variable, and hence it should not be used as a guide for surgery. Colonoscopy and angiography may be used as a guide for surgery in cases in which bleeding is initially identified and possibly treated through these modalities, and then recurs and requires surgery.

Obscure Gastrointestinal Bleeding

Obscure GI bleeding is bleeding that persists or recurs without an obvious source identified on upper and lower endoscopy. Obscure bleeding can be occult (positive fecal occult blood testing without frank recognizable blood loss) or overt (clinically evident). Obscure bleeding can be very challenging to the physician and, in cases of overt massive bleeding, life-threatening to the patient. The initial approach to the problem is the same as with upper and lower GI bleeding and includes resuscitation and stabilization, followed by a search for the source.

Differential Diagnosis

Missed lesions on upper and lower endoscopy should be considered first in the workup of obscure bleeding. Causes difficult to identify on routine endoscopy include hemosuccus pancreaticus, hemobilia, aortoenteric fistula, Dieulafoy ulcer, and extraesophageal varices. Small bowel lesions are another source of obscure bleeding and include tumors (lymphomas, carcinoids, adenocarcinomas), vascular ectasia, NSAID-induced ulcers, Meckel diverticulum, and other less common causes.[142]

Diagnostic Evaluation

Repeat upper and lower endoscopy is usually warranted at least once after the index endoscopy, with the uncommon and subtle lesions just listed kept in mind. When the patient has active ongoing bleeding, radionuclide scanning and angiography should be considered. In young patients, Meckel diverticulum scan may be helpful. If results of all these tests are negative, the focus should shift to evaluation of the small bowel. Radiographic, endoscopic, and surgical modalities are used for this purpose.

Radiographic imaging of the small bowel may help when Crohn disease or malignancy is suspected. These modalities have lost favor with the advent of capsule endoscopy and device-assisted enteroscopy (except in cases in which there may be narrowing of the small bowel). Small bowel push enteroscopy can be very helpful in identifying and, in some cases, treating lesions in the small bowel that are responsible for obscure bleeding. Unfortunately, it can examine only 50 to 150 cm of small bowel.[143] Device-assisted enteroscopy (double- and single-balloon enteroscopy and spiral enteroscopy) has comparable diagnostic yield to capsule endoscopy but has the advantage of performing therapeutic interventions and obtaining biopsies.[144]

Capsule endoscopy gained great interest in evaluation of the small bowel because of its ability to examine the entire small bowel and its noninvasive nature. It consists of swallowing a pill-sized camera with sufficient battery life to image the entire small bowel. Studies have supported the role of capsule endoscopy in the evaluation of obscure GI bleeding with an overall diagnostic yield of 55% to 70%.[142] The diagnostic yield is even higher when it is

administered to patients with ongoing bleeding (87%–92%).[145,146] In our opinion, efforts should be made to perform capsule endoscopy in patients with obscure overt bleeding while they are still in the hospital instead of waiting until discharge (which is the current standard practice in most centers). In patients who can tolerate an invasive procedure, device-assisted enteroscopy can be used when available and has the advantage of therapeutic ability. However, this procedure achieves total enteroscopy in only 29% of patients. Other limitations include limited availability, time, and sedation requirements. The procedure's risk of complications is low (<1%).[144]

Exploratory laparotomy is generally the last option in the evaluation of obscure GI bleeding. When combined with intraoperative enteroscopy, the diagnostic yield reaches 50% to 100%.[142]

Conclusion

In summary, acute GI bleeding is a life-threatening emergency that requires a quick response and a coordinated team approach. Acute management is the same regardless of the source of bleeding (Fig. 72.10) and should be orchestrated by a critical care team. The prime direction in resuscitation should be restoration of euvolemia. Once a source is suspected, specific management and therapeutic options are considered and may require communication with gastroenterologists, surgeons, and interventional radiologists. Prevention of bleeding from SRMD is indicated in a specific population of critically ill patients. Endoscopy plays a major role in the diagnosis and management of acute GI bleeding. Endoscopic therapy with standard and innovative techniques has been shown to have a major impact on the prognosis of bleeding patients.

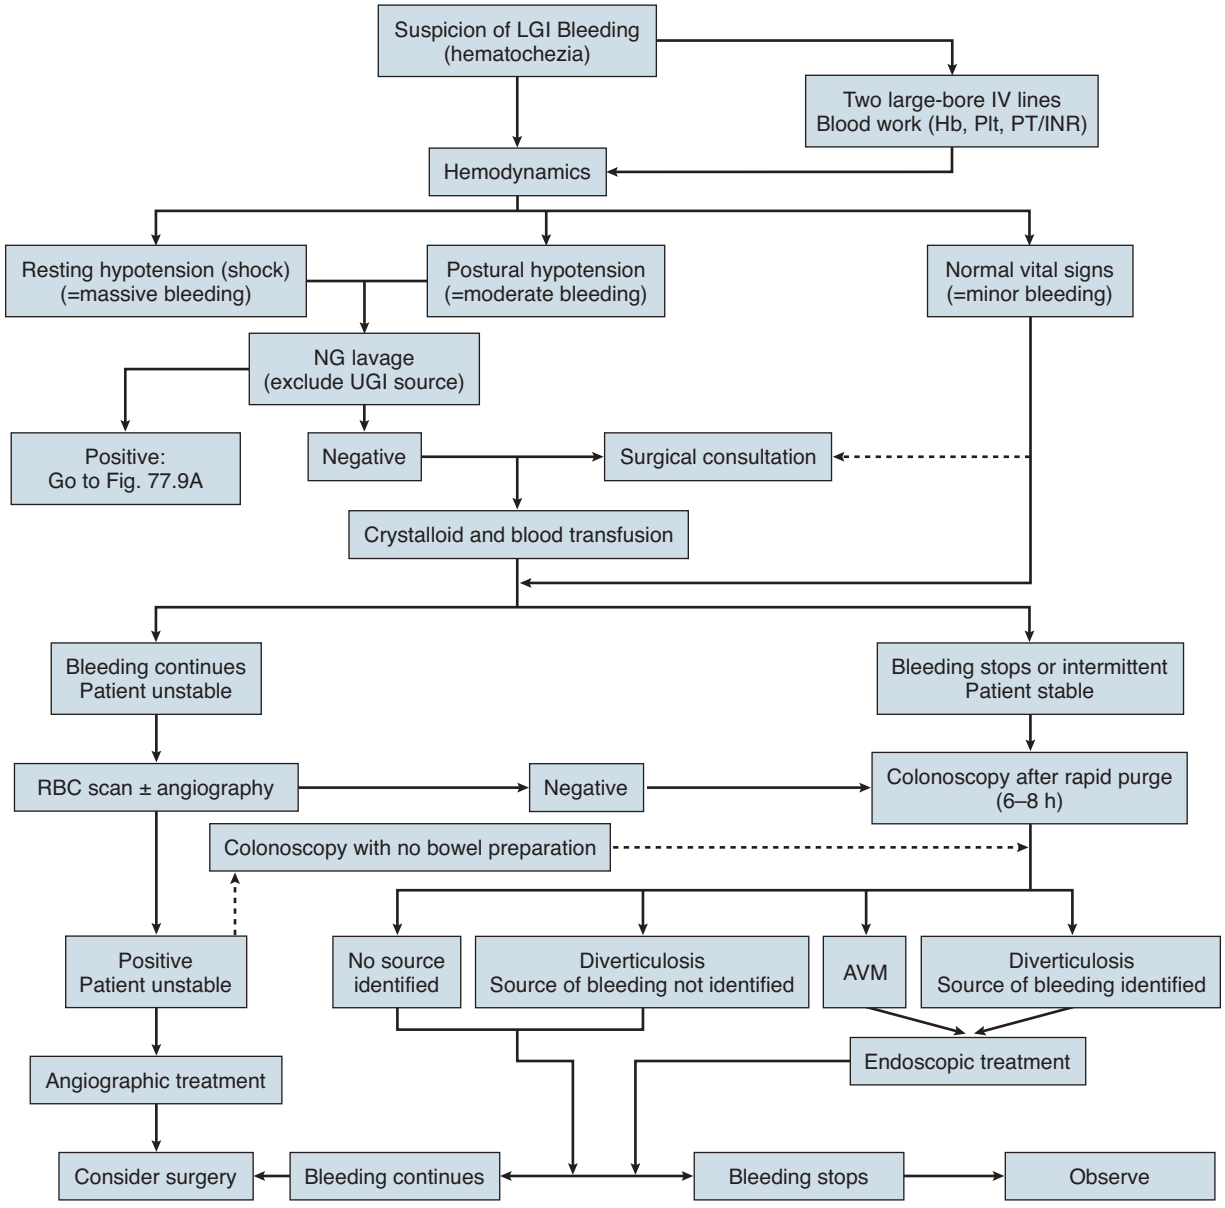
• **Fig. 72.10** A, Approach to managing upper gastrointestinal bleeding in critical care patients.

Continued



B

• **Fig. 72.10, cont'd** B, Approach to managing lower gastrointestinal bleeding in critical care patients. *AVM,* Arteriovenous malformation; *EGD,* esophagogastroduodenoscopy; *Hb,* hemoglobin; *H. pylori, Helicobacter pylori*; *INR,* international normalized ratio; *LGI,* lower gastrointestinal; *NG,* nasogastric; *NSAIDs,* nonsteroidal antiinflammatory drugs; *Plt,* platelets; *PPI,* proton pump inhibitor; *PT,* prothrombin time; *PUD,* peptic ulcer disease; *RBC,* red blood cell; *TIPSS,* transjugular intrahepatic portosystemic stent shunt; *UGI,* upper gastrointestinal.

Key Points

- The patient's history provides important clues regarding the cause of the acute GI bleeding and helps direct initial management.
- Management of GI bleeding relies on a team approach involving an intensivist, endoscopist, radiologist, and surgeon.
- The prime direction of evaluation and resuscitation in a bleeding patient should be restoration of euvolemia.
- SRMD is a common source of upper GI bleeding in physiologically stressed patients, and prophylaxis with acid suppressants should be given to patients with coagulopathy and those undergoing prolonged mechanical ventilation.
- PPIs in drip form should be given to patients with upper GI bleeding after endoscopic treatment of lesions with a high risk of rebleeding.

- Antibiotic therapy decreases the mortality rate in patients with variceal bleeding. It should be given empirically along with vasoactive agents (octreotide).
- Several forms of endoscopic therapy are effective for nonvariceal bleeding, including injection, thermal, and mechanical therapy.
- Endoscopic band ligation is the most commonly used and preferred technique for the treatment of bleeding varices.
- Early colonoscopy has become an attractive choice in lower GI bleeding because of its diagnostic and therapeutic abilities.
- Videocapsule endoscopy has an important role in the evaluation of patients with obscure overt GI bleeding, and efforts should aim at performing it in hospitalized patients. Device-assisted enteroscopy has the benefit, when available, of therapeutic ability and should be performed in the appropriate setting.

Review Questions

1. A 46-year-old man with no significant medical problems presents to the emergency department after multiple episodes of melena with palpitation and dizziness. He has been taking NSAIDs for acute onset back pain for 1 week. On presentation, his pulse is 122 beats/min, blood pressure 98/52 mm Hg. His hemoglobin level is 7.8 g/dL, and results of liver tests and coagulation factors are normal. Which one of the following statements is most correct?
   - **a.** The presence of melena indicates with a high degree of certainty the origin of the bleeding as being in the upper GI tract proximal to the ligament of Treitz.
   - **b.** In addition to hemodynamic resuscitation, blood transfusion should be immediately administered with the goal to reach a hemoglobin level of 10 mg/dL.
   - **c.** Endoscopy should be performed within 6 hours of presentation, as this will decrease both the rebleeding risk and overall mortality.
   - **d.** Nasogastric tube placement should be avoided, given the lack of proven benefit in decreasing mortality or rebleeding rates and in predicting the culprit lesion.

   Answer: d. The source of melena may be the small bowel distal to the ligament of Treitz and sometimes even the proximal part of the colon. Blood transfusion should be avoided if hemoglobin is above 7 g/dL. A study evaluating blood transfusion for upper gastrointestinal (GI) bleeding found a significantly higher survival rate and lower rebleeding rate when a restrictive transfusion threshold of transfusing only if the hemoglobin level is below 7g/dL was followed compared with a threshold of 9 g/dL. Although urgent endoscopy (within 12 hours of presentation) may decrease the length of hospital stay and transfusion requirements in patients with high-risk clinical features, it has no impact on rebleeding risk and mortality. Nasogastric tube placement should be avoided for the reasons mentioned in option d.
2. In the previous case, an upper endoscopy was performed and showed a large gastric ulcer with an adherent clot. Which one of the following statements is most correct?
   - **a.** Unlike an ulcer with a visible vessel, an ulcer with adherent clot has a low risk of rebleeding
   - **b.** Acid suppression with an intravenous proton pump inhibitor (PPI) should be administered immediately after the endoscopy as this will decrease the risk of rebleeding.
   - **d.** Endoscopic therapy with topical hemostatic spray is the simplest and most effective way to treat the ulcer described.
   - **d.** A repeat endoscopy in 72 hours is indicated to assess the response to treatment and need for further endoscopic intervention.

   Answer: b. An ulcer with adherent clot has a high rebleeding risk (see Table 72.5). Although topical hemostatic sprays have shown some promising results, the role of this new modality remains ill-defined in the absence of trials comparing it to other traditional hemostasis methods. A repeat endoscopy is not indicated unless there are signs or symptoms of recurrent bleeding. In patients found to have high-risk lesions treated endoscopically, the guidelines recommend an intravenous bolus followed by continuous-infusion PPI therapy.
3. 76-year-old man presents with five episodes of moderate to large amounts of hematochezia and complains of lightheadedness. His pulse is initially 130 beats/min with hypotension. After fluid bolus his blood pressure normalized and his pulse decreased to 112 beats/min. He has another episode of hematochezia in the emergency department.

   After placement of a Foley catheter and further fluid resuscitation targeting blood pressure, heart rate, and urine output, which one of the following statements concerning the management of this patient is most correct?
   - **a.** A radionuclide scan should be done next for the purpose of confirming the site of bleeding is in the colon in anticipation of surgical intervention.
   - **b.** Colonoscopy should be performed within 24 hours of presentation for diagnostic and therapeutic purposes.
   - **c.** Proceeding directly to surgical intervention is the most appropriate course of action as this patient is at high risk of catastrophic rebleeding.
   - **d.** Radionuclide scan is preferred over computed tomography (CT) angiography as a modality to localize the site of bleeding before angiography.

   Answer: b. Colonoscopy should be performed within 24 hours of presentation for diagnostic and potential therapeutic purposes. The role of radionuclide scanning is controversial because of inconsistent and widely variable accuracy in localizing the bleeding and the high rate of false-positive results. CT angiography can better localize the bleeding source when compared with radionuclide scanning. Surgery is indicated in cases of continued bleeding (especially diverticular) and massive ongoing bleeding with high transfusion requirements (generally >6 units of packed red blood cells in a 24-hour period).

Long-Term Outcome and Quality of Life

Conclusions

Acute pancreatitis is a complex disease with a highly variable clinical course. It is responsible for more than 275,000 hospital admissions each year in the United States[1] and has an annual incidence of 10 to 80 cases/100,000 in the developed world.[2–5] Incidence rates have been increasing over recent decades, reflecting the obesity epidemic, an independent pancreatitis risk factor in its own right, as well as the strong association with the most common etiology of acute pancreatitis, gallstones.[1,6] The crude mortality rate for patients hospitalized with acute pancreatitis is less than 2%.[7] The majority (80%) of patients with acute pancreatitis experience a benign and self-limited disease, resulting in a hospital stay usually lasting only a few days with no significant lasting sequelae.[7] In the remaining proportion of patients, however, acute pancreatitis is severe enough to lead to admission to an intensive care or high-dependency unit, and a prolonged clinical course with a mortality risk of that may exceed 15% depending on the presence and degree of infectious complications and associated end-organ failure.[1,8,9] These patients can present intensivists with formidable challenges during the course of their illness; however, those who recover, as most do, can return to their premorbid state of health with no significant reduction in quality of life.[10–13]

The prognosis for patients with severe acute pancreatitis has improved considerably over the 40 years since Ranson proposed his widely known severity criteria.[14] In the mid-1970s, the mortality for patients with severe pancreatitis approached 100%[14]; today the risk is now less than 20%.[15–17] This improved outcome can be ascribed in part to general improvements in critical care but, more importantly, to fundamental changes in the treatment approach to the patient with acute pancreatitis that, in turn, reflect an evolving understanding of the pathophysiology of the disease and a growing shared experience in treating patients affected by it.

Definitions and Terminology

Pancreatitis is an acute inflammatory disorder that arises as a consequence of the activation of pancreatic digestive enzymes present within the parenchyma of the gland, and in severe cases, the surrounding tissues of the peritoneal cavity and retroperitoneum. The most widely used classification system is the Atlanta classification,[18] created in 1991 and revised in 2012. Its original reproducibility was poor,[19] and as such, the revision[20–21] (Table 73.1) sought to clarify and standardize the terminology used to classify the range of acute pancreatitis severity based on whether the primary parenchymal process is interstitial edema or glandular necrosis and the presence, if any, and duration of associated multiorgan failure. Similarly, it sought to define the spectrum of local (peripancreatic) complications that may result.[20] In the mildest form of the disease, leakage of activated enzymes is minimal, and the most prominent manifestation is pancreatic interstitial edema secondary to a local inflammation. In more severe cases, the presence of extraductal enzymes results in glandular necrosis, when pancreatic ductal disruption results in leakage of pancreatic enzymes into adjacent tissues (Fig. 73.1). If the leakage occurs anteriorly into the "lesser sac" (retrogastric portion) of the peritoneal cavity, fluid collections are evident. The resulting local peritoneal inflammatory response triggers coagulation and fibrin deposition, walling off the collection, and in time (usually 4–6 weeks), creating a pancreatic pseudocyst—so-called as it is a fluid collection that lacks an epithelial lining. Alternatively, if leakage is into the retroperitoneum, necrosis of pancreatic tissue and surrounding fat predominates, although loculated necrotic fluid collections can result. In time, pancreatic necrosis may become walled off by fibrin deposition and the influx of granulation tissue, resulting in the demarcation of viable from nonviable tissue. In patients with severe acute pancreatitis, both intraperitoneal and retroperitoneal involvement is often present.

Drainage of pancreatic ascites into the chest via diaphragmatic lymphatics can create a pleural effusion, typically on the left side. Marked elevation of amylase in the pleural fluid establishes the

TABLE 73.1 Atlanta Classification System for Acute Pancreatitis (2012 Revision)[20]

Term	Definition
Acute pancreatitis	Acute inflammation of the pancreas with variable involvement of peripancreatic tissues
Mild acute pancreatitis	Interstitial edema of pancreas; typically benign clinical course with minimal organ dysfunction and full recovery
Moderately severe acute pancreatitis	Evidence of pancreatic necrosis with infectious complications and/or organ failure that resolves within 48 h of onset
Severe acute pancreatitis	Pancreatitis with associated organ failure that persists beyond 48 hours' duration
Acute fluid collection	Pancreatic or peripancreatic fluid, evident early in course of disease; lacks wall/organization
Pancreatic pseudocyst	Collection of pancreatic juice contained within a capsule of fibrous tissue that arises after an episode of acute pancreatitis
Pancreatic necrosis	Diffuse or focal loss of viability of pancreatic parenchyma or peripancreatic fat, evident as nonenhancing tissue on a contrast-enhanced CT scan
Pancreatic abscess	Localized collection of pus within pancreatic or peripancreatic tissue, containing little or no necrotic material

CT, Computed tomography.

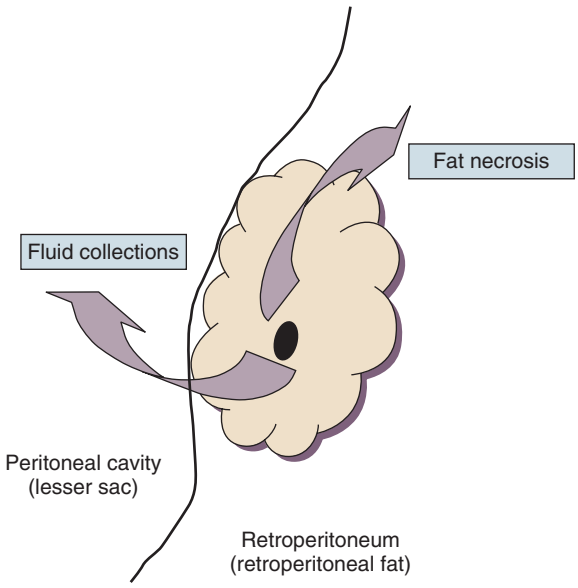
collection as pancreatic fluid, rather than as a reaction to an inflammatory process on the abdominal side of the diaphragm.

Pancreatic fluid collections can become secondarily infected by microorganisms from the gastrointestinal (GI) tract, giving rise to infected pancreatic or peripancreatic necrosis, infected pseudocysts, or pancreatic abscesses—the latter terms being largely interchangeable.

The older term, *hemorrhagic pancreatitis,* describes the sequelae of extension of necrosis into blood vessels of the retroperitoneum causing bleeding. Extraperitoneal tracking of the resulting hematoma gives rise to the physical examination findings of Grey-Turner sign, where the ecchymosis is evident in the flanks, and Cullen sign, when it tracks anteriorly through the falciform ligament to present at the umbilicus.[22]

Pathogenesis

Acute pancreatitis arises as a result of the leakage of activated pancreatic enzymes into pancreatic and peripancreatic tissues after ductal obstruction or disruption. The characteristic clinical syndrome (described later), however, reflects the activation of a massive systemic inflammatory response to that local tissue injury, mediated through the activation of the inflammasome—a multiprotein intracellular complex that leads to the activation of the key inflammatory cytokine, interleukin (IL) 1.[23]



• **Fig. 73.1** Disruption of the pancreatic ductal system results in leakage of activated digestive enzymes into the peripancreatic tissues. When the predominant direction is anteriorly into the lesser sac, the result is one or more fluid collections that either resolve or coalesce to form a pseudocyst. Leakage posteriorly into the fatty tissues of the retroperitoneum results in fat necrosis.

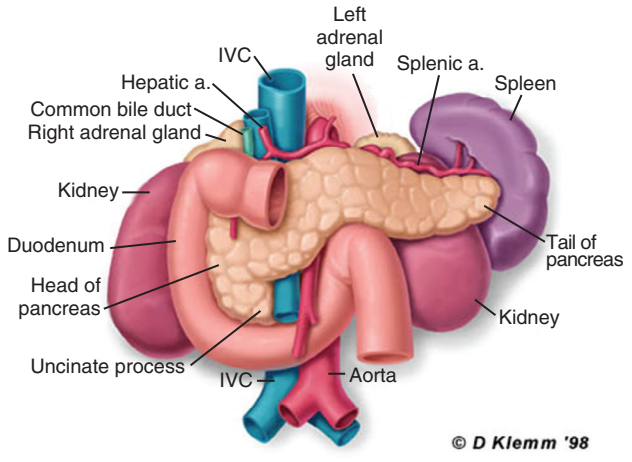
Beyond its role as an endocrine organ, the pancreas plays a fundamental role in the digestion of foodstuffs through the production of enzymes that degrade the major constituents of ingested food—protein (proteases), fat (lipases), starch (amylase), and nucleic acids (nucleases). Pancreatic enzymes are synthesized by the acinar cells lining the pancreatic ductal system and then released from the cell as inactive zymogens.[24] They pass via the pancreatic duct into the lumen of the duodenum, where they are activated by mucosal enzymes such as enterokinase, and become capable of degrading their target substrates. Under normal circumstances, intrapancreatic activation is inhibited by sequestration of newly synthesized enzymes within zymogen granules, and further through the local action of a specific inhibitor of trypsin activation called SPINK (serine protease inhibitor, Kazal type).[25] The importance of this latter mechanism is underlined by the observation that genetic mutations in the *SPINK* gene that result in reduced activity have been implicated in the pathogenesis of hereditary pancreatitis.[26]

The activation of pancreatic enzymes within the pancreas initiates autodigestion of the gland and surrounding tissues.[27,28] Activation of trypsinogen to trypsin appears to be a critical event during the early pathogenesis of the acute process[29,30] and may be mediated by an increase in intracellular calcium concentrations.[31] Trypsinogen can also be activated by lysosomal cathepsin B within acinar cells.[32] Pancreatic acinar cells can die by either necrosis or apoptosis. Necrotic death is characterized by cell lysis, with leakage of intracellular constituents into the surrounding microenvironment, and the activation of an acute inflammatory response. Neutrophil recruitment in response to local tissue injury has been implicated in the amplification of cellular damage in acute pancreatitis.[33–35] Apoptotic death, in contrast, is noninflammatory. Cells are degraded into membrane-bound vesicles that are taken up by tissue macrophages. Phagocytosis of an apoptotic cell not only prevents the local activation of inflammation, but also triggers transcriptional

programs in the phagocytosing cell that are antiinflammatory and reparative in nature, with upregulation of counterinflammatory cytokines such as IL-10.[36] The local cellular injury in acute pancreatitis can also be conceptualized as an imbalance between necrotic and apoptotic cell death. Activation of caspases—the intracellular enzymes that mediate apoptosis—attenuate the severity of pancreatitis,[37] whereas severe pancreatitis is associated with reduced levels of IL-10.[38]

Activated pancreatic enzymes injure not only cells of the pancreas, but also those of surrounding tissues. Fat cells appear to be particularly vulnerable, and the disease tends to be more severe in the obese because of the greater volume of peripancreatic fat necrosis.[39] However, the degradative effects of pancreatic enzymes, and the secondary tissue injury resulting from the host response, can injure other structures in the vicinity of the pancreas, particularly the transverse colon, and major vessels such as the splenic artery and vein.[40] Thus pancreatitis can rapidly evolve from an inflammatory disease of the pancreas to a chemical burn of the retroperitoneum.

The pathogenesis of the clinical syndrome is further complicated by the presence of the GI tract immediately adjacent to the pancreas (Fig. 73.2). The head of the pancreas lies within the curve of the duodenum, immediately behind the stomach and above the transverse colon. Damage to terminal feeding vessels in the colonic fat can result in focal perforation of the colon, with leakage of colonic bacteria into the peritoneal cavity.[41] Although the stomach and duodenum are only lightly colonized in health, the local ileus induced by the acute pancreatic inflammation promotes proximal gut bacterial overgrowth.[42] In addition, changes in the function of the GI mucosal barrier function arising from local inflammation and the absence of enteral nutrients promote the translocation of luminal bacteria and their by-products, such as endotoxin, into the injured or necrotic peripancreatic tissues.[43] The clinical syndrome of acute pancreatitis evolves as a result of a systemically activated inflammatory response, with the same changes in microvascular blood flow, endothelial permeability, and inflammatory mediator release that also characterize bacterial sepsis, even in the absence of infection.[44]



• **Fig. 73.2** The pancreas is a retroperitoneal organ, lying posterior to the stomach, within the curve of the duodenum. It lies in immediate proximity to a number of large blood vessels including the splenic artery and vein, the superior mesenteric artery and vein, and the portal vein. *Hepatic a.,* Hepatic artery; *IVC,* inferior vena cava; *Splenic a.,* splenic artery.

Etiology and Risk Factors

Acute pancreatitis has many causes (Table 73.2), although 80% of cases in the developed world result from either alcohol or gallstones, with the latter being slightly more common. Alcohol-induced pancreatitis typically occurs after acute binge ingestion on a background of chronic use, occurring in 25% to 5% of chronic alcohol abusers.[1] The mechanism of alcohol-induced pancreatitis is unknown; acinar cells of the pancreas are capable of metabolizing alcohol, and appear to be the primary target of alcohol-mediated pancreatic injury.[45] In vitro studies show that alcohol reduces the sensitivity of isolated acini to zymogen activation by cholecystokinin.[46]

Gallstone pancreatitis appears to be a consequence of a transient acute increase in pancreatic ductal pressures associated with passage of a small gallstone through the sphincter of Oddi in patients with a common channel for the distalmost bile and pancreatic ducts.[47] True ductal obstruction is uncommon, and approximately 90% of affected patients are found to have gallstones in the stool, implicating the actual passage of the stone, rather than a fixed obstructive mechanism, in the etiology of the resulting pancreatic inflammation.

Drug-associated pancreatitis is typically mild and not common, representing less than 5% of cases.[1] The list of drugs implicated in the etiology of acute pancreatitis is long[48]; some of the more prominent associations are shown in Table 73.2.

Genetic factors have also been associated with the development of acute pancreatitis. A polymorphism in the secretory trypsin inhibitor *(SPINK1)* gene is associated with an increased risk for acute pancreatitis,[49] as are mutations in the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene,[50] and *PRSS1,* a peptidase-encoding gene.[51] Polymorphisms in the genes for tumor necrosis factor α and heat shock protein 70 have also been linked to increased risk for acute pancreatitis,[52] although the associations are less clear.

TABLE 73.2 Causes of Acute Pancreatitis

Congenital	
Anatomic abnormalities: Pancreas divisum, choledochocele, periampullary diverticulum	
Familial pancreatitis	
Cystic fibrosis	
Hereditary angioedema	
Acquired	
Toxic	Alcohol, scorpion venom
Obstructive	Gallstones, duodenojejunal intussusception
Metabolic	Hypercalcemia, hypertriglyceridemia
Trauma	Blunt/penetrating
	Endoscopic retrograde cholangiopancreatography–induced
	Operative
Drugs	Thiazides, corticosteroids, valproate, sulfasalazine
Ischemia	Low flow state
Infectious	Mumps, human immunodeficiency virus, cytomegalovirus, other viral infections, *Salmonella,* ascariasis, tuberculosis, brucellosis, leptospirosis
Autoimmune	Systemic lupus erythematosus, autoimmune (immunoglobulin G-related) pancreatitis
Carcinoma of the Pancreas	
Idiopathic	

Clinical Presentation and Diagnosis

Acute pancreatitis typically presents as severe acute epigastric pain that radiates to the back, a reflection of the retroperitoneal position of the pancreas. Nausea and vomiting are common associated symptoms. From the perspective of the intensivist, the predominant manifestations of severe acute pancreatitis are those that reflect hemodynamic instability secondary to an activated systemic inflammatory response. These can evolve with alarming rapidity, and the severity of the process is frequently not appreciated until it is quite advanced.

The causes of shock in the patient with acute pancreatitis are multifactorial. Initially, the acute inflammatory process in the retroperitoneum elicits local inflammation, with an outpouring of fluid into the relatively confined space of the retroperitoneum, or into the peritoneal cavity itself. Intra-abdominal inflammation evokes secondary ileus of the GI tract, resulting in intraluminal fluid sequestration, increasing the relative intravascular volume deficit. Nausea, vomiting, and a reluctance to take fluids by mouth further exacerbate this fluid deficit. As the process evolves, a systemic inflammatory response to the local abdominal process results in diffuse vasodilatation and capillary leak syndrome. In aggregate, the effective loss of intravascular volume can be enormous, and thus the initial resuscitation often requires large volumes of intravenous fluid to achieve end-organ perfusion. Acute hypocalcemia, possibly driven by abnormal pancreatic enzyme activation,[31] may also contribute to the clinical picture of cardiovascular compromise. Indeed, the classical prognostic criteria articulated by Ranson (Table 73.3) emphasize the importance of secondary hemodynamic sequelae in determining the ultimate prognosis of the patient with acute pancreatitis.[14]

The diagnosis of pancreatitis is usually straightforward, based on the combination of clinical manifestations and characteristic biochemical findings of elevated (more than three times the local upper limit of normal) circulating levels of amylase and lipase, the latter being somewhat more diagnostically useful (higher specificity and sensitivity; earlier detection).[53,54] The diagnosis can be confirmed by computed tomography (CT) (Fig. 73.3), which can also be used to assess disease severity by using the grading system developed by Balthazar (Table 73.4).[55] Radiographic manifestations of acute pancreatitis tend to lag behind the clinical condition.

Other radiographic studies pertinent to the management of acute pancreatitis include focused abdominal ultrasound to assess for the presence of gallstones and/or biliary dilatation, and if further detail regarding possible biliary pathology is needed, magnetic resonance cholangiopancreatography.

An assessment of the initial severity of the disease is useful primarily in determining the optimal venue for the early management of the patient, because at least some of the delayed morbidity of acute pancreatitis can be reduced through aggressive initial resuscitation and support.[54] A variety of approaches have been used to quantify disease severity. Ranson identified 11 variables—5 at initial presentation and 9 over the ensuing 48 hours—that correlated in a graded fashion with the ultimate risk of mortality (see Table 73.3).[14] The Glasgow-Imrie criteria are a modification of the Ranson criteria and represent an alternate model of severity scoring. In head-to-head studies, APACHE II (Acute Physiology and Chronic Health Evaluation II)—a generic severity of illness scale—performs at least as well as the Ranson or Glasgow-Imrie criteria in predicting severe disease and hospital survival.[56] Moreover, even simpler scales appear to provide comparable prognostic

information; however, most acute pancreatitis scoring systems tend to overcall "severe" pancreatitis.[23,49,54,57]

A variety of biochemical measures, including C-reactive protein, procalcitonin, interleukins 6, 8, 10, and trypsinogen activation peptide, are purported to differentiate mild and severe pancreatitis early in the disease course[1,58–60]; however, their clinical utility remains unclear. The degree of amylase/lipase elevation is not overly informative in regard to disease severity, and thus there is no role for repeated measurements once the diagnosis has been made.

Persistence of clinical manifestations of systemic inflammation beyond 48 hours is also associated with subsequent organ dysfunction and a higher mortality.[61] Precision in prognostication is less important than the early identification of patients for whom close monitoring and aggressive resuscitation in an intensive care environment may alter their clinical course.[62]

Early Management of the Critically Ill Patient With Acute Pancreatitis

Initial Resuscitation

Intravascular fluid deficits early in the course of pancreatitis can be substantial. Prompt and aggressive fluid resuscitation is the cornerstone of initial successful management.[63] Volume status should be monitored with a urinary catheter and serial laboratory investigations (serum creatinine, hematocrit, and so on). Although few studies specific to pancreatitis have been performed, there is every reason to believe that the principles of goal-directed resuscitation should be followed.[64,65] The key is to administer sufficient volumes rapidly enough to restore an adequate circulating volume and prevent (or reverse) hemoconcentration, which may in turn prevent or minimize pancreatic necrosis.[66] There is some evidence to suggest that use of Ringer lactate solution results in a reduced systemic inflammation, compared with normal saline solution, when used for the acute resuscitation of pancreatitis.[65]

Typically resuscitation requires many liters of fluid, and not infrequently, the sickest patients will receive more than 10 to 15 L of fluid resuscitation over the first 24 hours. Such aggressive resuscitation is best carried out within the well-monitored environment of the intensive care unit (ICU) to assess for resuscitation response in real time, as well as to facilitate interventions such as vasopressor administration or positive-pressure ventilation that severe cases often require.

Although aggressive fluid resuscitation can minimize later complications such as pancreatic necrosis and acute renal failure, in patients with increased vascular permeability, it carries a high risk of complications related to interstitial edema. Frequently patients will require endotracheal intubation and mechanical ventilation. Development of the abdominal compartment syndrome is a relatively common and underdiagnosed complication of resuscitated acute pancreatitis.[67] Intra-abdominal pressure can be measured by transducing a urinary catheter in the bladder. Normal pressures approximate the central venous pressure, whereas pressures greater than 12 cm H_2O indicate intra-abdominal hypertension. When the latter is associated with end-organ failure (renal failure, inability to ventilate, and so on), this represents formal abdominal compartment syndrome, which is usually associated with pressures in excess of 20 cm H_2O. The first-line management of abdominal compartment syndrome consists of nonsurgical interventions directed at reducing intra-abdominal contents (nasogastric decompression, paracentesis, and so on) and maximizing abdominal wall compliance (i.e., chemical paralysis).[68] In refractory cases, management requires abdominal decompression by formal laparotomy, sometimes even in the ICU, for very unstable cases. Anterior abdominal fasciotomy (without peritoneal violation) has been proposed as a less invasive alternative for surgical decompression.[69] Laparotomy complicates the subsequent management of pancreatitis, and so surgical decompression should be avoided if at all possible.

Infection Prophylaxis

Infection is a common complication of acute necrotizing pancreatitis, and its development is associated with an increased risk of morbidity and mortality.[70] For the patient with severe acute pancreatitis, these infections may arise within necrotic pancreatic or peripancreatic tissues, or at distant sites as nosocomial infections (i.e., ventilator-associated pneumonia). Infected pancreatic necrosis occurs in about one-third of cases of necrotizing pancreatitis, representing about 5% of all patients with acute pancreatitis.[1]

The characteristic microbial flora of peripancreatic infection includes organisms that normally reside within the GI tract,[71] as well as those that characteristically colonize the proximal GI tract of the critically ill patient (Box 73.1).[42] Anaerobes may be present but are uncommon, whereas organisms such as *Candida*, *Enterococci*, and coagulase-negative *Staphylococci* are encountered with increasing frequency.[72,73] These flora reflect the role of the GI tract as the reservoir of organisms that induce superinfection of acute pancreatitis.[74] Peripancreatic infections are typically monomicrobial.[1]

Infection of necrotic tissue in the retroperitoneum can arise by one of several routes. Bacteremic spread from a distant site, retrograde passage up the pancreatic duct, and direct extension through a defect in the adjacent GI tract are all plausible mechanisms. However, the most significant mechanism of infection appears to be the translocation of viable microorganisms across an anatomically GI tract, from either colon or small intestine. Bacterial translocation is readily demonstrable in animal models of acute pancreatitis,[75,76] and indirect evidence suggests that the phenomenon contributes to infectious complications in human pancreatitis.[77] Patients with severe pancreatitis, for example, have higher rates of proximal gut colonization with the same enteric organisms that produce infection,[78] and colonization invariably precedes the development of invasive infection.[79] Moreover, suppression of pathologic gut colonization reduces the risk of infection.[80]

• BOX 73.1 Common Microbial Isolates in Pancreatic and Peripancreatic Infections

Gram-negative aerobes
- *Escherichia coli*
- *Klebsiella*
- *Pseudomonas*
- *Proteus*
- *Enterobacter*

Gram-positive aerobes
- *Enterococcus*
- *Staphylococcus aureus*
- *Staphylcococcus epidermidis*

Anaerobes
- Bacteroides

Fungi
- *Candida*

Host-microbial interactions within the GI tract are complex,[81,82] and the changes that occur in pancreatitis are much more than a state of generalized leakiness. Colectomy, for example, increases rates of small bowel microbial colonization and bacterial translocation.[83] Moreover, the anaerobic flora of the gut provides a barrier to intestinal mucosal colonization with pathogenic aerobes, and thus inhibits bacterial translocation.[84] Anaerobes are uncommonly found in pancreatic infections, and the isolation of an anaerobic organism from an area of infected pancreatic necrosis is highly suggestive of a physical breach of the GI tract.

Infection of pancreatic necrosis is a relatively late event, occurring maximally during the second or third week after the onset of the acute disease.[85] Nevertheless, circulating bacterial DNA or endotoxins may be detected earlier during the course of the disease.[86,87]

The role of antibiotic prophylaxis, however, is controversial. An early meta-analysis of randomized controlled trials of prophylactic antibiotics for patients with acute pancreatitis concluded that prophylaxis can improve survival without significantly altered rates of pancreatic infection.[88] A consensus conference of critical care organizations, however, recommended that routine antibiotic prophylaxis should not be used in the absence of more compelling evidence,[62] and more recent compilations of data from clinical trials fail to show clear benefit for antibiotic prophylaxis.[89,90] A preference for conservatism is driven by three principal factors: the low methodologic quality of trials that support antibiotic prophylaxis, concerns regarding adverse ecologic consequences of prolonged broad-spectrum antibiotic administration (i.e., *Clostridium difficile* colitis, antibiotic resistance, and fungal infections), and the increasing use of an alternate prophylactic strategy, enteral feeding.[91] One of the most influential studies of prophylactic antibiotics in pancreatitis, for example, reported a significant survival improvement associated with antibiotic prophylaxis in a cohort of 60 patients; in that study, however, antibiotic use had no impact on rates of pancreatic infection, and three-quarters of patients in the control arm effectively crossed over by receiving antibiotics early in the course of their disease.[92]

The prevention of pathologic gut colonization through the use of selective digestive tract decontamination has been shown to reduce rates of pancreatic infectious complications[80] and to reduce mortality associated with gram-negative infections.[93] Whether antifungal prophylaxis is efficacious is also controversial.[94,95]

Nutritional Support

In contrast to the persistent controversy regarding the utility of antibiotic prophylaxis in severe acute pancreatitis, it is now generally accepted that patients fare better, and in particular, experience less infectious and inflammatory morbidity, if they are fed earlier and enterally rather than parenterally. This is contrary to historical thinking that espoused "bowel rest" as a core tenet of the acute management of pancreatitis. Enteral feeding is associated with maintained epithelial barrier function and reduced rates of translocation of endotoxin and viable bacteria in experimental animals.[96,97] A meta-analysis found lower rates of infectious complications (relative risk [RR] 0.39; 95% confidence interval [CI] 0.23–0.65), operative intervention (RR 0.44; 95% CI 0.29–0.67), organ failure (RR 0.55; 95% CI 0.37–0.81), and mortality (RR 0.50; 95% CI 0.28–0.91).[98] Shorter hospital lengths of stay and improved pain outcomes were observed.[98]

Current guidelines recommend the early institution of enteral feedings in patients with severe acute pancreatitis, supplemented with parenteral support to meet full nutritional requirements.[62,99,100] Evidence suggests "early" initiation should ideally be between 3 and 5 days after presentation, with no benefit evident for initiation before 3 days.[101] Although the frequent presence of gastric ileus in acute pancreatitis has resulted in a preference for the nasojejunal, rather than the nasogastric (or oral, if possible), route of feeding, there is no evidence to suggest the inferiority of nasogastric feeding.[102,103] Similarly, there is no compelling evidence at present to favor any particular nutritional formulation. Intestinal ileus may cause feeding intolerance and thus may mandate total parenteral nutrition; however, enteric feeding should be frequently retried.

Adjuvant Therapy

Despite a substantial body of literature suggesting a benefit for a variety of different adjuvant treatments in preclinical models, there is no evidence for any specific therapy in human disease. A systematic review of the use of cimetidine found no evidence that suppression of gastric acid secretion improved outcomes, but rather a trend to a higher risk of complications.[104] Pooled data from small studies have suggested that somatostatin or octreotide can improve survival for patients with severe acute pancreatitis,[105] but data from larger, more robust trials continue to be lacking.

Endoscopic Retrograde Cholangiopancreatography in Acute Gallstone Pancreatitis

Gallstone pancreatitis is caused by a gallstone that has migrated from the gallbladder into the common bile duct producing transient obstruction of the pancreatic duct. This pathogenetic mechanism raises the possibility that measures to relieve relative obstruction of the sphincter of Oddi (and facilitate bile flow) might reduce the severity of the disease. This possibility has been evaluated in at least four clinical trials, the pooled data from which suggest benefit for patients with severe pancreatitis in reducing subsequent complications.[106] It is unclear whether the benefit extends to all patients or simply to the subset of patients with persistent common bile duct obstruction and concomitant cholangitis.[107,108] In stable patients with uncomplicated gallstone pancreatitis, the definitive management is cholecystectomy to prevent relapse and other stone-related complications, ideally performed on the index admission to prevent interval relapse.[109] Endoscopic retrograde cholangiopancreatography can be used to minimize relapse risk in patients with prohibitive operative risk.

Management of the Late Complications of Severe Acute Pancreatitis

The initial management of severe acute pancreatitis is focused primarily on adequate resuscitation and organ support. Early lethal postresuscitation complications are uncommon[110] and include intestinal ischemia (typically secondary to a low flow state or mesenteric venous thrombosis after delayed resuscitation)[111] and bleeding secondary to erosion into a major vessel. In the absence of these catastrophic and fortunately rare complications, the subsequent management of the critically ill patient with acute pancreatitis involves optimal intensive care,[112] close monitoring, and patience. About 40% of cases of necrotizing pancreatitis require an invasive intervention for local management of complications of the disease.[113]

Pancreatic Pseudocysts

Serial evaluation by CT shows that the diffuse fluid collections evident in early pancreatitis coalesce to form discrete cystlike collections contained within an organized capsule of fibrin, termed a *pseudocyst.* Typically these arise in the lesser sac, between the pancreas and the posterior wall of the stomach (Fig. 73.4). Management is expectant in the absence of complications,[114] and rarely is intervention required in the ICU setting. The most common symptom precipitating drainage is persistent pain or symptoms of gastric obstruction. Other important complications include infection or hemorrhage into the cyst.

The classic approach to the management of a pancreatic pseudocyst involved waiting until the fibrous capsule of the cyst has matured (usually after 4–6 weeks), then draining the cyst into the back wall of the stomach. Open surgical pseudocyst gastrostomy has largely given way to less invasive approaches, creating a cyst gastrostomy by radiologic image–guided,[115] endoscopic,[116] or laparoscopic approaches.[117] A pseudocyst forms because of injury to the main pancreatic duct or one of its branches, and persists because of obstruction to the flow of pancreatic juice through the duct. If that obstruction persists, then external drainage will result in a persistent pancreaticocutaneous fistula. Drainage into the stomach avoids this complication by an internal pancreaticogastric fistula that is without clinical importance. Open operation may be required for massive hemorrhage; angiographic embolization of the bleeding vessel is a modern alternative in reasonably stable patients.[118]

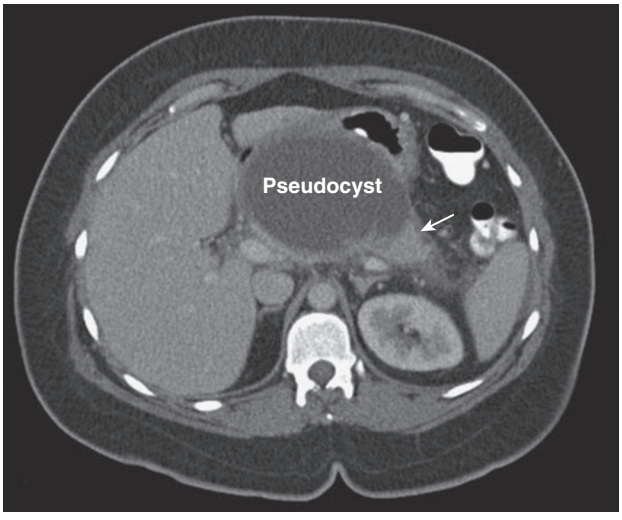
Infected Necrosis and Pancreatic Abscess

One of the more significant recent advances in the management of severe pancreatitis has been the adoption of a policy of surgical conservatism in managing patients with suspected pancreatic or peripancreatic infection. Case series demonstrate improved survival rates when surgery is delayed,[119–123] and a single randomized trial showed that delaying surgical intervention for at least 2 weeks in patients with necrotizing pancreatitis improves clinical outcomes.[124] This improvement can be attributed to a reduced frequency of major bleeding and systemic inflammatory complications associated with the debridement of necrotic, infected retroperitoneal tissue.

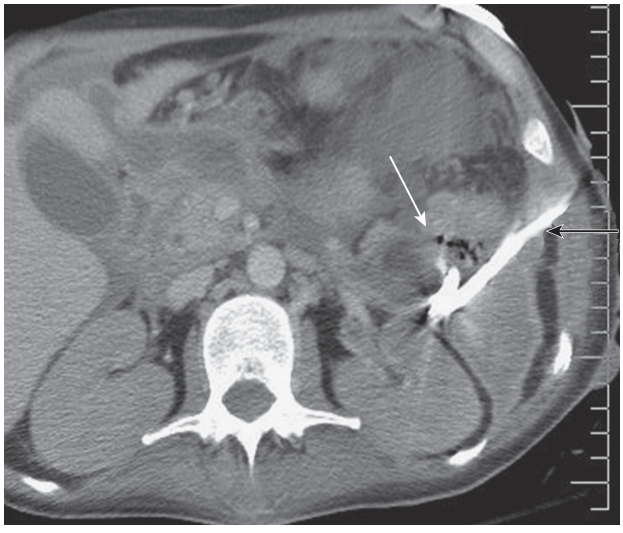
Just as serial CT evaluation reveals unification of pancreatic fluid collections, serial study of areas of pancreatic necrosis shows that they too coalesce with time, and importantly, become circumscribed by the development of a wall of granulation tissue between the areas of necrosis and viable surrounding tissues. It is this clear demarcation between viable and nonviable tissue that renders percutaneous drainage feasible and operative intervention safe and obviates the need for repeat operation or open abdomen approaches. Typically, the process of demarcation takes 3 to 4 weeks or longer to occur; thus surgical intervention, if contemplated, should be deferred. Repeat CT scans should be performed only as mandated by patient signs and symptoms and not according to a timed schedule. A strategy of surgical conservatism in the face of a patient with clinical manifestations of sepsis and ongoing organ dysfunction may appear counterintuitive, but it is both well tolerated and safer than the alternative.[125]

There is general consensus that the indication for operative intervention in a patient with severe pancreatitis is infected necrosis; sterile necrosis should be managed expectantly.[120,126,127] The diagnosis of infection of pancreatic necrosis can be challenging to establish, as the clinical manifestations of systemic inflammation are common in the acutely ill patient with pancreatitis, even in the absence of infection, as are nosocomial infections in sites other than the necrotic retroperitoneal tissues. A diagnosis of infection may be suggested by new elevation in levels of procalcitonin[128,129] or by CT findings of air in the necrotic tissues (Fig. 73.5). However, definitive diagnosis of infection is best established by CT-guided fine-needle aspiration of the peripancreatic necrotic tissues.[130] Aspiration should be performed only when infection is suspected on clinical grounds, and not as a matter of routine when fluid collections or necrosis are detected, as iatrogenic infection of these potentially sterile entities may occur.

Documentation of infection on a fine-needle aspirate is not an absolute indication for operative intervention. Antibiotics should be administered as guided by the results of culture and sensitivity and then source control options evaluated. Early in the course of the disease, before the demarcation of necrotic and viable tissues,



• **Fig. 73.4** A maturing pancreatic pseudocyst, evident as a well-circumscribed fluid collection in the lesser sac, compressing the residual pancreas *(white arrow).*



• **Fig. 73.5** Infected pancreatic necrosis *(white arrow)*; the fluid component of the collection was decompressed with a percutaneously placed drain *(black arrow),* allowing delayed laparoscopic debridement.

percutaneous drainage of the fluid component of the collection can temporize until operative intervention is safer (see Fig. 73.5). Percutaneous drainage alone is often curative.[16,131–134]

The surgical management of infected pancreatic necrosis entails the debridement of the necrotic retroperitoneal tissues and drainage of the resulting cavity. Approaches span the surgical spectrum from minimal access techniques[135–137] to open abdomen approaches.[138,139] Improved clinical outcomes have also been seen with the use of less invasive, staged procedures. van Santvoort and colleagues reported a randomized controlled trial of a staged "step-up" approach to pancreatic necrosectomy consisting of initial percutaneous drainage of the liquid elements of a pancreatic infection, followed by a minimally invasive necrosectomy, using the drain tract as a route of access.[16] The minimally invasive approach resulted in significantly lower rates of major complications and new-onset organ dysfunction, as well as lower rates of delayed complications including diabetes and incisional hernia. This same group has also reported lower rates of new organ dysfunction and pancreatic fistula when patients were managed by transgastric endoscopic necrosectomy compared with open necrosectomy.[140]

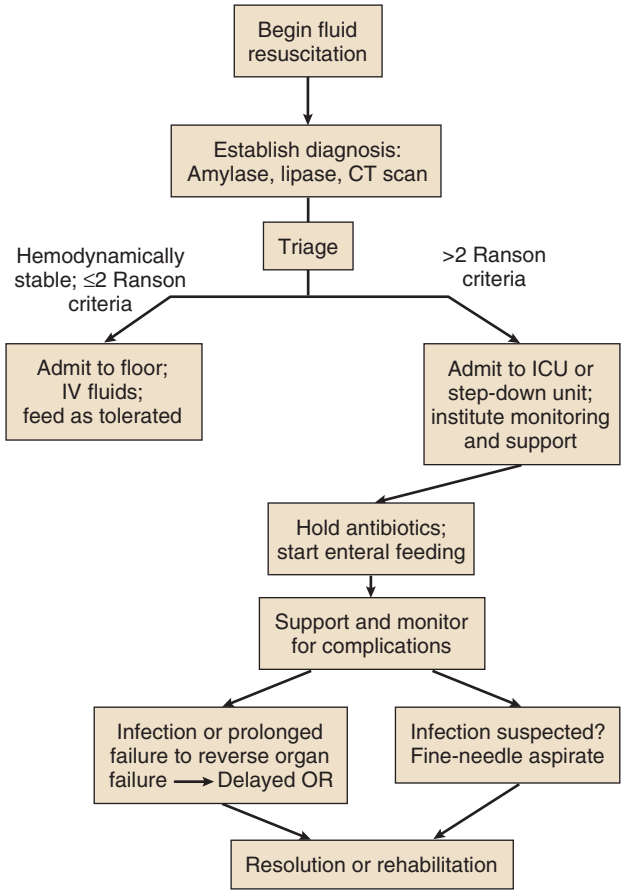
Overall, the optimal approach is the one that entails the least anatomic and physiologic upset to the patient. An open laparotomy can be performed using either a midline or bilateral subcostal incision. With the aid of a recent CT scan to guide the dissection, the infected retroperitoneal necrosis is approached either through the gastrocolic omentum and the lesser sac or through the inferior aspect of the transverse mesocolon. Dissection is performed largely blindly and bluntly, evacuating necrotic retroperitoneal fat and pus. Soft drains are left in the resulting cavity to provide egress for pancreatic juice, and the abdomen can usually be closed primarily. If there is evidence of significant involvement of the mesocolon or preoperative cultures yield anaerobic organisms, a proximal diverting ileostomy may be added to minimize contamination from the adjacent colon.

Laparoscopic techniques have the added advantage of permitting direct visualization of the abscess cavity,[137,141,142] but they may be challenging if there is extensive or multiloculated areas of necrosis. Infected necrosis can also be approached via the flank, using a nephroscope or laparoscope to aid in visualization of the abscess contents.[16,143] Further insights into the role of minimally invasive approaches should emerge from several ongoing clinical trials.[117,144] The role for open abdomen approaches in the management of infected pancreatic necrosis is diminishing as surgical practice shifts to delayed intervention with more minimally invasive techniques.[145]

Peritoneal lavage with the objective of evacuating activated pancreatic enzymes enjoyed a period of popularity[146] but is now used less frequently. Some authors recommend continuous postoperative lavage after pancreatic necrosectomy,[145] though the benefits of this approach are unproven.

Vascular Complications of Necrotizing Pancreatitis

The vascular complications of acute pancreatitis include both thrombosis and hemorrhage.[147,148] Thrombosis of the splenic, superior mesenteric, or portal vein develops as a consequence of the prothrombotic effects of the adjacent inflamed pancreas and reduced flow before full resuscitation. Less commonly, more distant vessels such as the inferior vena cava or renal veins may thrombose. Venous thrombosis may give rise to portal venous gas on CT; in the absence of clinical findings dictating a need for emergent intervention, both the venous thrombosis and the associated CT findings can be managed medically with anticoagulation and aggressive fluid resuscitation.[149] Intestinal infarction secondary to venous thrombosis in patients with acute pancreatitis carries a prohibitive mortality, even with surgery.



• **Fig. 73.6** Approach to the patient with acute pancreatitis. *CT,* Computed tomography; *ICU,* intensive care unit; *IV,* intravenous; *OR,* operation.

Erosion of the retroperitoneal inflammatory process into a major artery can produce bleeding into either the peritoneal cavity or the gut lumen, which may present as peritonitis and GI hemorrhage, respectively, and in either case, hemorrhagic shock if significant blood loss occurs. Commonly involved vessels include the splenic artery, the gastroduodenal artery, and the pancreaticoduodenal arcade.[150] Operative exposure is challenging in the face of acute retroperitoneal inflammation, and whenever feasible, bleeding is best managed by angiographic embolization.[118]

An algorithm summarizing the key elements in management of the patient with severe acute pancreatitis is provided in Fig. 73.6.

Long-Term Outcome and Quality of Life

Acute necrotizing pancreatitis can be an enormously challenging process to treat. Although the mortality for all cases of acute pancreatitis is only approximately 2% (and decreasing annually), the mortality for patients with end-organ failure persisting beyond 48 hours and/or infectious complications of pancreatic necrosis is higher, typically in the range of 15% to 20%. Additional risk factors for death include obesity (body mass index >30; >25 for

Asian populations), increasing age, and mounting preexisting comorbid conditions.[1]

For the survivors, the ICU and hospital stay is often prolonged, and in addition to procedures undertaken during the acute episode, there is often a need for later interventions, such as incisional hernia repair, cholecystectomy, or drainage of symptomatic pseudocysts. Yet there is ample evidence that most patients who survive their acute illness return to a health-related quality of life that is no different from age-matched controls.[10–13] Abnormalities of both endocrine and exocrine function are commonly evident at follow-up,[151] and approximately one-third of survivors of severe necrotizing pancreatitis develop diabetes.[152] Finally, about 10% will also progress to develop chronic pancreatitis, which manifests with chronic pain that can be quite debilitating.[153] Efforts to prevent recurrent episodes of pancreatitis should reflect the presumed underlying etiology of the individual patient's pancreatitis (cholecystectomy, alcohol cessation, lipid profile optimization, and so on).

Conclusions

Necrotizing pancreatitis is a challenging but often an enormously satisfying disease to manage. Current management approaches are supportive, with treatment directed at correcting complications of the disease process. Modern management is multidisciplinary involving the intensivist, surgeons, endoscopists, and allied health team members such as dieticians, and as such may ultimately mandate transfer to a specialist center to meet the needs of patients with complex disease. Adjunctive treatment strategies that target the pathologic host inflammatory response are not yet available but should emerge over the coming decade. Although the outcome is heavily dependent on disease severity, with early and aggressive resuscitation, optimal supportive care in an ICU, and judicious and delayed intervention to manage infected necrosis, the overwhelming majority of patients survive and are rehabilitated to an excellent quality of life.

Key Points

- The incidence of acute pancreatitis is increasing over time; the most common etiologies are gallstones and excessive consumption of alcohol.
- The initial presentation of severe acute pancreatitis can be subtle; early objective assessment of disease severity is important in guiding the vigor of resuscitation and informing patient disposition.
- Aggressive fluid resuscitation is the cornerstone of successful management. Large volumes of intravenous fluids are often required, and the development of acute respiratory failure with a need for mechanical ventilation and admission to the ICU is not uncommon.
- The use of prophylactic antibiotics is discouraged and should be limited to cases in which there is a high likelihood of infectious complications.
- Nutritional support should be instituted early, prioritizing the enteral route. Parenteral nutrition should be reserved for patients who cannot meet their full caloric needs enterally.
- Serial CT scans can document the severity of the disease and monitor its progression. CT-guided fine-needle aspiration is the diagnostic technique of choice to confirm infected necrosis; the presence of gas formation within tissue necrosis on CT scans serves as a surrogate.
- The management of infected necrosis consists of culture-guided systemic antibiotics and source control, of which the first line measures are minimally invasive techniques of pancreatic debridement, including endoscopic and interventional radiology options. Surgical debridement is now reserved for refractory cases.
- Despite the complexity and morbidity of acute episodes, long-term health-related quality of life for survivors of acute necrotizing pancreatitis is excellent.

Review Questions

1. Which of the following statements regarding the provision of nutrition to patients with complicated acute pancreatitis is the most correct?
   - **a.** In the acute phase, parenteral nutrition is preferred over enteral nutrition to prevent stimulation of the pancreas.
   - **b.** Early initiation of enteral nutrition reduces the frequency of infectious complications.
   - **d.** Nasojejunal (postpyloric) administration of enteral feedings is superior to nasogastric feeding.
   - **d.** Paralytic gastrointestinal (GI) ileus is a rare complication of complicated pancreatitis.

   Answer: b. Early (day 3–5) initiation of enteral nutrition in patients with severe pancreatitis has been demonstrated to be safe and results in improved survival and infectious outcomes relative to parenteral nutrition. Parenteral nutrition, either partial or total, may still be required in the setting of paralytic GI ileus, which remains common in the setting of complicated, especially infected, pancreatitis. Owing to the proximity of the stomach to the pancreas, isolated gastric ileus may be a concern in some cases, and in which case, patients may benefit from the placement of a nasojejunal feeding tube to bypass the stomach to provide ongoing enteric nutrition. A commonly held belief has been that routine nasojejunal feeding may be beneficial by minimizing pancreatic stimulation; however, outcomes have been shown to be equivalent comparing nasogastric and nasojejunal approaches to feeding.
2. A 57-year-old man was admitted to the intensive care unit (ICU) with necrotizing pancreatitis secondary to alcohol. He has received massive fluid resuscitation, transient vasopressor support, and invasive positive-pressure ventilation. His status had been improving, but as he enters the second week of his admission, he develops new fevers and reinitiation of vasopressor support. Infected pancreatic necrosis is suspected. With respect to infected pancreatic necrosis, which of the following statements is the most correct?
   - **a.** Anaerobic bacteria are the most commonly isolated microorganisms from cultures of infected pancreatic necrosis.
   - **b.** Early drainage of pancreatic pseudocysts upon detection prevents infection.
   - **c.** Prophylactic antibiotics reduce the risk of pancreatic infection.
   - **d.** Approximately one-third of patients with necrotizing pancreatitis will develop infected necrosis.

   Answer: d. About one-third of patients with necrotizing pancreatitis develop infected pancreatic necrosis. The use of prophylactic antibiotics has not been clearly shown to prevent pancreatic infection. The most likely source of causative microbes is translocation of aerobic GI flora, especially from the upper GI tract. Anaerobic bacterial infection of pancreatic necrosis is less common, and is likely the result of discrete intestinal breach (i.e., colonic perforation secondary to ischemia).

   Pancreatic pseudocysts arise from the leakage of pancreatic enzymes from the ducts of the damaged gland in the retrogastric lesser sac of the peritoneal cavity. Pseudocysts may become symptomatic owing to mass effect (i.e., pain, gastric outlet obstruction) or secondary infection. In such cases, drainage via surgical, endoscopic, or radiographic means is beneficial. However, pseudocysts are initially sterile and routine drainage may result in iatrogenic infection; thus is not encouraged. In addition, percutaneous drainage may result in the formation of a persisting pancreatic-cutaneous fistula.
3. With respect to gallstone pancreatitis, which of the following statements is most correct?
   - **a.** The definitive management of gallstone pancreatitis is endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy.
   - **b.** The incidence of gallstone pancreatitis is declining.
   - **c.** Cholecystectomy is the most effective therapy to prevent recurrence.
   - **d.** Gallstone pancreatitis results from persisting bile duct obstruction by a gallstone.

   Answer: d. Gallstone pancreatitis is the most common cause of acute pancreatitis. Its incidence is increasing, reflecting the growing global obesity burden. The underlying pathophysiology results from a transient increase in intraductal pressure within the biliary tree upon stone passage from the gallbladder into the duodenum, rather than from persistent obstruction of the common bile duct by a gallstone.

   Patients with proven or suspected persisting ductal gallstones should undergo ERCP to clear the stones; in patients with prohibitive operative risk, ERCP with sphincterotomy can be used to decrease the risk of subsequent bouts of gallstone pancreatitis. However, the most effective means of preventing subsequent bouts of gallstone pancreatitis is to remove the source of the gallstones by removal of the gallbladder (cholecystectomy).

- Therapy for Venous Thromboembolism
- Inferior Vena Cava Filter

Anticoagulants
- Heparin, Heparin Derivatives, and Heparinoid
- Direct Thrombin Inhibitors
- Direct Oral Anticoagulants
- Direct Oral Thrombin Inhibitors
- Direct Oral Factor Xa Inhibitors
- Warfarin

Approach to a Critically Ill Patient With Hemorrhage or Thrombosis

In the patient with acute hemorrhage or thrombosis, the history taker must be a detective interviewing the patient, family members, and outside health care providers. Useful information includes a personal or family history of a known bleeding disorder; bleeding after previous trauma, surgery, or dental procedures; a personal history of recent bleeding, bruising, or menorrhagia; and a history of liver or kidney disease, malabsorption, or recent chemotherapy. Perhaps the most challenging is obtaining a medication history, particularly as it may relate to covert heparin exposure. The use of anticoagulants, antiplatelet agents, aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and herbs should be determined. Recently started or intermittently used medications (e.g., quinine) that may cause thrombocytopenia should be elicited. In a hypercoaguable patient, a personal or family history of a known thrombophilia defect, thrombosis, recurrent miscarriage, or stillbirth may be useful.

Laboratory Tests of Coagulation

Although not reflective of the current model of coagulation, the integrity of coagulation is routinely tested by a limited set of in vitro assays (Fig. 74.1). The prothrombin time (PT) reflects the cascade of reactions traditionally called the extrinsic pathway, whereas the activated partial thromboplastin time (aPTT) reflects the intrinsic pathway. They intersect in the common pathway. The thrombin time (TT) measures the rate of conversion of fibrinogen to insoluble fibrin polymer after thrombin is added to plasma. A prolonged TT may be due to an inhibitor of thrombin (e.g., heparin, direct thrombin inhibitor [DTI]), hypofibrinogenemia or dysfibrinogenemia, fibrin degradation products (FDPs), and, rarely, paraproteins. The only specific coagulation factor that is routinely measured is fibrinogen. These four tests can usually localize abnormalities in the coagulation cascade.

Once a coagulopathy has been identified, the next step is to determine whether it is due to a factor deficiency or a circulating inhibitor. In the inhibitor or mixing study, the patient's plasma is mixed with an equal volume of normal pooled plasma. Normalization of the coagulation test in such a "mixing study" reflects a deficiency of one or more coagulation factors. It also implies that administration of fresh frozen plasma (FFP) should correct the coagulopathy. Further diagnosis requires specific factor assays. If there is partial or no correction in the mixing study, an inhibitor is suspected, most often contaminating heparin or a lupus anticoagulant in the nonbleeding patient or a factor VIII inhibitor in the patient with bleeding.

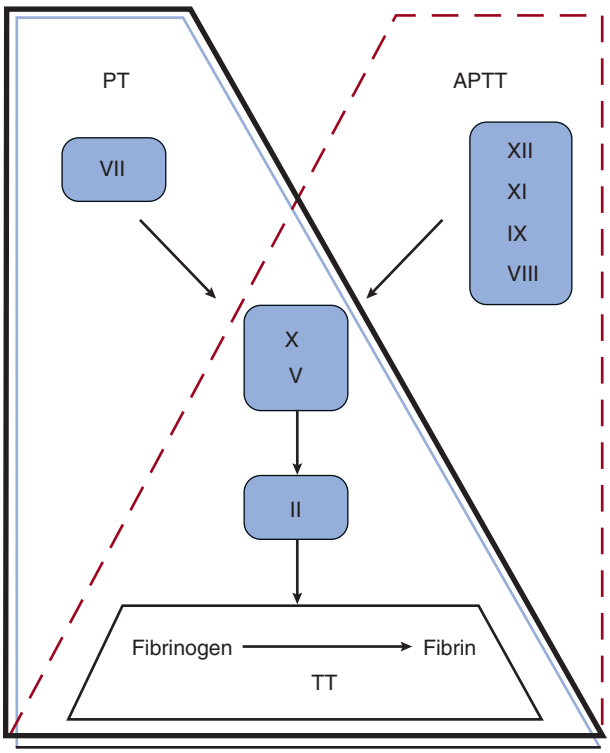
The template bleeding time (BT) is no longer used to assess in vivo platelet function given its technical issues and lack of reproducibility.

Disorders of Platelets

Thrombocytopenia

Mechanisms and General Management

Thrombocytopenia is common in the intensive care unit (ICU). It has been estimated that 23% to 50% of patients in the ICU



• **Fig. 74.1** Coagulation factors evaluated in routine coagulation assays. *aPTT,* Activated partial thromboplastin time; *IV,* intravenous; *PT,* prothrombin time; *STAT,* immediately; *TT,* thrombin time.

Hypothermia

have a platelet count below 100,000/μL, and 10% to 17% have a count below 5000/μL.[1,2] Common causes of thrombocytopenia in the ICU are shown in Box 74.1. In complex, acutely ill patients, many of these mechanisms may operate simultaneously. Sepsis is the most common cause of thrombocytopenia in the ICU.[2]

• BOX 74.2 Drugs Commonly Causing Thrombocytopenia in the Intensive Care Unit

Abciximab
Carbamazepine
Cephalosporins
Clopidogrel
Digoxin
Eptifibatide
Heparins
Hydrochlorothiazide
Linezolid
Quinidine
Quinine
Ranitidine
Tirofiban
Trimethoprim/sulfamethoxazole
Valproic acid
Vancomycin

Frequently, thrombocytopenia must be managed without a specific diagnosis. Medications should be reviewed for potential offending agents.[3,4] Inhibitors of platelet function should be avoided with platelet counts below 50,000/μL. Although not always evidence based, if there is bleeding or if invasive procedures are anticipated, platelet transfusions should be given, unless contraindicated. A platelet count above 20,000 to 50,000/μL may be used depending on the procedure.[2] In life-threatening situations, the goal should be a platelet count higher than 100,000/μL. In nonbleeding patients, maintenance of a platelet count above 10,000/μL (20,000/μL with fever or infection) with prophylactic transfusions is usually adequate.[2,5]

Although an uncommon cause of thrombocytopenia, hemophagocytic syndrome needs to be considered in any acutely ill patient with multisystem disease.

Pseudothrombocytopenia

Pseudothrombocytopenia is a laboratory artifact.[2,6] The platelet count is factitiously lowered because of the presence of naturally occurring antibodies that cause platelet agglutination in the presence of ethylenediamine tetraacetic acid (EDTA) at room temperature. The diagnosis is suspected by finding platelet clumps on the peripheral blood smear. Repeating the platelet count with a different anticoagulant such as citrate generally produces a normal platelet count.

Drug-Induced Thrombocytopenia

A limited number of drugs have evidence-based data to support a causal role in the development of thrombocytopenia.[3,4,7,8] Medications commonly used in the ICU can cause thrombocytopenia (Box 74.2). Drug-induced thrombocytopenia most commonly occurs 7 to 21 days after exposure to the offending agent. Clinical manifestations can range from an asymptomatic decrease in platelets to life-threatening bleeding. The diagnosis is established by (1) finding a temporal relationship between starting the drug and the fall in the platelet count, (2) having no alternative diagnosis, and (3) having the platelet count recover after removal of the putative offending agent. Unfortunately, this is usually difficult to establish in the typical ICU patient. Treatment is based on removing the putative offending agent and initiating a drug of another class if

possible. Although often used, steroids in general have not been shown to hasten the rate of platelet recovery. In severe thrombocytopenia with bleeding such as seen with quinine, intravenous immunoglobulin (IVIG) (1 g/kg per day for 2 days) and platelet transfusion are beneficial.

Glycoprotein IIb/IIIa Inhibitors

All platelet glycoprotein IIb/IIIa inhibitors have been associated with severe thrombocytopenia that can occur within hours of exposure (up to 2 weeks with abciximab).[7] Heparin-induced thrombocytopenia (HIT) is the main differential diagnosis. Bleeding is very uncommon with HIT because of the strong prothrombotic state. Conversely, with glycoprotein IIb/IIIa inhibitor–associated thrombocytopenia, bleeding or hematoma formation may occur, especially at the site of the sheath. A platelet count less than 20,000/μL and clinical bleeding are indications for platelet transfusion. The use of IVIG and corticosteroids is not evidence based.

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura results from the destruction of immunoglobulin (Ig) G–coated platelets in the reticuloendothelial system, primarily the spleen. There is no significant compensatory increase in thrombopoiesis. Anemia, if present, may be autoimmune (Evans syndrome) or due to bleeding and iron deficiency. Immune thrombocytopenia may be primary (idiopathic [ITP]) or secondary. The differential diagnosis includes pseudothrombocytopenia; immune thrombocytopenia secondary to systemic lupus, human immunodeficiency virus (HIV) infection, or hepatitis C; and drug-induced thrombocytopenia.

Guidelines for the diagnosis and management of ITP have been developed.[9,10] Indications for therapy in ITP are platelet count less than 20,000 to 30,000/μL or clinical bleeding. Corticosteroids (pulse dexamethasone, 40 mg/day for 4 days, or prednisone, 1 mg/kg per day) are the usual initial therapy for ITP.[9,10] Individuals with ITP in the ICU usually have severe or life-threatening bleeding. Several modalities of therapy should be used in concert to raise the platelet count in urgent situations (methylprednisolone, 1 g/day for 3 days, and IVIG, 1 g/kg per day for 2 days). Although platelets may be destroyed quickly, platelet transfusions should still be used as initial therapy. The response to platelet transfusion may improve after IVIG is given. Anti-Rh(D) IgG (WinRho), 50 to 75 μg/kg, has also been used.[11] Because the dose of anti-Rh(D) must be reduced in the face of anemia, its use may be problematic in a patient with severe bleeding. Anti-Rh(D) IgG is ineffective in Rh-negative patients and after splenectomy. ε-Aminocaproic acid (4–5 g intravenous [IV] followed by either 2–4 g IV every 4 hours or 0.5–1.0 g/h continuous IV infusion [maximum 24 g/24 h]) may be useful for mucosal bleeding and severe menorrhagia.

Posttransfusion Purpura

Posttransfusion purpura is a rare condition characterized by acute, severe immune-mediated thrombocytopenia. Posttransfusion purpura occurs in human platelet antigen-1 (HPA-1)-negative individuals who receive HPA-1–positive platelets (most commonly as a contaminant in packed red blood cells [RBCs]). These individuals have previously been sensitized to HPA-1 through transfusion or pregnancy. Usually 7 to 10 days after reexposure to HPA-1, an anamnestic response occurs, resulting in a precipitous fall in the platelet count. Petechiae and bleeding are common. IVIG and plasma exchange are effective.[12]

Acquired Platelet Dysfunction

Medication-Induced Abnormalities

Aspirin irreversibly acetylates cyclooxygenase (COX), inhibiting platelet function for the life of the platelet (7–10 days). The aspirin effect can be overcome with the infusion of desmopressin (DDAVP). Platelet transfusion can be tried but is not evidence based to improve outcome.[2] The effect of NSAIDs is reversible and disappears as the drug is cleared, usually within 24 to 48 hours for ibuprofen. The risk of bleeding from NSAIDs is lowest with ibuprofen and greatest with ketorolac. Three thienopyridines bind the platelet adenosine diphosphate (ADP) P2Y12 receptor. All should ideally be withheld for 7 days before invasive procedures with 5 days as a minimum for urgencies.[13,14] Clopidogrel tightly binds the platelet ADP P2Y12 receptor. In an emergency, platelet transfusion and DDAVP can be tried, but platelet function may not be fully restored because of circulating active clopidogrel metabolites, which have a half-life of 8 hours and bind to the transfused platelets.[14] Prasugrel irreversibly binds the P2Y12 receptor and has active metabolites with a 4-hour half-life and can affect platelet function. Platelet transfusion and DDAVP can be tried.[14] Ticagrelor reversibly binds the P2Y12 receptor. Its major metabolites have a 7 hour half-life. Platelet transfusion can be tried but is not evidence-based.[14] Cyclooxygenase 2 inhibitors do not affect platelet function.

Renal Failure

The hemorrhagic diathesis of renal failure is the result of metabolic derangements related to uremic toxins.[15] Bleeding may worsen when the hematocrit falls below 30% owing to a rheologic phenomenon in which rapidly flowing RBCs gravitate to the center of the streaming blood and force the platelets toward the vessel wall.[16] Uremic bleeding is uncommon in the modern era of dialysis.[16] For clinical bleeding, IV DDAVP (0.3 μg/kg given over 30 minutes) is often therapeutic.[15] If the hematocrit is less than 30%, the patient should have a transfusion of packed RBCs.[15,16] An alternative to DDAVP is cryoprecipitate (10 bags every 12–24 hours).[15] IV conjugated estrogen (0.6 mg/kg per day for 5 days) is also effective.[15] An unexpected "coagulopathy" (prolonged aPTT and TT) may develop as a result of delayed clearance of heparin after dialysis. If available, an anti–factor Xa assay will show the presence of heparin.

Thrombocytosis

Although not as common as thrombocytopenia, reactive thrombocytosis often the result of splenectomy, surgery, or bleeding may be seen in the ICU. Reactive thrombocytosis does not have an increased risk of thrombosis. Antiplatelet therapy is not needed even for platelet counts higher than 1,000,000/μL.

Complex Thrombohemorrhagic Disorders

Heparin-Induced Thrombocytopenia

Although commonly looked for, HIT is an uncommon cause of thrombocytopenia in the ICU.[2,17] HIT is a paradoxical condition in which modest thrombocytopenia may be associated with devastating thrombosis. Thus the entire health care team needs to be vigilant for the development of HIT in any patient receiving heparin. HIT has been associated with all types of heparin (unfractionated [UFH] and low–molecular-weight [LMWH]), at any dose, and by any route, including flushes and heparin-coated catheters.[1,18] The incidence of HIT has been estimated to be less than 1% of patients

in the ICU.[2,17,19] HIT occurs in three time intervals. Classic HIT occurs 5 to 15 days after the initiation of heparin. Rapid-onset HIT develops hours to 1 to 2 days after heparin therapy is started in individuals who have preformed circulating antibodies from a previous exposure to heparin, usually in the past 2 months. Classic and rapid-onset HIT may be manifested as thrombocytopenia with or without thrombosis. Delayed-onset HIT occurs an average of 12 days after the discontinuation of heparin and is manifested as isolated thrombosis. Rare cases of true autoimmune HIT without heparin exposure have been described. The thrombocytopenia of HIT is usually modest with an average platelet count of 50,000 to 60,000/μL.[20] Severe thrombocytopenia (<10,000/μL) should suggest an alternative diagnosis. HIT may be associated with a normal platelet count if there is a baseline thrombocytosis (e.g., postoperatively). HIT may be manifested as isolated thrombocytopenia or thrombocytopenia with potentially devastating thrombosis. Venous complications include deep vein thrombosis (DVT), pulmonary embolism (PE), cerebral sinus thrombosis, infarctive adrenal hemorrhage, and skin necrosis at the heparin injection site. Arterial complications include iliofemoral artery thrombosis, digital ischemia, myocardial infarction, stroke, and mesenteric artery thrombosis.

• BOX 74.3 Clinical Situations to Suspect Heparin-Induced Thrombocytopenia

Current Use of Heparin or Heparin Exposure Within 40 Days and at Least One of the Following:

- Platelets <100,000/μL
- Platelets <50% of baseline or <50% of the maximum level if reactive thrombocytosis is present
- Platelets less than baseline 5 days after open heart surgery
- New arterial or venous thrombotic event
- Inflammation or necrosis at heparin injection sites
- Acute allergic or anaphylactic reaction to a heparin bolus

Recent Admission to a Hospital, Nursing, or Rehabilitation Facility Plus

- A new venous thromboembolic event
- A new arterial ischemic event

HIT is an immune-mediated process in which the heparin–platelet factor 4 complex becomes immunogenic. Antibodies are formed that activate platelets, causing the release of thrombogenic microparticles.[17,20,21] The antibodies can also activate monocytes and endothelial cells.

The diagnosis of HIT is clinicopathologic. HIT should be thought of in appropriate clinical situations (Box 74.3). The "4T" score has been used to predict the likelihood (pretest probability) of HIT (Table 74.1).[17,22] The HIT Expert Probability score, devised by an expert consensus panel, has also been validated.[23] Although the decision to initiate therapy should be based on the clinical likelihood of HIT, laboratory testing should be used for the retrospective confirmation of the pretest likelihood of HIT. The complexities of HIT antibody testing are reviewed elsewhere.[17,21,24,25] In general, a strongly positive HIT enzyme-linked immunosorbent assay (ELISA) and strongly positive serotonin release assay (SRA) with a high pretest probability confirm the diagnosis of HIT, whereas a negative ELISA and SRA make the diagnosis of HIT unlikely with a low pretest probability. In other situations, clinical judgment prevails in establishing or excluding a diagnosis of HIT, especially because ELISA and SRA testing from commercial laboratories has not been validated in clinical studies.[1,17,24]

Once the diagnosis of HIT is thought to be likely, all heparin should be discontinued. Heparin-coated pulmonary artery catheters should be replaced with noncoated catheters. Catheters for dialysis or apheresis should be locked with 4% citrate or tissue plasminogen activator. The patient's chart and bedside should be labeled *heparin allergy.* Platelet transfusions should be avoided except for life-threatening bleeding, given the anecdotal observations of acute thrombosis occurring after platelet transfusion. A patient with life- or limb-threatening arterial thrombosis should be evaluated for surgical intervention. Anticoagulation with a DTI should be initiated in all patients unless contraindicated. Fondaparinux is a factor Xa inhibitor, but unlike direct factor Xa inhibitors, it mediates its effects indirectly through antithrombin (AT) III, and unlike heparin, it is selective for factor Xa. Although not approved by the U.S. Food and Drug Administration (FDA) because of lower cost, fondaparinux has been used off-label in some centers.[25] LMWH is contraindicated in HIT caused by UFH. Bridging to warfarin can be considered after a minimum of 5 days of DTI therapy if the platelet count has returned to normal (suggesting that the

process has cooled off and the patient is no longer hyperprothrombotic) and no future invasive procedures are planned. Simply discontinuing heparin therapy and not starting a DTI is inappropriate because occult thrombosis may have already developed.[26] Starting or continuing warfarin monotherapy is also contraindicated because of the risk of venous limb gangrene.[27] If warfarin has been given at the time HIT is diagnosed, vitamin K should be given to replenish proteins C and S. If invasive procedures are needed (e.g., tracheostomy, pacemaker), it is best to delay them, if medically safe, until the platelet count is normal to minimize the risk of developing thrombosis during the time that DTI therapy is withheld. Inferior vena cava (IVC) filters should be avoided because of the risk of vena cava thrombosis. Patients with active HIT may need percutaneous coronary intervention (PCI). Bivalirudin and argatroban have been approved by the Food and Drug Administration (FDA) for use during PCI in patients with HIT.[28,29] In a patient who has active HIT or persistent HIT antibodies and who needs open heart surgery, medical management is recommended until the antibody becomes negative. If urgent surgery is needed, bivalirudin is most commonly used.[30] For the patient with a past history of HIT who needs open heart surgery and is currently HIT ELISA and serotonin release assay antibody negative, heparin can be used during bypass and a DTI started as soon as it is surgically safe postoperatively.[30,31]

Thrombotic Microangiopathies

There are three thrombotic microangiopathies with overlapping clinical features: thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and atypical hemolytic uremic syndrome.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a relatively rare disorder whose hallmarks are thrombocytopenia, microangiopathic hemolytic anemia (MAHA), and neurologic dysfunction. The diagnosis of TTP should be considered in any patient with unexplained thrombocytopenia and MAHA.[32] TTP is the clinical manifestation of a heterogeneous group of underlying disorders driven by different pathophysiologic processes. Although most cases of TTP are idiopathic, TTP may be associated with exposure to drugs (e.g., quinine, proteasome inhibitors, oxaliplatin, gemcitabine, quetiapine, oxymorphone), pregnancy, and HIV infection.[33,34] The morphologic hallmark of TTP is hyaline thrombi in precapillary arterioles composed primarily of platelets. Classic TTP is due to an immune-mediated deficiency of the metalloproteinase ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13), which cleaves ultralarge multimers of von Willebrand factor (vWF) into smaller forms that are less platelet reactive.[35] Deficiency of this enzyme allows ultralarge forms of vWF that are normally sequestered in the endothelium to bind platelets and form microthrombi in the circulation. ADAMTS13 activity is low in classic TTP. Conversely, ADAMTS13 activity is normal in TTP, associated with bone marrow transplantation and in the hemolytic-uremic syndrome (HUS).[33,35] Organ dysfunction is due to microvascular thrombosis. Commonly involved organs are the brain, kidneys, heart, and pancreas. It is critical to establish the diagnosis quickly because TTP can be rapidly fatal if not properly treated.

The core laboratory features of TTP are those of MAHA (more than two schistocytes per oil immersion field on a peripheral smear, increased lactate dehydrogenase, and very low haptoglobin). ADAMTS13 activity is less than 10%. The differential diagnosis includes classic and atypical HUS, disseminated intravascular coagulation (DIC), severe vasculitis, eclampsia, HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) syndrome, malignant hypertension, sepsis, catastrophic antiphospholipid syndrome, and malignancy, particularly metastatic adenocarcinomas.

Once the diagnosis of TTP is thought to be likely, therapy should be initiated quickly because of the proclivity of the disease to progress rapidly. All patients should initially be treated in the ICU. Platelet transfusions should be avoided except for life-threatening bleeding because of anecdotal reports of acute decompensation after platelet transfusions. A large-bore catheter will need to be placed, even in the face of severe thrombocytopenia, because the mainstay and only evidence-based component of therapy for TTP is plasma exchange.[36,37] Most commonly, 1.5 plasma volumes of FFP are exchanged daily. A clue that TTP is the correct diagnosis is the color of the plasma removed from the first plasmapheresis. A red or brown color suggests free hemoglobin or methemoglobin from intravascular hemolysis. If plasma exchange cannot be initiated in a timely manner, infusion of 30 mL/kg of FFP daily can be a temporizing maneuver.[36] Corticosteroids (e.g., prednisone, 1 mg/kg per day) are commonly used as well.[37] The use of vincristine is controversial.[38] In patients who do not respond to initial therapy, rituximab is an attractive second-line therapy.[33,39,40]

Hemolytic-Uremic Syndrome

HUS, the triad of thrombocytopenia, MAHA, and acute kidney injury, is most commonly due to infection with Shiga toxin–producing *Escherichia coli* in children.[41] Adult atypical HUS (aHUS) is not Shiga toxin associated. It may be idiopathic or associated with medications (calcineurin inhibitors [cyclosporin, tacrolimus, sirolimus, gemcitabine bevacizumab, interferon]), stem cell transplantation, and cancer.[33,41] aHUS is a complement deposition disease. Mutations in complement regulator proteins are found in approximately 50% (complement factors H and I, membrane cofactor protein/CD46 [MCP], factor B [FB]) as well as in nonregulatory proteins (thrombomodulin [THBD], diacylglycerol kinase epsilon [DGKE]). Although not as efficacious as when used for TTP, plasma exchange should be initiated when aHUS is suspected until the diagnosis can be confirmed and the anti-C5 antibody eculizumab (Soliris), which has been FDA approved for the treatment of aHUS, has been obtained.[42,43] Plasma exchange may be continued if there appears to be a response. Supplemental eculizumab dosing is required after each plasma exchange.[44] Patients need to receive quadrivalent meningococcal vaccine and possibly meningococcal B vaccine before starting eculizumab.[45]

Disseminated Intravascular Coagulation

DIC is always a manifestation of a severe underlying pathologic process (Box 74.4). The final common pathway is the generation of thrombin, which produces microthrombi that can lead to organ dysfunction.[46] In the process, natural anticoagulants are consumed and fibrinolysis is activated. Circulating FDPs, along with the consumption of platelets and coagulation factors, lead to a bleeding diathesis. The balance between these competing processes results in the clinical manifestations in any particular individual.

The clinical manifestations of DIC are protean. Microvascular thromboses produce ischemia in many tissues, including the brain (delirium, coma), skin (digital gangrene, purpura fulminans), kidney, lungs (acute respiratory distress syndrome), gastrointestinal tract (mucosal ulceration), and blood (MAHA). The bleeding associated with DIC is due to the combination of depletion of coagulation

factors, thrombocytopenia, inhibitory effects of FDPs on coagulation and platelet function, and tissue necrosis with ulceration. Common manifestations are intracerebral hemorrhage, global oozing at lines and venipuncture sites, hematuria, epistaxis, and gingival and gastrointestinal bleeding.

There are no strict evidence-based laboratory criteria for the diagnosis of DIC.[46] The diagnosis is based on identifying an underlying predisposition, the clinical features, and laboratory testing. The most common laboratory features of DIC are thrombocytopenia, elevated FDP or D-dimers, and decreased fibrinogen. The PT and aPTT may or may not be prolonged, depending on the sensitivity of the assay, degree of baseline elevation of coagulation factors as acute-phase reactants, the rate of consumption of coagulation factors, and the amount of FDPs released. An absolute decrease in fibrinogen is very suggestive of DIC. However, fibrinogen activity in the normal range may still be consistent with DIC because fibrinogen is an acute-phase reactant and its level may be inappropriately low for the underlying physiologic state.[47] Serial measurement of fibrinogen is often useful. Schistocytes are seen in half the cases. Although the natural anticoagulants AT (previously called AT-III) and proteins C and S are decreased, and thrombin-AT complexes are increased, their levels usually cannot be measured in real time and are of limited clinical value.

The International Society on Thrombosis and Haemostasis has developed a scoring system for the identification of overt DIC using four commonly available tests (platelets, PT, FDPs such as D-dimer or soluble fibrin monomer, and fibrinogen) that has been prospectively validated.[48,49] It is important to remember that all the laboratory abnormalities seen in DIC can be caused by other disease processes. Vitamin K deficiency,[50] a heparin-contaminated blood sample, or a lupus anticoagulant can cause a coagulopathy, whereas elevations in FDPs can be seen with metastatic cancer or can be found after surgery or trauma. Other microangiopathies cause thrombocytopenia and RBC fragmentation. Liver failure can produce a constellation of laboratory abnormalities indistinguishable from those observed in DIC.[51]

The most important principle in the management of DIC is to treat the underlying cause. If the driving process cannot be controlled, the DIC will progress unabated. Hypothermia and acidosis should be corrected because they interfere with the function of coagulation factors.

If the diagnosis is suspected only because of laboratory abnormalities, management should be conservative. Alternative, potentially correctable processes should be kept in mind, such as vitamin K deficiency and drug-induced thrombocytopenia.

If clinically significant bleeding becomes apparent, a patient with overt DIC should receive blood component therapy (cryoprecipitate if fibrinogen <100 mg/dL, FFP, and platelets). A realistic goal is to keep the fibrinogen level above 150 mg/dL and the platelet count greater than 50,000/μL. Heparin is not routinely used for the treatment of DIC. Heparin may be helpful for thrombotic or ischemic manifestations.[52] Other treatment modalities have been tried in DIC. The use of AT concentrates showed no significant decrease in mortality rate.[53] Activated protein C (drotrecogin alfa) used for the treatment of sepsis has been withdrawn from the U.S. market. Because of the intense fibrinolytic activity in DIC, antifibrinolytic agents (ε-aminocaproic acid and tranexamic acid) have been tried in an attempt to reduce bleeding. In general, failure rates have been quite high, and serious thromboses have occurred because the lysis of diffuse microthrombi was suppressed.[54]

Catastrophic Antiphospholipid Syndrome

Catastrophic antiphospholipid syndrome is an uncommon disorder manifested as multiple-organ dysfunction secondary to microvascular thrombi. The diagnosis should be considered in patients with an acute onset of three or more of the following: respiratory failure, stroke or other neurologic impairment, abnormal liver function, renal impairment, skin infarction, and thrombocytopenia. Laboratory testing should show evidence of antiphospholipid antibodies. Although not evidence based, empiric therapy has centered around the combined use of high-dose corticosteroids, anticoagulation, and plasma exchange or IVIG.[52]

Disorders of Hemostasis

It has been estimated that 16% of ICU patients have bleeding caused by a coagulation defect and another 66% have abnormal coagulation test results.

Artifacts

A common cause of an unexplained prolongation of the aPTT is unsuspected heparin in the line from which the blood was drawn. A diagnostic clue is a prolonged TT with a normal fibrinogen. A heparin level (anti–factor Xa assay) will confirm the diagnosis. Although venous access is often an issue in the ICU, blood for coagulation studies should be drawn by venipuncture if possible.

Coagulation Factor Abnormalities

Acquired Deficiencies of Procoagulants

Vitamin K Deficiency

Vitamin K is essential for the posttranslational modification (γ-carboxylation) of factors II, VII, IX, and X and proteins C, S, and Z. The daily requirement of vitamin K is 50 μg. Normal daily

intake of vitamin K is 200 μg from the diet and 200 μg from intestinal flora. Thus vitamin K deficiency occurs commonly in the ICU in the patient who is not being fed and who is receiving antibiotics that alter the gut flora. Vitamin K stores last approximately 1 week.

Because factor VII has the shortest half-life (~4 hours), early vitamin K deficiency is manifested by an isolated prolongation of the PT. As factors II, IX, and X become depleted, the aPTT will become prolonged. Vitamin K deficiency is common in critically ill patients and may result in serious bleeding.[50] Treatment of vitamin K deficiency depends on the clinical situation. In a nonbleeding patient, vitamin K should be given enterally if the gut is working. Subcutaneous vitamin K should be avoided if the gut is working because of its erratic absorption, especially in face of impaired tissue perfusion, and because anaphylactic reactions have been reported with subcutaneous vitamin K.[55] In a bleeding patient, FFP will correct the coagulopathy most quickly. In critically ill patients with an urgent need for vitamin K replacement, phytonadione may be administered intravenously if the benefits are thought to outweigh the risk of anaphylaxis. Vitamin K should be given no faster than 1 mg/min with cardiorespiratory monitoring because anaphylactic reactions can occur even at this slow infusion rate.[55] One milligram of vitamin K twice a week can prevent vitamin K deficiency.

Liver Disease

The perturbation of hemostasis in liver disease is complex. All hemostatic factors except for vWF and plasminogen activator inhibitor-1 are synthesized in the liver. Loss of the ability to synthesize factor VII is disproportionately greater in patients with liver disease than in those receiving warfarin. Thus the bleeding risk of a prolonged international normalized ratio (INR) from liver disease is not as great as the same INR with warfarin therapy.[56] As outlined later, changes in factor VIII/vWF and decreased synthesis of natural anticoagulants and fibrinolytic proteins may help keep the patient with liver disease in hemostatic balance,[51] making the autoanticoagulation of liver disease promulgated among house staff a myth.

Although hepatic dysfunction is most commonly associated with bleeding, the risk of thrombosis has been underappreciated.[51] Synthesis of hemostatic proteins becomes impaired when the albumin falls below 2.5 g/dL. Similar to vitamin K deficiency, the earliest abnormality is a reduction in factor VII. In more severe liver disease, the other coagulation factors become deficient. Factor V and fibrinogen do not usually decrease significantly until the liver failure is severe. In contrast, the activities of factor VIII and vWF are normal or elevated. AT, proteins C and S, and plasminogen are decreased. Hepatic clearance of activated procoagulants and FDP is reduced. Thrombocytopenia may develop owing to decreased thrombopoietin production or splenic sequestration. Advanced liver disease may also be complicated by vitamin K deficiency from malnutrition and decreased vitamin K absorption owing to cholestasis.

A variety of approaches have been used to treat the coagulopathy of liver disease. If the patient is not bleeding, a trial of vitamin K can be given for 3 days to see if the coagulopathy corrects. Because all patients with liver disease have some degree of biliary obstruction and fat malabsorption, the subcutaneous route has been preferred over oral administration. Although the risk of anaphylaxis with IV and subcutaneous vitamin K is low, it is not generally recommended empirically in a patient with liver disease because of the low likelihood that vitamin K will completely correct the coagulopathy.[55] If bleeding is a problem, FFP should be administered. Because the relationship between the levels of coagulation factors and the PT/aPTT is nonlinear, the greater the prolongation of the PT and aPTT, the greater the chance of correction with FFP. However, it is difficult to normalize the PT.[57] On average, 1 unit of FFP increases all coagulation factors by 6% to 7%. A typical patient with the coagulopathy of liver disease may have approximately 10% to 15% of the normal level of coagulation factors. If a factor level of 50% of normal is needed for hemostasis, 6 units of FFP would be expected to correct the bleeding diathesis. The PT and aPTT may still be prolonged, however, depending on the sensitivities of PT and aPTT assays. The PT (and aPTT) should be checked immediately after the FFP is administered. Given the short half-life of factor VII, waiting until the next morning's routine blood draw will produce a prolongation of at least the PT and give the impression that the coagulopathy is uncorrectable.

Massive Transfusion

Massive volume replacement (>1 blood volume in <24 hours) may not give the liver sufficient time to replace coagulation factors. In a hemodynamically stable patient, coagulation studies should be followed serially and FFP infused when a coagulopathy develops. Conversely, exsanguinating patients should be managed with balanced transfusion of RBC:FFP:platelets in a ratio of 1:1:1 (either 1 unit of single donor or 6 units or random donor platelets).[58]

Acquired Circulating Inhibitors

Factor VIII Inhibitors

The clinical manifestations of factor VIII inhibitors can range from an unexplained prolongation of the aPTT to severe bleeding. The aPTT is markedly prolonged with a normal BT, PT, TT, and fibrinogen. The mixing study does not correct. Further evaluation includes factor VIII, IX, XI, and XII activities and a lupus anticoagulant panel. Hematomas should not be drained except in severe circumstances (e.g., compartment syndrome) because of the risk for bleeding, even with replacement therapy. Treatment options depend on the severity of the inhibitor. A low-titer inhibitor (<5 Bethesda units [BU]) may be treated with factor VIII infusion (200 U/kg every 8–12 hours). For a high-titer antibody (≥5 BU), the treatment options are recombinant human factor VIIa (rH-VIIa; NovoSeven) and virally inactivated concentrates containing activated coagulation factors (FEIBA [factor eight inhibitor bypass activity]). The dose of rH-VIIa is 90 μg/kg, which can be repeated every 2 hours until the bleeding stops. rH-VIIa carries a risk of thrombotic and ischemic events even in individuals with severe coagulopathy.[59] Coagulation studies are not used to adjust the dose. The PT always falls below the lower end of normal. The FEIBA dose is 50 to 100 U/kg, which is repeated every 6 to 12 hours (maximum daily dose 200 U/kg per day owing to thrombotic risk). A total of 500 units of heparin can be added to each bag to prevent infusion phlebitis. The response to FEIBA is monitored clinically. The choice of rH-VIIa versus FEIBA should be dictated by local practice.

Factor V Inhibitor

Topical thrombin (a.k.a. fibrin glue) is used to achieve hemostasis with many invasive procedures. Bovine thrombin is contaminated with factor V. Approximately 7 to 10 days after the use of fibrin glue, the PT and aPTT may prolong as a result of the development of antibodies against bovine factor V and rarely factor II. Bleeding

is uncommon because platelet factor V is protected from the antibody.

Inherited Deficiencies of Procoagulants

Management of critically ill patients with inherited coagulopathies requires specialized expertise. A hematologist or coagulationist should be consulted. Laboratory measurement of coagulation factor activity should be available on site.

von Willebrand Disease

von Willebrand disease (vWD) is the most common inherited coagulopathy. Synthesized in the vascular endothelium and megakaryocytes, vWF is the ligand that binds to the platelet GP Ib/IX/V complex and promotes platelet adhesion in vivo. vWF is a complex multimeric protein, with the largest molecular weight forms having the greatest platelet-binding capacity. Factor VIII procoagulant, which is synthesized by the liver, circulates bound to vWF.

vWD is inherited in an autosomal dominant manner with partial penetrance. The clinical features, diagnosis, and subclassification of vWD are reviewed elsewhere.[60]

Patients with vWD in the ICU most commonly have had major surgery, closed head trauma, major trauma, or life-threatening hemorrhage. The goal of therapy is to increase vWF activity and factor VIII activity to 100% of normal and to maintain them above 50%. Two virally inactivated factor VIII concentrates available in the United States (Humate-P and Alphanate) are rich enough in vWF to be of clinical use for treating vWD. The dose is 40 to 50 U/kg of vWF followed by 20 to 25 U/kg every 12 hours. Peak and trough levels of factor VIII (and vWF activity if available) should be obtained to help guide therapy. Doses should be rounded to the size of the nearest vial, if possible, so that these expensive factors are not wasted. The other brands of factor VIII concentrate do not contain enough vWF to be of clinical value in vWD. rH-VIII, used in hemophilia A, is of no benefit in vWD. In an emergency situation in a smaller facility that does not stock hemostatic factors on site, cryoprecipitate can be used at a dose of 2 bags per 5 kg followed by 1 bag per 5 kg every 12 hours until the patient can be transferred to a referral center. In mild cases of type I vWD, DDAVP may be adequate for promoting hemostasis in known DDAVP responders. Repeat doses may be given every 12 hours, although tachyphylaxis will likely develop as the result of exhaustion of vWF stores in the Weibel-Palade bodies of the endothelium. Patients should be monitored for hyponatremia, especially if large volumes of fluid are given.

Factor VIII Deficiency

Factor VIII deficiency (hemophilia A) is an X-linked recessive disorder that occurs in approximately 1 in 10,000 Caucasian males. Bleeding characteristically occurs in the joints, soft tissues, and gastrointestinal tract. Although the platelet count should be normal, individuals with hemophilia A complicated by hepatitis C or HIV infection (primarily from exposure to contaminated blood products before the era of viral inactivation) may have a concomitant immune thrombocytopenia.

For major surgery, closed head trauma, major trauma, or life-threatening hemorrhage, the factor VIII level should be raised to 100% and then maintained continuously above 50% for the first 5 to 7 days and above 40% for an additional 5 to 7 days. rH-factor VIII is the treatment of choice because it has no risk of viral infection. Infusing 1 unit of factor VIII per kilogram should raise the plasma factor VIII activity by 2%. Thus the initial dose is 50 U/kg followed by 25 U/kg every 8 hours. Peak and trough factor VIII levels should be obtained after the first dose and at least daily. In an emergency situation if rH-factor VIII is not available, virally inactivated factor VIII would be the treatment of choice. The dosing schema is similar to that of rH-factor VIII. In an emergency situation in a smaller facility that does not stock hemostatic factors on site, cryoprecipitate can be given every 8 hours until the patient can be transferred. Similar to vWD, DDAVP can be given for mild or moderate factor VIII deficiency in known DDAVP responders. As the hemophilia population ages, coronary artery disease is becoming an increasing problem. Individuals with hemophilia A should be supported through indicated cardiac procedures and surgery.[61]

Factor IX Deficiency

Except for the rate of spontaneous mutations, the clinical picture of factor IX deficiency (hemophilia B) is indistinguishable from that of hemophilia A. The laboratory features are similar except factor IX activity is decreased and factor VIII activity is normal. The treatment of choice is rH-factor IX. Because of differences in the volume of distribution compared with rH-factor VIII, the initial loading dose of rH-factor IX is 100 U/kg followed by half the dose every 12 hours. At least 30% of individuals require a higher dose. Thus it is not unreasonable to start with a dose of 125 U/kg, especially in a patient you do not want to underdose. Peak and trough levels should be monitored. If rH-IX is not available in an emergency situation, virally inactivated prothrombin complex concentrate (PCC) can be used. The initial dose is factor IX 100 U/kg followed by 50 U/kg every 12 hours. DDAVP and cryoprecipitate are not effective.

Factor XI Deficiency

Factor XI deficiency is an autosomal recessive disorder most commonly seen in Ashkenazi Jews. The bleeding history is variable, ranging from menorrhagia to bleeding with delivery or surgery. Therapy depends on the clinical situation and the patient's past bleeding history.[62] For severe deficiency, FFP (10–20 mL/kg followed by 3–6 mL/kg every 6 hours) is used. The goal is factor XI activity greater than 40% to 45%. Antifibrinolytic therapy may also be of value. Individuals with factor XI deficiency may be seen in the ICU because factor XI deficiency is not protective against coronary artery disease as was once thought.[63,64] These individuals may require emergency cardiac catheterization with PCI or coronary bypass.[63] Clopidogrel, prasugrel, and aspirin have been given safely.[63,64,65]

Venous Thromboembolism

Venous thromboembolism (VTE) is common in critically ill patients. Twenty-nine percent of medical ICU patients have been found to have asymptomatic lower extremity DVT, although 5.8% and 4.2% have symptomatic DVT and pulmonary emboli (PE), respectively.[66] Most patients admitted to the ICU have multiple risk factors, including recent surgery, trauma, sepsis, malignancy, immobilization, stroke, advanced age, heart or respiratory failure, previous VTE, and indwelling catheters.[66–68]

Deep Venous Thrombosis Prophylaxis

All patients admitted to the ICU should be evaluated for their perceived risk of thrombosis and bleeding.[66] The International Medical Prevention Registry on Venous Thromboembolism

(IMPROVE) score and Caprini score have been used for medical and surgical patients, respectively.[69,70] In medical patients, options for pharmacologic prophylaxis are LMWH and UFH, whereas mechanical prophylaxis is recommended for those with a high risk of bleeding.[66] Beyond the size limitations of this chapter, specific recommendations for DVT prophylaxis are available for trauma, abdominal/pelvic, thoracic, cardiac, and neurologic surgery.[71]

Therapy for Venous Thromboembolism

In the noncritical care setting, VTE is routinely treated with either (1) at least 5 days of UFH, LMWH, or fondaparinux, followed by warfarin or (2) a direct oral anticoagulant (DOAC).[72] In the ICU, IV UFH is the safest mode for immediate anticoagulation given its rapid reversibility for procedures or bleeding. LMWH has the disadvantages of a longer half-life and being only partially reversed with protamine. As discussed in the following section on anticoagulation, fondaparinux should not be used routinely in the ICU. ICU patients should not be transitioned to warfarin given their risk of bleeding and frequent need for invasive procedures. Warfarin is hard to regulate because of frequent drug interactions (especially with antibiotics) and erratic oral intake. Warfarin may stick to feeding tubes.[73] Warfarin is absorbed in the upper small bowel and may not be absorbed if given via J-tube.[74]

Inferior Vena Cava Filter

Approximately 80% of PE occur as a result of a lower extremity DVT. IVC filter placement is indicated in two situations: (1) acute DVT and a contraindication to anticoagulation (e.g., recent intracranial hemorrhage or stroke, recent neurologic or ophthalmologic surgery, active gastrointestinal hemorrhage, cerebral metastasis with a high risk of bleeding [e.g., melanoma, renal cell, seminoma][75]), and (2) recurrent PE despite therapeutic anticoagulation. Filters may have some benefit in face of PE causing hypotension.[72] IVC filters are not indicated for PE without DVT. IVC filters do not eliminate all risk of PE and their routine use does not decrease mortality rates.[72,76]

Anticoagulants

A variety of parenteral and oral anticoagulants acting through different mechanisms are commercially available with many more in development. The University of Washington Pharmacy Department Anticoagulation Service has an excellent reference website (http://depts.washington.edu/anticoag/home/).

Heparin, Heparin Derivatives, and Heparinoid

Heparin

Heparin is a glycosaminoglycan that anticoagulates blood by augmenting the activity of AT.[77] Complexes of heparin and AT inhibit thrombin, factor Xa, and other procoagulant proteases. The first five sugars of heparin bind to AT. The additional sugars determine the protein binding properties and pharmacokinetics of UFH and LMWH.[77]

Unfractionated Heparin

Binding of heparin to AT varies markedly between individuals, making monitoring a requirement. The anti–factor IIa property of heparin is measured by the aPTT. Because the anti-IIa and anti-Xa properties of UFH are equal, UFH may be monitored by the aPTT or by heparin (anti-Xa) level.

The goal of therapeutic heparin is to maintain the aPTT in a range that corresponds to a heparin level of 0.3 to 0.7 U/mL.[77] Given the marked variability in aPTT response to heparin because of differences in reagents and laboratory equipment, this range needs to be determined in each laboratory. An aPTT ratio of 1.5 to 2.5 times the control value correlates very poorly with the anti-Xa heparin assay and should not be used. The dose of heparin is weight based. No adjustments are needed for obesity, hepatic dysfunction, or renal impairment.[78,79] The hemoglobin and platelet count should be monitored daily as surveillance for occult bleeding and HIT. Overanticoagulation with heparin can usually be managed by simply interrupting the infusion. With serious bleeding, heparin can be reversed immediately with IV protamine sulfate.[77] One milligram of protamine will neutralize 100 units of heparin. If bleeding occurs during the constant infusion, the amount of heparin given during the previous 2 hours should be used for the calculation. Thus a patient who is bleeding after a 5000-unit heparin bolus will need 50 mg of protamine, whereas a patient receiving a 1250 U/h infusion will need only 25 mg of protamine. Protamine should be given slowly over 1 to 3 minutes to minimize the risk for hypotension and bradycardia. The risk for anaphylaxis is increased in those who have received protamine zinc insulin or who have had a vasectomy.

Low–Molecular-Weight Heparin

The properties of LMWH vary significantly from those of UFH.[77,78] The anti-Xa:anti-IIa ratio of LMWH is approximately 4:1. Thus LMWH does not significantly affect the aPTT. There is little protein binding, allowing for predictable renal excretion. The properties of the available LMWHs (enoxaparin, dalteparin, tinzaparin) are different.[78] Their kinetics and dosing are not interchangeable.[77] In a normal-sized adult (50–150 kg) with normal renal function, routine laboratory monitoring is not necessary. If monitoring is necessary (weight outside the usual range, impaired renal function), anti-Xa activity is measured 3.5 to 4.0 hours after an enoxaparin dose. The therapeutic range for enoxaparin (1 mg/kg every 12 hours) is 0.5 to 1.0 U/mL. LMWH is only 60% reversible by protamine.[77] If bleeding occurs within 8 hours of an LMWH injection, 1 mg of protamine per 100 anti-Xa units should be given. Because of the kinetics of LMWH, a second protamine dose of 0.5 mg per 100 anti-Xa units should be given if the bleeding persists.[77]

Pentasaccharide

Fondaparinux (Arixtra) is a synthetic analog of the first five sugars of heparin. Because of its small size, it is a pure factor Xa antagonist. Fondaparinux is FDA approved for treatment of DVT and PE and for DVT prophylaxis in orthopedic and abdominal surgery. Although not FDA approved, fondaparinux has been used off-label for the prophylaxis and treatment of heparin-induced thrombocytopenia and thrombosis (HITT).[17,52] As a result of its 18- to 21-hour half-life, its use in the ICU is limited because it is not rapidly cleared in a patient population that needs frequent procedures, that has a high risk of bleeding, and often has renal impairment (contraindicated with creatinine clearance [CrCl] <30 mL/min). It does not prolong the PT, aPTT, or TT. It can be measured in the anti-Xa assay calibrated for fondaparinux. It is not reversed by protamine. Bleeding owing to pentasaccharide should be supported by transfusion. rH-factor VIIa can also be tried.

Heparinoid

Danaparoid is a mixture of sulfated glycosoaminoglycans, distinct from heparin, that produces an anticoagulant effect primarily by enhancing the activity of AT. Danaparoid is primarily used in the setting of HIT. Dosing schema are available for most clinical situations.[79,80] If monitoring is necessary, such as during renal failure, anti-Xa activity must be determined. Although no longer available in the United States, danaparoid is available in Canada and Europe.

Direct Thrombin Inhibitors

As the name implies, DTIs directly bind to and inhibit the function of thrombin. Because of their expense, parenteral DTIs are generally reserved for the treatment of patients with HITT or true heparin allergy. Although none of them have an antidote, rH-VIIa has anecdotally been used off-label to stop life-threatening bleeding.

Argatroban is an arginine analog with a 40-minute half-life that is FDA approved for the treatment of HITT and for anticoagulation during PCI in face of HITT. It is metabolized in the liver, and its half-life increases to around 140 minutes with hepatic dysfunction. Because of its short half-life, an initial bolus is not needed. The standard dose is 2 μg/kg per minute as a continuous infusion, which should be decreased to 0.5 μg/kg per minute in individuals with significant liver disease or in the ICU (e.g., open heart surgery, congestive heart failure). Although argatroban is monitored by the aPTT, it has a significant effect on the PT.[81] Argatroban monotherapy will approximately double the INR and can markedly prolong the INR with concomitant warfarin therapy. As long as the aPTT is therapeutic, this exaggerated increase in INR does not increase the bleeding risk.

Hirudin is a family of recombinant proteins originally extracted from the salivary glands of leeches.[82]

Lepirudin is no longer commercially available worldwide.

Bivalirudin is a reversible synthetic analog of hirudin that is FDA approved for anticoagulation during PCI with HITT.[30] Bivalirudin has the advantage of a 25-minute half-life. Although it is cleared primarily by intravascular proteolysis, the dose must be reduced with renal dysfunction. Although not FDA approved, bivalirudin is used off-label in many centers for systemic anticoagulation for HITT.[83,84] It is also used off-label for cardiac bypass surgery in individuals with HIT.[30]

Dabigatran (Pradaxa) is the first FDA-approved oral DTI. It is approved for prevention of stroke and systemic embolization with nonvalvular atrial fibrillation and the treatment of VTE.[85,86] It binds free and clot-bound thrombin and is primarily cleared via the kidneys with a half-life of 12 to 17 hours.[87] The CrCl should be determined by the Cockcroft-Gault formula when using dabigatran. It should be used with extreme caution in the elderly, especially because of the risk of bleeding owing to overestimation of the CrCl and risk of trauma in the infirm. Recommendations for dosing with renal impairment are extrapolated from pharmacokinetic data because individuals with impaired renal function (CrCl <30 mL/min) were excluded form clinical trials.[88,89] Recommendations have included that it should not be used (1) with a CrCl 15–30 mL/min and concomitant use of a strong permeability glycoprotein (P-gp) inhibitor, with a CrCl <15 mL/min[90]; or (2) with a CrCl <30 mL/min.[88,91] P-gps are a family of xenobiotic efflux transporters found on the luminal side of enterocytes whose function is to prevent the absorption of potentially toxic substances.[90] Dabigatran is best absorbed in the stomach and duodenum, which have the lowest P-gp absorption compared with the distal small bowel. Gastric bypass surgery may impair the absorption of dabigatran.[92] Capsules should be given intact and not by nasogastric tube.[93]

Although dabigatran levels can be determined in reference laboratories, there is no standardized laboratory test to measure the dabigatran level in real time. Thus in a patient who is having bleeding or thrombotic events while taking dabigatran, there is no test to tell whether the event may be related to overanticoagulation or underanticoagulation. Ideally, a sample level should be sent to a reference laboratory. If possible, the sensitivity of the aPTT and TT to dabigatran should be predetermined in the local laboratory. As a screening test, given its sensitivity, a normal TT generally suggests that there is no dabigatran present. Although the blood concentration after fixed dosing is known, the therapeutic range for dabigatran has not been determined. How long dabigatran should be discontinued before procedures depends on the renal function and the bleeding risk of the procedure.[87,88]

Approaches to the reversal of dabigatran in a bleeding patient and before emergent surgery are shown in Figs. 74.2 and 74.3, respectively. In the bleeding patient, activated charcoal may be given if within 2 hours of ingestion. Idarucizumab (Praxbind) is an FDA-approved monoclonal antibody that rapidly reverses the anticoagulant effect of dabigatran and is the treatment of choice for the patient with severe or life-threatening bleeding. There is a risk of recurrent VTE during the period of dabigatran reversal. Because it is a humanized, mouse monoclonal antibody, idarucizumab may be immunogenic.[93] Whether it can be used on multiple occasions without causing allergic reactions or affecting idarucizumab excretion is not known.

Direct Oral Anticoagulants

Direct oral anticoagulants (DOACs) to thrombin and factor Xa are commercially available.

Direct Oral Thrombin Inhibitors

See the previous discussion of dabigatran.

Direct Oral Factor Xa Inhibitors

Three oral factor Xa inhibitors are currently FDA approved for stroke prevention in nonvalvular atrial fibrillation and treatment of VTE. They have distinct pharmacologic properties and are not interchangeable.[94] The CrCl should be determined by the Cockcroft-Gault formula when using any DOAC. Dosing in patients with end-stage renal disease and those using dialysis is not evidence based because individuals with CrCl below 25 to 30 mL/min were excluded from clinical trials.[88,91] All oral factor Xa inhibitors are substrates affected by inducers or inhibitors of P-gp.[88] Although levels of all three factor Xa inhibitors can be determined in reference laboratories, there is no standardized laboratory test to measure their levels in real time. Thus in a patient having bleeding or thrombotic events while taking any oral factor Xa inhibitor, there is no test to tell whether the event may be related to overanticoagulation or underanticoagulation. A blood level should be sent to a reference laboratory at the time of any event. Although not as accurate as using liquid chromatography/mass spectroscopy, the levels of all three factor Xa inhibitors can be measured by the anti-Xa assay used to monitor heparins. Unfortunately, standards to calibrate the assay are not available in the United States. A normal anti-Xa level calibrated either for UFH or LMWH will exclude the presence of a clinically relevant level of an oral factor Xa inhibitor. Although the blood concentration

after fixed dosing is known, the therapeutic range for the oral factor Xa inhibitors has not been determined. How long these agents should be discontinued before procedures depends on the renal function and the bleeding risk of the procedure.[88,95] In general, oral factor Xa inhibitors should be withheld for 24 to 48 hours before standard risk and 48 to 72 hours for high-risk surgical procedures depending on renal function.[88] They should be held for at least 72 hours before neuroaxial procedures. Most commonly, individuals taking DOACs are admitted to the ICU for bleeding or need emergent procedures. Approaches to the reversal of oral factor Xa inhibitors in the bleeding patient and before emergent surgery are shown in Figs. 74.4 and 74.5, respectively. All factor Xa inhibitors have a relatively short half-life. Because their anticoagulant activity is significantly decreased after two half-lives, many individuals need just supportive care by the time they present with bleeding.[88] Although not yet FDA approved, andexanet alfa and ciraparantag are undergoing clinical trials for the reversal of the class of oral factor Xa inhibitors. Because there are no evidence-based data regarding the reversal of oral factor Xa inhibitors in the bleeding patient and given the ubiquity of renal dysfunction in the ICU, these agents should be used with caution, if at all, in the ICU.

Apixaban

Apixaban (Eliquis) is FDA approved for the prevention of stroke in atrial fibrillation and treatment of deep venous thrombosis and pulmonary embolus.[96] It has an 8- to 15-hour half-life, and its elimination is fecal and renal. P-gp inhibitors and strong cytochrome 450 (CYP) 3A4 inhibitors significantly increase its plasma concentration, whereas strong P-gp inducers may increase the risk of stroke.[90] When treating atrial fibrillation, the dose of apixaban should be reduced for any two of the following: age older than 80 years, weight 60 kg or less, or creatinine level of 1.5 mg/dL of less, Because of its relatively limited renal excretion compared with the other DOAC, it may be the safest DOAC to give to patients with renal insufficiency. However, there are no evidence-based data on

its efficacy and safety in individuals with end-stage renal disease or those using dialysis who are receiving chronic apixaban.[88,91,95] It may be crushed and given immediately via nasogastric tube.

Rivaroxaban

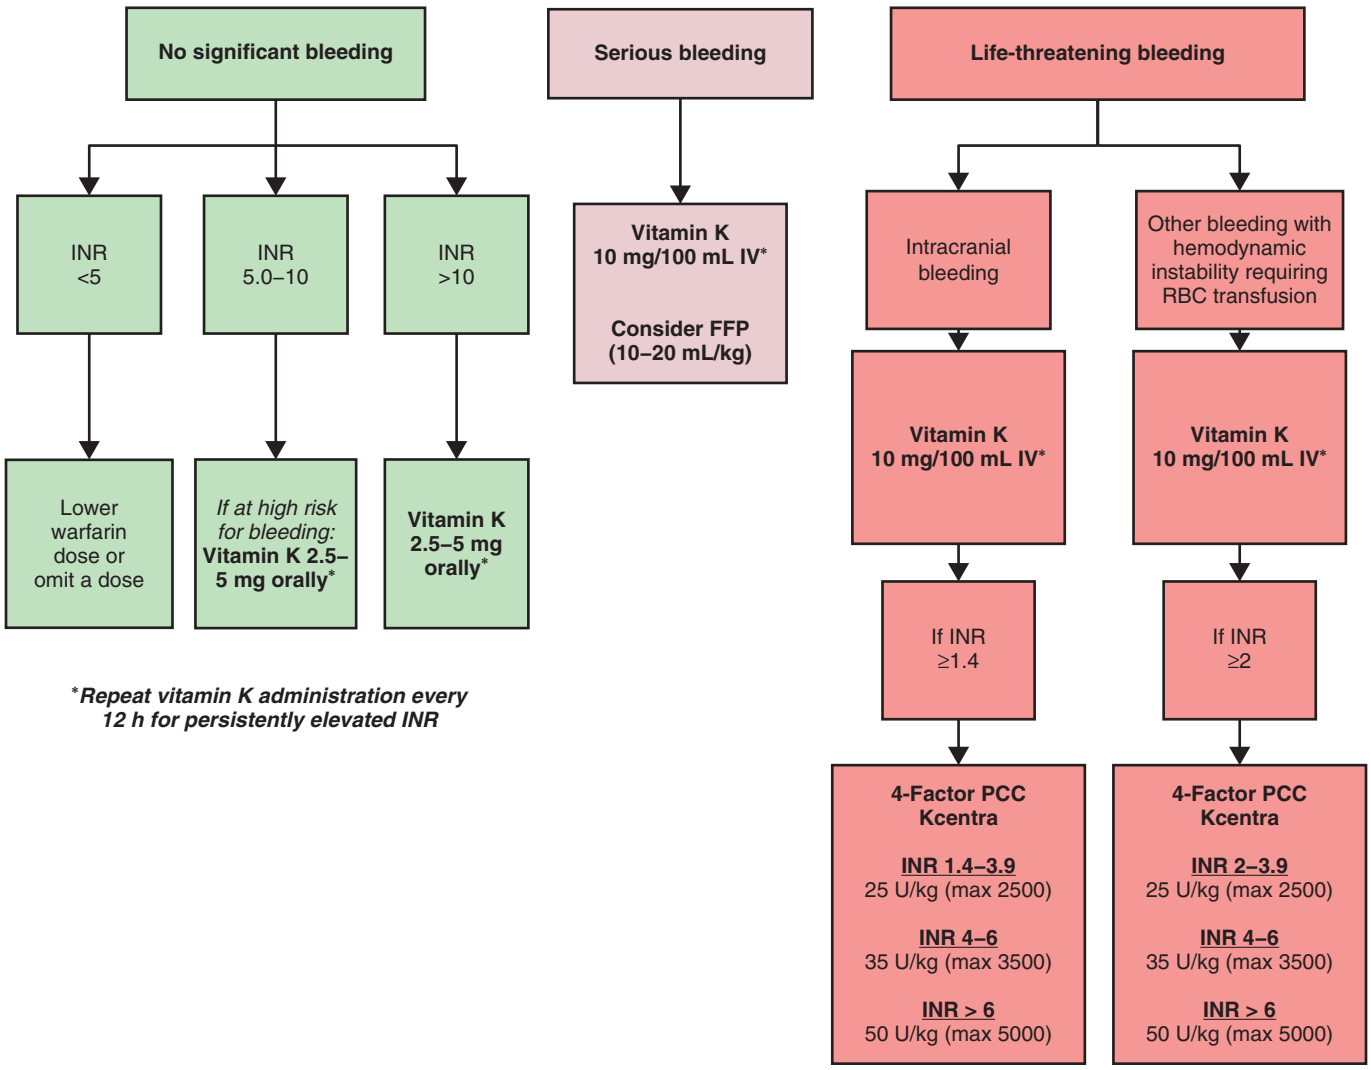
Rivaroxaban (Xarelto) is FDA approved for the prevention of stroke in atrial fibrillation and, treatment of deep venous thrombosis and pulmonary embolus.[97,98] It has a 5- to 9-hour half-life (9–13 hours in the elderly) and is metabolized primarily via the cytochrome system. Combined strong P-gp and strong CYP 3A4 inhibitors may significantly increase the plasma concentration of rivaroxaban, whereas strong P-gp inducers may increase the risk of recurrent VTE.[88,90] It should be avoided in the face of significant hepatic dysfunction. Dosing recommendations have included dose reduction for atrial fibrillation and a CrCl of 15 to 50 mL/min versus not using it with a CrCl less than 30 mL/min.[89] It should not be used for treatment of VTE with a CrCl less than 30 mL/min.[78,88] It should not be administered via feeding tube distal to the stomach.

Edoxaban

Edoxaban (Savaysa) has a 10- to 14-hour half-life and is excreted primarily as unchanged drug in the urine. The dose should be reduced in the face of cardiac medications that are strong P-gp inhibitors.[90] Recommendations have included dose reduction for CrCl 15 to 50 mL/min versus withholding it for a CrCl less than 30 mL/min.[88] It is contraindicated for a CrCl greater than 95 mL/min owing to increased clearance and an increased risk of stroke. There are no data on crushing tablets or giving edoxaban via feeding tube.

Warfarin

The vitamin K antagonist warfarin decreases the activities of factors II, VII, IX, and X and proteins C, S, and Z. Although prolongation of the PT is often seen within the first 24 to 48 hours after initiation of warfarin as result of the decrease in factor VII, 4 to



• **Fig. 74.6** Approach to the reversal of warfarin. *FFP,* Fresh frozen plasma; *INR,* international normalized ratio; *IV,* intravenous; PCC, prothrombin complex concentrate; *RBC,* red blood cell count. (Adapted from Ageno W, Gallus AS, Wittkowsky A, et al. Oral anticoagulant therapy: antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest.* 2012;141(2 suppl):e44S–e88S.)

5 days are required for factors II and X to drop to antithrombotic levels.

The response to warfarin is variable and is affected by many factors common in the ICU, such as poor nutrition (vitamin K deficiency), liver dysfunction, and coadministration of medications that affect warfarin pharmacokinetics. It is not uncommon for patients to become overanticoagulated with warfarin. An approach to warfarin reversal is shown in Fig. 74.6.[99,100] Specific therapy (4-factor PCC [Kcentra]), if available, is recommended over FFP.[101,102] Kcentra contains heparin and is contraindicated in individuals with a history of HIT or true heparin allergy.

Key Points

- Hemorrhagic and thrombotic complications in a critically ill patient can usually be anticipated and avoided by careful history taking and physical examination. Routine laboratory tests (platelet count, PT, aPTT, TT, fibrinogen) are helpful in evaluating hemorrhagic disorders but not thrombotic disorders.
- Vitamin K deficiency is a relatively common coagulopathy in critically ill patients, and it is easily treated if recognized.
- von Willebrand disease, the most common inherited coagulopathy, varies highly in clinical severity. Humate-P and Alphanate are the only "factor VIII" concentrates that are therapeutic.
- The bleeding diathesis of uremia can improve with several different treatments, including dialysis, DDAVP, IV administration of estrogens, and cryoprecipitate.

- Idiopathic thrombocytopenic purpura in adults is usually chronic. If life threatening, several modalities are available for urgent elevation of the platelet count.
- DIC is always a secondary disease process. Treatment must be focused on the underlying cause. If bleeding occurs, blood components should be given. Heparin is generally reserved for clinically evident thrombosis.
- TTP is a clinical diagnosis associated with multiple inciting events. It is often fatal unless recognized early and treated with plasma exchange.
- HIT with thrombosis may be life threatening. It should be looked for in any patient with thrombocytopenia who has been exposed to heparin. It can be managed with DTIs.
- Deep venous thrombosis is common in critically ill patients. Prophylactic treatment should be considered for every patient in the ICU. IV UFH is often the safest treatment of established DVT in the critical care setting.
- Direct DOACs (thrombin and factor Xa inhibitors) are being used with increasing frequency. They do not need routine monitoring. They should be used with caution in the face of renal dysfunction because of an increased risk of bleeding.

Review Questions/Answers

1. A 70-year-old-male has end stage renal disease and is being treated with hemodialysis. He develops a pulmonary embolus that requires anticoagulation. Which of the following would be the *best* option for initial anticoagulation?
a. Weight-based unfractionated heparin
b. Argatroban 2 μg/kg/min constant infusion
c. Fondaparinux with a 50% dose reduction
d. Full-dose rivaroxaban
e. Full-dose apixaban
Answer: a. Weight-based unfractionated heparin dosing is not affected by renal function. Although argatroban is metabolized by the liver and does not need dose reduction for renal disease, its cost limits its use to individuals with heparin-induced thrombocytopenia or true heparin allergy. Fondaparinux has an 18-hour half-life in normal individuals and is excreted through the kidneys. It is contraindicated with a creatinine clearance (CrCl) less than 30 mL/min. None of the trials with rivaroxaban or apixaban have included individuals with a CrCl less than 25 to 30 mL/min. Rivaroxaban should not be used with a CrCl less than 15 to 25 mL/min. Apixaban is an intriguing option because it has the least renal clearance of the direct oral anticoagulants (DOACs). Although there was no difference in apixaban level in individuals on dialysis who were given a single dose of apixaban compared to normal individuals, there are no efficacy and safety data on the use of apixaban when given chronically to individuals using dialysis.

2. A 68-year-old male with a history of hypertension, diabetes, and atrial fibrillation presents with altered mental status who was initially "found down," unconscious. Per his daughter, the patient takes metformin, aspirin, lisinopril, and dabigatran. He took these medications 1 hour ago. Vital signs are normal. His complete metabolic panel (CMP) and complete blood cell count (CBC) are within normal limits. International normalized ratio (INR) is 1.1 (normal <1.2) and activated partial thromboplastin time (aPTT) is 27 seconds (normal 22–29 seconds). A computed tomography (CT) head shows a subdural hemorrhage with no mass effect. What is the *best* treatment modality?
a. Vitamin K
b. Prothrombin complex concentrate
c. Idarucizumab
d. Protamine
e. No intervention needed because his prothrombin time (PT) and aPTT are normal
Answer: c. Idarucizumab is a humanized mouse monoclonal antibody that binds to dabigatran with high affinity, reversing its anticoagulant effects and concentrations in serum. This was illustrated in the Reversal Effects of Idarucizumab on Active Dabigatran (RE-VERSE-AD) trial. Vitamin K is a reversal agent for warfarin. Prothrombin concentration (PCC) has mainly been used in vitro studies and animal models, but no strong clinical evidence in humans. Although the patient is taking dabigatran, the PT and aPTT may be normal depending on the sensitivity of the assays and how long after the dose was taken that the blood is obtained.

3. A 28-year-old female with no significant past medical history is admitted to the intensive care unit with a saddle pulmonary embolus. Her INR is 1.0 (normal <1.2) with an aPTT of 41.4 seconds (normal 22–29 seconds). Results of a CBC and a CMP are normal. There is no history of bleeding in the patient or any family members. Which of the following is the *best* diagnostic test?
a. ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) level
b. von Willebrand profile
c. Factor X level
d. Mixing studies
e. Complement factor H
Answer: d. Mixing studies will determine whether the prolonged aPTT is due to factor deficiency or the presence of a circulating inhibitor. Mixing studies are tests performed on *blood plasma* and used to distinguish factor deficiencies from *factor inhibitors* (such as *lupus anticoagulant*). Mixing studies take advantage of the fact that factor levels that are 50% of normal should give a normal PT or *partial thromboplastin time* (PTT) result. Mixing studies are a useful tool for the assessment of a coagulopathy. ADAMTS13 is deficient in thrombotic thrombocytopenic purpura and would not be helpful with a normal CBC. Although most patients with von Willebrand disease have an elevated aPTT, she has no history of bleeding, thus making this unlikely. Factor X deficiency causes elevation of INR and APTT because it resides in the common pathway. Abnormalities in complement protein H may predispose to adult atypical hemolytic-uremic syndrome, which is not in the differential diagnosis with a normal CBC and normal renal function.

Use of Blood Components in the Intensive Care Unit

FAISAL ZAHIRUDDIN AND JANICE L. ZIMMERMAN

CHAPTER OUTLINE

Blood Components and Indications for Transfusion
- Whole Blood and Red Blood Cells
- Platelets
- Plasma-Derived Components

Adverse Effects of Blood Component Transfusion
- Acute Transfusion Reactions
- Delayed Hemolytic Transfusion Reactions
- Transfusion-Associated Circulatory Overload
- Transfusion-Related Acute Lung Injury
- Transfusion-Associated Graft-Versus-Host Disease
- Transfusion-Related Immunomodulation
- Transfusion-Transmitted Infectious Diseases

Special Transfusion Situations in the Critical Care Setting
- Massive Transfusion
- Autoimmune Hemolytic Anemia
- Necessary Transfusion of Incompatible Blood

Alternatives to Transfusion of Blood Components
- Blood Substitutes
- Desmopressin
- Antifibrinolytic Agents
- Vitamin K
- Hematopoietic Growth Factors
- Cell Salvage Technology

Legal Issues in Transfusion Medicine

Transfusion of blood components is a frequent intervention in hospitalized patients, particularly in critically ill patients. An estimated 20,933,000 units of red blood cells (RBCs), platelets, plasma, and cryoprecipitate were transfused in 2011 in the United States.[1] RBC transfusion is often used to optimize oxygen-carrying capacity and tissue perfusion that may be due to blood loss, inadequate marrow function, and RBC destruction. Additionally, hemostatic disorders may necessitate the administration of other blood components such as plasma, platelet concentrates, or cryoprecipitate.

Blood components should be considered therapeutic agents with potential benefits as well as adverse effects. Unlike pharmaceutical agents, however, blood components have fewer objective indications for use and no therapeutic index relating dose to safety. Although infectious risks of blood component transfusion have diminished, recognition of risks such as immunomodulation and transfusion-related acute lung injury (TRALI) has increased. Programs of blood conservation management are proposed to determine appropriate evidence-based use of blood components and to minimize use of blood products.[2] Although more quality evidence has become available to guide clinical decisions in transfusion, more questions remain to be explored through clinical trials, particularly in critically ill patients.

Blood Components and Indications for Transfusion

Blood component therapy is used to optimize management of the blood supply. The basic principle of blood component therapy is to use the specific blood product that meets the patient's need. Up to four components (RBCs, plasma, platelets, cryoprecipitate) can be derived from a single whole blood (WB) donation and then distributed to several recipients with differing physiologic needs. Component therapy thus meets the clinical requirements of increased safety, efficacy, and conservation of limited resources. As the variety of available blood product components increases, however, the complexity of transfusion medicine also increases. A WB donation is typically separated into RBCs, a platelet concentrate, and fresh frozen plasma (FFP). The plasma may be further processed into cryoprecipitate and supernatant (cryopoor) plasma. The characteristics of more commonly transfused blood products are described in Table 75.1.

Whole Blood and Red Blood Cells

Unseparated venous donor blood with a preservative solution constitutes a WB unit. It contains all blood components, but after less than 24 hours of refrigerated storage, platelet and leukocyte function is lost. With further storage, levels of the labile coagulation factors V and VIII markedly decrease.[3] The growing need for specialized blood components has resulted in processing the majority of blood donations into components, thus limiting the availability of WB.

RBCs, commonly known as *packed red blood cells* (PRBCs), are the blood component most commonly transfused to increase RBC mass. PRBCs are derived from the centrifugation or sedimentation of WB and removal of most of the plasma/anticoagulant solution.

TABLE 75.1 Characteristics of Blood Components

Blood Component	Content	Volume (mL)	Plasma (mL)	Shelf Life
Red Cell Products				
Whole blood	RBCs (Hct 40%–45%), WBCs, plasma, platelets (nonviable)	500–515	~300	21–35 days at 1°C–6°C (depending on anticoagulant) 24 h if unrefrigerated
Packed RBCs	RBCs (Hct 60%–80%), WBCs, plasma, platelets (nonviable)	250–300	~25–50 mL	21–42 days at 1°C–6°C (depending on anticoagulant)
Leukocyte-reduced RBCs (filtered)	RBCs (Hct 90%), minimal plasma	200	Minimal	21–42 days at 1°C–6°C (depending on anticoagulant)
Washed RBC	RBCs (Hct 60%), some WBCs	340	0	24 h
Frozen RBCs	RBCs (Hct 90%, minimal WBC and platelets (nonviable)	170–190	0	10 years at –80°C
Platelets				
	Platelets, some WBCs, some RBCs, plasma			Open, 24 h at 20°C–24°C with continuous agitation Closed, 5 days at 20°C–24°C with continuous agitation
Single-donor (apheresis)	$\geq 3 \times 10^{11}$ platelets/unit	~300 (200–400)	~250	
Random donor	$\geq 5.5 \times 10^{10}$ platelets/unit	50	50	
Plasma-Derived Products				
Fresh frozen plasma (frozen within 6–8 h of phlebotomy)	Plasma with all coagulation factors and inhibitors, complement, fibrinogen, albumin, globulins	*Whole blood donor:* 200–250 *Apheresis donor:* 400–600	200–250 400–600	1 year at –18°C; 24 h at 1°C–6°C once thawed
Plasma frozen within 24 h (separated from whole blood stored at 4°C–6°C within 24 h of collection)	Plasma with all coagulation factors and inhibitors but with lower levels of V and VIII; complement, fibrinogen, albumin, globulins	200–250	200–250	1 year at –18°C 24 h at 1°C–6°C once thawed
Cryoprecipitate-reduced plasma (fresh frozen plasma with cold-induced precipitate removed)	Similar to fresh frozen plasma but deficient in XIII, VIII, fibrinogen, and von Willebrand factor	200–225	200–225	1 year at –18°C 24 h at 1°C–6°C once thawed
Cryoprecipitate	Factor VIII (minimum 80 IU), XIII, fibrinogen (minimum 150 mg), von Willebrand factor, plasma, fibronectin	5–20	5–20	1 year at –18°C 4–6 h at room temperature once thawed

Hct, Hematocrit, *RBCs,* red blood cells; *WBCs,* white blood cells.

PRBCs may be further modified to meet the specific needs of patients or blood bank regulations. Leukocyte-reduced PRBCs are the most commonly transfused modified RBC product. Transfusion of blood components containing leukocytes may lead to nonhemolytic febrile transfusion reactions, a greater propensity for platelet alloimmunization, and transmission of pathogens carried by leukocytes, such as cytomegalovirus (CMV). Leukocyte reduction requires filtration of the blood component by a special filter at the time of blood donation and processing or later at the time of transfusion ("bedside filtration"). Leukocyte-reduced RBC units must contain less than 5.0×10^6 leukocytes. Filtration before storage conveys the benefit of removing white blood cells (WBCs) before they can deteriorate and elaborate cytokines and other unwanted substances during storage.[4] Because of proven and theoretical benefits of leukocyte reduction of blood components (discussed later in the section covering the adverse effects of transfusion), many European countries and Canada require that all PRBCs be leukocyte reduced, a process called *universal leukoreduction*. Some institutions in the United States have also made that decision, but either method of leukocyte reduction adds significantly to the cost of each transfusion, and the benefits of this measure when applied globally are still debated.[5] Almost 85% of transfused PRBCs are leukoreduced in the United States.[1]

Washing PRBCs involves recentrifuging in normal saline solution to remove the plasma/preservative solution from the unit. Washing removes 99% of the plasma proteins and 85% of leukocytes. Washing may take an hour or more, limits subsequent storage time to 24 hours, and causes loss of RBCs (10%–20%). Washing

is not an effective method of leukoreduction. Washed PRBCs may be indicated for patients with febrile transfusion reactions not prevented by leukoreduction, immunoglobulin (Ig) A deficiency with documented antibodies to IgA, and history of a previous anaphylactic reaction to blood transfusion.

PRBCs can also be modified by irradiation to inactivate lymphocytes. Transfusion of irradiated blood is indicated in severely immunocompromised patients at risk of graft-versus-host disease (GVHD), such as transplant recipients, those with aggressively treated malignancies, and those with congenital immunodeficiencies. The transfusion of irradiated PRBCs in the United States is increasing and accounted for 13.4% of blood transfusions in 2011.[1] Irradiation of RBCs reduces RBC viability and increases release of intracellular potassium.

PRBCs can be frozen in cryoprotective solution and stored for extended periods. Frozen RBCs are generally limited to units of special value, such as those with a rare RBC antigen profile or autologous blood donations that need to be stored for future use. A rare-donor registry of frozen PRBCs exists in most countries to assist in providing blood to patients with complex or multiple alloantibodies to RBC antigens. Significant advance planning is necessary to acquire and thaw frozen PRBCs for transfusion, thus limiting their use in acute situations.

RBC components incur some cell loss during storage. The current technology with preservative solutions attempts to optimize cell quality and quantity by using strict criteria to determine the allowable storage time. Nonetheless, as RBC metabolism decreases progressively, a "storage lesion" results, with accumulation of a variety of undesirable substances and loss of cellular function.[6] During storage, a slow rise in the concentration of potassium, lactate, aspartate aminotransferase, lactate dehydrogenase, ammonia, phosphate, and free hemoglobin and a slow decrease in pH and bicarbonate concentration occur. Cytokines and inflammatory mediators such as interleukin (IL) 1, IL-6, and tumor necrosis factor also accumulate. The pH of freshly stored blood in citrate solution is 7.16, which declines to approximately 6.73 at the end of the unit's shelf life. As potassium leaks from RBCs during storage, levels as high as 25 mEq/L may result. However, each unit transfused supplies at most 7 mEq of potassium, which is usually well tolerated.

During the storage period there is also a progressive decrease in RBC-associated 2,3-diphosphoglycerate (2,3-DPG) and adenosine triphosphate.[6] A decrease in 2,3-DPG increases the affinity of hemoglobin for oxygen, which shifts the oxyhemoglobin dissociation curve to the left and decreases oxygen delivery to tissues. There is little evidence, however, that this transient increase in oxygen affinity has clinical importance. After infusion, 2,3-DPG gradually increases as the transfused RBCs circulate, with 25% recovery in 8 hours and full replacement by 24 hours.[7] Decreased adenosine triphosphate during storage diminishes the viability of RBCs after transfusion and is one of the chief factors limiting storage time. The majority of blood transfusions are in the form of PRBCs, the component indicated for normovolemic patients or those for whom intravascular volume constraints are necessary. Resuscitation in patients requiring increased oxygen-carrying capacity and volume is effectively achieved with the use of PRBCs and crystalloid or colloid solutions. Each unit of PRBCs is expected to raise the hemoglobin concentration by approximately 1 g/dL and the hematocrit by 3% in stable, nonbleeding, average-sized adults.

Indications for RBC Transfusion

Despite a long tradition of transfusion of RBCs in critically ill patients, the precise indications and hemoglobin threshold for transfusion remain a source of debate, and transfusion practices may vary widely among clinicians, intensive care units (ICUs), institutions, and geographic regions. Multiple observational studies document transfusion rates in ICU patients that vary from 17% to 53%,[8–12] and the rate of transfusion increases with longer ICU length of stay.[8,13] There has been a trend over time for use of a lower transfusion threshold in critically ill and hospitalized patients.[14,15]

RBCs should be transfused to enhance tissue oxygen delivery, but the underlying physiology of anemia, the complex adaptations to anemia, and the potential advantages and disadvantages to particular groups of patients are not as well understood. Determining when an anemic patient would truly benefit from increased oxygen-carrying capacity remains an imprecise task. In addition, evidence argues that transfusions may result in donor-recipient interactions deleterious to the critically ill patient, including the disruption of compensatory physiology, the immunomodulation caused by the presence of foreign cells, and the introduction of unintended plasma contents.

Compensatory mechanisms for acute and chronic anemia are complex and work in concert to maintain oxygenation within the microcirculation.[16,17] Cardiovascular adjustments leading to increased cardiac output include decreased afterload and increased preload resulting from changes in vascular tone, increased myocardial contractility, and elevated heart rate. Lowered blood viscosity permits improved flow of RBCs within capillaries. Blood flow is redistributed to favor critical organs with higher oxygen extraction such as the heart and brain. Pulmonary mechanisms, though contributing relatively little to short-term oxygenation demands, exert potent effects on related metabolic variables. Finally, the hemoglobin molecule can undergo biochemical and conformational changes to enhance the unloading of oxygen at the capillary level. Increased synthesis of RBC 2,3-DPG in anemia results in a rightward shift of the oxyhemoglobin dissociation curve and facilitates the release of oxygen to tissues. A rightward shift of the oxyhemoglobin curve can also occur with a decrease in pH (Bohr effect) but the clinical significance is small.[16] All these mechanisms contribute to an oxygen reserve capacity that exceeds baseline requirements by approximately fourfold. Unfortunately, acute illness and chronic morbidities may limit these compensatory mechanisms in critically ill patients. Reports in patients refusing transfusion indicate that an extremely low hematocrit is tolerated if tissue perfusion is adequate.[17,18]

Although RBC transfusion can increase oxygen-carrying capacity and thus oxygen delivery, it may not improve tissue oxygen consumption. Multiple case series evaluating the effects of RBC transfusion in critically ill patients have failed to document increased oxygen consumption or improvement in lactate level.[19,20–22] Hypotheses to explain this discrepancy include an increase in blood viscosity limiting microvascular flow and impaired tissue and cellular oxygen utilization.

In practice, the hemoglobin concentration is most often used to determine the need for blood transfusion. The relevant issue for clinicians is determining the most appropriate hemoglobin threshold that should trigger RBC transfusion. Although anemia has been associated with increased mortality in critically ill patients,[23–25] results of multiple randomized clinical trials in different patient populations suggest that restrictive transfusion strategies are equivalent to liberal transfusion strategies for most patients. The first multicenter randomized trial of RBC transfusion strategies in the critically ill (Transfusion Requirement in Critical Care [TRICC]) compared a liberal (transfusion threshold, hemoglobin 10 g/dL) with a restrictive (transfusion threshold, hemoglobin 7 g/dL)

RBC transfusion policy in 838 euvolemic patients.[26] The primary outcome measure of 30-day all-cause mortality rate was not statistically different between the restrictive strategy and the liberal strategy groups ($P = 0.11$). A secondary outcome measure of overall hospital mortality rate was significantly lower in the restrictive strategy group ($P = 0.05$). The restrictive strategy was superior for subgroups of patients younger than 55 years and patients with lower (<20) APACHE (Acute Physiology, Age, and Chronic Health Evaluation) II scores. In addition, liberal transfusion was not associated with shorter ICU or hospital stays or less organ failure; longer mechanical ventilation times and cardiac events were more frequent in the liberal strategy group. The number of transfusions was reduced by 54% with the restrictive strategy.

The results of the TRICC study were replicated in a study of transfusion strategy in critically ill pediatric patients.[27] A liberal transfusion threshold of 9.5 g/dL was compared with a restrictive transfusion threshold of 7.0 g/dL. The primary outcomes of death and new or progressive multiple organ dysfunction as well as adverse events were similar in both treatment groups, but 54% of patients in the restrictive group did not receive transfusion compared with only 2% in the liberal group. Additional prospective randomized trials have validated the use of a restrictive transfusion strategy in other adult patient populations.[28–35] The FOCUS (Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair) transfusion trial enrolled 2016 high-risk elderly patients who had a history of or risk factors for cardiovascular disease who underwent surgery for hip fracture. The liberal transfusion strategy used a hemoglobin threshold of 10 g/dL and the restrictive strategy used a hemoglobin threshold of 8 g/dL. Mortality and functional recovery were similar in both groups.[28] The multicenter Transfusion Requirements in Septic Shock (TRISS) trial in 998 patients compared transfusion thresholds of 7 g/dL and 9 g/dL and found similar mortality and fewer transfusions in the restrictive group.[29] A liberal transfusion strategy (threshold hemoglobin 10 g/dL) did not result in improved neurologic outcomes compared to a restrictive strategy (threshold hemoglobin 7 g/dL) in patients with closed head injury.[30] A restrictive transfusion strategy has also been tested in patients with acute severe upper gastrointestinal bleeding including patients with cirrhosis.[31] The single-center study found that a restrictive strategy using a hemoglobin threshold of 7 g/dL compared with a threshold of 9 g/dL resulted in improved mortality and decreased rate of further bleeding. A multicenter, cluster randomized trial is planned to further assess these transfusion strategies in acute upper gastrointestinal bleeding.[32]

Transfusion strategies in patients with cardiovascular disease continue to be debated and clinical trial results have been variable.[33,34] The single-center Transfusion Requirements After Cardiac Surgery (TRACS) study compared transfusion thresholds of hematocrit less than 30% (hemoglobin ~10 g/dL) with hematocrit less than 24% (hemoglobin ~8 g/dL) from the start of surgery through the ICU stay.[33] There was no difference in the composite outcome of 30-day all-cause mortality rate and severe morbidity between the liberal and restrictive strategies, and fewer blood products were administered in the restrictive group. A multicenter study in cardiovascular surgery patients assessed slightly different transfusion thresholds (hemoglobin 7.5 g/dL and hemoglobin 9 g/dL) in the postoperative period.[34] No difference was found between groups in the primary outcome of serious infection or ischemic events within 3 months. However, a secondary outcome analysis of all-cause mortality at 3 months found more deaths in the restrictive threshold group (4.2% vs. 2.6%). Transfusion studies in patients undergoing elective cardiac surgery do not answer the question of whether patients with acute coronary syndromes (current or recent ischemia) would benefit from a liberal transfusion strategy. Results from retrospective and prospective observational studies of anemia and transfusion in patients with acute coronary syndrome have yielded conflicting results.[36–40] A prospective, randomized pilot study of 45 patients with acute myocardial infarction (MI) and hematocrit 30% or less compared a transfusion threshold of hematocrit less than 24% with hematocrit less than 30%.[41] The composite safety endpoint of in-hospital death, new MI, or new or worsening heart failure occurred in 38% of the liberal strategy patients versus 13% in the conservative strategy patients ($P = 0.046$). Another pilot study in 110 patients with acute coronary syndrome or stable angina compared a similar protocol with a liberal threshold of 10 g/dL and restrictive threshold of 8 g/dL.[42] A composite outcome of death, MI, or unscheduled revascularization within 30 days trended in favor of the liberal group with more frequent events in the restrictive group (25.5% vs. 10.9%, $P = 0.054$). Larger studies in the future should help determine whether a restrictive transfusion strategy should be adopted in patients with acute coronary syndromes.

Prior guidelines for transfusion of RBCs did not specifically address critically ill patients and were primarily based on consensus rather than evidence. Current guidelines of the American Association of Blood Banks,[43] American Red Cross,[44] National Institute for Health and Care Excellence,[45] British Committee for Standards in Haematology,[46] American Society of Anesthesiologists,[47] and the National Blood Authority of Australia[48] provide an evaluation of clinical evidence and recommendations for transfusion that are applicable to the critically ill. A summary of the guideline recommendations is presented in Box 75.1. A Cochrane review of transfusion thresholds concluded that a restrictive strategy (hemoglobin threshold of 7 to 8 g/dL) reduces exposure to transfusion and does not have an impact on mortality of morbidity.[49] There was insufficient evidence to determine the safety of transfusion strategies in certain subgroups of patients, such as those with acute coronary syndrome, neurologic injury, and malignancy. Transfusion of single units of RBCs is recommended by several guidelines,[44,45,47,48] and most clinical trials of transfusion strategies use protocols with single-unit transfusions. The threshold for administration of RBCs should also be considered as part of a comprehensive, multidisciplinary patient blood management program to detect and treat anemia, reduce surgical blood loss, and optimize hemostasis.[2]

Because of concerns regarding RBC storage lesion, the use of "fresh" rather than older RBC units has been considered to avoid any negative impact on critically ill patients.[50–52] Clinical trials in adult and pediatric populations have provided evidence that the age of RBC units does not affect mortality.[53–56] Some transfusion guidelines contain recommendations regarding use of fresher blood (see Box 75.1).[43,46]

Platelets

Platelet components are available as random donor units or single-donor apheresis units. Because of the limited storage time and the increasing demand for this component, platelets are often subject to supply shortages. A random donor platelet concentrate is obtained by centrifugation from a unit of WB. This type of platelet concentrate contains up to 50% of the leukocytes from the WB unit. The average transfused dose of random donor platelets has been decreasing over time and is now 5 units in the United States.[1] If bags are entered for pooling before transfusion, the platelets must

• BOX 75.1 Guideline Recommendations for Transfusion of Red Blood Cells

American Association of Blood Banks[43] (2016)

- Recommend a restrictive strategy in hospitalized, hemodynamically stable patients including critically ill patients (*strong recommendation*).
  - Transfuse when hemoglobin ≤7 g/dL.
- Recommend restrictive strategy in patients undergoing orthopedic or cardiac surgery or those with cardiovascular disease *(strong recommendation).*
  - Transfuse when hemoglobin ≤8 g/dL.
- Adhere to a restrictive strategy in hospitalized, hemodynamically stable patients with preexisting cardiovascular disease (*weak recommendation*).
  - Consider transfusion when hemoglobin ≤8 g/dL.
- There is insufficient evidence to recommend a specific transfusion strategy in patients with acute coronary syndrome, severe thrombocytopenia, and chronic transfusion-dependent anemia.
- Recommend that patients receive RBC units at any point within their licensed dating period (standard issue) rather than limiting to transfusion of only fresh (<10 days storage) RBC units *(strong recommendation).*

American Society of Anesthesiology Task Force on Perioperative Blood Management[47] (2015)

- A restrictive RBC transfusion strategy (hemoglobin <8 g/dL) may be used to reduce transfusion requirements.
  - RBCs should be administered unit by unit, when possible, with interval reevaluation.

National Blood Authority, Australia[48] (2012)

- A restrictive transfusion strategy should be used in critically ill patients.
  - RBC transfusion is likely to be appropriate with hemoglobin <7 g/dL.
  - The decision to transfuse with hemoglobin 7 to 9 g/dL should be based on clinical signs and symptoms of anemia.
  - RBC transfusion is likely to be appropriate for patients with acute coronary syndrome with hemoglobin <8 g/dL.
- Transfusion of a single RBC unit is appropriate followed by reassessment to determine the need for further transfusion.

British Committee for Standards in Haematology[46] (2013)

- A transfusion threshold of ≤7 g/dL should be the default for all critically ill patients, unless specific comorbidities or illness-related factors modify decision making *(strong recommendation).*
- There is insufficient evidence to support the routine administration of fresher blood to critically ill patients.

RBCs, *Red blood cells.*

be administered within 4 hours. A single-donor apheresis platelet unit contains the equivalent of 4 to 6 units of random donor platelet concentrates. This type of platelet concentrate is considered to be leukoreduced and no additional filtration is needed. Single-donor platelets offer the benefit of reducing the risk of multiple-donor exposure to the recipient, and may also be the only available alternative for recipients who have been alloimmunized by previous platelet transfusions.

Platelets are stored at room temperature to avoid loss of function from refrigeration and are constantly agitated to maximize gas exchange. Some loss of viability and platelet numbers occurs during storage, but 5-day-old platelets still effect hemostasis. The plasma contained in platelet concentrates is a good source of stable coagulation factors and contains diminished but still potentially beneficial amounts of factors V and VIII. Platelet components may be modified by leukocyte reduction, irradiation, and washing similar to that for RBCs. Transfusion of ABO-compatible platelets is desirable but not essential. When ABO-mismatched platelets are given, removal of some of the incompatible plasma can be carried out before transfusion. Single-donor apheresis platelets may be matched to an alloimmunized recipient for human leukocyte antigens (HLA) or platelet antigens. There is no contraindication to the use of Rh-positive platelets in Rh-negative patients. However, if Rh-positive random donor platelets are administered to Rh-negative women with childbearing potential, Rh immune globulin should be used prophylactically owing to the small risk of Rh alloimmunization from RBCs that may be contained in the platelet concentrate. In similar circumstances, Rh immune globulin is not indicated if single-donor apheresis platelets are transfused because they contain few RBCs.

Each unit of random donor platelets is expected to increase the platelet count by 10×10^9/L (sometimes expressed as $10^3/\mu L$) in a typical 70-kg adult. A 1-hour posttransfusion platelet count should be obtained to determine the adequacy of response. The following equation, which relates platelet number and body size to the posttransfusion increment, can be used to assess the effectiveness of the transfusion:

$$\text{Corrected count increment (CCI)} = \frac{\text{Observed rise in platelet count} \times \text{Body surface area } (m^2)}{\text{Number of platelet units transfused}}$$

A CCI of 10×10^9/L or higher can be considered a good response, whereas a CCI of 5×10^9/L or lower indicates a poor response to transfusion.[57] The increment in platelet count is higher with single-donor apheresis units, ABO-identical platelets, and platelets stored no longer than 3 days.[58–60] However, there is no advantage of these platelet characteristics on prevention of clinical bleeding.[58]

Indications for Platelet Transfusion

Although the prevalence of thrombocytopenia in the critically ill varies with the definition used and clinical setting, thrombocytopenia is associated with platelet transfusions and increased mortality rate in ICU patients.[61,62] Guidelines for transfusion of platelets are derived from consensus opinion and clinical studies primarily in patients with chemotherapy-induced thrombocytopenia rather than critically ill patients.[44,45,63–67] Extrapolation of these guidelines to critically ill patients is problematic because the cause, risks, and consequences of thrombocytopenia may be different. General indications for platelet transfusions include active bleeding as the result of thrombocytopenia or functional platelet defects (therapeutic transfusion) or prevention of bleeding at specified low platelet counts (prophylactic transfusion). The majority of platelet transfusions in the ICU are performed for prophylactic indications.[68] Suggested guideline recommendations for platelet transfusion are summarized in Table 75.2.[44,45,63–67] Most medical or surgical patients with active bleeding and platelet counts of 50×10^9/L or above will not benefit from transfusion of platelets if thrombocytopenia is the only abnormality. The threshold for transfusing platelets is higher in bleeding patients in whom the consequences of continued bleeding pose significant risk to survival or functional ability such as neurosurgical bleeding. Recommendations for platelet transfusion in trauma with massive transfusion have varied.

In nonbleeding patients, previous debate centered on whether to transfuse platelets prophylactically or to transfuse therapeutically when bleeding occurred. A clinical trial comparing a no-prophylaxis strategy for platelet transfusion with a prophylactic strategy when

TABLE 75.2 Indications for Platelet Transfusion

Clinical Situation	Transfusion Trigger: Platelet Count $\times 10^9$/L
Therapeutic	
Active bleeding	≤50
Major bleeding and massive transfusion	≤50–100
Active bleeding with central nervous system/spinal/ocular surgery	≤100
Prophylactic	
High risk of spontaneous bleeding	≤10
High risk of spontaneous bleeding with concomitant coagulation abnormality, anticoagulant therapy, sepsis, fever, concurrent antibiotic use, rapidly decreasing count, or planned minor invasive procedure (central venous catheter)	≤20
Invasive procedure with high risk of bleeding or life-threatening hemorrhage (nonneuroaxial surgery, neuroaxial anesthesia, lumbar puncture)	≤50
Neuroaxial or ocular surgery	≤100
Platelet Dysfunction	
Bleeding, invasive procedure or surgery with abnormal platelet function test, use of antiplatelet drugs, or severe uremia	No specific trigger

the platelet count was less than 10×10^9/L in patients with hematologic cancers found more bleeding in the no-prophylaxis group.[69] It is often assumed that a prophylactic platelet transfusion strategy will have similar benefits in the critically ill.

Prophylactic platelet transfusions are administered to prevent spontaneous bleeding or bleeding with invasive procedures. Patients who have platelet counts of 5×10^9/L or lower are at increased risk for significant spontaneous bleeding, and guidelines propose prophylactic platelet transfusion to prevent hemorrhage at a threshold of 10×10^9/L or less.[44,45,63–67] The recommendations are based on clinical trials in patients with hematologic malignancies and chemotherapy-induced hypoproliferative thrombocytopenia.[70] A prospective study of a more conservative platelet transfusion protocol found that major bleeding episodes occurred on 1.9% of days with counts of less than 10×10^9/L and on only 0.07% of days with counts of 10 to 20×10^9/L.[71] Additional studies have confirmed the safety of using 10×10^9/L or less as a prophylactic platelet transfusion threshold in patients with hematologic malignancies or stem cell transplants.[72–74] The trigger for prophylactic platelet transfusion threshold of 10×10^9/L or less, however, applies primarily to a specific population of thrombocytopenic patients in stable condition. Factors such as fever, use of anticoagulant or antiplatelet drugs, and invasive procedures must be considered when generating a treatment plan for individual patients. Patients experiencing rapid drops in platelet count may be at greater risk than those at steady state and thus may benefit from transfusion at higher counts. Prospective studies in critically ill patients have not been reported. Benefits to the patient of more conservative use of platelet transfusion include decreased donor exposure, which lessens the risk of transfusion-transmitted disease; fewer febrile and allergic reactions that may complicate the hospital course; and the potential delay or prevention of alloimmunization to HLA and platelet antigens.

The threshold for platelet transfusion before invasive procedures should take into account the type of procedure, bleeding risks associated with the procedure, consequences of bleeding, and concomitant factors affecting hemostasis. For critical invasive procedures in which even a small amount of bleeding could lead to loss of vital organ function or death, maintaining the platelet count greater than 50×10^9/L is typically preferred. The presence of factors that affect platelet function, such as certain drugs, foreign intravascular devices (e.g., intraaortic balloon pump or membrane oxygenator), infection, or uremia, alter this requirement upward. Patients at risk for small but strategically important hemorrhage, such as neurosurgical patients, may need to be maintained at platelet counts of 100×10^9/L.

The most appropriate platelet count for procedures that may be performed in critically ill patients, such as placement of central venous catheters and arterial catheters, thoracentesis, and paracentesis, has not been definitively established. Most ICU procedures carry a low risk of bleeding but coagulopathy or thrombocytopenia may increase that risk.[75] A retrospective study suggests that central venous catheters can be placed safely when the platelet count is 20×10^9/L or higher.[76] However, there are no randomized clinical trials to suggest that platelet transfusion is necessary before central line insertion or the optimum platelet count.[77] Likewise, there is no evidence to determine the correct platelet transfusion threshold for lumbar puncture.[78]

Patients undergoing cardiac bypass surgery experience a drop in platelet count and often acquire a transient platelet functional defect from damage associated with the bypass equipment.[79] Most patients do not experience platelet-associated bleeding, however, and prophylactic transfusion in the absence of bleeding is not warranted. In a patient who continues to bleed postoperatively, more likely causes are a localized, surgically correctable lesion or failure to reverse the effects of heparin. If these conditions are excluded or platelet function testing results are abnormal, empiric transfusion of platelets may be justified.

Patients who are thrombocytopenic by virtue of immunologic destructive processes such as idiopathic thrombocytopenic purpura may receive little benefit from platelet transfusions because transfused platelets are rapidly removed from the circulation. In the event of life-threatening hemorrhage or an extensive surgical procedure, transfusion may prove beneficial for its short-term effect but may require higher doses of platelets or increased frequency of transfusion. Platelet transfusion may be more effective when high-dose immunoglobulin or high-dose anti-D antiserum are administered.[80,81] Platelet transfusion is usually not recommended in thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome, and heparin-induced thrombocytopenia.[44,45,65,67] Cautious administration of platelets may be considered in cases of life-threatening thrombocytopenic bleeding.

Platelets are less commonly transfused for platelet dysfunction, but prophylactic and therapeutic transfusion of platelets has increased in patients receiving antiplatelet drugs. Some in vitro studies show that platelet dysfunction related to antiplatelet drugs can be reversed with platelet transfusion, and limited clinical studies suggest improved platelet function after platelet transfusion in intracranial hemorrhage.[82,83] However, improved platelet function may not translate into better outcomes.[84,85] A randomized clinical

trial of platelet transfusion in intracerebral hemorrhage associated with antiplatelet drugs found worse outcomes for death or dependence at 3 months for the group receiving platelet transfusion.[86] Currently platelet transfusion guidelines provide either no recommendation or weak recommendations regarding platelet transfusion in the setting of bleeding or prophylaxis associated with antiplatelet drugs owing to the lack of high-quality evidence.[44,46,63,65,87]

The development of refractoriness to platelet transfusions as the result of alloimmunization is a serious event. Poor response to platelet transfusions owing to increased platelet consumption also occurs with splenomegaly, fever, trauma and crush injury, burns, disseminated intravascular coagulation (DIC), concomitant drugs, and transfusion of platelets of substandard quality.[88] These factors should be identified and corrected if possible. Alloimmunization is characterized by the development of anti-HLA or platelet-specific antibodies, with resultant immune platelet destruction. Leukocyte depletion of transfused components can prevent or delay this phenomenon, but it is important to use leukoreduced components early in the course of transfusion therapy.[88,89] When patients fail to achieve expected increments after platelet transfusion, provision of single-donor ABO-specific platelet concentrates that are less than 48 hours old may improve the response. If no improvement is seen, the patient should be screened for HLA antibodies or be HLA typed and provided with HLA-compatible single-donor platelets. Alternatively, platelet cross-matching with the patient's serum can be carried out. There is no advantage to unmatched single-donor platelets in this situation.

Plasma-Derived Components

Plasma

Standard FFP is prepared by centrifugation of WB or single-donor apheresis and is frozen within 8 hours of blood donation. Standard FFP contains all coagulation factors (including the labile factors V and VIII) and inhibitors, approximately 400 mg fibrinogen, complement, albumin, and globulins. By convention, the coagulation factors are present in concentrations of 1 units/mL. Plasma that is separated and frozen from refrigerated WB more than 8 hours but within 24 hours of phlebotomy is referred to as PF24. PF24 differs from standard FFP by having lower levels (~15%–25% reduction) of factors V and VIII, but the decrease in labile factor levels is not considered clinically significant. The processing technique for PF24 allows for clinical utilization of plasma collected at distant sites and increases the plasma supply. Cryoprecipitate-reduced plasma (also called *cryopoor plasma*) refers to FFP with the cold-induced precipitate removed. Cryopoor plasma is thus deficient in factors VIII and XIII, fibrinogen, and von Willebrand factor. The most common method of thawing FFP requires about 30 to 45 minutes in a 37°C water bath. Cross-matching to the recipient is not performed, but FFP must be ABO compatible. Standard FFP is as likely to transmit hepatitis, HIV, and most other transfusion-related infections as cellular components. A pathogen-reduced solvent-/detergent-treated pooled plasma product is available in the United States and other countries. The following types of other pathogen-reduced plasma products may be available in some countries outside the United States: methylene blue–treated plasma, psoralen- and ultraviolet light–treated plasma, and riboflavin- and ultraviolet light–treated plasma.[90]

Indications for Fresh Frozen Plasma

FFP is frequently transfused inappropriately in critically ill patients who are not bleeding or in whom the international normalized ratio (INR) is less than 1.5.[91,92] Guidelines for transfusion of FFP have been primarily based on expert opinion rather than any clinical evidence (Box 75.2).[44,93–95] A summary of practice recommendations for specific clinical circumstances based on a systematic review is presented in Box 75.3. The review emphasized the lack of high-quality evidence on plasma infusion and the need for well-designed trials to address relevant knowledge gaps.[96] The use of prothrombin complex concentrate is often recommended as initial therapy instead of FFP for significant warfarin-related bleeding owing to more rapid correction of the INR.[44]

FFP should be administered only to provide coagulation factors or plasma proteins that cannot be obtained from safer sources. FFP is commonly used to treat bleeding patients with acquired deficiency of multiple coagulation factors, as in liver disease, DIC, or dilutional coagulopathy as the result of massive transfusion. However, changes in INR after FFP transfusion are usually minimal and not clinically significant when the pretransfusion INR is less than 2.0.[92,97] FFP may be indicated for the provision of protein C or S in patients who are deficient and have acute thrombosis. FFP should be administered as boluses as rapidly as feasible so that the resulting factor levels achieve hemostasis. The use of continuous FFP infusions is not helpful. Variable doses of FFP have been recommended including 2 units initially (probably

Deficiency of coagulation factors with abnormal coagulation tests AND
  Active bleeding
  OR
  Planned surgery or invasive procedure
Immediate reversal of warfarin effect with active bleeding or planned procedure
Thrombotic thrombocytopenic purpura
Congenital factor deficiency with bleeding or need for prophylaxis and no alternative therapy
Rare protein deficiencies (protein C or S)

• BOX 75.3 Recommendations Regarding Fresh Frozen Plasma Transfusion in Specific Conditions[a]

1. Suggest that FFP be transfused to trauma patients requiring massive transfusion.
2. Cannot recommend for or against of FFP transfusion at a plasma-to-RBC ratio of 1:3 or more in trauma patients with massive transfusion.
3. Cannot recommend for or against FFP transfusion in patients undergoing surgery in the absence of massive transfusion.
4. Suggest FFP be transfused in patients with warfarin-related intracranial hemorrhage.
5. Cannot recommend for or against FFP transfusion to reverse warfarin in patients without intracranial hemorrhage.
6. Suggest against FFP transfusion in other groups of patients (in the absence of massive transfusion, surgery, bleeding, or overanticoagulation).

underdosage) up to 10 to 20 mL/kg. However, some studies suggest that doses as high as 30 mL/kg may be needed to achieve adequate factor levels.[98] FFP is frequently incorporated into massive transfusion protocols in a ratio of 1 unit for every 1 to 2 units of RBCs transfused.[99,100] Because of the short half-life of factor VII, FFP should be infused every 6 to 8 hours if bleeding continues. FFP should not be used for volume expansion or as a nutritional source of protein. Anticoagulation induced by heparin, direct thrombin inhibitors (e.g., dabigatran), or direct factor Xa inhibitors (e.g., rivaroxaban) is not reversed by FFP.

Patients do not usually bleed as a result of coagulation factor deficiency when the INR is less than about 2.0, and even then the results are not always predictable.[101] The partial thromboplastin time is also not useful in predicting procedural bleeding risk.[102] Prophylactic administration of FFP does not improve patient outcome in the setting of cardiac surgery unless there is bleeding with an associated documented coagulation abnormality.[103,104] FFP is often requested prophylactically before an invasive procedure when the patient exhibits mild prolongation in coagulation studies. Most of these procedures may be carried out safely without transfusing FFP.[101,105] A randomized trial of FFP versus no FFP in critically ill nonbleeding patients with INR between 1.5 and 3.0 scheduled to undergo central venous catheter placement, thoracentesis, percutaneous tracheostomy, or drainage of abscess or fluid found no differences in bleeding complications.[106]

Coagulation factors are normally present in the blood far in excess of the minimum levels required for hemostasis. As little as 10% to 30% of the normal plasma concentration of several factors will effect hemostasis. Conversely, FFP treatment of acquired multiple deficiencies, as in hepatic failure, is often ineffective because many patients cannot tolerate the infusion volumes required to achieve hemostatic levels of coagulation factors, even transiently.[107] The plasma half-life of transfused factor VII is only 2 to 6 hours. It may be impossible to administer sufficient FFP every few hours without encountering intravascular volume overload. Finally, in some instances, transfusion of seemingly adequate volumes may still fail to correct the coagulopathy.[108] Careful documentation of both the need for FFP and the adequacy and outcomes of therapy is essential.[109]

Transfusion of FFP is associated with significant adverse effects. It may be implicated in the development of TRALI. Because of the large volumes that may be transfused, FFP administration is a risk factor for transfusion-associated circulatory overload (TACO). Allergic reactions to FFP are usually mild with the exception of anaphylactic reactions to IgA proteins that can occur when plasma is transfused in IgA-deficient patients.

Cryoprecipitate

A total of 1.1 million units of cryoprecipitate was transfused in 2011 in the United States.[1] Cryoprecipitate is prepared by thawing and centrifuging FFP below 6°C and resuspending the precipitated proteins in a small volume of supernatant plasma. Each unit is a concentrated source of factor VIII (≥80 IU), von Willebrand factor (50% of original plasma content), fibrinogen (≥150 mg), factor XIII (30% of original plasma content), and fibronectin. It is considered to be leukoreduced without additional filtration. Cryoprecipitate offers the advantage of transfusing more specific protein and less total volume than an equivalent dose of FFP. Cryoprecipitate does not require cross-matching, but ABO compatibility with the recipient is preferred. Cryoprecipitate must be transfused within 4 to 6 hours of thawing with the shorter time required for units exposed to an open process.

Indications for Cryoprecipitate Transfusion

In the past, cryoprecipitate was used to treat patients with inherited coagulopathies, such as hemophilia A, von Willebrand disease, and factor XIII deficiency. However, the availability of safer specific factor concentrates makes use of cryoprecipitate unwarranted for these conditions unless factor concentrates are unavailable. In the critical care setting, cryoprecipitate is most commonly used to replenish fibrinogen, especially in bleeding patients with hypofibrinogenemia caused by dilutional or consumptive coagulopathy. Transfusion of cryoprecipitate is usually recommended when fibrinogen levels are less than 100 to 150 mg/dL in the setting of bleeding or need for an invasive procedure.[44,95,110] Cryoprecipitate also reportedly improves hemostasis in uremic patients, presumably by reversing the functional platelet defect,[111] but desmopressin or dialysis should be used preferentially to avoid potential transfusion-related complications. Similar to other blood components, cryoprecipitate is often transfused inappropriately.[112]

The usual dose of cryoprecipitate to treat hypofibrinogenemia is 10 units to start, then 6 to 10 units every 8 hours or as necessary to keep the fibrinogen level above 100 mg/dL. The fibrinogen response will depend on the patient's plasma volume (varies with gender and weight), initial fibrinogen level, and consumption of fibrinogen. Although several formulas are available to calculate the fibrinogen requirement, most dosing is empiric with reassessment of fibrinogen levels.[44] Each unit of cryoprecipitate carries a risk of disease transmission equivalent to that of 1 unit of blood.

Adverse Effects of Blood Component Transfusion

The decision to transfuse blood components must be made with full awareness of the potential risk to the recipient, as well as the expected benefits. For some patients, the benefit from transfusion of a blood product is so obvious that the associated risks are not significant compared to the consequences of withholding transfusion. However, the clinician's knowledge of the incidence and management of the adverse effects to transfusion is vital, not only to ensure the best patient care but also to provide appropriate patient education and true informed consent.

The nature of adverse reactions associated with blood product transfusion ranges from those that are common but clinically unimportant to those that may cause significant morbidity or death. The U.S. Food and Drug Administration reported 41 transfusion-related or potentially transfusion-related deaths in 2015, compared with 58 in 2011.[113] From 2011 through 2015, TRALI accounted for 38% of fatalities followed by TACO in 24%.

Why blood component transfusions may be harmful in critical care patients is not well understood. With the modern techniques in screening, storing, and matching RBCs, the mortality rate directly attributable to transfusions is extremely low; however, retrospective data often link increased numbers of transfusions to increased mortality or adverse outcomes.[8,9,12,40,114] It is difficult to distinguish whether this trend is a function of anemia as a signal for increased severity of illness versus an actual consequence of the transfusion. Nevertheless, the relationship between transfusions and increased mortality rates is concerning, and a better understanding would help both clinicians and patients understand the risks involved with transfusions, as well as to aid investigators to develop new methods of safer transfusions. Potential mechanisms of recipient harm include risk of infections or multiorgan failure via immunomodulatory effects from the introduction during transfusion of

unintended lipid breakdown products, cell-signaling factors, and donor-recipient antigen-antibody interactions.

Acute Transfusion Reactions

The signs and symptoms of severe, life-threatening transfusion reactions are frequently indistinguishable from those of less significant reactions. However, every transfused patient who experiences a significant change in condition, such as an elevation in temperature, change in pulse or blood pressure, dyspnea, or pain, must be promptly and fully evaluated to identify the cause of the reaction and to institute treatment when necessary.[115] The basic approach to all acute reactions should be to maintain a high index of suspicion for acute hemolytic reactions (with RBC components) by stopping the transfusion immediately, maintaining venous access with intravenous fluids, and informing the blood bank laboratory immediately so that the appropriate transfusion reaction protocol can be instituted and posttransfusion specimens obtained. Early recognition of severe transfusion reactions may be lifesaving.

Acute Hemolytic Transfusion Reaction

Acute hemolytic transfusion reactions (AHTRs) are caused by the recipient's existing complement-fixing antibodies attaching to donor RBC antigens with resultant intravascular RBC lysis. Non-ABO incompatibility is now more commonly implicated than ABO incompatibility in these incidents.[113] In addition to hemolysis, complement activation stimulates the release of inflammatory mediators and cytokines and can lead to hypotension and vascular collapse. Activation of the coagulation system may result in DIC and bleeding. Acute renal failure may also occur, presumably on the basis of immune complex interactions. Morbidity and mortality rates are directly related to the quantity of incompatible blood transfused, which is why prompt recognition and cessation of transfusion are imperative. Misidentification of the patient, or clerical error, at any time beginning with acquisition of the donor specimen through release of the unit and initiation of infusion is the major cause of AHTRs.[116] It is preferable to transfuse non–cross-matched group O RBCs than to chance ABO incompatibility caused by improper patient and specimen identification procedures.

The most common clinical sign of an AHTR is sudden onset of fever, with or without chills.[115] Other common signs and symptoms include back or flank pain, anxiety, nausea, light-headedness, dyspnea, and hemodynamic instability. In a comatose or anesthetized patient, these symptoms may not be evident; therefore signs such as hypotension, hemoglobinuria, and diffuse oozing from puncture sites or incisions may be the only notable features.

Immediate management of suspected AHTRs includes cessation of the transfusion; the remainder of care is supportive. Rapid verification of patient and unit identification must be made, not only to confirm the suspected reaction but also to prevent a second patient from receiving a reciprocally incompatible unit if a clerical error has been made. Steroids, heparin, or other pharmacologic interventions have no role in treatment.

Febrile Nonhemolytic Transfusion Reactions

Febrile nonhemolytic transfusion reactions (FNHTRs) are the most commonly occurring acute reaction to RBC and platelet transfusions. These reactions can cause significant discomfort and must be investigated because they share manifestations with AHTRs and bacterially contaminated blood. Although a temperature increase of 1°C is often used to define an FNHTR, fever may be absent in patients pretreated with antipyretics. Additional clinical signs include chills or rigors usually beginning 1 to 2 hours after the start of the transfusion but occasionally delayed up to 4 to 6 hours. Associated manifestations may include nausea, vomiting, and dyspnea. FNHTRs occur in approximately 1.0% of transfusion episodes but are more common with platelet transfusions (4%–31%).[117,118] The cause of FNHTRs varies with the transfused product, but the release or presence of cytokines and pyrogens results in the clinical manifestations. This reaction to RBC transfusion is usually initiated by the interaction of recipient antibodies to donor leukocytes. Nonhemolytic transfusion reactions (NHTRs) with platelet products are most commonly initiated by leukocyte- or platelet-derived cytokines or other biologic response modifiers.[118] Management of NHTRs includes discontinuation of transfusion and initiation of the appropriate transfusion reaction evaluation. Antipyretics such as acetaminophen may be administered. Antihistamines are neither preventive nor therapeutic. Once acute hemolysis is excluded, transfusion of a new unit may be instituted. If repeated NHTRs become problematic, leukocyte-depleted blood components should be supplied. The implementation of universal leukocyte reduction results in a reduction in the frequency of all fever seen after transfusion by about 12%.[119] Pretreatment with antipyretics or corticosteroids may also minimize FHTRs.

Anaphylaxis

Anaphylactic reactions to blood transfusions are rare but may be life-threatening. The usual cause is recipient antibody to a component of plasma that the patient lacks, most commonly antibody to IgA in IgA-deficient individuals. However, antibodies to other proteins (antihaptoglobin) have been demonstrated and activated platelet membranes may also play a role.[120,121] The highest rate of anaphylaxis occurs with platelets followed by FFP and RBCs. Signs and symptoms usually begin within minutes after transfusion is initiated and include severe anxiety, flushing, dizziness, dyspnea, bronchospasm, abdominal pain, vomiting, diarrhea, hypotension, and eventually shock. Fever and hemolysis do not occur. Management includes immediate cessation of transfusion and standard therapy for anaphylaxis. If anti-IgA antibodies are determined to be the cause of this reaction, the patient must receive blood components donated by IgA-deficient individuals or, if unavailable, specially prepared washed RBCs and platelet concentrates. Plasma-derived preparations, such as albumin, and immunoglobulins contain varying amounts of IgA and pose a substantial risk in these patients.

Allergic and Urticarial Reactions

Hives and pruritus are relatively common cutaneous adverse effects of transfusion and may occur with transfusion of RBCs, platelets, and FFP.[117] They are a hypersensitivity reaction localized to the skin, and their cause is unknown but may include both donor and recipient characteristics. These reactions consist of localized or generalized urticaria beginning shortly after the start of transfusion without fever or signs or symptoms of anaphylaxis or hemolysis. The transfusion should be temporarily interrupted, and antihistamines administered. If the hives resolve in a short time, the same unit of blood may be cautiously restarted. If repeated urticarial reactions occur, premedication with antihistamines may be effective.

Delayed Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions (DHTRs) are an uncommon but probably underrecognized reaction to RBC transfusion

that result from the stimulation of a primary or secondary (anamnestic) recipient antibody response to foreign RBC antigens. These antibodies are below the limit of detection at the time of transfusion but increase after transfusion. DHTRs typically occur 3 to 14 days after transfusion but may not be recognized because of the lack of a clear temporal association with transfusion. DHTRs are more likely in patients requiring frequent RBC transfusion such as those with sickle cell disease.[115,117] Patients may be asymptomatic or experience fever, chills, and an unexplained decline in hematocrit.[115] Transient elevation in unconjugated bilirubin and lactate dehydrogenase may also occur. The diagnosis is established by a positive direct antiglobulin (Coombs) test resulting from recipient antibody coating donor RBCs. The specificity of the antibody is often against such RBC antigens as the Rh family, Kidd, Duffy, or Kell systems. Hemolysis may not occur, but if it does, it is likely to be extravascular and only rarely causes renal failure or DIC.

Prevention of these reactions is difficult. Alloimmunization to foreign RBC antigens occurs in approximately 1% of transfusions. Detection of delayed antibodies is the purpose for requiring a new blood bank specimen every 72 hours if the patient has recently been transfused. Permanent transfusion records should record the occurrence of delayed antibodies, even though they may not be apparent at a later cross-match.

Transfusion-Associated Circulatory Overload

TACO has been associated with increased mortality and hospital length of stay and accounted for 24% of transfusion-related fatalities in the United States between 2011 and 2015.[113,122,123] It is more likely to occur with RBC or FFP transfusion because of the higher volumes of these blood components.[121] Aside from the inherent volume of the blood components, the concurrently administered normal saline solution adds to the volume load. Risk factors for TACO include older age, critical care patients, cardiac and renal dysfunction, chronic anemia, positive fluid balance, increased volume of blood products, and rapid rate of transfusion.[115,122,123] Clinical manifestations of TACO include dyspnea, orthopnea, cough, and worsening oxygenation owing to hydrostatic pulmonary edema. Management options include slowing the rate of transfusion and administration of diuretics. Careful attention to transfusion requirements and use of the smallest volumes necessary can help minimize volume overload in most instances. TACO may be difficult to distinguish clinically from TRALI, but TACO is less likely to be associated with fever and hypotension and more likely to be associated with a significantly elevated brain natriuretic peptide and hypertension.

Transfusion-Related Acute Lung Injury

TRALI is the leading cause of transfusion-related deaths in the United States.[113] Products containing plasma (e.g., FFP and platelets) seemed to have a higher risk before current risk mitigation interventions, but the reaction can be seen with all types of blood components. Transfusion of plasma from female donors increases the risk of TRALI.[124,125] TRALI is defined as the development of acute lung injury (hypoxia and bilateral infiltrates of noncardiac cause) within 6 hours of transfusion in the absence of another more likely cause.[125,126]

In patients without prior respiratory compromise, TRALI manifests as acute hypoxia with the development of rales and diffuse infiltrates on chest radiograph.[127] It may also be accompanied by tachycardia, fever or hypothermia, and hypotension or hypertension. Recognition of TRALI may be difficult in critically ill patients who may have other reasons for dyspnea or may already require mechanical ventilation. In addition, TRALI and TACO may be difficult to distinguish. Clinical features that favor TRALI over TACO include the presence of fever and leukopenia.

Unlike other forms of acute lung injury (ALI), TRALI is usually self-limiting and resolves within 1 to 4 days. However, reactions can be severe and may necessitate mechanical ventilation. Treatment consists of supportive care, including the prompt management of hypoxia. If mechanical ventilation is required, lung-protective ventilation and a restrictive fluid strategy should be implemented. Because the inciting factor is derived from the donor product rather than the patient, additional blood products can still be transfused if necessary with low risk of redevelopment.

Studies have suggested several mechanisms in the development of TRALI. The presence of leukocyte antibodies in the donor blood has been consistently linked to many cases, although other triggers such as lipids and biologic response modifiers (cytokines) have also been implicated.[125,128,129] When exposed to donor antibodies, neutrophils that are already recruited to the pulmonary vascular endothelium release inflammatory products, leading to injury of the endothelial cells and increased vascular permeability. Recipient factors are also involved, as blood products from the same donor do not consistently cause TRALI in different recipients. Critically ill patients may be more susceptible to TRALI owing to increased localization of neutrophils in the pulmonary vasculature.

To reduce the risk of TRALI, blood agencies have adopted a risk mitigation strategy of using male-predominant plasma transfusion to reduce exposure to donor leukocyte antibodies.[130] The number of fatalities related to plasma have been decreasing in the United States and elsewhere, most likely owing to reduced plasma transfusion from female donors.[113]

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated GVHD (TA-GVHD) is a rare and usually fatal immunologic complication of blood component transfusion.[117] Immunocompromised patients infused with blood components containing viable donor lymphocytes are at risk for engraftment of the allogeneic lymphocytes and ensuing rejection of recipient (host) tissues. Transfusion recipients who are at highest risk include bone marrow and organ transplant recipients, patients with leukemia and lymphoma, and recipients of blood donated by relatives. TA-GVHD has been reported in patients after cardiac surgery who received designated donor blood from relatives; presumably, the HLA antigenic differences between donor and recipient were insufficient to stimulate a recipient immune response but sufficient to elicit a donor immune response.[131] The onset of TA-GVHD is usually within 8 to 30 days after transfusion, and it is manifested as fever and skin rash, followed by diarrhea and evidence of liver dysfunction and bone marrow suppression. TA-GVHD differs from that seen in bone marrow transplantation by its involvement of the marrow and far greater mortality risk. Treatment is largely ineffective, and mortality rate exceeds 90%.

Irradiation of blood components at 25 Gy prevents TA-GVHD by eliminating the donor lymphocyte mitogenic response. All cellular blood components should be irradiated before transfusion to high-risk patients. The functions of the cellular components of blood are unaffected, although damage to RBC membranes limits the duration of postirradiation storage of PRBCs to 28 days. Blood

donated by a relative for any patient should be irradiated, as should HLA-matched or cross-matched platelet products.

Transfusion-Related Immunomodulation

Transfusion-related immunomodulation (TRIM) may potentially have significant adverse effects that affect patient outcome. Allogeneic RBC transfusion has been shown to suppress the recipient's immune response, an effect first noted with kidney transplantation that resulted in increased survival of the transplanted kidney.[132] However, immunosuppression is generally undesirable in critically ill patients, even though the clinical impact of blood component transfusion is not well defined. As noted in previous sections, immunomodulation likely contributes to AHTRs, NHTRs, anaphylaxis, and TRALI. The major clinical issues regarding TRIM center around the association between blood product transfusion and the increased risk of infection and increased and more rapid rates of tumor recurrence in surgical oncology patients. The largest prospective trial of colorectal cancer resection, for example, had negative findings,[133] but a meta-analysis of existing data suggests that an adverse effect on recurrence does exist.[134] Significant heterogeneity exists in the reported studies and makes definitive conclusions difficult.[135] Most retrospective and prospective trials of postoperative or critical care unit infections suggest an adverse effect of blood component transfusion.[136–138]

The precise mechanism of the immunomodulation induced by transfusion has not yet been delineated, and several mechanisms may be involved. Allogeneic plasma, leukocytes, and substances that accumulate in stored blood components may contribute to TRIM. Alterations identified in laboratory and clinical transfusion recipients have included depression of the T-helper/T-suppressor lymphocyte ratio, decreased natural killer cell activity, diminished IL-2 generation, formation of anti-idiotype antibodies, impairment of phagocytic cell function, and chronic persistence of donor lymphocytes (microchimerism), suggestive of low-level GVHD. Difficulties in analysis of human data arise because patients requiring blood component transfusions have conditions that may induce immune changes. Well-designed prospective trials are needed to more clearly elucidate the impact of any immunomodulatory effects of transfusing blood products.

Transfusion-Transmitted Infectious Diseases

Transfusion-associated AIDS has done more to revolutionize transfusion practice than any other transfusion risk by resulting in more conservative blood use, more stringent donor selection criteria, and improved screening tests. The result is that viral transmission rates are now difficult to measure, and the risk of transfusion-related infectious diseases is lower than ever.[139] Bacterial infection has become the most common infectious risk.

Microbial and Endotoxin Contamination

Several fatalities are reported yearly from the transfusion of blood components contaminated with viable bacteria, with or without the accumulation of endotoxin.[113,140] Platelet concentrates stored at room temperature are particularly prone to bacterial growth, with a reported incidence of 1.13 in 10,000 components with apheresis units having the highest contamination rate.[141] Organisms isolated from platelets and implicated in fatal transfusion reactions include *Staphylococcus* and *Streptococcus* species and gram-negative bacilli. Fatalities resulting from bacterial contamination of refrigerated RBCs have occurred as well and more often involve cryophilic bacteria. RBC transfusions contaminated by *Yersinia enterocolitica* have been consistently reported.[142] Transfusion reactions caused by bacterial or endotoxin contamination are fortunately quite rare, but the mortality rate may exceed 60%.

Signs and symptoms of reactions caused by microbial contamination overlap those of hemolytic transfusion reactions and consist primarily of fever and hypotension, along with other signs of septic shock. A Gram stain of the implicated unit can be prepared immediately and, if positive, appropriate antibiotic and supportive therapy instituted. Autologous blood components may also be contaminated at the time of collection; therefore reactions occurring in patients who are receiving their own blood should be evaluated as fully as though they were receiving allogeneic blood.

Hepatitis

The success of viral screening measures is most clearly illustrated by the fall in the risk for posttransfusion hepatitis over the past several decades. The elimination of paid donors in 1972 and the introduction of nucleic acid tests for hepatitis B virus (HBV) and hepatitis C virus (HCV) have resulted in a steady reduction in the rates of posttransfusion hepatitis. The estimated residual risk for hepatitis B surface antigen is 1 per 300,000 donations.[143] Although about 30% to 40% of HBV transmissions result in acute hepatitis, chronic HBV infection develops in less than 10% of such patients. In contrast, the risk for chronic HCV infection after transfusion is higher, nearly 50%.[144] The risk of HCV transmission is even lower than HBV with a residual risk estimate of 8.7 per 10 million transfused blood components.[145] The clinical course of hepatitis A is generally milder, and the lack of a chronic carrier state means that with donor screening for symptoms of the acute illness, the risk of transmission is rare.

Retroviruses

Retroviruses known to be capable of transmission by transfusion are human immunodeficiency virus (HIV-1, HIV-2) and human T-cell leukemia/lymphoma virus (HTLV I and II). The screening enzyme-linked immunosorbent assay to detect antibody to HIV-1 was incorporated into the blood-screening process in 1985. Improved confidential donor screening also decreased the risk of infectious units appearing in the donor pool.[146] The discovery that heat treatment decreased transmission resulted in a reduction in transmission by plasma products, especially to persons with hemophilia. Removal of donor units with seropositivity by enzyme-linked immunosorbent assay was insufficient to prevent transmission of HIV-1. Subsequent development of an assay for the p24 antigen and nucleic acid testing have lowered the risk of transfusion-associated HIV-1 infection to an estimated 1 in 1,467,000 transfused blood components.[145] Despite donor screening and sensitive assays, an extremely small but finite risk of HIV-1 transmission by screened blood transfusions remains. This risk is largely due to the interval between infection and development of detectable concentrations of HIV ribonucleic acid in plasma in newly infected donors.

A second retrovirus, HIV-2, first described in residents of countries in West Africa and subsequently detected in migrants to western Europe, causes an immunodeficiency syndrome similar to that caused by HIV-1. Although very few cases of HIV-2 have been reported in donors in the United States, experience with other retroviruses suggests that screening may prevent the majority of potential transmissions. Therefore donated blood is now screened for the presence of HIV-2.

The retrovirus HTLV-I is the causative agent of adult T-cell leukemia (ATL) and is strongly implicated in the chronic, progressive

neurologic disorder termed *tropical spastic paraparesis* or *HTLV-I–associated myelopathy* (TSP/HAM). HTLV-II has been linked to hairy cell leukemia, but no transfusion-transmitted cases have been reported. The virus exhibits strong serologic cross-reactivity with HTLV-I such that screening assays fail to distinguish between the two viruses. Transfusion-transmitted HTLV-I has been demonstrated.[147] The prevalence of HTLV-I in first time donors in the United States is 5.1 per 10^5 and 14.7 per 10^5 for HTLV-II.[147] Donated blood is currently screened for antibodies to HTLV-I and HTLV-II.

Cytomegalovirus

CMV is a human herpesvirus that establishes latent infection in the host's tissues, particularly leukocytes, and is transmitted by all cellular blood components. Seropositivity, or the presence of antibody, denotes previous exposure to the virus but does not confer protective immunity. Secondary reinfection or reactivation of latent infection can occur. Antibodies to CMV persist for life and serve as a marker indicating the potential for transmission of live virus.

Immunocompetent recipients of transfused CMV-positive blood experience minimal morbidity and mortality risks. The majority of cases are asymptomatic, whereas a heterophile-negative mononucleosis syndrome may develop in a few patients. Immunocompromised patients, however, may incur life-threatening manifestations such as severe interstitial pneumonitis, gastroenteritis, hepatitis, or disseminated disease. Several groups of patients are at particular risk (Box 75.4),[148] and these patients should receive blood incapable of transmitting the virus. Screening of donated blood for CMV is not routine but can be performed quickly if necessary. Because the prevalence of donor seropositivity is quite high, CMV-seronegative blood may not be readily available. Leukocyte-depleted blood may be as effective as seronegative blood in the prevention of CMV transmission. However, a recent systematic review found that data were of poor quality and insufficient to propose any specific guideline regarding CMV-seronegative blood versus leukocyte-depleted blood for preventing CMV transmission by transfusion.[149] Pathogen inactivation techniques available for FFP and platelets may be effective in preventing CMV transmission but are not available for blood.

Parasites

Many blood-borne parasites may be transmitted by transfusion, although this is a rare occurrence in the United States because of donor screening questions and the low endemicity of implicated agents. Changing immigration patterns and global travel, however, make transfusion-transmitted parasites an increasing concern.

On a worldwide basis, malaria is the most important transfusion-transmitted infective parasite, although only a few cases are reported in the United States each year.[150] Such infections are manifested by delayed fever, chills, diaphoresis, and hemolysis, often masked by underlying medical conditions. Fatalities have occurred. Babesiosis, a tick-borne disease caused by *Babesia microti*, is endemic in regions of the northeastern United States. Transfusion-transmitted cases have been reported, with asplenic, elderly, or immunocompromised patients being particularly susceptible.[151] Babesiosis was the second leading cause of infectious transfusion-related fatality in the United States from 2011 to 2015 (after *Staphylococcus aureus*). Although there are no licensed tests for screening donor blood, an investigational product recently resulted in a decrease in the risk of transfusion-transmitted babesiosis.[152] With increases in the number of Central and South American immigrants to North America, Chagas disease, transmitted by the protozoan parasite *Trypanosoma cruzi,* has emerged as a potential transfusion-transmissible infection.[153] Other parasitic diseases that have been transmitted by transfusion include toxoplasmosis, leishmaniasis, and Lyme disease.

• BOX 75.4 Patients for Whom Cytomegalovirus-Safe Blood Components Are Strongly Recommended

Seronegative pregnant women
Seronegative premature infants weighing <1200 g
Seronegative allogeneic or autologous bone marrow transplant recipients
Seronegative transplant recipients of seronegative organs

Emerging Infections in Transfusion Medicine

Human parvovirus B19 has been recognized as a pathogen capable of transmission by transfusion, with typical clinical findings and the potential for aplastic anemia. Epstein-Barr virus infection with a typical mononucleosis-like illness has been reported after transfusion. West Nile and dengue virus can also be transmitted by transfusion. Transmission of Zika virus infection by platelet transfusion has been reported.[154,155] H2N1 influenza, severe acute respiratory syndrome, and other new viral infections should be capable of transmission by transfusion, although cases have not been reported and the prevalence of asymptomatic disease is unknown. A rising concern is the transmission of prion disease, either Creutzfeldt-Jakob disease or bovine spongiform encephalopathy. Donor referral criteria were implemented in 1987 for these diseases, and transfusion transmission of bovine spongiform encephalopathy has been reported in the United Kingdom.

Special Transfusion Situations in the Critical Care Setting

Massive Transfusion

Massive transfusion is commonly defined as the administration of blood components in excess of one blood volume or greater than or equal to 10 units PRBCs within a 24-hour period.[156] Massive transfusion may cause complications not generally seen in usual transfusion practice: accumulation of undesirable substances present within stored blood, electrolyte abnormalities, hypothermia, and dilutional depletion of normal blood constituents that are lacking in stored units. Trauma victims, surgical patients undergoing complex or emergent procedures, and patients with vascular or coagulation disorders may require massive transfusion in the critical care setting. The first priority in such patients is to stop the bleeding but transfusion of blood products occurs simultaneously to maintain hemostasis and ensure oxygen-carrying capacity. Survival is determined more by the nature and degree of the patient's injuries or medical conditions than by the transfusions, but the presence of adverse effects of massive transfusion can complicate a patient's course in the ICU.

Blood preservative solutions contain citrate, which anticoagulates stored blood by binding ionized calcium. PRBCs and FFP contain approximately 3 g of citrate. Patients with normal liver function can metabolize this amount of citrate in 5 minutes, but hepatic

impairment may extend removal time. Toxicity may result when citrate is administered in excess of the metabolic capacity, thereby causing a decrease in ionized calcium levels.[157] Although paresthesias, cramps, and myoclonus can result from citrate excess, the principal danger of hypocalcemia is depression of myocardial contractility and potential prolongation of the QT interval. Because the effects of citrate are transient and the use of PRBCs containing little residual citrated plasma is far more common than massive transfusion with WB, routine administration of calcium is not indicated. Ionized calcium levels should be monitored and calcium administration used to maintain levels in the normal range. Hypomagnesemia is common in patients with massive transfusion, and it is often associated with hypocalcemia.[158] Citrate binds magnesium as well as calcium and may play a role in the development of hypomagnesemia.[156] Hypomagnesemia does not appear to affect outcomes in patients receiving massive transfusions.

Potassium leaks from RBCs during storage and up to 7 mEq of extracellular potassium may accumulate in each unit. Irradiation of RBCs increases extracellular potassium. However, dangerous levels of potassium rarely develop from transfused blood in adults; the potassium level is more likely to be determined by the patient's acid-base status and underlying renal function.[159] Studies of patients who receive massive transfusions have demonstrated a wide range of potassium levels, with hypokalemia seen as frequently as hyperkalemia. Because of the complexity of physiologic changes during resuscitation, it is impossible to predict the net effect of massive transfusion on serum potassium levels. Potassium levels need to be monitored closely in patients receiving large amounts of PRBCs.

The pH of stored blood drops during storage, from 7.16 at the time of collection to as low as 6.73 after several weeks of storage. The administration of large quantities of acidic blood, together with the metabolic acidosis common in these patients before resuscitation, would lead one to expect worsening acidosis as the outcome of massive transfusion. However, patients are more likely to exhibit metabolic alkalosis at the end of the transfusion episode,[159,160] partly because of improved tissue perfusion and the metabolism of citrate and lactate to bicarbonate. Patients in renal failure may be unable to handle the bicarbonate load and require dialysis. Acidosis persisting after transfusion suggests inadequate tissue perfusion.[157] Empiric administration of bicarbonate to counter the acid load is not warranted.

RBC components are stored at approximately 4°C and require 30 to 45 minutes to warm to room temperature. Elective transfusions at standard flow rates are tolerated without the need to warm the blood; however, core body temperature, measured by esophageal probe, can fall to 30°C or lower with the administration of large volumes of cold blood over a period of 1 to 2 hours.[161] Adverse effects of hypothermia include a decreased heart rate and myocardial contractility, cardiac arrhythmias, vasoconstriction, increased affinity of hemoglobin for oxygen resulting in decreased tissue oxygen delivery, coagulopathy, and impaired ability to metabolize the citrate load of stored blood. Both blood warmers and patient warming may be instituted during massive transfusion, and patient core temperature should be monitored during resuscitative efforts.

Massive transfusion might precipitate acute respiratory distress syndrome (ARDS) because all cellular transfusions contain damaged or activated WBCs, cell membranes, aggregated platelets, and microthrombi, all of which are capable of lodging in and damaging pulmonary capillaries. Despite this possibility, neither microfiltration of transfusions nor routine leukocyte depletion has shown a significant impact on the incidence of ARDS in patients receiving massive transfusions.[162] Certainly, other causes of ARDS exist in patients who undergo massive transfusion, and the possibility of TACO and TRALI should be considered in the evaluation of patients with hypoxia and diffuse pulmonary infiltrates after massive transfusion.

Autoimmune Hemolytic Anemia

Patients with autoimmune hemolytic anemia have an autoantibody, usually of broad specificity, that fixes itself to their RBCs and triggers extravascular immune-mediated destruction. Patients with autoimmune hemolytic anemia have a positive result on direct antiglobulin testing (commonly known as the Coombs test)[163] and varying degrees of hemolysis, and their autoantibodies cause agglutination of RBCs from all donors during cross-matching. If the hemolysis is brisk, patients may require RBC transfusion to support oxygen needs before medical management is effective. Hence, transfusion is difficult because agglutination during cross-matching interferes with proper definition of compatible units of RBCs and because the transfused RBCs are themselves subject to the same immune hemolysis as the host RBCs. Many blood banks have methods for depletion of autoantibodies from the recipient's plasma and elution of antibodies from RBCs to arrive at a proper cross-match.[164] Although such cross-matches are time consuming and not generally available on an emergency basis, they can be lifesaving. Criteria for transfusion should remain the same as for other recipients.

Necessary Transfusion of Incompatible Blood

RBCs are cross-matched for RBC antigens in the ABO and Rh_0(D) groups and for other RBC antigens when antibodies are present. However, there are several hundred other RBC antigens in the human family and recipients with repeated transfusion may become alloimmunized to other antigens. Generally, alloimmunization occurs in approximately 1% of transfusions, but the prevalence of alloantibodies is higher in chronically transfused, relatively immunocompetent patients, especially African Americans, whose distribution of RBC antigens has significant variation from the white population. Alloimmunization may present difficulties in cross-matching of blood to the point that compatible blood must be obtained from rare-donor registries, if at all. In some patients the alloantibody is never precisely identified, yet the majority of blood available for transfusion is incompatible. The delay engendered by working with multiple or unidentified antibodies may be unacceptable in some critical care situations in which the need for oxygen-carrying capacity leaves no choice but to transfuse incompatible blood. The behavior of these antibodies in the laboratory may assist in predicting the clinical outcome of the incompatible transfusion.[165] Special procedures such as clearance studies, flow cytometry, and in vivo cross-matching (cautious administration of a small aliquot of blood, with subsequent observation of serum and urine for evidence of hemolysis) are useful if time permits.

Emergency transfusion of type O, Rh-negative non–cross-matched blood is generally reserved for the resuscitation of trauma patients, for whom the delay in cross-matching may be life-threatening. The risks of alloimmunization to non-ABO antigens are generally accepted as low, and one study found antigen-incompatible RBCs were transfused in 2.6% of patients who required emergency blood release.[166] Even Rh-positive type O RBCs may be used because rates of alloimmunization to Rh_0(D) are low under the circumstances of emergency transfusion.

Alternatives to Transfusion of Blood Components

The safest transfusion is one that is not given. Therefore alternatives to blood component therapy continue to be sought. It may be possible to limit blood component exposure by the appropriate use of pharmacologic agents that promote hemostasis and the administration of recombinant hematopoietic growth factors to stimulate marrow hematopoiesis.

Blood Substitutes

Two types of alternative oxygen carriers have been evaluated for clinical use, but no oxygen-carrying blood substitute is currently approved for use in the United States.[167,168] Perfluorocarbons are hydrophobic molecules with high oxygen-carrying capacity that have to be administered as an emulsion to be soluble in plasma. The perfluorocarbon solutions have failed to demonstrate any utility as intravascular oxygen carriers because of their unfavorable P-50 (oxygen half-saturation pressure) and oxygen off-loading characteristics. The other type of preparation that has been explored in clinical trials is cell-free hemoglobin solutions cross-linked or polymerized by chemical manipulation to prevent rapid clearance from the circulation. Known as hemoglobin-based oxygen carriers, they are intended to provide short-term oxygen-carrying capacity for acutely ill patients and have the advantage of not requiring cross-matching and no risk of infection. Although these proposed products may have a longer shelf life and are easier to transport, they have many drawbacks. Most have a circulatory half-life of only about 24 hours. The oxygen dissociation curve for these substitutes is also frequently not favorable: either a high fraction of inspired oxygen (FIO_2) is required to "load" these molecules or they are less likely to deliver oxygen efficiently at lower partial pressure of oxygen (PO_2) levels. Main concerns for hemoglobin-based oxygen carriers have been unfavorable side effects, including hypertension, increased cardiovascular mortality risk, and renal dysfunction. Because the hemoglobin source is reclaimed bovine or human RBCs, it is unlikely that patients who do not accept blood components because of their religious beliefs (Jehovah's Witnesses) will accept these types of hemoglobin solutions.

Desmopressin

The synthetic vasopressin analog, desmopressin (DDAVP), increases plasma factor VIII:c and promotes the release of von Willebrand factor from endothelial stores.[169] DDAVP has provided effective hemostasis in bleeding patients with mild hemophilia A and type I von Willebrand disease and has been used as prophylaxis for patients undergoing surgery. DDAVP reportedly improves platelet function in some patients with qualitative platelet disorders associated with uremia, cirrhosis, and aspirin ingestion. Studies of its efficacy in cardiopulmonary bypass procedures are conflicting, but a subset of these patients may benefit. The chief drawback to its use is tachyphylaxis, which develops in essentially all cases after short-term repeated administration.

Antifibrinolytic Agents

The lysine analogs ε-aminocaproic acid and tranexamic acid inhibit fibrinolysis by blocking the binding of plasminogen and plasmin to fibrin. These antifibrinolytic agents may decrease bleeding and thus the need for blood components in patients with hemophilia, thrombocytopenia, and systemic fibrinolysis. A novel and effective use of tranexamic acid involves administration as a mouthwash in preparation for oral surgery in patients with hemophilia or those receiving oral anticoagulant therapy. Tranexamic acid has also been demonstrated to effectively decrease mortality rates in high-risk trauma patients when given within 3 hours of presentation.[170] Use may also be promising in decreasing blood transfusion requirements in high-risk surgical procedures, such as radical prostatectomy.[171] The most serious side effect of these agents when systemically administered is thrombosis; thus it is important to use them appropriately and monitor the patient carefully during their use.

Aprotinin is a naturally occurring bovine serine protease inhibitor that acts on plasma serine proteases such as plasmin, kallikrein, trypsin, and some coagulation proteins. Aprotinin was previously shown to reduce blood loss in patients undergoing cardiopulmonary bypass surgery by inhibiting fibrinolysis and preventing platelet damage.[172] However, an observational study and a large multicenter randomized trial in cardiovascular surgery patients found that use of aprotinin was associated with an increased mortality rate, and therefore should not be used routinely.[173,174]

Vitamin K

When time permits, vitamin K is the preferred agent to reverse the coagulopathy induced by warfarin. Normalization of the prothrombin time (PT) can be seen in as few as 6 to 12 hours. Additionally, selected patients with cirrhosis may exhibit improvement in the PT when treated with therapeutic doses of vitamin K. Many patients in critical care units exhibit a prolonged PT, especially if dietary supplements are limited and broad-spectrum antibiotic therapy is given. Vitamin K is a safe and effective agent for reversing this effect. Intravenous administration of vitamin K is associated with a small risk of anaphylaxis, and oral replacement is preferred over subcutaneous administration for more consistent absorption.

Hematopoietic Growth Factors

Recombinant erythropoietin (EPO) has dramatically reduced the RBC transfusion requirements of patients with chronic renal failure, in which decreased renal EPO production accounts for the anemia. Studies of EPO efficacy in reducing perioperative RBC transfusion requirements by increasing the yield of predeposited autologous blood or stimulating bone marrow synthesis after surgery have shown benefit in reducing blood transfusion, although preoperative planning and autologous deposits are required.[175] Despite initial promising results, use of EPO in critically ill patients lacked efficacy in decreasing RBC transfusions and increased the risk for thrombotic vascular events.[176] Consideration for EPO administration may be appropriate in select patients who are unable to receive blood transfusions after risks and benefits are addressed.

Cell Salvage Technology

Cell salvage equipment has been in clinical use for several decades, and although cell salvage is clearly capable of rescuing otherwise "lost" RBCs, its full impact on transfusions has been poorly documented. Cell salvage generally consists of collection of shed blood from a clean, uncontaminated operating field, followed by removal of the cellular elements and retransfusion into the patient. Cell

salvage has been used both intraoperatively and postoperatively, especially in cardiac surgery. Although clinical studies of cell salvage have many methodologic flaws, it does reduce the need for blood transfusion in adult elective cardiac and orthopedic surgery.[177] Risks include bacterial contamination, febrile reactions, triggering of DIC, and coagulopathy as a result of dilution. When combined with acute intraoperative hemodilution, this technology is also potentially cost saving.[178]

Legal Issues in Transfusion Medicine

Most states regulate blood banking and medical practice, but blood products are regarded as a service, not as a commodity, so standard product liability does not pertain to blood components.[179] However, negligence in the course of preparing, testing, transferring, cross-matching, and administering blood products is still a potential cause for legal action. Every clinician who orders transfusions must be aware that blood components, like drugs, are approved for specific uses and that the indications should be clearly documented in the medical record.

The informed consent of the patient is an important area of potential liability. The Joint Commission has required written patient consent for blood transfusions since 1996. What constitutes adequate informed consent and who is responsible for advising the patient are still debated. Elements of informed consent include an understanding of the need for transfusion, its risks and benefits, and the alternatives, including the risk of not undergoing transfusion, as well as the opportunity to ask questions. Whether the clinician documents informed consent with an individual progress note in the patient record or with a standardized form is generally established as institutional policy. Similarly, institutions vary with respect to policies for consenting adults who are temporarily incompetent, such as sedated patients in the ICU.

A competent adult patient may refuse blood transfusion, and Jehovah's Witnesses commonly do so for religious reasons. Case law is clear in upholding this right of the patient,[180] which extends to care given at such time as the patient may become incompetent (i.e., comatose) after such refusal was expressed before becoming incompetent. Courts will usually order a lifesaving transfusion for minors. Exceptions have been made in the case of some "emancipated minors" who are at the age of reason. Most states have evoked a "special interest" in the welfare of a fetus in ordering transfusions to pregnant women.

The advent of sentinel event reviews and other quality management procedures for patient safety has had an impact on transfusion practice as well. Procedures for patient identification before surgical procedures, including devices such as bar code readers, have also been applied to transfusion practice.

Key Points

- Blood components should be prescribed like therapeutic agents as part of a blood management program.
- RBC transfusion can be considered when the hemoglobin is 7 g/dL or lower for the majority of hemodynamically stable ICU patients. A transfusion threshold of less than 8 g/dL may be appropriate for patients with symptomatic cardiovascular disease and postoperative surgical patients.
- Platelet transfusions are indicated for patients who have active bleeding as the result of thrombocytopenia or functional platelet defects and for the prevention of bleeding related to thrombocytopenia.
- FFP is indicated for the repletion of coagulation factors in bleeding patients deficient in those factors or to provide specific plasma proteins that cannot be obtained from safer sources.
- Cryoprecipitate is a concentrated source of fibrinogen and selected coagulation factors. Cryoprecipitate may be more helpful than FFP in correcting the hypofibrinogenemia of dilutional or consumptive coagulopathy.
- Adverse reactions to blood components occur in 1% to 2% of transfusion episodes. Adherence to routine protocols for the evaluation of transfusion reactions may save lives.
- Transmission of infectious agents by transfusion has been markedly reduced, and bacterial infection is now the most common infectious complication of transfusion.
- Informed consent for blood transfusion is a standard of practice. A competent adult has the legal right to refuse blood transfusion.

Review Questions

1. A 48-year-old man with a history of multiple myeloma has undergone bone marrow transplantation. He is admitted to the intensive care unit (ICU) because of minor bleeding with profound thrombocytopenia (platelet count 4000/mm^3). Five units of random donor platelets are transfused with a post-transfusion platelet count of 10,000/mm^3. He still experiences minor bleeding. Which one of the following is the *best* next treatment decision?

a. Screen for human leukocyte antigen (HLA) antibodies and transfuse HLA-compatible, single-donor platelets.
b. Transfuse ABO-specific platelet concentrates that are less than 48 hours old.
c. No further transfusion is necessary; monitor platelet count in 8 hours.
d. Administer a 2-week course of prednisone.

Answer: a. Transfusion of ABO-specific platelet concentrates that are less than 48 hours old is optimal in this case. Poor response to platelet transfusion can be seen with splenomegaly, fever, disseminated intravascular coagulation (DIC), substandard-quality platelets, and similar to this patient, bone marrow transplantation. When patients do not achieve expected increments in platelet counts after platelet transfusion, ABO-specific platelet concentrates less than 48 hours old may improve the response. If no incremental improvement is seen in a patient with no risk factors for poor response to platelet transfusion, the patient should be screened for HLA antibodies and transfused with HLA-compatible, single-donor platelets. This patient is still symptomatic after platelet transfusion and will need additional platelet concentrates. Prednisone will not improve the response to platelet transfusion.

2. A 78-year-old woman was hospitalized 10 days ago because of anemia from gastrointestinal (GI) bleeding. During the hospitalization, she required transfusion of 4 units of packed red blood cells. She now arrives at the emergency department with fever, chills, a hematocrit of 18%, and no evidence of active GI bleeding. Her total bilirubin is 5.0 mg/dL, and her lactate dehydrogenase (LDH) level is 1400 U/L. Which one of the following laboratory tests will establish the diagnosis?

a. This is a clinical diagnosis, no laboratory tests are recommended.
b. Peripheral blood smear
c. Indirect antiglobulin test
d. Direct antiglobulin test (Coombs test)

Answer: d. The direct antiglobulin test (Coombs test) will establish the diagnosis. This patient is showing a classic delayed transfusion reaction, delayed hemolytic reaction, and serologic reaction. These reactions typically occur 3 to 14 days after transfusion but are unrecognized because of the lack of temporal association. Patients present with fevers, chills, and an unexplained drop in hematocrit. A transient elevation in LDH and bilirubin levels may also be present. The diagnosis is established by a direct antiglobulin test (Coombs test) resulting from recipient antibody coating of donor red blood cells (RBCs). The disease is recognized by the clinical scenario but can be established with Coombs testing. Detection of delayed antibodies is the reason that a new blood specimen is required every 72 hours if the patient has had a transfusion recently. Peripheral blood smear may show evidence of hemolysis but will not delineate between a delayed hemolytic reaction and other hemolytic processes. In addition, the direct antiglobulin test will detect recipient antibody coating of donor RBCs, but the indirect antiglobulin test will not.

3. Which of the following is the most common infectious etiology of transfusion-related fatality?

a. Bacterial
b. Viral
c. Fungal
d. Parasitic

Answer: a. Bacterial contamination is the leading cause of infection-related transfusion deaths in the United States and apheresis platelets are the most commonly contaminated blood product. *Staphylococcus aureus* is the most common organism followed by *Babesia microti* for the period from 2011 to 2015.

4. Which one of the following is most responsible for a decrease in the incidence of transfusion-related acute lung injury (TRALI)?

a. Leukocyte reduction of RBC products
b. ABO matching of platelets
c. Use of male donor fresh frozen plasma
d. Use of RBC products less than 14 days old

Answer 4: c. The frequency of TRALI has been decreasing since blood banks adopted a strategy of male-predominant plasma transfusion. This approach decreases exposure of recipients to donor leukocytes antibodies believed to be important in precipitating TRALI. Leukocyte reduction, ABO cross-matched platelets, and fresh blood have not been associated with a decrease in TRALI.

Triage of Cancer Patients for ICU Care

Palliative, Ethics, and End-of-Life Care Issues

Summary

Despite a 25% decline in the overall cancer mortality rate between 1991 and 2014, and a 1.5% annual decline among men and women from 2005 to 2014, cancer remains the second leading cause of death in the United States.[1] Cancer is the leading cause of death, however, among certain demographic groups, including men and women 40 to 59 years of age, men and women 60 to 79 years of age, and Hispanic and Asian Americans.[2–4] Although the mortality rates for female breast, prostate, colorectal, and lung cancers have declined, mortality rates for liver cancer and uterine cancer increased from 2010 to 2014.[1]

The overall cancer incidence between 2004 and 2013 has been stable for U.S. women and declined by nearly 2% annually in U.S. men.[1] Over the past 2 decades, notable advances in the diagnosis and management of cancer patients, including the use of high-dose chemotherapy, stem cell transplantation, targeted therapies, and immunotherapy, have translated to an increasing number of people living with cancer. From 2006 to 2012, nearly 67% of patients diagnosed with cancer survived 5 years or more after their diagnosis. An estimated 14.1 million people were living with cancer in the United States in 2013, and this is expected to reach 19 million by 2024.[5]

Worldwide the global cancer burden continues to increase, accounting for an estimated 14.1 million new cancer cases and 8.2 million cancer deaths in 2012.[1,6] Cancer may soon become the leading cause of death in many developed countries. If rates remain unchanged, the global cancer burden is expected to increase to 23.9 million cases and 14.6 million deaths by 2035.[6]

Patients with malignancy have been reported to account for 10% to 15% of all intensive care unit (ICU) admissions.[7,8] As the prevalence of patients living with cancer increases, it can also be anticipated that there will be more patients who require ICU admission.

Critical care of the cancer patient is a complex and expanding field as the mechanisms underlying cancer biology continue to be elucidated and novel therapeutics are developed. This chapter reviews select oncologic clinical syndromes and cancer treatment toxicities seen among patients with cancer who require ICU management. The multidisciplinary care of the patient with cancer requires consideration of these unique complications, in addition to pathologic conditions seen among patients without cancer. The triage of patients with cancer for ICU care is discussed, as well as the ethical, palliative, and end-of-life care aspects of treating cancer patients in the ICU setting.

Reasons for ICU Admission

Patients with cancer may require ICU admission because of the malignancy itself or the result of complications of cancer therapy (Box 76.1). The most frequent indications for ICU admission include acute respiratory failure from infectious and noninfectious causes; neutropenic sepsis; oncologic emergencies, such as tumor lysis syndrome and hypercalcemia; and postoperative management of complications from high-risk cancer surgery. Acute kidney injury (AKI), cardiovascular disease, and neurologic complications are other common reasons. ICU admission may also be offered for the administration of high-risk antineoplastic therapies in noncritically ill patients, adverse drug reactions, or the administration of medications not routinely offered on medical wards.

Pulmonary Complications in Patients With Cancer

Acute Respiratory Failure

Acute respiratory failure (ARF) is the leading cause for ICU admission in cancer patients and is usually associated with high mortality rates, especially in those requiring mechanical ventilation. The incidence of ARF is about 5% in the patients with solid tumors and up to 50% in those with hematologic malignancies. ARF accounts for up to 80% of hematopoietic stem cell transplant (HSCT) recipients hospitalized for respiratory complications, with an overall survival rate of approximately only 15% in those receiving mechanical ventilation.

The most common causes of ARF in cancer patients include infections, cardiogenic and noncardiogenic pulmonary edema (acute

respiratory distress syndrome [ARDS]), antineoplastic (chemotherapy or immunotherapy, radiation) therapy-induced lung injury, malignancy-related medical disorders, and progression of underlying cancer.

Diagnostic Strategy and Management of ARF in Patients With Cancer

A detailed clinical history and thorough physical examination are the first steps to identifying the cause of ARF in patients with cancer. Making a diagnosis on clinical grounds is often difficult, however, as the physical examination and radiographic findings for a number of causes in this patient population overlap. A diagnostic algorithm to determine the etiology of ARF in patients with malignancy has been proposed and is based on factors encapsulated by the mnemonic DIRECT (*d*elay since malignancy onset or HSCT, since symptom onset, or since implementation of antibiotics/prophylaxis; pattern of *i*mmune deficiency; *r*adiographic appearance; clinical *e*xperience and knowledge of the literature; *c*linical picture; and findings on high-resolution computed tomography).[9,10] Further diagnostic investigations and empiric therapy as well as other life support measures can be selected based on the suspected diagnosis.

In particular, the appearance of acute or subacute pulmonary infiltrates with severe hypoxemia in the initial phase of malignancy, especially hematologic, may suggest infectious pneumonia or malignancy-related lung infiltration. Progressive, subacute lung infiltrates that occur late after the presentation of malignancy may suggest infiltrative disease, toxicity to antineoplastic therapy, or the occurrence of a second malignancy. Infectious etiologies and cardiogenic pulmonary edema should be excluded in all cases of ARF. A follow-up cohort analysis assessed the performance of the DIRECT approach and associated bacterial pneumonia with solid tumors, multiple myeloma, neutropenia, shock, less than 3 days since symptom onset, unilateral pulmonary crackles, and a unilateral radiographic pattern.[10] Use of steroids, lymphoproliferative disorders, and HSCT were associated with opportunistic infections, and acute leukemia was associated with noninfectious causes of ARF.

Fiberoptic bronchoscopy with bronchoalveolar lavage (FB-BAL) is the diagnostic strategy of choice for cancer patients whose respiratory symptoms are not severe enough to warrant ICU admission because their respiratory reserve will allow them to tolerate the procedure. Among patients with ARF, however, FB-BAL has been associated with respiratory deterioration and the need for mechanical ventilation.[11] Advances in noninvasive diagnostic testing (Box 76.2) have warranted reassessment of the role of semi-invasive or invasive tests such as FB-BAL and lung biopsy. In a randomized controlled trial comparing early FB-BAL plus a

standardized panel of noninvasive tests to noninvasive tests alone, noninvasive testing was not inferior to the combined strategy in diagnosing the etiology of ARF and was not associated with an increase in mortality rate.[12] In addition, noninvasive testing identified the cause of ARF more frequently and more rapidly than FB-BAL. FB-BAL added diagnostic information to noninvasive testing in only 18% of patients. Although no significant difference was found in the rate of intubation between both strategies, 25% of those patients who were not intubated at the time of early FB-BAL experienced respiratory decline induced by the procedure. All patients in the noninvasive strategy who had an undetermined diagnosis by day 3 underwent FB-BAL and required intubation afterward. Overall, even though early FB-BAL is safe in oncologic patients with ARF, it may be of little benefit and may risk respiratory deterioration earlier than a noninvasive strategy. Among patients who do not have a diagnosis after noninvasive testing, FB-BAL may yield additional diagnostic information; however, intubation before bronchoscopy should be considered.

Despite advances in the comprehensive noninvasive diagnostic workup and the use of empiric therapy, failure to determine an etiology of ARF and to make therapeutic modifications based on the diagnosis is associated with increased mortality, particularly among patients with hematologic malignancy.[13,14] The addition of invasive testing, including transbronchial lung biopsy and surgical lung biopsy, to noninvasive testing and FB-BAL in patients with ARF and diffuse pulmonary infiltrates may further increase the diagnostic yield and increase the opportunity for therapeutic modification.[14,15] In select patients, invasive testing does not risk additional procedure-related death or compromise overall outcomes compared to patients with complications from FB-BAL. The decision whether or not to pursue lung biopsy in cancer patients with ARF should be made after carefully weighing the risks and benefits of the procedure; factors such as thrombocytopenia, coagulopathy, severe hypoxemia, and multiple organ dysfunction may increase the risk of complications.

Basic management principles in patients with ARF include supplemental oxygen to correct hypoxemia, early initiation of appropriate empiric antimicrobial therapy in patients with suspected pneumonia, diuretics to decrease pulmonary congestion, and ventilator support including early use of noninvasive positive-pressure ventilation (NIPPV) as well as invasive mechanical ventilation, if necessary.[16] Previous observational studies have demonstrated that NIPPV is effective in improving gas exchange, reducing the need for mechanical ventilation, and is associated with improved outcomes compared with first-line invasive mechanical ventilation (IMV). However, NIPPV failure is associated with a high mortality that exceeds that of patients who received IMV, suggesting that the application of NIPPV or delay in intubation may have additional adverse effects in some patients.[17] Factors associated with NIPPV failure include infectious causes of respiratory failure, the concurrent need for vasopressors or RRT, ARDS, and a high respiratory rate under NIPPV. Alternatively, patients with risk factors for NIPPV failure on presentation of ARF should be considered for early IMV. Contemporary studies suggest there may be no benefit of early NIPPV compared to standard oxygen among patients with hematologic malignancies and isolated hypoxemic respiratory failure.[18,19]

High-flow nasal cannula (HFNC) oxygen therapy was recently shown to improve the survival rate among unselected patients with hypoxemic ARF, even though there was no difference in intubation rate observed with HFNC compared with standard oxygen therapy or NIPPV.[20] Similarly, Mokart et al. reported significant improvement in 28-day mortality in cancer patients with ARF treated with HFNC.[21]

Pulmonary Toxicity of Antineoplastic Therapy

Toxicity to antineoplastic therapy can occur at any time after treatment initiation; however, toxicity to a specific agent should be considered only after the exclusion of other causes and careful consideration of known clinical and radiographic presentations, associated dose regimens and exposure to additional antineoplastic therapy, and the reported frequency of toxicity. Treatment of toxicity to antineoplastic therapy may include any combination of supportive care, dose reduction or cessation of the suspected agent, or glucocorticoids. The decision to halt a particular antineoplastic therapy must take into account the severity of toxicity, the loss of benefit with regard to treatment of the underlying malignancy, and the availability and efficacy of other treatment options. Examples of antineoplastic therapy associated with ARF are provided (Table 76.1). The literature describing complications of antineoplastic therapy is abundant and beyond the scope of this chapter.

Pulmonary Tumor Embolism and Lymphangitic Carcinomatosis

Pulmonary tumor emboli result from the accumulation of circulating tumor cells within the pulmonary microvasculature, causing obstruction to circulation without changes in vessel architecture. Pulmonary tumor thrombotic microangiopathy is a related condition resulting in nonocclusive small vessel injury, with activation of local coagulation and inflammatory cascades ultimately leading to increased pulmonary vascular resistance and pulmonary hypertension. Tumor cells can also become embedded within pulmonary lymphatics causing lymphangitic carcinomatosis. Rather than distinct entities, these syndromes may represent a spectrum of embolic disease, with varying degrees of overlap seen clinically. The incidence of these syndromes is unknown; however, in autopsy series up to 26% of patients with solid tumors have evidence of tumor emboli, although this may overestimate clinical morbidity. Pulmonary embolization syndromes can complicate any malignancy; however, the risk appears to be highest in renal cell and hepatocellular carcinoma, as well as adenocarcinomas of breast, colon, stomach and lung.

Patients present with nonspecific subacute and progressive dyspnea. Imaging techniques are often nondiagnostic, whereas findings are variable depending on syndrome.[22] The presentation resembles thromboembolic disease, which must be excluded. Pulmonary tumor emboli are associated with an absence of pulmonary parenchymal disease, although case reports have identified dilated and beaded peripheral pulmonary arteries, and tree-in-bud opacities. Ventilation-perfusion scanning may demonstrate multiple symmetric peripheral defects producing a beaded appearance, sometimes with a segmental contour pattern. Pulmonary angiography also has poor sensitivity and specificity for pulmonary tumor thrombotic microangiopathy. The presence of tumor cells in bronchoalveolar lavage or aspiration of blood from the pulmonary capillary bed can confirm the presence of malignant disease. Lymphangitic carcinomatosis may present with thickening of the bronchovascular bundles and interstitial septae and pleural effusion on chest imaging. Transbronchial lung biopsy or surgical biopsy demonstrating tumor cells in the pulmonary vasculature or lymphatic is diagnostic. The prognosis is poor, although reports suggest combination therapy, including pulmonary vasodilators, anticoagulation, and chemotherapy, may extend survival.

TABLE 76.1 Selected Organ System Complications of Antineoplastic Therapies

Organ System	Antineoplastic Agent
Respiratory	
Acute pneumonitis	Bleomycin, bortezomib, cyclophosphamide, methotrexate, paclitaxel
NCPE	Cytarabine, interleukin 2, gemcitabine, mitomycin, IT, methotrexate
Pulmonary hemorrhage	Bevacizumab
Bronchospasm	Mitomycin, rituximab, vinblastine, cetuximab
Cardiac	
Heart failure	Bortezomib, cyclophosphamide, doxorubicin, trastuzumab
Myocardial ischemia	Fluorouracil, vinca alkaloids
Pulmonary hypertension	Dasatinib, mitomycin
Bradycardia	Crizotinib, paclitaxel
Atrial fibrillation	Ibrutinib
Hypertension	Bevacizumab
QTc prolongation	Arsenic trioxide
Neurologic	
Encephalopathy	Capecitabine, cisplatin, ifosfamide, methotrexate
Seizures	Busulfan, cisplatin, fluorouracil, ifosfamide
PRES	Cisplatin, methotrexate, cytarabine, carboplatin, gemcitabine
Central demyelination syndrome	Levamisole, fluorouracil
Renal and Metabolic	
SIADH	Cisplatin, cyclophosphamide, vinca alkaloids
TMA	Bevacizumab, gemcitabine, mitomycin, sirolimus
Renal tubular injury	Cisplatin, ifosfamide, pemetrexed, ipilimumab
Hypocalcemia	Mithramycin
Hypomagnesemia	Cisplatin, cetuximab
Hypophosphatemia	Imatinib
Hyperglycemia	Everolimus

IT, Intrathecal; *NCPE,* noncardiogenic pulmonary edema; *PRES,* posterior reversible encephalopathy syndrome; *SIADH,* syndrome of inappropriate antidiuretic hormone; *TMA,* thrombotic microangiopathy.

Infectious Complications

Febrile Neutropenia

Febrile neutropenia (FN) is a common complication of many chemotherapy regimens, although the incidence varies by cancer type and myelosuppressive regimen used.[23] It is associated with mortality rates of up to 20% among patients who are hospitalized for FN and more than 40% among critically ill patients.[23,24]

Identifying the cause of fever in patients with FN can be challenging, as the inflammatory response to infection may be muted. A careful physical examination, with attention to skin and mucosal surfaces including the oral cavity and perianal region, and inspection of intravenous (IV) catheters, is important to localize the site of infection. The diagnostic workup for FN should include cultures from a central venous catheter if present. Early use of fungal cell antigen tests such as (1-3)-β-D-glucan and *Aspergillus* galactomannan may be useful for early diagnosis of fungal infections. Additional imaging studies are guided by the clinical picture; however, chest radiographs may appear normal in neutropenic patients with lung infection. The evaluation should also consider noninfectious causes of fever that are common in this patient population, including drug fever, venous thromboembolism, or reaction to blood product transfusion. An unrevealing diagnostic workup for FN is common. Procalcitonin (PCT) does not appear to be helpful in distinguishing bacterial from nonbacterial inflammation in neutropenic patients with sepsis.[25] Furthermore, PCT levels should be assessed only in the context of a physical examination and when appropriate microbiological testing is performed.

Patients with FN should be risk stratified based on degree and anticipated length of neutropenia, symptom burden, and the presence of significant comorbidities. The Multinational Association for Supportive Care in Cancer (MASCC) risk index is a well-validated tool for predicting patients at low risk for serious complications. However, the MASCC score does not perform as well in patients with hematologic malignancy.[26] Additional PCT testing may be useful in predicting adverse outcomes even in patients with a low-risk MASCC score.[27] High-risk MASCC scores, as well as comorbidities including thrombocytopenia, hypoproteinemia, renal failure, and elevated inflammatory markers, are associated with unfavorable outcomes in patients with FN.[27–29] Among critically ill cancer patients with neutropenia and severe sepsis or septic shock, older age, vasopressor use, and neurologic, respiratory or hepatic dysfunction are associated with higher mortality, as is the presence of an acute concurrent noninfectious condition.[24]

The microbial pathogens that infect neutropenic patients have changed over time. Recent epidemiologic data demonstrate that gram-positive and gram-negative bacteria account for 55% and 45%, respectively, of bacteremia in cancer patients.[30] The incidence of multidrug-resistant bacteria remains substantial.

Patients at high risk for severe or complicated infection should be hospitalized to receive empiric treatment with IV broad-spectrum antibacterial agents for coverage of gram-positive and gram-negative pathogens as soon as possible. The selection of agent should be guided by clinical presentation, recent antibiotic use and culture data, and risk factors for resistant bacteria, such as patient colonization or previous infection with a multidrug-resistant pathogen, and local epidemiology. Antibiotic therapy should be initiated promptly after blood cultures have been obtained. Initial monotherapy with an antipseudomonal β-lactam antimicrobial agent is recommended. Vancomycin is not recommended as standard therapy but should be considered for suspected skin or soft tissue infections, catheter-related infections, or hemodynamic instability. Anaerobic coverage can be considered in cases of suspected anaerobic infection, such as necrotizing mucositis, sinusitis, neutropenic enterocolitis, and pelvic infection. Modifications to the initial empiric regimen may be considered for patients who are at risk for antibiotic-resistant organisms, clinically unstable, or who have blood cultures suspicious for resistant bacteria. Antibiotic de-escalation from a regimen targeting resistant bacteria should be considered if resistant pathogens are not isolated, with no apparent increased risk of mortality.[31]

Antibiotic combinations such as a β-lactam with a fluoroquinolone or an aminoglycoside as empiric therapy for FN is controversial, as such combinations do not appear to be superior to monotherapy and may risk toxicity. The addition of aminoglycosides, for example, does not appear to improve outcomes but may increase the risk of kidney injury.[32] Such combinations may be considered in the subset of patients with septic shock.[24]

Empiric antifungal agents should be considered in high-risk patients who have persistent fever without an apparent cause after 4 to 7 days and are expected to have a prolonged duration of neutropenia, or earlier in patients in unstable condition or those who have a suspected fungal infection. The choice of empiric antifungal agent should be based on clinical suspicion for infection, comorbidities, and previous exposure to antifungal agents

Source control remains an important part of sepsis management in the neutropenic cancer patient, and central venous catheter removal should be considered among those in septic shock without an obvious source of infection, or with evidence of site infection, endocarditis, septic thrombosis, or with persistent culture positivity. Early catheter removal in neutropenic patients with severe sepsis or septic shock without an obvious source of infection may improve survival.[24] Catheter-related sepsis should also be considered when an infection is caused by certain microorganisms, including *S. aureus*, *Pseudomonas aeruginosa*, vancomycin-resistant *Enterococcus*, *Acinetobacter* spp., or *Candida*.

Although the addition of colony-stimulating factors (CSFs), such as granulocyte-CSF or granulocyte-macrophage CSF to antibiotics for chemotherapy-induced FN, hastens neutrophil recovery, it does not appear to improve infection-related mortality.[33]

Cardiovascular Complications

Pericardial Disease and Cardiac Tamponade

Malignant involvement of the pericardium can manifest as pericarditis, pericardial effusion, cardiac tamponade, or constrictive pericarditis. Among cancer patients admitted to the ICU, the most frequent causes of cardiac tamponade are metastatic tumors of the breast, lung, and esophagus, and melanoma, and leukemias and lymphomas. The median time from cancer diagnosis to the onset of tamponade varies with cancer diagnosis, and the appearance of cardiac tamponade appears to be a marker for poor 1-year survival despite drainage, especially among patients with lung and gastric or esophageal cancers. Although a pericardial effusion in a patient with cancer usually represents pericardial disease, a negative cytology result does not exclude the diagnosis of malignancy and other etiologies should be considered including radiation- or treatment-induced pericarditis with pericardial effusion, or infectious or autoimmune pericardial effusions. Pericardiocentesis for relief of tamponade is indicated emergently when clinical evidence of hemodynamic compromise is present.

Pericardiocentesis may be complicated by paradoxical hemodynamic instability (PHI), or low cardiac output syndrome, the occurrence of unexpected hemodynamic compromise after pericardial fluid drainage. This has been reported in cancer patients with cardiac tamponade, and the presence of malignant cells in pericardial fluid increases the risk of PHI. The pathophysiology of PHI is not clear; however, it may be due to delayed recovery of myocardial function after relief of tamponade physiology. Drainage of pericardial fluid may also expose underlying constrictive physiology among patients with previous radiation exposure.

Therapies for durable prevention of pericardial fluid accumulation may be tailored according to etiology and include use of intrapericardial chemotherapy, corticosteroids, or sclerosing agents; extended catheter drainage; or creation of a pericardial window. Extended catheter drainage, pericardial sclerosis, and balloon pericardiotomy offer similarly low rates of recurrence compared with isolated pericardiocentesis.

Superior Vena Cava Syndrome

Obstruction of the superior vena cava (SVC) can be caused by invasion or external compression from pathologic processes involving adjacent structures, or by thrombosis within the SVC. Malignancy, particularly lung cancer and lymphoma, is the most common cause of SVC syndrome, although thrombosis on intravascular devices and postradiation vascular fibrosis can also occur during oncologic care. Duplex ultrasound can exclude thrombus in central upper extremity veins, and dampening of waveforms with loss of venous pulsatility and respiratory variation may suggest SVC obstruction. Contrast-enhanced computed tomography of the chest can identify obstruction as well as the underlying cause. In its most severe presentation, the resulting upper extremity venous congestion can result in central airway obstruction or laryngeal edema, or coma from cerebral edema. In these situations, immediate radiotherapy or endovascular stent placement should be pursued. In other cases, therapy depends on the underlying cause and may include chemotherapy, corticosteroids, and radiation therapy for susceptible malignancies. Thrombolysis is effective in catheter-associated SVC syndrome.

Cardiac Arrest

The outcomes of patients with cancer who undergo cardiopulmonary resuscitation (CPR) appears to be improving.[34] Among patients admitted to an ICU for out-of-hospital cardiac arrest or in-hospital cardiac arrest, 18% of patients survived to hospital discharge, and the majority had good neurologic outcome, and 14% survived to at least 6 months.[35] Survival did not differ significantly by malignancy type or status. Moreover, survival was not significantly different among matched controls with no malignancy. Among patients who underwent CPR in an ICU, however, mortality was worse, with 7.8% surviving to ICU discharge and only 5.8% surviving to hospital discharge.[36] CPR duration appears to be the only factor associated with outcome, with a 10% increase in mortality per minute of resuscitation time. Improved CPR outcomes reflect not only improved care of cardiac arrest patients, but also careful patient selection after treatment-limiting decisions.

Metabolic and Endocrine Complications

Hypercalcemia

Hypercalcemia is common among patients with malignancy, occurring in 10% to 20% of patients with solid tumors, particularly among those with multiple myeloma, breast, lung, kidney, and head and neck cancer. Increased mobilization of calcium from bone and decreased renal tubular calcium excretion are driven by tumor production of bone-resorbing hormones and cytokines such as parathyroid hormone-related peptide (PTHrP), as well as local osteolysis at metastatic sites. Increased production of calcitriol has been observed in cases of Hodgkin and non-Hodgkin lymphoma. Primary hyperparathyroidism should be excluded, as the incidence appears to be elevated in patients with cancer. Hypercalcemia of malignancy can be distinguished from other causes of hypercalcemia by high and more rapid increases in serum calcium, with greater symptomatology. A low serum parathyroid hormone level with an elevated PTHrP level is diagnostic of hypercalcemia of malignancy.

Bisphosphonates are potent osteoclast inhibitors and are essential in the treatment of hypercalcemia of malignancy, in addition to IV hydration and the short-term use of calcitonin. The maximum effect of bisphosphonates occurs in 2 to 4 days and is prolonged

over the course of weeks. Patients with high levels of PTH-rP may have an inferior response to bisphosphonates and may require higher doses. Bisphosphonates have potential nephrotoxicity and should be used with caution in patients with underlying kidney disease after careful consideration of specific agents associated with less risk.

Denosumab, a monoclonal antibody for receptor activator of nuclear factor κB ligand, an essential mediator of osteoclast formation and function, has demonstrated efficacy in a number of case series for the treatment of hypercalcemia of malignancy and should be considered for patients with bisphosphonate-resistant hypercalcemia. Denosumab is not cleared by the kidneys and thus may be used in patients with chronic kidney disease.

Additional alternatives to treat hypercalcemia include calcium-sensitizing calcimimetic agents to suppress parathyroid hormone secretion in patients with severe hypercalcemia owing to parathyroid carcinoma, and glucocorticoids in lymphoma patients with increased calcitriol production. Renal replacement therapy (RRT) may be necessary for severe AKI or in patients with underlying heart failure or AKI in whom hydration cannot be safely administered.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) describes the release of large amounts of intracellular potassium, phosphate, and nucleic acids into the systemic circulation resulting from massive tumor cell breakdown that may lead to life-threatening AKI, arrhythmias, and neurologic complications. TLS is typically associated with highly proliferative, chemosensitive hematologic malignancies, but it has also been rarely reported in solid tumors. It usually occurs after the initiation of antineoplastic therapies, although it can occur spontaneously.

AKI in TLS is likely multifactorial and involves the deposition of uric acid, phosphate, and xanthine within the renal tubules. Prevention and treatment of TLS involves aggressive fluid resuscitation to augment renal perfusion, glomerular filtration, and maintenance of a high urine output. Additional hypouricemic agents are used to reduce the risk of uric acid nephropathy. Allopurinol is a hypoxanthine analog and competitive inhibitor of xanthine oxidase, preventing the formation of additional uric acid. Caution is advised in its use among East Asian populations who may have severe cutaneous adverse events with allopurinol. Febuxostat is a selective inhibitor of xanthine oxidase that may be a reasonable alternative to allopurinol in the prevention of TLS; however, its use may be limited owing to concerns for drug-induced hepatoxicity. Neither allopurinol nor febuxostat addresses the accumulation of the uric acid precursor xanthine, and this may contribute to xanthine nephropathy. Rasburicase is a recombinant urate oxidase that catalyzes the oxidation of uric acid to allantoin, which is more soluble and readily excreted. The reduction in plasma uric acid levels is profound and rapid; however, severe adverse reactions including anaphylaxis, methemoglobinemia, and hemolytic anemia among those with glucose-6-phosphate dehydrogenase deficiency may occur.

Routine use of diuretics is not recommended unless there is evidence of volume overload. Urinary alkalinization is controversial and may increase the risk of phosphate and xanthine crystallization. RRT should be considered for those who have persistent metabolic abnormalities or renal failure despite fluid replacement. Continuous RRT may be preferred for ongoing TLS; however, intermittent hemodialysis should be considered in life-threatening hyperkalemia.

Hyponatremia

Moderate to severe hyponatremia (<130 mmol/L) occurs in nearly 4% of hospitalized cancer patients. Multiple etiologies contribute to this hyponatremia including volume status and concomitant medications. Of particular concern is the syndrome of inappropriate antidiuretic hormone (SIADH), which may be caused by tumors and antineoplastic therapies. SIADH is associated with carcinoid tumors, myeloma, lymphoma, and carcinomas originating in the lung, prostate, esophagus, head and neck, adrenal gland, and pancreas. Cerebral metastasis from any tumor can also give rise to SIADH. SIADH has also been reported as a complication of a number of antineoplastic agents (see Table 76.1) and commonly used palliative medications, including opioids, antidepressants, and antiemetics.

Salt-wasting nephropathy is another cause of hyponatremia in cancer patients and may be due to adrenal insufficiency, cerebral salt wasting after subarachnoid hemorrhage or intracranial surgery, or certain antineoplastic agents (e.g., cisplatin).

Hypoglycemia

Tumor-induced hypoglycemia is uncommon but can result in serious consequences. Several different mechanisms can give rise to hypoglycemia. Autonomous insulin production is most commonly associated with islet cell tumors, whereas production of insulin-like growth factors (IGF-1 or IGF-2) is seen with non–islet cell tumors. Slow-growing mesenchymal tumors such as leiomyosarcoma, mesothelioma, and fibrosarcoma are the most common non–islet cell tumors to produce insulin-like products; however, this is seen in other tumor types including hematomas and neuroblastomas. Hypoglycemia may also be the result of excessive glucose consumption by large tumors that exceed hepatic production or from hepatic or pituitary failure. A poor response on glucagon stimulation testing may be helpful in identifying hypoglycemia owing to poor hepatic reserve or function.

Primary treatment of tumor-related hypoglycemia involves control of the tumor. Supportive therapy involves dietary modification, glucose infusions, and corticosteroids. Insulinomas may respond to diazoxide, an inhibitor of insulin secretion. Continuous glucagon infusions may be appropriate for those who show a glycemic response to glucagon.

Adrenal Failure

More than 90% of adrenal tissue must be destroyed before clinical manifestations of adrenal insufficiency, such as weakness, weight loss, hyperpigmentation, hypotension, hyponatremia, hyperkalemia, and hypoglycemia, appear. Adrenal failure should also be considered in patients with hypotension refractory to fluid resuscitation and vasopressor agents. Primary adrenal insufficiency may be suspected in patients with metastatic cancer, particularly of tumors of lung, breast, kidney, stomach, pancreas, and melanoma origin, and evidence of metastases on imaging. Chronic corticosteroid therapy can mask adrenal failure or precipitate it after withdrawal. More often, however, adrenal insufficiency is iatrogenic in origin, following adrenalectomy or hypophysectomy, or treatment with medications including mitotane, aminoglutethimide, megestrol acetate, or chronic corticosteroids. Adrenal failure has also been reported in patients who developed T-cell–mediated hypophysitis after treatment of advanced melanoma with the cytotoxic T-lymphocyte antigen 4 (CTLA-4) inhibitors. The diagnosis of adrenal failure depends on measurement of inappropriately low serum cortisol, with concurrent measurement of adrenocorticotropic hormone to differentiate among primary, secondary, or tertiary failure. Alternatively, a normal cortisol response to a short adrenocorticotropic hormone stimulation test excludes primary adrenal insufficiency. Treatment with exogenous corticosteroids should not be delayed, especially in the setting of possible adrenal crisis.

Type B Lactic Acidosis

Type B lactic acidosis, without associated contribution from hypoperfusion, severe tissue hypoxia, or organ dysfunction, has been reported as a complication of hematologic malignancies, particularly rapidly progressive leukemia and lymphoma. The Warburg effect describes the observation that many cancer cells have higher glycolytic rates than their normal tissues of origin, even in the presence of adequate amounts of oxygen. This may be due to the overexpression of glycolytic enzymes to support malignant cell proliferation. Tumor pyruvate kinase isoenzyme type M2 (M2-PK), a form of pyruvate kinase, has been found in a variety of cancer cells and is associated with rapid glycolysis and accelerated tumor growth. Lactic acidosis secondary to cancer is rare and should prompt further workup for other potentially treatable causes. The prognosis of patients presenting with cancer-related type B lactic acidosis is poor, even among patients who receive chemotherapy with subsequent correction of the acidosis.

Idiopathic Hyperammonemia

Hyperammonemia has been described after high-dose cytoreductive therapy for hematologic malignancy or after HSCT in the absence of marked liver impairment, evidence of deficiencies in urea cycle metabolism, or other causes of elevated serum ammonia, although recent case reports describe idiopathic hyperammonemia among patients treated with corticosteroids for leukemia[37] or chemotherapy for solid tumors.[38] The etiology is unclear; however, the suggested mechanisms include acquired or relative deficiencies in urea cycle metabolism after chemotherapy. Cases of idiopathic hyperammonemia may occur days after chemotherapy or up to 2 months after HSCT. Neurologic sequelae are abrupt and may be irreversible. Recurrence is possible, and mortality is high. Idiopathic hyperammonemia is rare; however, it should be considered in cases of abrupt changes in mental status. Elevation of liver enzymes should trigger evaluation of secondary causes of hepatic dysfunction, such as liver metastases or exposure to hepatotoxic chemotherapy; however, with the exception of asparaginase, severe hepatic failure and hyperammonemia owing to chemotherapy are rare.

Neurologic Complications

Malignant Cord Compression

Malignant cord compression (MCC) owing to bony metastases to the vertebral spine with subsequent collapse and cord compression, local tumor extension into the spinal cord, epidural metastases, or intramedullary spinal cord metastases, occurs in 3% to 5% of all patients with cancer. Although carcinomas of the breast, lung, and prostate and multiple myeloma are common causes of MCC, virtually any tumor can metastasize to the spine. Moreover, MCC is a presenting symptom of cancer in up to 23% of cases. Presenting deficits depend on the level of cord involvement, with the thoracic spinal cord being most common, followed by the lumbosacral cord; however, multilevel involvement is common. Bladder and bowel dysfunction as presenting signs of autonomic dysfunction may be missed among patients with advanced cancer who have multiple reasons for these symptoms. Cervical involvement can be severe and present with quadriplegia or respiratory arrest. Severe back pain on movement may be suggestive of spinal instability. Patients who present with back pain and rapid onset of neurologic signs of spinal cord or cauda equina compression should receive a magnetic resonance imaging scan of the whole spine.

Treatment for MCC starts with maintaining neutral spine alignment until bony and neurologic stability is ensured. Empiric corticosteroids should be started emergently in patients who present with myelopathy and should not be delayed for imaging. Clinical trials demonstrate improved functional outcomes in patients who have received adjunctive corticosteroids. Definitive treatment may include any combination of radiotherapy, surgery, or chemotherapy, and depends on clinical factors, including the presence of spinal instability, the degree of spinal cord compression, and the relative radiosensitivity of the tumor, as well as prognostic indicators, such as age, disease burden, and overall cancer prognosis. The role of surgical decompression is controversial, with conflicting study results on the benefit of surgical decompression followed by radiotherapy over radiotherapy alone. Regardless of modality, minimizing delay to definitive treatment improves functional outcome after treatment.

Vasogenic Edema

Intracranial metastases may be accompanied by significant vasogenic edema. Upregulated production of factors, such as vascular endothelial growth factor (VEGF), acidic fibroblast growth factor, basic fibroblast growth factor, and nitric oxide, by tumor cells stimulates angiogenesis and the production of disorganized and leaky blood vessels, allowing exudative fluid accumulation in the extracellular space. Within the central nervous system (CNS), edema alters neurologic function and can contribute to symptoms, including headache, focal neurologic deficit, seizures, and encephalopathy. Symptomatic plateau waves describe the phenomenon of syncope precipitated by normal activities that transiently further raise intracranial pressure (ICP) above cerebral perfusion pressure. Dysregulated fluid accumulation within the rigid cranium may result in intracranial hypertension and brain herniation.

Glucocorticoids have demonstrated efficacy in reducing peritumoral edema and are indicated in all symptomatic patients. Improvements in ICP and neurologic symptoms are seen within hours, and changes in diffusion-weighted magnetic resonance imaging scans may be seen within 48 hours. The peak effect of glucocorticoids on reducing peritumoral edema may take several days. For patients requiring emergent reductions in ICP, additional therapies including osmotherapy and sedation and paralysis should be considered. Anti–vascular endothelial growth factor monoclonal antibodies such as bevacizumab may be useful as steroid-sparing agents.

Leptomeningeal Metastases

Leptomeningeal spread of cancer should be considered in patients who have multifocal neurologic deficits. Although diffuse involvement throughout the CNS is characteristic, the basal cisterns and cauda equina are the most symptomatic sites, resulting in cranial nerve deficits, ataxia, radiculopathy, and increased ICP. Breast cancer, lung cancer, melanoma, aggressive non-Hodgkin lymphoma, and acute lymphocytic leukemia are the most common cancers to metastasize to the leptomeninges. Brain metastases are not required for leptomeningeal disease, and although the majority of patients have active systemic disease, 20% of patients may present after a cancer-free interval.

Definitive diagnosis of leptomeningeal disease is difficult owing to the limited sensitivity of neuroimaging and cerebrospinal fluid (CSF) studies. CSF yield can be improved by a larger sample size, minimizing processing delays, and repeat sampling. CSF flow cytometry is a more sensitive test in patients with hematologic malignancies. A clinical diagnosis of leptomeningeal disease can

be made based on positive CSF cytology, or supportive clinical findings in the presence of consistent radiologic findings or abnormal CSF. The prognosis of leptomeningeal spread is generally poor, and therapies, including radiation therapy, systemic chemotherapy, and intrathecal chemotherapy, are not curative.

Hematologic Complications

Hyperleukocytosis

Peripheral white blood cell counts exceeding 100,000/μL may be seen in hematologic malignancies, particularly acute myelogenous leukemia and acute lymphoblastic leukemia, and are associated with increased morbidity and mortality. The associated increase in blood viscosity may lead to the development of symptoms or leukostasis owing to reduced tissue perfusion. The number 100,000/μL itself is arbitrary and the degree of leukocytosis needed cause symptoms varies by the type of leukemia. Severe symptoms can occur in acute myelogenous leukemia with a leukocyte count of 50,000/μL, whereas higher cell counts appear to be better tolerated in acute lymphoblastic leukemia or chronic lymphocytic leukemia. Hyperleukocytosis in acute promyelocytic leukemia usually refers to a level above 10,000/μL.

The lungs and CNS are the most common sites of vascular obstruction, and in severe cases, patients may present with hypoxemia, pulmonary infiltrates, altered mental status, focal neurologic deficits, and retinal and intracranial hemorrhage. Evidence of ischemia or vascular congestion involving other organs may be present as well. Disseminated intravascular coagulation (DIC) and spontaneous tumor lysis syndrome may complicate hyperleukocytosis.

Management of hyperleukocytosis involves supportive care with aggressive hydration to promote hemodilution and reduction of viscosity, and management of TLS and DIC until the initiation of cytoreductive therapy, such as corticosteroids or cytarabine. Leukapheresis should be reserved for symptomatic patients who are unable to start induction chemotherapy immediately, after consideration of its benefits and risks for a specific patient. There are conflicting data regarding the efficacy of leukapheresis in reducing early mortality.

Hyperleukocytosis in acute promyelocytic leukemia presents a uniquely complex situation particularly associated with an increased risk of morbidity from DIC-related bleeding. Early treatment with all-*trans* retinoic acid is essential to reducing early mortality. However, this may induce differentiation syndrome characterized by signs and symptoms of a cytokine release syndrome, including life-threatening hypotension, ARDS, and serositis. Prophylactic corticosteroids may offer some benefit in preventing the consequences of differentiation syndrome.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a rare syndrome of pathologic immune activation characterized by marked systemic immune activation and the presence of abnormal immunopathology. It occurs as a familial disorder or a sporadic condition associated with a variety of triggers. Lymphomas and leukemias of T or natural killer cell lineage have been associated with HLH; however, HLH has also been reported with B-cell lymphoblastic leukemia, myeloid leukemias, mediastinal germ cell tumors, and rarely other solid tumors, and in HSCT recipients. Immune dysfunction as a result of malignancy or antineoplastic therapy exposes these patients to bacterial, viral, or fungal infection that may also trigger HLH.

• BOX 76.3 Diagnostic Criteria for Hematophagocytic Lymphohistiocytosis

A. Molecular diagnosis consistent with hematophagocytic lymphohistiocytosis, OR
B. Five of the eight following criteria:
   1. Fever
   2. Splenomegaly
   3. Cytopenias
      a. Hemoglobin < 9 g/dL
      b. Platelets $<100 \times 10^3$/mL
      c. Neutrophils $<1 \times 10^3$/mL
   4. Hypertriglyceridemia (fasting, >265 mg/dL) and/or hypofibrinogenemia (<150 mg/dL)
   5. Hemophagocytosis in bone marrow, spleen, lymph nodes, or liver
   6. Low or absent natural killer cell activity
   7. Ferritin >500 ng/mL
   8. Elevated sCD25 (α-chain of sIL-2 receptor) ≥ 2400 units/mL

sCD25, *Soluble CD25;* sIL-2, *soluble interleukin 2.*
From Henter JI, Horne A, Aricó M, et al. HLH-2004: diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. Pediatr Blood Cancer. *2007;48:124–131.*

The diagnosis of HLH depends on the presence of known associated gene or on a constellation of clinical signs and symptoms (Box 76.3). The presentation is variable, and not all criteria may be met at onset. A ferritin level greater than 10,000 g/dL is a highly sensitive and specific marker for HLH, whereas soluble interleukin-2 receptor (sCD25) may correlate with disease activity. Hemophagocytosis is neither sensitive nor specific for HLH. Additionally, HLH is frequently associated with evidence of liver inflammation and neurologic dysfunction and may present with a variety of skin manifestations and pulmonary infiltrates. There is a notable overlap in these findings with macrophage activation syndrome, as well as in presentations of severe sepsis. Measurement of inflammatory markers may help to distinguish these disorders.

Current treatment of HLH begins with prolonged induction with etoposide and dexamethasone, or intrathecal methotrexate and hydrocortisone in patients with proven CNS involvement, before transitioning to continuation or salvage therapy. The clinical course is unpredictable and may require dose or frequency adjustment. Disease-specific therapies may be initiated once inflammatory markers normalize. Relapse of fever or inflammatory markers after response should trigger a search for opportunistic infection.

Renal Complications

Acute Kidney Injury

Critically ill cancer patients are at risk for AKI caused by underlying comorbidities, fluid and electrolyte disturbances, obstructive uropathy, sepsis, and exposure to nephrotoxic agents including antibiotics, contrast media, and antineoplastic treatments. Although the incidence of AKI in this population varies depending on the diagnostic criteria used and the study population, studies have shown that up 60% of patients with hematologic malignancy and critical illness will develop AKI, and up to 40% of them will need RRT. Cancer patients with AKI have a longer ICU length of stay as well as higher mortality than those without AKI. Furthermore the development of AKI can limit the receipt of additional cancer treatments or increase their toxicity. Given these outcomes,

comprehensive efforts must be made to prevent and mitigate factors that contribute to AKI in critically ill cancer patients.

Notably, decreased creatinine production is often seen in cancer patients owing to loss of cell mass, cachexia, low protein intake, inflammation, volume expansion, or medications, and diagnostic criteria based solely on a fixed serum creatinine will underdiagnose AKI. A novel biomarker, tissue inhibitor of metalloproteinase-2, and insulin-like growth factor-binding protein 7 are reported to be early predictors of AKI in high-risk medical and surgical patients including patients with cancer who are frequently exposed to nephrotoxic medications.

Complications of Novel Biologic Therapies

Chimeric Antigen Receptor T-Cell Therapy

Genetically modified human T cells targeting specific antigens expressed by hematologic and solid malignancies are associated with toxicity through a number of mechanisms. Off-tumor, on-target toxicity occurs when chimeric antigen receptor (CAR) T cells damage normal cells expressing the targeted antigen. Organ damage may result from off-target toxicity when CAR T cells cross-react with normal tissue expressing an antigen similar to the target antigen. Allergic reactions and anaphylaxis to autologous CAR T cells can also occur. TLS has also been reported in association with CAR T-cell therapy.

Cytokine release syndrome is the most common acute toxicity of CAR T cells, resulting in systemic organ dysfunction.[64] It can present with fever, arrhythmia, cardiomyopathy, pulmonary edema, AKI, electrolyte disturbances, gastrointestinal symptoms, transaminitis, and cytopenias. A wide variety of cytokines, including interleukin (IL)-6, IL-2, IL-8, IL-10, IL-2–receptor α, interferon gamma, and tumor necrosis factor, are elevated in patients who develop toxicity after CAR T-cell infusion, and the degree of elevation of these cytokines correlates with the severity of toxicity. Higher disease burden also correlates with degree of cytokine elevation and severity of CRS and may predict toxicity. The presentation can be difficult to differentiate from sepsis, and CRS-associated neutropenia and lymphopenia can predispose patients to opportunistic infection. Neurologic toxicities, including seizures, are also reported and may occur dyssynchronous to, or in the absence of, other CRS toxicity, suggesting a mechanism different from that associated with other CRS presentations.

Supportive management is paramount in CAR T-cell–associated CRS, and medications that may worsen toxicity should be avoided. Fever can be managed with acetaminophen and cooling blankets. Tocilizumab is an IL-6 receptor antagonist that has demonstrated efficacy in mitigating or resolving CRS toxicity after CAR T-cell infusion. Corticosteroids should be reserved for tocilizumab failure as they may inhibit the antineoplastic activity of CAR T cells. It is unclear if tocilizumab is beneficial in relieving neurotoxicity, and in such cases systemic corticosteroids, dexamethasone in particular, are the preferred treatment. The design of CAR T-cell therapies continues to evolve to improve antineoplastic activity and minimize systemic side effects. Some novel next-generation designs include suicide genes to stimulate CAR T-cell apoptosis in the presence of an administered prodrug.

Immune Checkpoint Inhibitors

Blockade of immunomodulation through the use of immune checkpoint inhibitors (ICIs), including antibodies CTLA-4 and programmed cell death protein 1 or its ligand, result in an enhanced immune response to combat cancer cells. ICIs have demonstrated improved survival in metastatic melanoma, lung cancer, and renal cancer. However, the augmented immune response also impairs self-tolerance and has been associated with a spectrum of side effects referred to as immune-related adverse events (irAEs). irAEs can involve any organ; however diarrhea, colitis, hepatitis, skin toxicities and endocrinopathies, hypothyroidism, and hypophysitis in particular, are common. Severe presentations, including intestinal perforation, fulminant hepatic failure, toxic epidermal necrolysis, and primary or secondary adrenal insufficiency, are rare. Pneumonitis is uncommon and neurologic complications are rare. However, severe presentations, including myasthenia gravis, Guillain-Barré syndrome, and posterior reversible leukoencephalopathy, have been reported. As with other complications from antineoplastic therapies, the dosage of ICI, time course to presentation, and histopathology may be helpful in distinguishing irAEs from other etiologies. Anti–programmed cell death protein 1 antibodies appear to have a different toxicity profile compared with anti–CTLA-4 antibodies, with less severe events. However, use of both agents in combination is associated with higher risk for irAEs generally and with more severe irAEs.

Management of irAEs depends on organ involvement and severity. In severe cases, cessation of ICIs and use of high-dose corticosteroids, or other immunosuppressants in refractory cases, should be considered. Hormone replacement alone may be sufficient in cases of isolated endocrinopathy.

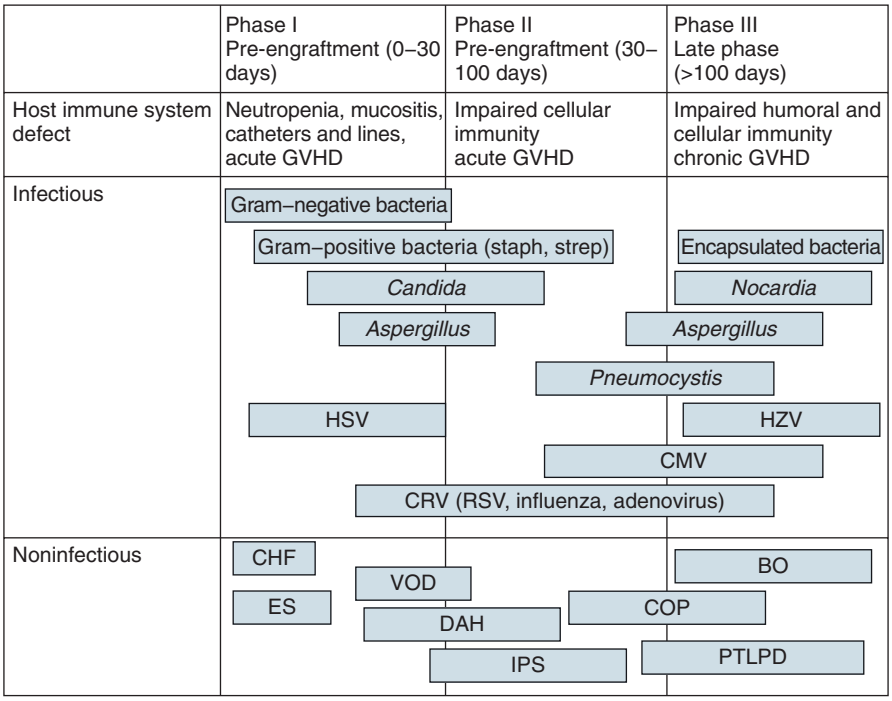
Delivery of Antineoplastic Therapy in the ICU

The delivery of chemotherapy to critically ill patients for life-threatening malignancy-related complications remains controversial. The benefits of antineoplastic therapy must be weighed against their potential to cause further harm in already vulnerable patients. Moreover, many aspects of the administration of antineoplastic therapies in the ICU setting, particularly dose adjustment in the setting of organ failure and the use of extracorporeal life support, and interactions with medications commonly used in the ICU, are not well defined.

Recent studies suggest that antineoplastic therapies can be given safely to select cancer patients with critical illness. In small-cohort studies of patients with predominantly hematologic malignancies admitted to an ICU with critical illness including respiratory failure and severe infection, the administration of chemotherapy was associated with survival rates approximating those seen among critically ill cancer patients in other studies.[39,40] Factors associated with increased mortality included older age, high disease severity scores, septic shock, the use of mechanical ventilation, and DIC. Disease status, severity of neutropenia, and infection at the time of chemotherapy initiation were not associated with ICU mortality.[39] Outcomes were likely biased by the selection of patients deemed to have life-extending therapeutic options before ICU admission, many of whom were treatment naïve and had good performance status, as first presentation of malignancy when receiving chemotherapy in the ICU may be protective.

Complications of Hematopoietic Stem Cell Transplantation

In addition to the life-threatening complications seen among other patients with cancer, HSCT recipients may face a number of complications unique to this form of cancer therapy. The hematopoietic cell donor, the source of progenitor cells, the preparative regimen, and the phase of host immune system dysfunction



• **Fig. 76.1** The timeline of pulmonary complications after hematopoietic stem cell transplantation. *BO,* Bronchiolitis obliterans; *CHF,* congestive heart failure; *CMV,* cytomegalovirus; *COP,* cryptogenic-organizing pneumonia; *CRV,* coronaviruses; *DAH,* diffuse alveolar hemorrhage; *ES,* engraftment syndrome; *GVHD,* graft-versus-host disease; *HSV,* herpes simplex virus; *HZV,* herpes zoster virus; *IPS,* idiopathic pneumonia syndrome; *PTLPD,* posttransplant lymphoproliferative disorder; *RSV,* respiratory syncytial virus; *VOD,* veno-occlusive disease. (From Chi AK, Soubani AO, White AC, et al. An update on pulmonary complications of hematopoietic stem cell transplantation. *Chest.* 2013;144:1913–1922.)

are important factors in determining the risk for complications (Fig. 76.1).[63]

Infectious Complications

The use of myeloablative regimens during preparation and the continued use of immunosuppressive therapies after HSCT results in delayed immune reconstitution and places patients at risk for infectious pneumonias by organisms that can be predicted by phase of immune recovery. During the neutropenic phase, pneumonias caused by gram-negative and gram-positive bacteria are common. In addition, skin and mucosal barriers are disrupted in the period after myeloablative chemotherapy, increasing the risk for aspiration pneumonia and septicemia from intestinal bacteria and *Candida* organisms. Invasive pulmonary aspergillosis is the most common invasive fungal infection among HSCT recipients and may be seen any time after HSCT.

Cellular immunity defects persist for months beyond engraftment while transplanted marrow and gamma globulin infusions provide temporary humoral immunity. Pneumonias from common respiratory viruses and *Pneumocystis jiroveci* pneumonia are seen during the postengraftment phase. During the late phase humoral and cellular immunity defects persist, and pneumonias from encapsulated bacteria, *Nocardia, Aspergillus,* and opportunistic viral infections may be seen until immune recovery.

Pulmonary Complications

Pulmonary complications are common in HSCT recipients and account for a substantial proportion of mortality. Contemporary studies suggest infectious pneumonias account for 68% of pulmonary complications during the first year, whereas noninfectious etiologies were responsible for 29% of complications.[41] Pulmonary complications may be distinguished by radiographic appearance and phase after transplantation; however, noninvasive testing and FB-BAL should routinely be used to identify specific etiologies of ARF. As with ARF in the non-HSCT cancer patient, treatment includes empiric broad-spectrum antimicrobials with de-escalation to organism-specific therapy when possible. Treatment for noninfectious conditions is supportive, with the additional use of immunosuppression in severe cases after excluding infectious etiologies.

Noninfectious Pulmonary Complications

Engraftment syndrome is a noninfectious inflammatory complication seen early after HSCT during neutrophil recovery before engraftment. Findings include fever, nonspecific pulmonary opacities suggestive of noncardiogenic pulmonary edema, and the appearance of an erythematous maculopapular rash. Skin biopsy may distinguish acute graft-versus-host disease (GVHD) from engraftment syndrome.

Diffuse alveolar hemorrhage (DAH) is an uncommon complication of HSCT but is associated with high mortality rates. It may present with patchy or diffuse opacities with air bronchograms on computed tomography imaging late before engraftment or early after engraftment, and hemoptysis is often absent. Progressively hemorrhagic return on sequential bronchoalveolar lavage from the same subsegment during FB-BAL and the presence of hemosiderin-laden macrophages on cytology are diagnostic. In addition to general supportive care, the use of antimicrobials when an infection is present, or immunosuppression, the treatment of DAH includes

blood product support and use of procoagulants such as antifibrinolytics (e.g., ε-aminocaproic acid) or recombinant factor VII.

Idiopathic pneumonia syndrome is a noninfectious complication characterized by clinical and radiographic features of multifocal pneumonia in the absence of lower respiratory tract infection on FB-BAL or lung biopsy. It typically occurs during the postengraftment phase after HSCT. Histology is nonspecific with findings of interstitial pneumonitis and diffuse alveolar damage. Even with appropriate therapy, disease progression in IPS is rapid and is associated with high long-term mortality.[42]

Acute Graft-Versus-Host Disease

Acute GVHD is a common multisystem complication of allogeneic HSCT that occurs when donor cells recognize the transplant recipient as foreign and initiate inflammatory pathways, leading to organ dysfunction within the recipient. Signs and symptoms typically occur around the time of white blood cell engraftment or after a reduction of immunosuppression and most commonly involve the skin, gastrointestinal tract, and liver.

Acute cutaneous GVHD typically begins with a maculopapular rash involving the neck, ears, shoulders, palms, and soles before becoming more generalized and confluent. In severe cases bullous lesions and lesions of the oral mucosa may develop, mimicking Stevens-Johnson syndrome or toxic epidermal necrolysis. Gastrointestinal GVHD usually presents with nonspecific signs of gastrointestinal upset, typically abdominal pain and diarrhea with or without hematochezia. The diarrhea is secretory, and in severe cases may exceed several liters daily. Hepatic GVHD usually presents with a cholestatic pattern on liver function tests, although patients may develop more severe clinical signs of cholestasis. Acute GVHD may be diagnosed clinically in the patient who presents with the triad of a stereotypical rash, diarrhea, and rising serum bilirubin around the time of engraftment; however, other etiologies for the isolated abnormities should be excluded. A definitive diagnosis of acute GVHD may be made by histologic examination of tissue from the gastrointestinal tract or liver. Findings on skin biopsy are nonspecific, and the diagnosis of acute cutaneous GVHD is challenging without the concomitant extracutaneous manifestations.

The severity of acute GHVD is defined by the degree of cutaneous, hepatic, and gastrointestinal involvement (Table 76.2). Treatment relies on the immunosuppression of donor cells through the use of glucocorticoids, methotrexate, and calcineurin inhibitors. High-volume IV fluid infusions may be necessary to account for substantial gastrointestinal and insensible fluid loss. Aggressive wound care may be necessary to prevent skin breakdown, limit insensible loss, and reduce the risk of infection.

TABLE 76.2 International Bone Marrow Transplant Registry Severity Index for Acute Graft-Versus-Host Disease

Index[a]	Extent of Rash	Total Bilirubin (μmol/L)	Volume of Diarrhea (mL/day)
A	<25%	<34	<500
B	25%–50%	34–102	550–1500
C	>50%	103–255	>1500
D	Bullae	>255	Severe pain and ileus

From Rowlings PA, Przepiorka D, Klein JP, et al. IBMTR Severity Index for grading acute graft-versus-host disease: retrospective comparison with Glucksberg grade. *Br J Haematol.* 1997;97:855–864.

Hepatic Sinusoidal Obstruction Syndrome/ Veno-Occlusive Disease

Hepatic sinusoidal obstruction syndrome (SOS) is an uncommon complication of HSCT characterized by progressive injury to sinusoidal endothelial cells, leading to occlusion and then late sclerosis and fibrosis of hepatic venules and centrilobular hemorrhagic necrosis. It has also been described after use of chemotherapies among non-HSCT patients and may be due to hepatic toxicity from the preparative regimen rather than the HSCT. It typically presents early in the posttransplant period with fluid retention, followed by elevated liver function test results, hepatomegaly, and ascites. Severe cases may result in hepatorenal syndrome, hepatic encephalopathy, multiorgan failure, and death. New criteria for the diagnosis and grading of SOS have been proposed (Table 76.3). Additional testing may be required to exclude other causes. Liver biopsy is diagnostic but is often avoided owing to concurrent thrombocytopenia and coagulopathy.

Ursodeoxycholic acid and heparin may be used as prophylaxis for SOS. Supportive measures are recommended in all cases, whereas severe cases are associated with poor outcome and should be treated with defibrotide. Defibrotide stimulates the activity of fibrinolytic enzymes and is contraindicated in patients receiving anticoagulation or fibrinolytic therapies and in patients with significant active bleeding.

Triage of Cancer Patients for ICU Care

Multiple cohort studies demonstrate improved ICU, hospital, and 1-year survival rates among critically ill patients with cancer over the past 2 decades.[43] The general prognosis depends on the type of ICU admission and the type of cancer. Hospital mortality is higher for medical and emergency surgical patients than for patients with cancer scheduled for surgery[44] and higher among those with hematologic malignancies compared with solid tumors.[8,44] Survival among hematologic cancer patients has been improving in recent years.[45] This trend in improved survival is further reflected among mixed cohorts of patients admitted for neutropenic sepsis,[24] septic shock,[46,47] and ARDS.[17]

Although historically patients with cancer may have been denied access to ICU care given their poor prognosis, recent trends of improved survival suggest refusal of care based on cancer alone can no longer be justified. Moreover, risk factors traditionally associated with poorer outcome, including cancer type and neutropenia, are no longer considered significant factors in determining ICU mortality.[48–50] Rather, poor performance status, recurrent or progressive malignancy, and the degree of organ dysfunction have been confirmed as predictors of mortality in several studies across a variety of populations.[24,47–54]

Moreover, delayed admission to the ICU has been associated with worsened outcomes, suggesting that early admission to the ICU is crucial to prevent or ameliorate further organ dysfunction.[55] Although predictive models have been developed and applied to cancer patients with critical illness, none have been sufficiently validated to guide in triage for ICU admission. In addition, whether overall trends in survival are due to real improvements in ICU care or better ICU triage is unclear. More recently organizational

TABLE 76.3 Diagnosis and Grading of Sinusoidal Obstructive Syndrome[62]

Diagnosis

Classical SOS Within first 21 days after-HCT	Late-onset SOS ≥21 days after HCT
Bilirubin ≥2 mg/dL and 2 of the following: • Painful hepatomegaly • Weight gain >5% • Ascites	Classical SOS beyond day 21 OR Histologically proven SOS OR Two or more of the following: • Bilirubin ≥2 mg/dL • Painful hepatomegaly • Weight gain >5% • Ascites AND Hemodynamic or ultrasound evidence of SOS

Severity Grading[a,b]

	Mild	Moderate	Severe	Very Severe[b]
Time since diagnosis (days)	>7	5–7	≤4	Any
Bilirubin (mg/dL)	2–3	3–5	5–8	≥8
Bilirubin kinetics			×2 within 48 h	
Transaminases	≤2× normal	2–5× normal	5–8× normal	>8× normal
Weight increase	<5%	5%–10%	5%–10%	≥10%
Renal function	<1.2× baseline	1.2–1.5× baseline	1.5–2× baseline	≥2× baseline

[a]Grading based on meeting two or more criteria.
[b]Presence of multiorgan dysfunction is classified as very severe.
HCT, hematopoietic stem cell transplantation; *SOS,* sinusoidal obstructive syndrome.

characteristics, such as the implementation of protocols and presence of clinical pharmacists in the ICU, and close collaboration between oncologists and ICU teams, have been shown to be independently associated with lower mortality and a more efficient resource unit.[56]

Given the overall improved mortality among critically ill cancer patients and the importance of early intervention to prevent further deterioration, as well as the absence of reliable predictors of outcome beyond performance status or disease progression, some authors suggest critically ill cancer patients receive unrestrained access to ICU care. Others have advocated for an "ICU trial" approach, whereby the patient trajectory is considered in the decision to continue full intensive care. Among patients who are not bedridden or for whom palliative care is not the only cancer treatment option, organ failure scores on day 6 of ICU admission may be more accurate in predicting hospital survival than scores on admission.[57] Those who remain critically ill with persistent or increasing organ dysfunction after a trial of ICU care have a significantly higher mortality. Although the results support delayed prognostication of patients with cancer and critical illness, additional multicenter studies are needed to confirm these results.

Palliative, Ethics, and End-of-Life Care Issues

Although the recent outcomes for critically ill cancer patients admitted to the ICU have improved, the overall ICU mortality and hospital mortality rates remain high. Furthermore, the overall long-term survival of cancer patients after ICU discharge remains uncertain, with some contemporary studies demonstrating 13% to 43% survival at 1 year. There is also conflicting evidence regarding the quality of life of ICU cancer survivors.

Ideally triage decisions upon referral to the ICU and reassessments regarding the continuation of intensive care[57] should take into account the expected short-term mortality as well as long-term mortality and quality of life. When a patient's declining medical condition is deemed irreversible or quality of life is expected to be poor, a change from restorative care to end-of-life care should be offered. A recent study showed that early palliative care significantly reduced ICU use at the end of life; however, it did not change patients' experiences within the ICU, such as number of procedures, code status, length of stay, or disposition.[58]

Infrequently, ethical issues or conflicts arise in the care of critically ill cancer patients. Ethics consultations in an oncologic ICU often involve disagreements between the patients' surrogates and the ICU team regarding end-of-life care, including proposed limitations and/or withdrawal of life-sustaining interventions. We find that ethics consultations are helpful in resolving seemingly irreconcilable differences between our ICU team and the patients' surrogates in the majority of cases. Ethics consultation also facilitated the increased provision of palliative care and chaplaincy services for patients and their surrogates at the end of life.[59]

Summary

Intensive care of patients with cancer requires an understanding of the broad and complex disorders unique to these patients as a consequence of their malignancy or its treatment, in addition to the pathologies seen among patients without cancer. A multidisciplinary and collaborative approach to care that incorporates patient values and oncologic prognosis and treatment options in the ICU is crucial. Early identification of patients who are most likely to benefit from ICU care through early intervention, including diagnostic testing, respiratory and hemodynamic support, early administration of effective antibiotics, and other measures to treat cancer and mitigate comorbidities, can improve outcomes such as short- and long-term mortality. Recognition of patients who are unlikely to benefit from initial or continued restorative care is also an important part of high-quality critical care and may improve equally important outcomes, such as patient comfort, relief from unnecessary suffering, and improved quality and length of remaining life through the initiation of end-of-life care.

Key Points

- A cancer diagnosis should not preclude ICU care. Poor performance status, recurrent or progressive malignancy, and severe degrees of organ dysfunction are associated with increased mortality.
- Acute respiratory failure is the most common reason for ICU admission in patients with cancer. Noninvasive testing offers diagnostic yield comparable to that of invasive testing.
- Recent studies suggest no benefit for the use of early noninvasive positive-pressure ventilation compared to standard oxygen among patients with hematologic malignancies and isolated hypoxemic respiratory failure.
- Early identification of infectious etiologies, risk stratification, administration of appropriate antimicrobial therapy, and source control are key components of management in patients with febrile neutropenic sepsis.
- Tumor lysis syndrome is associated with hyperkalemia, hyperphosphatemia, and hyperuricemia in the setting of tumor cell breakdown. Treatment includes hydration, hypouricemic agents, and the mitigation of additional contributions to acute kidney injury.
- Hypercalcemia is the most common metabolic abnormality in patients with cancer. Bisphosphonates are essential in the treatment of hypercalcemia of malignancy, in addition to intravenous hydration and the short-term use of calcitonin.
- Cytokine release syndrome and immune-related adverse events are potentially severe multisystem complications of novel biologic cancer therapies (e.g., CAR T cells).
- Infectious and noninfectious complications of hematopoietic stem cell transplantation can be predicted by the phase of host immune recovery. Infectious pneumonias account for the majority of pulmonary complications.
- Acute graft-versus-host disease is commonly associated with allogeneic stem cell transplantation and typified by nonspecific skin, gastrointestinal tract, and liver involvement around the time of engraftment.
- Recognition of patients with cancer who are unlikely to benefit from initial or continued restorative care in the ICU is an important part of high-quality critical care. Early palliative care significantly reduces ICU use at the end of life.

Review Questions

1. A 66-year-old male is transferred to the intensive care unit (ICU) with acute respiratory failure associated with persistent fevers to 39.3°C and a dry cough for 2 days. The patient was diagnosed 6 months earlier with osteosarcoma of the thoracic spine for which he underwent T1 to T3 posterolateral resection of epidural tumor with high-grade T2 spinal cord compression and posterior segmental fixation of C7 to T4 followed by adjuvant chemotherapy with cisplatin and doxorubicin, the last dose of which he received through his tunneled central venous catheter 9 days before this ICU admission. Pertinent medical history includes coronary artery disease status post–drug-eluting stents to mid-left anterior descending artery and diagonal branch 10 years ago and hypertension. On ICU admission, his chest radiograph reveals bilateral diffuse patchy opacities. Laboratory data show a white blood cell count of 100/μL (0.1×10^9/L), hemoglobin of 7 g/dL, platelet count of 9×10^3/μL (9×10^9/L), blood urea nitrogen level of 29 mg/dL, creatinine 1.8 mg/dL, and procalcitonin level of 20.1 ng/mL. He required intubation and mechanical ventilation and was treated with intravenous meropenem and blood transfusions. Which of the following organisms is most likely to result in positive blood cultures in this patient?

a. *Corynebacterium jeikeium*
b. *Staphylococcus aureus*
c. *Propionibacterium acnes*
d. *Aspergillus fumigatus*

Answer: b. Fever in neutropenic patients is defined as a single oral temperature of 38.3°C (101°F) or higher or a temperature of 38.0°C (100.4°F) or higher sustained over a 1-hour period. Neutropenia is usually defined as an absolute neutrophil count (ANC) less than 1500 cells/μL, and severe neutropenia is usually defined as an ANC less than 500 cells/μL or an ANC that is expected to decrease to less than 500 cells/μL over the next 48 hours. Low-risk patients are those who are expected to be neutropenic (ANC <500 cells/μL) for 7 days or longer and those with no comorbidities or evidence of significant hepatic or renal dysfunction. High-risk patients are those who are expected to be neutropenic (ANC <500 cells/μL) for >7 days. Patients with neutropenic fever who have ongoing comorbidities or evidence of significant hepatic or renal dysfunction are also considered to be high risk, regardless of the duration of neutropenia. Gram-positive cocci have become the most common pathogens isolated in blood cultures in patients with febrile neutropenic sepsis. These include *Staphylococcus epidermidis* (the most common), *S. aureus*, and streptococci. Less common gram-positive organisms include *Corynebacterium jeikeium*, *Bacillus* spp., *Leuconostoc* spp., *Lactobacillus* spp., *Propionibacterium acnes*, and *Rhodococcus* spp. *Aspergillus* spp. rarely become positive in blood cultures. In addition to intravenous antibiotics, early catheter removal is recommended in neutropenic patients with sepsis and in patients with endocarditis, septic thrombosis, or with persistent culture positivity.

Critical Care Medicine in Pregnancy

STEPHEN E. LAPINSKY

CHAPTER OUTLINE

Physiologic Changes in Pregnancy

Critical Care Management
- General Care
- Radiologic Procedures and Fetal Risk
- Drug Therapy in Pregnancy
- Fetal Oxygenation and Monitoring
- Ventilatory Support
- Cardiopulmonary Resuscitation

Pregnancy-Specific Conditions ICU Care
- Preeclampsia
- HELLP Syndrome
- Acute Fatty Liver of Pregnancy
- Amniotic Fluid Embolism
- Obstetric Hemorrhage
- Peripartum Cardiomyopathy
- Tocolytic Pulmonary Edema
- Gestational Trophoblastic Disease

Conditions Not Specific to Pregnancy
- Septic Shock
- Acute Respiratory Distress Syndrome in Pregnancy
- Pulmonary Thromboembolic Disease
- Asthma
- Cardiac Disease
- Trauma

Management of the critically ill pregnant patient is a situation with which few intensive care physicians gain significant expertise. The usual clinical approach may be altered by the physiologic changes induced by pregnancy, by the relatively uncommon pregnancy-specific conditions, and by perceived limitations on therapy produced by the presence of a fetus (Fig. 77.1).

Physiologic Changes in Pregnancy

The pregnant woman undergoes a number of physiologic changes affecting various systems relevant to critical care management. From a respiratory perspective, the upper airways develop edema and hyperemia, which may be relevant during endotracheal intubation. Changes in lung volumes occur, with a 10% to 25% decrease in functional residual capacity (FRC), whereas total lung capacity decreases only minimally as the thoracic cage widens to compensate.[1] Forced expiratory volume in 1 second (FEV_1) is not altered by the pregnant state. Lung compliance remains unchanged, but chest wall and total respiratory compliance are reduced.[2]

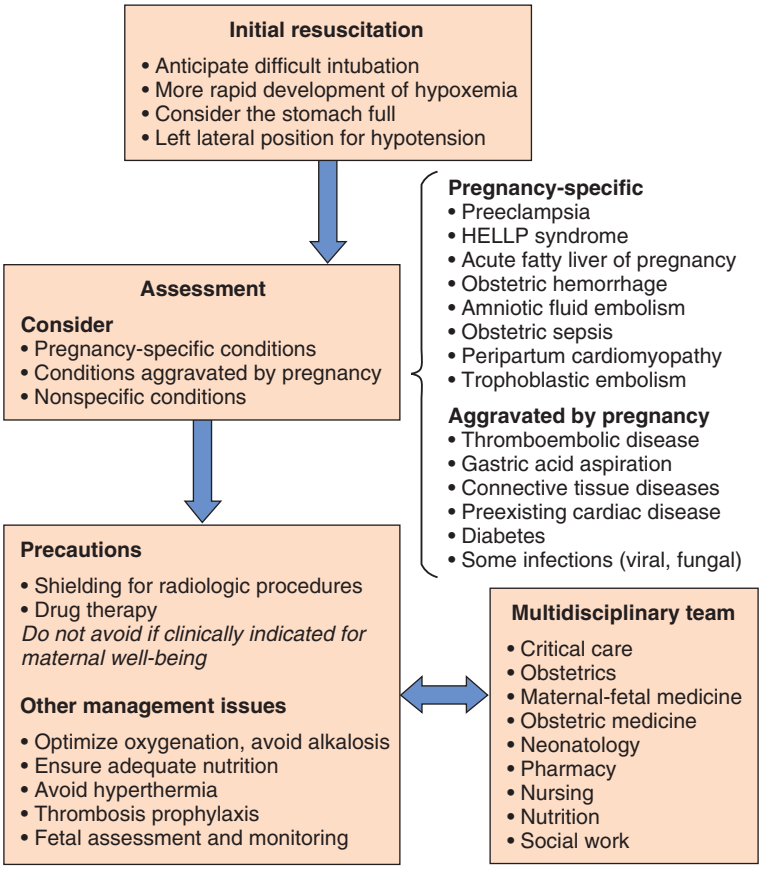
The rising progesterone level stimulates an increase in ventilation. Tidal volume and minute ventilation increase from the first trimester, reaching 20% to 40% above baseline by term (Table 77.1).[3] A mild respiratory alkalosis is produced with compensatory renal excretion of bicarbonate (partial pressure of arterial carbon dioxide [$PaCO_2$] 28–32 mm Hg; bicarbonate [HCO_3^-] 18–21 mEq/L). Oxygen consumption increases because of the demands of the fetus and maternal metabolic processes, reaching levels up to 33% above baseline by term. Arterial partial pressure of oxygen (PO_2) remains normal throughout pregnancy, but mild hypoxemia caused by an increased alveolar-arterial oxygen tension difference may develop in the supine position as FRC diminishes near term.

Maternal blood volume and cardiac output increase through pregnancy, reaching a peak at 30% to 50% above baseline levels by about 28 weeks (Fig. 77.2).[4] Hemodynamic measurements by pulmonary artery catheter in the near-term patient demonstrate increased cardiac output, with a reduced systemic vascular resistance and pulmonary vascular resistance (see Table 77.1).[5] During labor and continuing into the immediate postpartum period, cardiac output is further augmented by the return of 300 to 500 mL of blood to the central circulation.[6]

Oxygen delivery to the fetus is dependent on the maternal arterial oxygen content and the uterine blood flow. Maternal hypotension, alkalosis (e.g., hyperventilation), and endogenous or exogenous catecholamines can vasoconstrict the uterine artery and adversely affect fetal oxygenation.[7] Uterine blood flow is also reduced transiently by uterine contractions. Although umbilical venous blood returning to the fetus has a relatively low oxygen tension, a high oxygen content is maintained by the left shift of the oxygen dissociation curve of fetal hemoglobin.

Glomerular filtration rate increases early in pregnancy, reaching a value 50% above prepregnancy levels in the second trimester, and remains elevated throughout pregnancy (see Fig. 77.2).[8] The normal serum creatinine level is therefore in the range of 0.5 to 0.7 mg/dL (45–60 µmol/L). As pregnancy progresses, mild uteric dilation and mild hydronephrosis may occur as a result of uterine compression and smooth muscle relaxation.

Pregnancy is associated with a reduced lower esophageal sphincter pressure, reaching a nadir at 36 weeks. The position of the stomach is displaced, further decreasing the effectiveness of the gastroesophageal sphincter and reducing gastric emptying. The pregnant woman should therefore always be considered at risk



• **Fig. 77.1** Approach to the assessment and management of the critically ill obstetric patient. *HELLP, H*emolysis, elevated *l*iver enzymes, *l*ow *p*latelets.

TABLE 77.1 Physiologic Changes in Late Pregnancy

Parameter	Change
Respiratory	
Functional residual capacity	Decreased 10%–25%
Minute ventilation	Increased 20%–40%
Arterial partial pressure of oxygen	No change
Arterial partial pressure of carbon dioxide	Reduced to 28–32 mm Hg
Serum bicarbonate	Reduced to 18–21 mEq/L
Cardiac	
Heart rate	Increased 10%–30%
Pulmonary capillary wedge pressure	No change
Cardiac output	Increased 30%–50%
Systemic vascular resistance	Decreased 20%–30%
Pulmonary vascular resistance	Decreased 20%–30%
Renal	
Glomerular filtration rate	Increased 50%
Creatinine	Decreased (24–68 µmol/L; 0.29–0.77 mg/dL)

for aspiration of stomach contents, regardless of the time elapsed since her last meal.

The increase in plasma volume is associated with a lesser increase in red blood cell mass causing a physiologic anemia, with a hematocrit of 32% to 34% by the third trimester. A mild leukocytosis occurs with the white blood cell count rising further during labor. Platelet counts are usually unchanged, although a condition of benign mild thrombocytopenia may occur.[9] Procoagulant factors rise, contributing to the hypercoagulable state of pregnancy. The erythrocyte sedimentation rate rises related to increased levels of plasma globulins.

Critical Care Management

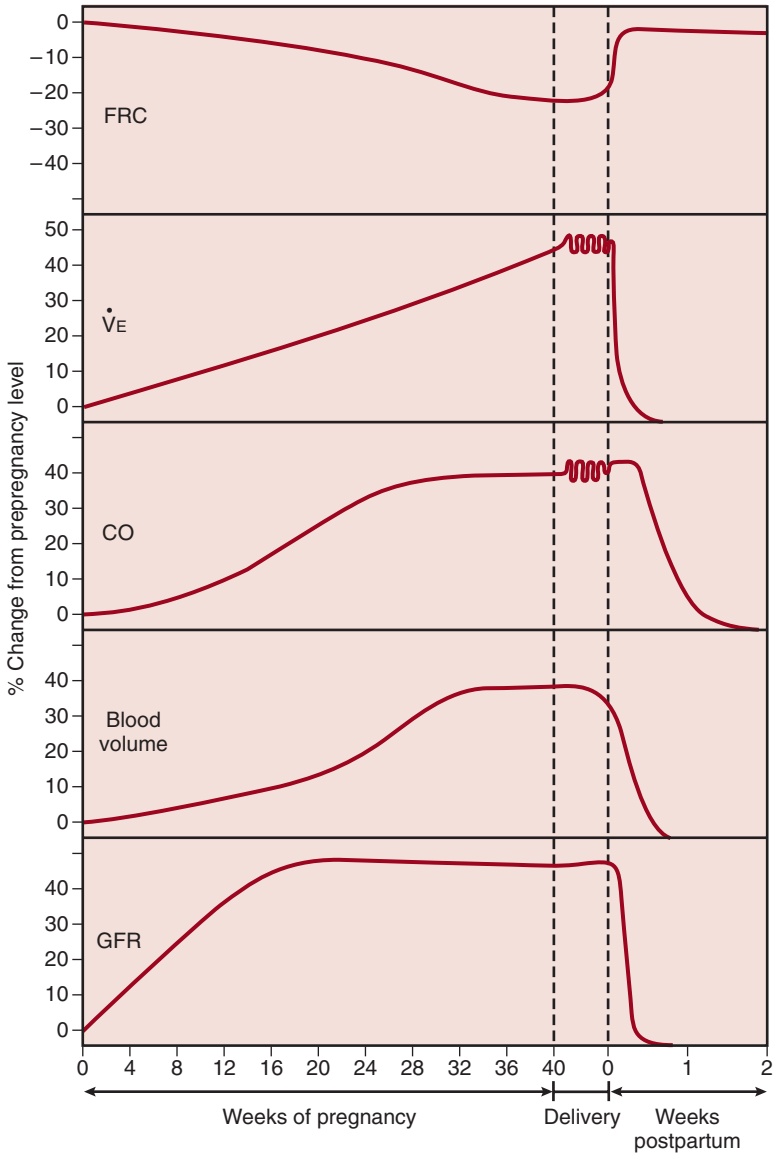
General Care

Positioning

In the supine position the gravid uterus produces mechanical effects on the vena cava and aorta, reducing central venous return. This results in a decrease in cardiac output and hypotension. This "supine hypotensive syndrome" should be considered in hemodynamically unstable patients.[10] Pregnant patients should be positioned on their left side, or at least with the right hip slightly elevated.

Nutrition

During starvation, maternal body stores are protected at the expense of the fetus and inadequate nutrition may result in intrauterine growth retardation and fetal loss. Growth restriction before 26 weeks' gestation may lead to fetal neurologic impairment. Caloric requirements in pregnancy increase by about 300 kcal/day, and protein intake should be augmented by 20% to 50%. Several nutrients have an increased requirement in pregnancy, including iron, folate, and calcium. Total parenteral nutrition has been used successfully to provide nutritional support during pregnancy in



• **Fig. 77.2** Graphic representation of some of the physiologic changes occurring in pregnancy. *CO,* Cardiac output; *FRC*, functional residual capacity; *GFR,* glomerular filtration rate; $\dot{V}_E$, minute ventilation. patients in whom enteral nutrition is not possible. The blood glucose level should be measured frequently in view of the predisposition to hyperglycemia.

Thrombosis Prophylaxis

Pregnancy increases the risks of venous thrombosis caused by hypercoagulability and venous stasis. Antithrombotic measures including physical interventions and heparin prophylaxis should be considered.

Radiologic Procedures and Fetal Risk

Radiologic investigations are often essential for the assessment and management of the critically ill pregnant patient. Although there are potential risks of exposing the fetus to ionizing radiation, fetal well-being depends on maternal recovery and appropriate radiologic procedures should not be avoided. Techniques such as shielding the abdomen with lead and using a well-collimated x-ray beam can effectively reduce exposure. With these precautions, estimated fetal radiation exposure can be limited to safe levels for most procedures, although investigations such as abdominal-pelvic computed tomography (CT) will obviously cause significant fetal radiation exposure (Table 77.2).[11]

The adverse effects of fetal exposure to radiation include oncogenicity and teratogenicity. A twofold increased risk of childhood leukemia may result from fetal exposure in the range of 20 to 50 mGy (2–5 rad). Most intensive care unit (ICU) procedures can be performed well below these levels of exposure to the fetus (see Table 77.2). Teratogenicity does not appear to occur at these radiation doses, requiring radiation exposure greater than 50 to 100 mGy (5–10 rad). Every effort should nonetheless be made to minimize uterine exposure, particularly in the first trimester.

TABLE 77.2 Risk of Fetal Radiation Exposure Resulting from Radiologic Studies in the Critically Ill Pregnant Patient

Investigation	Fetal Radiation Exposure (mGy) (1 mGy = 0.1 rad)
Chest radiograph (with abdomen shielded)	0.01
Ventilation-perfusion scan	
Perfusion	0.1–5
Ventilation	0.1–0.4
CT pulmonary angiogram	0.5–4
CT pelvis and abdomen	10–50
Radiation effect on the fetus:	
Teratogenicity	50–100
Oncogenicity	20–50

CT, Computed tomography.

Drug Therapy in Pregnancy

Pharmacotherapy during pregnancy requires consideration of the altered drug clearance, metabolism and volume of distribution of drugs in pregnancy, and the potential pharmacologic and teratogenic effects on the embryo. A detailed description of drug therapy in pregnancy is beyond the scope of this chapter. Consultation with an obstetrician and pharmacist is essential, and several excellent resources are available.[12,13] Some common ICU drugs are discussed briefly in the following sections.

Catecholamines

Catecholamines commonly used in the ICU, such as dobutamine, dopamine, norepinephrine, and epinephrine, all have the potential to reduce uterine blood flow. Both ephedrine and phenylephrine boluses are used for transient hypotension induced by neuraxial anesthesia.[14] Nonpharmacologic maneuvers such as volume replacement and left lateral positioning are essential to the management of hypotension, and the rapidity of correction of blood pressure may be more important than the specific inotropic agent used. If vasopressor infusion therapy is required to support maternal hemodynamics, this therapy should not be withheld because of concerns for potential adverse effects on the fetus.

Sedation, Analgesia, and Neuromuscular Blockade

Few data exist on the preferred drugs for prolonged sedation, analgesia, or neuromuscular blockade in pregnancy. Benzodiazepine use in early pregnancy has been associated with a small risk of congenital malformations, mainly cleft lip and palate. Midazolam crosses the placenta to a lesser degree than diazepam, which can accumulate in the fetus at levels greater than in the mother. Propofol has been used as an induction agent for cesarean section, but a single case report describes the development of non–anion gap acidosis in two pregnant women receiving propofol infusion for neurosurgical procedures.[15] Congenital malformations have not been demonstrated with use of narcotic analgesics, such as morphine, meperidine, and fentanyl. The majority of nondepolarizing neuromuscular blocking agents have been shown to cross the placenta, including pancuronium, vecuronium, and atracurium, but transfer is unlikely to have clinical effects on the fetus in the short term. The current approach of minimizing sedation in the ICU patient is clearly advantageous to the fetus. However, if sedative or paralyzing agents are used in the pregnant woman, this information must be communicated to the neonatologist, who should anticipate the need for ventilatory support for the fetus.

Antibiotics

Antibiotic regimens similar to those used in the nonpregnant patient are appropriate, with some precautions. Quinolones are sometimes avoided because of the potential risk of arthropathy. Tetracyclines produce adverse effects on fetal teeth and bone, and aminoglycosides and sulfonamides should be used with caution.

Fetal Oxygenation and Monitoring

Attention to interventions aimed at optimizing fetal oxygenation is important in the management of any critically ill pregnant patient. Depending on gestational age, delivery of the fetus may be the most appropriate intervention. Uteroplacental oxygen delivery can be optimized by increasing oxygen-carrying capacity—by blood transfusion, improving maternal cardiac output, and optimizing maternal oxygenation. The simple maneuver of tilting the patient to the left lateral position to increase cardiac output should always be considered.[10]

Continuous electronic monitoring of fetal heart rate (FHR) can be used to identify changes in fetal physiology. Abnormal patterns of FHR have been described with good sensitivity but varying specificity for fetal distress. Fetal tachycardia may occur in the presence of maternal infection or chorioamnionitis, but fetal bradycardia or sinusoidal variation in FHR is more ominous, suggesting fetal hypoxia. Changes in FHR occur in response to uterine activity. Early decelerations coinciding with contractions are benign, but late decelerations beginning beyond the peak in contraction and persisting after the contraction may indicate fetal compromise, particularly if associated with a reduced beat-to-beat variation. Fetal compromise may occur as a result of uteroplacental or fetal pathology but may also indicate maternal illness with reduced uterine oxygen delivery. The fetus may be further assessed by an ultrasound biophysical profile that evaluates factors such as spontaneous movement, breathing action, and amniotic fluid volume. A normal biophysical profile carries a good prognosis.

Ventilatory Support

Noninvasive Ventilation

Noninvasive ventilation avoids the adverse effects of endotracheal intubation, such as airway trauma, the increased risk of nosocomial pneumonia, and the complications associated with sedation. This modality is ideally suited to short-term ventilatory support, which is the case in many obstetric complications that reverse rapidly. The major concern with mask ventilation in pregnancy is the potential risk of aspiration because of the increased intra-abdominal pressure, delayed gastric emptying, and reduced lower esophageal sphincter tone accompanying pregnancy. Noninvasive ventilation should therefore be reserved for the patient who is alert, protecting her airway, and who has an expectation of a relatively brief requirement for mechanical ventilatory support.

Airway Management

Failed intubation is more common in the obstetric population than in other anesthetic intubations.[16] The reduced oxygen reserve

caused by diminished functional residual capacity and increased oxygen consumption produces rapid desaturation in response to apnea or hypoventilation.[17] Preoxygenation with 100% oxygen is beneficial, but respiratory alkalosis must be avoided. In view of the delayed gastric emptying and elevated intra-abdominal pressure, the pregnant patient should always be considered to have a full stomach and appropriate precautions should be taken. Upper airway hyperemia and edema may reduce visualization and necessitate use of a smaller endotracheal tube. The risk of bleeding is increased and nasal intubation should be avoided.

Mechanical Ventilation

The normal $PaCO_2$ of about 30 mm Hg in late pregnancy should be considered in the interpretation of arterial blood gas values when decisions are made to institute ventilatory support. Data on the prolonged mechanical ventilation of pregnant patients are limited. Hyperventilation should be avoided because this adversely affects uterine blood flow[18] because of the resulting alkalemia and the effect of positive-pressure ventilation in reducing cardiac output. The current ventilatory approach of avoiding excessive lung stretch by pressure limitation and permissive hypercapnia has not been assessed in pregnancy. The usual pressure limits (e.g., plateau pressure of 30 cm H_2O) may not be applicable in the near-term patient, where chest wall compliance is reduced. Transpulmonary pressures may not be elevated at a plateau pressure of 30 cm H_2O, and higher ventilatory pressures may be acceptable in pregnant patients near term. Although late pregnancy is associated with a mild respiratory alkalosis, maternal hypercapnia up to 60 mm Hg in the presence of adequate oxygenation does not appear to be detrimental to the fetus.[19] Maternal hypercapnia and respiratory acidosis may produce fetal acidosis, but this does not have the same ominous implications as fetal acidosis owing to lactic acidosis resulting from fetal hypoxia.[20] However, acidosis produces a right shift of the hemoglobin oxygen dissociation curve that may negate the beneficial oxygen-carrying characteristics of fetal hemoglobin. If marked respiratory acidosis results from permissive hypercapnia, treatment with bicarbonate may improve maternal and fetal acidemia.

It may be considered that, because of the effects of pregnancy on respiratory physiology, delivery of the pregnant patient will result in improvement in the mother's respiratory status.[21] Limited case series addressing this issue have not found a significant benefit to the mother, and delivery carries a risk of harm.[22,23] Improvement in oxygenation may occur in some patients, but without improvement in respiratory system compliance or reduction in positive end-expiratory pressure level.[22] Delivery is therefore not indicated purely in the hope of improving "maternal condition." If the fetus is considered viable but is at risk because of severe maternal hypoxia, consultation with a neonatologist may identify a benefit to delivery of the fetus. Obstetric indications should always determine the mode of delivery.

Cardiopulmonary Resuscitation

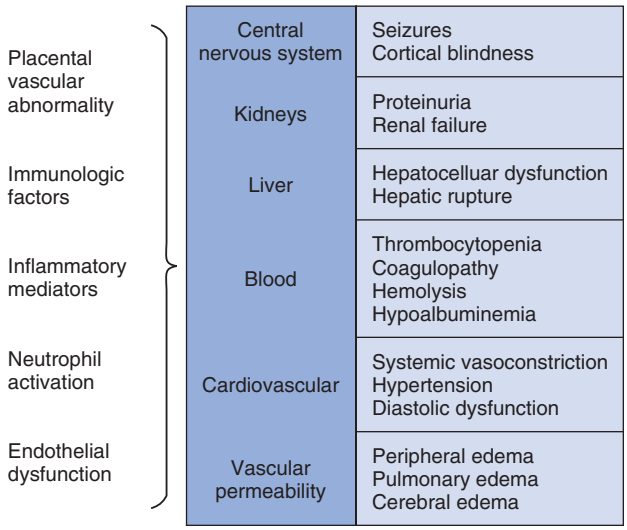
Cardiopulmonary resuscitation requires only minor modifications from standard protocols.[24] Intravenous (IV) access should be established above the diaphragm owing to potentially impeded inferior vena caval blood flow. Electrical cardioversion and defibrillation may be performed in pregnancy, but fetal monitoring leads should be removed to prevent electrical arcing. Management in the supine position may cause aortocaval compression, resulting in impaired venous return and inadequate cardiac output. Manual displacement of the uterus to the left should be used in preference to a left lateral tilt, which may impede cardiac compressions. Appropriate pharmacologic therapy should not be withheld if clinically indicated. Perimortem cesarean section may benefit the mother and save the fetus when initial attempts at resuscitation have failed in a woman with a fetus at a potentially viable gestation (e.g., uterine fundus above the umbilicus). Data suggest that infant survival without neurologic sequelae is highest if the postmortem cesarean section is initiated within 4 minutes of cardiac arrest, aiming for delivery within 5 minutes of arrest.

Pregnancy-Specific Conditions Requiring ICU Care

Preeclampsia

Preeclampsia is a pregnancy-induced condition that usually occurs after 20 weeks' gestation, characterized by hypertension and proteinuria.[25] The cause remains unknown but is likely related to a placental abnormality producing a diffuse maternal endothelial effect, which leads to vasospasm and reduced organ perfusion (Fig. 77.3). Preeclampsia and its complications account for 20% to 50% of obstetric admissions to the ICU.[26–28] Less common multisystem diseases should be considered in the differential diagnosis, including systemic lupus erythematosus (SLE), thrombotic thrombocytopenic purpura (TTP), and hemolytic-uremic syndrome (HUS) (Table 77.3). Complications of preeclampsia may result in critical illness, including pulmonary edema, cerebral edema, renal failure, hypertensive crisis, seizures (eclampsia), and the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) with microangiopathic hemolytic anemia, thrombocytopenia, and hepatic involvement.[29]

The only specific treatment is delivery of the fetus and placenta. Delivery is always in the best interest of the mother, but timing may depend on fetal maturity. The role of antihypertensive therapy is to prevent maternal hypertensive complications and it does not alter the natural history of the condition or benefit the fetus.[30] Commonly used agents include IV hydralazine or labetalol, as well as oral calcium antagonists.[25] Rapid reduction in blood pressure should usually be avoided because of the risk of reducing uteroplacental perfusion. Magnesium sulfate is used for seizure prophylaxis and treatment, giving an initial IV bolus (2–4 g) followed by an



• **Fig. 77.3** Pathophysiology and multiorgan effects of preeclampsia.

TABLE 77.3 Differential Diagnosis of Pregnancy-Related Complications

Clinical Finding	TYPE OF COMPLICATION	
	Pregnancy-Specific	Nonspecific
1. Hypertension	Preeclampsia	Essential hypertension Secondary hypertension (renal, pheochromocytoma)
2. Thrombocytopenia	Preeclampsia HELLP syndrome Acute fatty liver of pregnancy	TTP ITP Sepsis SLE
3. Abnormal liver enzymes	Preeclampsia HELLP syndrome Acute fatty liver of pregnancy Cholestasis of pregnancy	Viral hepatitis Drug-induced hepatitis Budd-Chiari syndrome
4. Renal dysfunction	Preeclampsia Acute fatty liver of pregnancy Idiopathic postpartum renal failure	Sepsis Hypovolemia/hemorrhage TTP/HUS SLE
5. Pulmonary edema	Preeclampsia Peripartum cardiomyopathy Tocolytic pulmonary edema Amniotic fluid emboli	Valvular heart disease Ischemic heart disease ARDS Aspiration

ARDS, Acute respiratory distress syndrome; *HELLP, h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets; *HUS,* hemolytic-uremic syndrome; *ITP,* idiopathic thrombocytopenic purpura; *SLE,* systemic lupus erythematosus; *TTP,* thrombotic thrombocytopenic purpura.

infusion of 1 to 3 g/h. Toxic magnesium levels may occur (>3.5 mmol/L), particularly in the presence of renal dysfunction, producing respiratory muscle weakness and cardiac conduction defects. Hypocalcemia may be noted during magnesium infusion and should not routinely be corrected because this would negate the therapeutic effects of magnesium. Fluid management in preeclampsia usually requires careful volume expansion, but excessive fluid administration can cause pulmonary or cerebral edema.

HELLP Syndrome

The HELLP syndrome is a condition associated with preeclampsia, characterized by the development of a microangiopathic hemolytic anemia and a consumptive thrombocytopenia.[29] Reduced hepatic perfusion results in periportal and focal parenchymal necrosis, elevated liver enzymes, and rarely, hepatic hemorrhage or rupture. The clinical presentation is often with epigastric or right upper quadrant pain, nausea, vomiting, or evidence of bleeding. Features of preeclampsia do not occur in all patients, and approximately 30% of patients with HELLP develop the disease only in the postpartum period.

The diagnosis is based on the presence of thrombocytopenia ($<100 \times 10^9$/L), with a moderate elevation of liver enzymes, and microangiopathic hemolytic anemia (increased lactate dehydrogenase, bilirubin, abnormal blood smear). Many patients are found to have a more widespread coagulation defect than just thrombocytopenia. The white blood cell count may be elevated, and hypoglycemia is uncommon, in contrast to acute fatty liver of pregnancy.

Management includes early delivery if the fetus is viable, blood product support, and management of associated preeclampsia. Dexamethasone initiated before delivery has been reported to produce more rapid recovery of thrombocytopenia in some studies, but this was not confirmed in a more recent study.[31,32] Delivery may require platelet support, and if cesarean section is necessary, hemorrhage should be anticipated and adequate drains should be inserted. Epidural anesthesia is usually contraindicated in the presence of thrombocytopenia.

The maternal complications of HELLP include hemorrhage, acute respiratory distress syndrome (ARDS), and acute renal failure. An uncommon but catastrophic consequence of the HELLP syndrome is hepatic subcapsular hemorrhage, which occurs in about 2% of patients and can progress to hepatic rupture. Hepatic rupture should be considered in any preeclamptic patient with sudden shock or acute abdominal pain. Management requires aggressive hemodynamic and blood product support, urgent delivery, and invasive control of the hemorrhage with embolization or laparotomy with packing of the liver. Hemorrhage without rupture may be managed conservatively if the patient remains hemodynamically stable.

Significant overlap exists between HELLP and other multisystem conditions and thrombotic microangiopathies (see Table 77.3). A response to plasmapheresis may be noted in some patients, possibly representing those with TTP or HUS rather than HELLP. Plasmapheresis is recommended for patients with delayed postpartum resolution when severe thrombocytopenia, hemolysis, or organ dysfunction persists more than 72 hours after delivery. The maternal mortality for women with HELLP syndrome is reported between 1% and 3% (with isolated reports as high as 25%) and with a significant perinatal mortality at 8% to 60%.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) is an uncommon condition affecting about 1 in 15,000 pregnancies. Although early reports described acute fulminant hepatic failure with a high maternal and

fetal mortality rate, the condition is now usually recognized at an earlier stage, allowing early delivery and a significantly improved outcome.[33] Maternal mortality has been reported at 0% to 18% with fetal loss of 23% to 60%. The etiology of this condition is unknown, but an association with a fetal inborn error of metabolism (L-CHAD [long-chain L-3 hydroxyacyl-CoA dehydrogenase deficiency]) has been described.[34] Pathologically, diffuse fatty infiltration of the liver occurs with necrosis and inflammation being mild or absent.

Patients usually present toward the end of the third trimester with a range of onset from as early as 30 weeks' gestation up until the puerperium. Prodromal symptoms of malaise, anorexia, and vomiting may precede the onset of jaundice by 1 to 2 weeks. Abdominal pain may occur, which may be diffuse or localized to the right upper quadrant. Laboratory investigations demonstrate a moderate elevation in transaminase levels (e.g., 300–600 units), in contrast with the higher levels occurring in acute hepatitis. The white blood cell count is often elevated and thrombocytopenia and fragmented red blood cells may be demonstrated. Features of hepatic dysfunction, such as hypoalbuminemia, hypoglycemia, and coagulopathy, occur in more severe cases.

The differential diagnosis of liver disease in pregnancy is wide, and the multisystemic effects of AFLP may resemble SLE, TTP, or HUS (see Table 77.3).

The definitive treatment is delivery of the fetus, and early recognition of this condition is responsible for an improved outcome. Because the presentation is usually close to term, the decision is usually easy and carries little additional risk for the fetus. However, AFLP is associated with placental insufficiency because of fibrin deposition, producing increased fetal loss. It has been reported that this process may be exacerbated by therapeutic coagulation factor replacement. Supportive therapy is similar to that for other causes of fulminant hepatic failure, including correction of coagulation abnormalities and hypoglycemia. Hepatic encephalopathy requires attention to airway protection, dietary protein restriction, bowel sterilization, and oral or rectal lactulose administration. Transient worsening of hepatic function may occur after delivery with improvement usually beginning within 2 to 3 days. A small subset of patients continues to experience deterioration after delivery, and liver transplantation may be indicated. Complications, such as hemorrhage, pancreatitis, renal failure, diabetes insipidus, and infection, should be sought and treated.

Amniotic Fluid Embolism

Amniotic fluid embolism is a catastrophic cardiopulmonary complication of pregnancy, carrying a mortality rate of 10% to 86%.[35] It usually occurs in association with labor and delivery but may be precipitated by uterine trauma or manipulations. Amniotic fluid enters the venous circulation and particulate contents or humoral factors produce acute pulmonary hypertension, as well as acute left ventricular dysfunction.[36] The pregnant woman develops sudden onset of dyspnea, hypoxemia, and cardiovascular collapse. The presenting feature may sometimes be seizures related to cerebral hypoxia, or acute fetal hypoxia and distress. Many patients with amniotic fluid embolism die within the first hour. No specific diagnostic test is available, and the diagnosis of amniotic fluid embolism is based on a typical clinical picture and exclusion of other conditions, such as septic shock, pulmonary thromboembolism, abruptio placentae, tension pneumothorax, or a myocardial ischemic event. Recently low levels of C1 esterase inhibitor have been demonstrated in patients with amniotic fluid embolism, suggesting both a new diagnostic and therapeutic option.[37]

Treatment involves routine resuscitative and supportive measures including mechanical ventilation and inotropic therapy. A role for corticosteroids has been suggested on the basis of the hypothesis that the process may involve an anaphylactoid reaction to amniotic fluid contents.[35] Survivors of the initial process may develop disseminated intravascular coagulopathy and ARDS. Neurologic damage caused by the initial hypotension and hypoxemia is common.

Obstetric Hemorrhage

Uterine blood flow reaches 600 mL/min near term, subjecting the pregnant patient to the risk of devastating blood loss. Antepartum hemorrhage occurs from disruption of the placenta, such as with placental abruption or a low-lying placenta (placenta previa) as the cervix dilates. Most hemorrhage occurs postpartum (postpartum hemorrhage) because of uterine atony, cervical or vaginal lacerations, related to antepartum hemorrhage, or associated with coagulopathy. The pregnant woman is physiologically prepared for blood loss and tolerates the loss from a normal vaginal delivery (600 mL) or cesarean section (1000 mL). However, excessive blood loss results in hypovolemic shock with compromise to fetus and maternal vital organs. The pregnant woman is particularly susceptible to hypoperfusion injury to the kidney. A high incidence of myocardial ischemia has been noted in pregnant women with hemorrhagic shock.

Supportive management of obstetric hemorrhage is similar to any cause of hemorrhage and involves rapid volume replacement, supplemental oxygen administration, and red blood cell and blood product support for an associated dilutional coagulopathy. Various pharmacologic agents are used to control uterine bleeding. Intramuscular administration of methylergonovine (0.2 mg) promotes uterine contractions and may be useful in the presence of uterine atony but is contraindicated in the presence of hypertension.[38] Oxytocin also facilitates uterine contraction and is infused intravenously in a dose greater than that used for augmentation of labor, up to 50 to 100 mU/min (e.g., 20 to 40 U in 1000 mL normal saline solution at 150 mL/h). This dose may produce an antidiuretic effect and cause hyponatremia. A prostaglandin $F_{2\alpha}$ analog (carboprost tromethamine [Hemabate]) given intramuscularly (0.25 mg, repeated every 15–90 minutes to maximum 2 mg) or intramyometrially is effective in controlling hemorrhage.[38,39] Side effects include vomiting, hypertension, bronchoconstriction, and increased intrapulmonary shunt.[40] Tranexamic acid, an antifibrinolytic agent, may have a role in the management of postpartum hemorrhage with an IV dose of 1 g within 3 hours of delivery, and repeated once if bleeding continues.[40] Intrauterine balloon devices may be placed to tamponade bleeding, with a high success rate.[41] Antibiotic prophylaxis is often given while the balloon is in place and analgesia is essential.

Isolated reports suggest that recombinant factor VIIa may be useful in the management of severe obstetric hemorrhage.[42] If the previous methods fail to control bleeding, radiologic transcatheter embolization of the internal iliac or uterine artery is usually effective.[43] Surgical exploration with arterial ligation or hysterectomy may become necessary.

Peripartum Cardiomyopathy

Cardiac failure may occur in the absence of preexisting heart disease because of peripartum cardiomyopathy. This idiopathic condition presents in the last month of pregnancy or within 5 months of

TABLE 77.4 Differential Diagnosis of Acute Respiratory Distress in Pregnancy

Disorder	Distinguishing Features
Pregnancy-Specific	
Amniotic fluid embolism	Cardiorespiratory collapse, seizures, DIC
Pulmonary edema secondary to preeclampsia	Hypertension, proteinuria
ARDS secondary to obstetric sepsis	Evidence of obstetric sepsis, shock
Tocolytic pulmonary edema	Tocolytic administration, rapid improvement
Peripartum cardiomyopathy	Gradual onset, cardiac gallop, cardiomegaly
Trophoblastic embolism	Nodular infiltrate, molar pregnancy
Risk Increased by Pregnancy	
Aspiration pneumonitis	Vomiting, aspiration
Venous thromboembolism	Evidence of DVT, positive V̇/Q̇ scan, leg Doppler, CT angiogram
Pneumomediastinum	Occurs during delivery, subcutaneous emphysema
Valvular heart disease	Pulmonary edema, cardiac murmur, cardiomegaly
ARDS secondary to sepsis	Evidence of sepsis (e.g., pyelonephritis)
Unrelated to Pregnancy	
Asthma	Features similar to nonpregnant patient
Pneumonia	Features similar to nonpregnant patient

ARDS, Acute respiratory distress syndrome; *CT,* computed tomography; *DIC,* disseminated intravascular coagulopathy; *DVT,* deep venous thrombosis; *V̇/Q̇*, ventilation-perfusion.

delivery, with an incidence of approximately 1 in 3500 live births.[44] The clinical presentation is usually after 36 weeks' gestation (in contrast to women with preexisting cardiac disease) and involves the gradual onset of symptoms of heart failure. The diagnosis is by the demonstration of left ventricular systolic dysfunction and by the exclusion of other causes of cardiomyopathy. During labor and the early postpartum period, tachycardia and increased cardiac output may precipitate acute pulmonary edema.

Treatment is similar to that of other patients with cardiac failure, although angiotensin-converting enzyme inhibitors should be avoided before delivery. Anticoagulation is essential because of the hypercoagulable state of pregnancy and the high incidence of thrombotic complications. A subset of patients may have an inflammatory myocarditis, and immunosuppressive therapy may be considered in those who do not improve after 2 weeks of standard treatment.[44] Although a high mortality rate has been described (10%–50%), about half of patients recover normal ventricular function.[45]

Tocolytic Pulmonary Edema

β-Adrenergic blockers can be used to inhibit uterine contractions in preterm labor, although this is less frequently used because studies demonstrated a lack of fetal benefit from this practice. A complication of this β-agonist therapy in pregnancy is the development of acute pulmonary edema.[46] Treatment involves discontinuing the β-agonist and supportive treatment including diuresis and oxygen therapy. Failure of the pulmonary edema to resolve within 24 hours should prompt a search for an alternative diagnosis (Table 77.4).

Gestational Trophoblastic Disease

Pulmonary hypertension and pulmonary edema may occur in the setting of benign hydatidiform mole, as a result of trophoblastic pulmonary embolism. This most commonly occurs during evacuation of the uterus, with a higher incidence of pulmonary complications in the woman later in pregnancy.[47] With supportive treatment resolution occurs within 48 to 72 hours. A molar pregnancy (hydatiform mole) occurs as a noncancerous tumor that develops in the uterus. Instead of a normal pregnancy, the uterus is filled with a cystic mass. Molar pregnancy may rarely develop into a choriocarcinoma, which can produce multiple, discrete, pulmonary metastases.

Conditions Not Specific to Pregnancy

Septic Shock

Changes occur in the immune status in pregnant women, facilitating tolerance to paternally derived fetal antigens. An altered T helper 1/T helper 2 (TH1/TH2) balance occurs, with the maternal immune response favoring humoral immunity (TH2 response), and suppressing cell-mediated immunity (TH1 response), which could be harmful to the fetus.[48] This altered immune response may predispose pregnant women to increased incidence or severity of certain infections, including *Listeria monocytogenes* infection, disseminated herpesvirus infections, varicella, and coccidioidomycosis infections. Human immunodeficiency virus infections should always be considered. Obstetric sepsis in the antepartum period produces chorioamnionitis, but most obstetric sepsis occurs in the postpartum period. The most common location of infection is the placental site, causing endometritis, which can spread to a peritonitis. Episiotomy sites or cesarean section wounds may also become infected. Infections often involve a mixed flora, with microorganisms originating from the vagina (e.g., anaerobes, group B streptococci), intestine (gram-negative organisms, enterococci, anaerobes), sexual transmission (e.g., *Neisseria gonorrhoeae*), or hematogenous spread (e.g., *Listeria*, group A streptococci).[49]

Management of septic shock is similar to that in the nonpregnant patient, with prompt resuscitation with volume expansion. If inotropic therapy is necessary in the antepartum patient, the effects of such drugs on uteroplacental perfusion should be considered. Adequate specimens for culture should be obtained including amniocentesis in the antepartum patient. Ultrasonography may be valuable to identify a source of localized infection and exclude retained products of conception.

Initial empiric antibiotic therapy should provide broad gram-negative, gram-positive, and anaerobic cover. Common regimens use drugs such as ampicillin, gentamicin, and clindamycin; ampicillin/sulbactam; ticarcillin/clavulanate; piperacillin and gentamicin; or carbapenems.[50] Urgent delivery may be required for management of chorioamnionitis with sepsis syndrome.

A poor response to antibiotic therapy may indicate a resistant organism (e.g., *Enterococcus*), a localized abscess, myometrial microabscesses, or septic pelvic thrombophlebitis. Gas in the subcutaneous tissues or uterine wall suggests clostridial gas gangrene. Patients with retained products or devitalized tissue are at significant risk. Toxic shock caused by *Staphylococcus aureus* or *Clostridium*

sordellii may occur, often associated with septic abortion. Surgical evacuation of the uterus or laparotomy with debridement or even hysterectomy may be required. Puerperal ovarian vein thrombophlebitis may complicate endometritis, presenting with acute deterioration with fever. The diagnosis can be confirmed with CT or magnetic resonance imaging scanning, and treatment requires anticoagulation and antibiotic therapy. Surgical intervention with venous ligation or excision may be required.

Group A streptococcal necrotizing fasciitis and toxic shock syndrome have been reported to occur unexpectedly after an uncomplicated pregnancy and delivery.[51] Management includes antibiotic therapy with penicillin and clindamycin and early surgical intervention. IV immunoglobulin (2 g/kg over 1 to 3 days) may be beneficial.

Acute Respiratory Distress Syndrome in Pregnancy

The pregnant patient is at risk of developing acute lung injury from pregnancy-associated complications and other conditions (see Table 77.4).[52] The pregnant patient appears to be at increased risk of developing pulmonary edema because of the cardiovascular changes, the reduced albumin level occurring in pregnancy, increased capillary leak, and possibly an upregulation of components of the acute inflammatory response.

Management is similar to that in the nonpregnant patient. Adequate maternal oxygenation is essential for fetal well-being, and in some situations delivery may benefit the mother and the fetus.[53] Survival from ARDS is as good as or better than that in the general population, likely because of these patients' young age, lack of comorbidity, and the reversibility of many of the predisposing conditions.

Pulmonary Thromboembolic Disease

Pulmonary thromboembolism is a leading cause of maternal mortality. Although the risk is significantly increased in pregnant women because of increased coagulation factors, hormonally mediated venous stasis, and local pressure effects, the incidence is relatively low at about 1 per 1000 deliveries. Pulmonary embolism occurs most frequently in the early postpartum period.

Investigation of suspected pulmonary embolism is not different from that in the nonpregnant patient, with duplex ultrasound as the initial investigation. False-positive results may occur with Doppler alone because of venous obstruction by the gravid uterus. Ventilation-perfusion scanning and CT pulmonary angiography can be performed with low risk of fetal radiation exposure (see Table 77.2).[11]

Warfarin is generally avoided in pregnancy because of the risk of a first-trimester embryopathy and central nervous system abnormalities with second- and third-trimester exposure. Heparin does not cross the placenta and can be readily reversed, and low–molecular-weight heparins are safe and effective in pregnancy although less easy to reverse acutely.[54] Thrombolysis has been used successfully in pregnancy but should be limited to life-threatening situations. Transvenous inferior vena caval filters have been used in the pregnant patient, although there is a risk of dislodgment because of venous dilation and pressure effects.

Asthma

The hormonal changes of pregnancy can affect asthma variably, with worsening, improvement, or no substantial change occurring. Asthma is a common condition, and acute asthmatic attacks are therefore an important cause of respiratory compromise in pregnancy. In assessment of the patient with a severe acute attack, the reduced $PaCO_2$ occurring in late pregnancy should be considered; a normal $PaCO_2$ level associated with acidosis may imply respiratory failure. Treatment is similar to that in the nonpregnant patient, including β-agonists and corticosteroids. Although there is a natural reluctance to prescribe drug therapy in these patients, pregnancy is not an absolute contraindication to systemic corticosteroid therapy.[55] Uncontrolled asthma is more dangerous to the fetus than appropriate drug therapy, and management should highlight the importance of adequate oxygenation.

Cardiac Disease

Overt or occult preexisting heart disease may produce acute cardiac decompensation as the blood volume and cardiac output increase during pregnancy. Women with prior cardiac events, cyanotic disease, or pulmonary hypertension are at particular risk. Patients with mitral and aortic stenosis are at risk of developing hemodynamic deterioration as the physiologic changes peak at about 28 weeks, but mild to moderate regurgitant valvular disease is generally well tolerated.[56] The onset of atrial fibrillation or severe hypertension can precipitate sudden hemodynamic deterioration even in those women with less severe cardiac disease.

Patients with moderate to severe mitral stenosis are likely to experience hemodynamic deterioration during the third trimester or during labor. Treatment is similar to the nonpregnant patient using digoxin and β-blockers to control heart rate and diuretics to reduce left atrial pressure.[57] Angiotensin-converting enzyme inhibitors should be avoided. Most patients with mitral stenosis can undergo vaginal delivery with consideration to invasive hemodynamic monitoring during labor and the early postpartum period. Epidural anesthesia is usually better tolerated hemodynamically than general anesthesia during labor and delivery. Electrical cardioversion can be performed safely if indicated.

Severe aortic stenosis is associated with significant risk during pregnancy,[57] with symptoms such as dyspnea, angina, or syncope appearing from late in the second trimester. Percutaneous aortic balloon valvuloplasty can be performed during pregnancy. Spinal and epidural anesthesia during labor may adversely affect hemodynamics because of the vasodilatory effects.

Ischemic heart disease is uncommon in pregnancy but may be missed because of masking of the symptoms, signs, and cardiac enzyme levels by pregnancy. Coronary artery dissection may occur, particularly in the immediate postpartum period. Aortic dissection may occur related to hypertension, aortic coarctation, or Marfan syndrome and is associated with significant maternal and fetal mortality.[58]

Woman with cyanotic congenital heart disease, particularly those with associated pulmonary hypertension, are at significant risk during pregnancy. Because of the inability of the right ventricle to tolerate the increases in cardiac output, primary or secondary pulmonary hypertension is associated with a high mortality rate in pregnancy.[59] New specific treatments are now available, and although clinical trials in pregnancy are lacking, mortality appears to be decreasing to some degree.[60] Vasodilators such as prostacyclin (inhaled or IV) or inhaled nitric oxide, as well as phosphodiesterase-5 inhibitors such as sildenafil, have been used successfully in pregnancy.[61,62] Endothelin receptor antagonists (e.g., bosentan) are avoided because of potential teratogenicity, and anticoagulation is recommended for most patients. Patients with pulmonary

hypertension should be managed in a center with expertise and experience in this area.

Trauma

The anatomic and physiologic changes of pregnancy may alter the manifestations and severity of traumatic injury. Uterine injury can produce severe hemorrhage because of the high uterine blood flow and may precipitate placental abruption or rarely, uterine rupture. Uterine rupture manifests with maternal shock, abdominal pain, and palpable fetal parts. Penetrating injury to the abdomen predominantly affects the uterus in later pregnancy, but because intra-abdominal viscera are compressed in the upper abdomen, minor injury may result in significant damage.[63] Fractures of the pelvis can produce severe retroperitoneal hemorrhage because of dilation of pelvic veins.

Maternal trauma is associated with a significant increase in fetal loss owing to maternal shock or hypoxia, placental injury, or direct fetal injury.[64] Direct fetal injury resulting from blunt trauma usually involves head injury related to maternal pelvic fracture. Other fetal injuries may occur after blunt or penetrating trauma, sometimes with minimal maternal injury. A high fetal mortality occurs in the presence of maternal burns to greater than 30% of the body surface area. Placental abruption is an important cause of fetal demise,[63] and may present with vaginal bleeding, abdominal cramps, uterine tenderness, amniotic fluid leakage, and unexplained fetal distress or maternal hypovolemia. Placental abruption is often complicated by disseminated intravascular coagulopathy owing to release of thromboplastin into the maternal circulation.

Evaluation of the pregnant trauma patient should include a detailed abdominal examination, but physical signs may be affected by changing organ position and the reduced peritoneal sensitivity that occurs in pregnancy.[65] Initial investigations should include blood type, including Rh status. Ultrasound is useful for evaluation of the fetus for injury and biophysical profile, and to assess intra-abdominal organ damage. Ultrasound-guided paracentesis or diagnostic peritoneal lavage (by open technique, above the uterus) may aid in detecting bowel perforation or intraperitoneal hemorrhage. Transplacental hemorrhage of fetal blood into the maternal circulation may occur and can result in fetal exsanguination and maternal Rh sensitization. Fetomaternal hemorrhage is detected by the Kleihauer-Betke test, which identifies fetal cells in the maternal blood smear, and can estimate the volume of fetal hemorrhage by the percentage of red blood cells of fetal origin. Fetal evaluation includes heart rate assessment by auscultation (possible from 20 weeks) or Doppler probe. Obstetric consultation and continuous fetal cardiotocography are important when the fetus is at a viable gestation.

Care of the severely injured pregnant patient requires a multidisciplinary approach involving the emergency physician, trauma surgeon, obstetrician, intensivist, and neonatologist. Initial resuscitation follows usual principles with efforts directed primarily at stabilizing the mother's condition. Fluid replacement may need to be given more rapidly than in nonpregnant women because of the physiologic increase in plasma volume, and maternal blood pressure and heart rate may not be reliable predictors of the degree of hemorrhage.[65] Left lateral positioning to prevent supine hypotensive syndrome is an important consideration in the hypotensive patient. Rh-negative mothers with abdominal trauma should receive Rh immune globulin even in the presence of a negative Kleihauer-Betke test. Higher doses of Rh immune globulin are necessary in the presence of significant fetomaternal hemorrhage.

In the unstable mother, management of maternal injuries takes precedence over fetal distress because correction of maternal hemodynamics is beneficial to the fetus. The fetus is extremely vulnerable to hypotension and hypoxemia, and uterine blood flow will be markedly reduced when maternal circulation is compromised. If the mother's condition is stable, cesarean section may be appropriate if the fetus is considered viable, the limits of viability being largely dependent on the level of neonatal care available.

Key Points

- The reduced FRC and increased oxygen consumption in pregnancy result in rapid oxygen desaturation during apnea or intubation.
- Although there is a risk to the fetus from radiologic procedures and drug therapy, necessary investigations and treatment should not be withheld, with appropriate precautions.
- The various pregnancy-specific conditions should be considered in the differential diagnosis of a critically ill pregnant woman, including preeclampsia, HELLP syndrome, acute fatty liver of pregnancy, and amniotic fluid embolism.
- Hypotension may occur in the supine position in late pregnancy because of aortocaval compression—the clinician should position the hypotensive pregnant patient in the left lateral position.
- Management of preeclampsia, the commonest cause of ICU admission, involves delivery of the fetus, seizure prophylaxis with magnesium sulfate, correction of fluid balance, and treatment of hypertension if clinically significant.

Review Questions

1. Which one of the following is an expected change in maternal respiratory physiology?
   - **a.** A 40% increase in respiratory rate
   - **b.** A compensated respiratory alkalosis
   - **c.** Reduced airflow (forced expiratory volume in 1 second [FEV_1]) as pregnancy progresses
   - **d.** Increased alveolar to arterial oxygen tension difference (P_{AO_2}-Pa_{O_2})
   - **e.** A decrease in diaphragmatic function

   Answer: b. Increased ventilation occurs as a result of central stimulation by progesterone and is mediated by an increased tidal volume rather than increased respiratory rate. This results in a compensated respiratory alkalosis. FEV_1 and P_{AO_2}-Pa_{O_2} are not affected by pregnancy and diaphragmatic function remains unchanged.
2. Which of the following is true regarding the investigation and treatment of pulmonary thromboembolic disease in pregnancy?
   - **a.** Radioisotope ventilation-perfusion scan in contraindicated.
   - **b.** Ultrasound of the legs has no role owing to a high false-positive rate.
   - **c.** Empiric treatment is usually preferable to diagnostic tests to minimize fetal harm.
   - **d.** Low–molecular-weight heparin (LMWH) is the default treatment of choice.
   - **e.** Computed tomography (CT) contrast angiography exposes the fetus to unacceptably high radiation levels.

   Answer: d. Investigation of pulmonary thromboembolic disease in pregnancy involves either ventilation-perfusion scan or CT contrast angiography, both of which have an acceptably low radiation exposure to the fetus. Although Doppler ultrasound may have an increased false-positive rate, compression ultrasound remains a useful and safe diagnostic test. Empiric anticoagulation likely carries more risk than diagnostic procedures, and the treatment of choice is LMWH.
3. Which of the following statements is incorrect regarding respiratory infections in pregnancy?
   - **a.** Bacterial pneumonia in pregnancy is caused by the same organisms as in the nonpregnant patient.
   - **b.** Alterations in cell-mediated immunity predispose the pregnant women to increased severity of certain respiratory infections.
   - **c.** Pregnant women should receive influenza vaccination.
   - **d.** Treatment of tuberculosis in pregnancy may include isoniazid, rifampin, and ethambutol.
   - **e.** Acyclovir therapy is contraindicated for the treatment of varicella pneumonia in pregnancy.

   Answer: e. Bacterial pneumonia is caused by the same organisms as in nonpregnant patients. Altered cell-mediated immunity predisposes to more severe influenza and varicella infection, mandating the use of influenza vaccination during pregnancy. Triple-drug therapy of tuberculosis with isoniazid, rifampin, and ethambutol is accepted in pregnancy. Acyclovir should be used in the treatment of severe varicella infection and may reduce mortality—it is not contraindicated.
4. Which of the following statements is true regarding cardiac arrest in pregnancy?
   - **a.** Cardiopulmonary resuscitation (CPR) should be performed with the woman in a 30-degree left lateral tilt position.
   - **b.** Perimortem cesarean section should be initiated at 4 minutes if the fetus is full term.
   - **c.** Defibrillation should be performed only with anteroposterior pads to avoid fetal harm.
   - **d.** Survival is worse than in nonpregnant patients owing to the cardiorespiratory physiologic changes of pregnancy.
   - **e.** Hypoxemia is an important cause, and early intubation when hypoxemia is present is advised.

   Answer: e. CPR is less effective at a 30-degree tilt and the uterus is preferably manually displaced to the left, while the woman remains supine during CPR. Perimortem cesarean section should be performed at any gestation over about 20 to 24 weeks (uterine height above the umbilicus) and not just at term. No changes to usual defibrillation are required due to pregnancy, and the survival is better than in nonpregnant patients (at about 58%). Pregnant women develop hypoxemia more rapidly than nonpregnant women, and early attention to oxygenation is warranted.
5. Which of the following statements is true regarding the management of respiratory failure in pregnancy?
   - **a.** Delivery does not always improve the maternal respiratory function.
   - **b.** Tidal volume needs to be adjusted for the increased maternal weight.
   - **c.** Ventilation to low partial pressure of arterial carbon dioxide (Pa_{CO_2}) levels is optimal for fetal well-being.
   - **d.** Oxygen saturation measurement is not reliable in pregnancy.
   - **e.** Noninvasive ventilation is contraindicated in pregnancy.

   Answer: a. Delivery does not necessarily improve respiratory function in women with respiratory failure. The precise tidal volume and blood gas targets during pregnancy remain unclear. Tidal volume is usually based on ideal body weight, a function of height, so unaffected by maternal weight gain in pregnancy. Low Pa_{CO_2} levels are potentially harmful to the fetus by causing uterine vasoconstriction. Oxygen saturation should not be unreliable in pregnancy and noninvasive ventilation is not contraindicated in the awake and alert pregnant patient.
6. Which of the following statements is *false* regarding obstetric hemorrhage?
   - **a.** The average blood loss from a cesarean delivery is 1 L.
   - **b.** Tranexamic acid is contraindicated because of the high risk of thromboembolism in pregnancy.
   - **c.** Inflatable balloon devices may be used to tamponade the uterus.
   - **d.** Oxytocin infusion may be complicated by hyponatremia.
   - **e.** Radiologic transcatheter embolism may avoid the need for surgical intervention.

   Answer: b. The average blood loss from a cesarean delivery is usually given as approximately 1 L. Inflatable balloon devices (e.g., Bakri balloon) are effective in tamponading the uterus and reducing blood loss. Oxytocin, related to its similarity with vasopressin, may cause hyponatremia in high doses. Embolism by interventional radiology is commonly used to stop bleeding and avoid surgical intervention. The World Maternal Antifibrinolytic Trial (WOMAN) demonstrated a reduction in death owing to bleeding by the early (<3 hour) administration of tranexamic acid.

CHAPTER OUTLINE

Malnutrition

Starvation Versus Stress Metabolism
- Carbohydrate Metabolism in Critical Illness
- Fat Metabolism in Critical Illness
- Protein Metabolism in Critical Illness

Indications for Nutrition Support

Goals of Nutrition Support

Nutrition Support in Critical Illness
- Calories
- Carbohydrate
- Fat
- Protein
- Electrolytes, Vitamins, and Trace Elements

Route and Timing of Administration
- Trophic Feeding

Types of Nutritional Formulas
- Organ-Specific Enteral Formulas
- Immunomodulating Enteral Formulas

Nutritional Assessment and Monitoring
- Complications of Nutrition Support

Malnutrition

Malnutrition is a disorder in body composition in which inadequate macronutrient (protein, carbohydrate, and fat) or micronutrient (vitamins, minerals, and trace elements) intake results in decreased body mass, reduced organ mass, and most important, decreased organ function. Although malnutrition is most frequently associated with a risk for immune dysfunction-related infection, wound healing/fascial dehiscence, and breakdown of surgical anastomoses, it can affect virtually all organ systems when severe. Skeletal muscle wasting, decreased myocardial mass, diastolic cardiac dysfunction and decreased sensitivity to inotropic agents, respiratory insufficiency/need for prolonged mechanical ventilation, renal cortical atrophy, and loss of gastrointestinal absorptive/barrier functions have all been associated with malnutrition.

Malnutrition can occur as a result of combined protein-calorie deficiency (marasmus), predominantly protein deficiency (kwashiorkor), and deficiencies in specific micronutrients, as well as altered metabolism arising from a disease state such as sepsis, burns, or trauma. Critically ill patients may be affected by a combination of these causes. Malnutrition is thought to be present in as many as 25% to 50% of patients on hospital admission and may affect an additional 25% to 30% of patients during their hospital stay. The National Surgical Quality Improvement Program has shown preoperative serum albumin, a measure of chronic nutritional status, to be an independent predictor of mortality risk in a study of more than 400,000 surgical patients and specifically in patients undergoing colectomy, proctectomy, transurethral resection of bladder tumors, and major lung resection.[1–4] Malnutrition becomes particularly important in critically ill patients, in whom the combination of bed rest and catabolic illnesses, such as sepsis, multiple trauma, burns, pancreatitis, and acute respiratory distress syndrome (ARDS), hasten the malnutrition, loss of lean body mass, and organ system dysfunction.

The purpose of this chapter is to contrast starvation and stress metabolism with emphasis on protein, carbohydrate, and fat metabolism; review the basic concepts of nutrition support with regard to energy and substrate requirements; discuss routes of nutrition support; provide an overview of organ-specific nutrition and immunonutrition; briefly summarize nutritional assessment and monitoring; and discuss the complications of nutrition support and their prevention.

Starvation Versus Stress Metabolism

Starvation is a clinical situation that develops whenever nutrient supply is inadequate to meet nutrient demand. It is characterized by a specific metabolic adaptive response aimed at preserving lean body mass, as well as by decreased energy expenditure, utilization of alternative fuel sources, and reduced protein wasting. During the initial 12 to 24 hours of starvation, glycogen is the primary oxidative fuel source. Thereafter gluconeogenesis increases temporarily and glucose synthesized from amino acids becomes the primary fuel source for the production of "obligate" glucose for use by tissues such as the brain and, to some degree, the liver and skeletal muscle. Over time, gluconeogenesis decreases as these organs adapt to ketone bodies as the primary oxidative fuel source, and in the fully adapted starved state, fatty acids, ketones, and glycerol become the primary fuel source in all tissues except the brain and red blood cells. The respiratory quotient (i.e., the ratio of carbon dioxide produced to oxygen consumed) is 0.6 to 0.7 as a result of the use of fat as the primary fuel source. Ultimately, rates of net protein catabolism and ureagenesis are decreased, relative to the fed state, during starvation. From a clinical perspective, it is important to understand that the metabolic response to starvation is reversible with feeding.

Stress metabolism is a generalized response whereby energy and substrate are mobilized to support inflammation, immune function,

TABLE 78.1 Starvation Versus Stress Hypermetabolism

Characteristic	Starvation	Hypermetabolism
Energy expenditure	Decreased	Increased
Respiratory quotient	Low (0.7)	High (0.85)
Response to feeding	+++	+
Mediator activation	+	+++
Primary fuels	Fat	Mixed
Gluconeogenesis	+	+++
Proteolysis	+	+++
Protein synthesis	+	++
Ureagenesis/urinary urea nitrogen	+	+++
Ketone formation	++++	+

and tissue repair. It occurs in response to a variety of stimuli, such as sepsis, multiple trauma, burns, pancreatitis, bone marrow transplantation, and major surgery. This mobilization of energy and substrate occurs at the expense of lean body mass. It is driven by endocrine hormones, such as cortisol, glucagon, and catecholamines, as well as by a multitude of inflammatory mediators. The stress response is often related to some degree of perfusion deficit (shock) and resultant microcirculatory injury. Clinically, the response is characterized by increased energy expenditure and increased oxygen consumption. The stress response is further characterized by hyperglycemia, elevated lactate levels, and increased urinary nitrogen excretion. The respiratory quotient is often elevated in the range of 0.80 to 0.95 as a result of the use of a mixed oxidative fuel source. Loss of lean body mass occurs more rapidly than with simple starvation because skeletal muscle protein stores become the "fuel" for the stress response. Most important, the malnutrition associated with stress metabolism is less responsive to nutrition support than is starvation metabolism. Reversal of stress-associated malnutrition is dependent not only on the provision of adequate nutrients but also on elimination of the underlying stress response (i.e., control of infection, stabilization of fractures, grafting of burns, or resolution of the inflammatory state). Starvation and stress metabolism are summarized in Table 78.1.

Carbohydrate Metabolism in Critical Illness

Carbohydrate metabolism in critical illness is characterized clinically by hyperglycemia, often described as being due to "insulin resistance" based on increased blood glucose levels in the presence of high circulating levels of insulin. In fact, cellular glucose uptake and oxidation in the critically ill are increased,[5–7] and hyperglycemia is associated with increased glucose production, decreased insulin-mediated glucose uptake, and increased non–insulin-mediated glucose uptake.[5,8]

Glucose production is increased primarily by increased hepatic gluconeogenesis, to a lesser extent by renal gluconeogenesis,[9] and by increased glycogenolysis. Increased glucose production occurs under the influence of glucagon, catecholamines, and cortisol, with glucagon being the most important stimulant of hepatic gluconeogenesis and epinephrine being the primary stimulant of glycogenolysis.[10,11] The hormonal changes observed in critical illness appear to be mediated by cytokines in both the central nervous system and peripheral tissues. Interleukin 1 (IL-1) stimulates the release of adrenocorticotropic hormone, which in turn favors the release of cortisol and glucagon, and tumor necrosis factor (TNF) stimulates increased secretion of glucagon.[12] Gluconeogenic substrates include lactate and alanine, as well as glutamine, glycine, serine, and glycerol. The amino acids used for gluconeogenesis are derived largely from proteolysis in skeletal muscle.

Glucose uptake into cells is regulated by a process of facilitated transport in which a carrier protein promotes the movement of glucose across the cell membrane down its concentration gradient. Three isoforms of this glucose carrier protein (glucose transporter 1 [GLUT-1], GLUT-2, and GLUT-4) are thought to be important in glucose transport.[13] Non–insulin-mediated glucose uptake is dependent on the GLUT-1 isoform, whereas insulin-mediated glucose transport is dependent on the GLUT-4 isoform. During stress, total body glucose uptake is increased, but largely via non–insulin-mediated pathways.[8] Non–insulin-mediated glucose uptake is particularly important in the central nervous system and in tissues rich in macrophages and neutrophils (e.g., lung, liver, intestine, spleen, wound), which use glucose for energy and in the process generate the respiratory burst.[5,14] Inflammatory cytokines may promote the uptake of glucose by increasing the synthesis, plasma membrane concentration, or activity of the glucose transporter.[15,16] Insulin-mediated glucose transport is suppressed in the liver, heart, and skeletal muscle.[17,18] Hepatic insulin resistance is characterized by elevated circulating levels of insulin-like growth factor–binding protein-1.[17,18] The mechanisms of insulin resistance are incompletely understood, although proinflammatory cytokines may alter insulin receptor signaling.[14,19,20]

The net result of these alterations in carbohydrate metabolism in critical illness is hyperglycemia inasmuch as the liver seems to be unresponsive to high levels of circulating insulin and glucose and continues to synthesize glucose via gluconeogenesis. In other tissues, non–insulin-mediated glucose uptake is enhanced and results in increased glycolytic oxidation to pyruvate and a stoichiometric rise in lactate.[5,6] Although hyperlactatemia is usually thought of as being reflective of anaerobic metabolism, it can be indicative of glycolytic flux and the level of metabolic stress when observed in conjunction with elevated pyruvate.[5]

Fat Metabolism in Critical Illness

In both starvation and stress metabolism, fat metabolism is characterized by increased lipolysis and decreased lipogenesis as fat stores are mobilized for energy. In the stressed state there is a marked increase in lipolytic activity in adipose tissue as a result of catecholamine-mediated stimulation of β_2-receptors; cytokines may also participate in this process.[21,22] Fatty acids are released from adipose tissue in quantities that exceed the amount oxidized, and approximately half of these fatty acids are re-esterified in the liver.[23] In this triglyceride–fatty acid cycle, triglycerides and fatty acids are shunted back and forth between the liver and adipose tissue in an apparently futile pathway.[24]

Stress fat metabolism is further characterized by increased oxidation of fatty acids of all chain lengths and decreased plasma levels of medium- and long-chain essential fatty acids relative to the quantities of oleic acid. The latter may reflect preferential oxidation of essential fatty acids, suppressed mobilization because of hyperinsulinemia, or conversion of ω-6 fatty acids to inflammatory mediators.

Hypertriglyceridemia is common in critically ill patients, particularly in the presence of multiple-organ dysfunction, and results from the combination of increased hepatic triglyceride production and decreased clearance.[25,26] Hepatic steatosis has classically been attributed to overfeeding because triglycerides are constructed from fatty acids synthesized from excess carbohydrate. This theory has been called into question inasmuch as a substantial proportion of hepatic triglyceride may be synthesized from recycled fatty acids rather than from fatty acids synthesized de novo from carbohydrate.[27] It is possible that fatty infiltration of the liver reflects a cytokine-mediated defect in triglyceride secretion that represents an organ-specific response to critical illness rather than an adverse effect of carbohydrate overfeeding.[28,29] Regardless of the immediate source of the fatty acids used in triglyceride synthesis, experience suggests that clinically apparent fatty infiltration of the liver can be prevented by avoiding overfeeding.

Ketonemia is common in starvation, whereas ketogenesis is decreased in stress metabolism.[30] Acetoacetate continues to be used as an oxidative fuel source, although the reduction of β-hydroxybutyrate to acetoacetate is impaired.[31] With the development of multiple-organ dysfunction, there is a progressive decrease in the acetoacetate/β-hydroxybutyrate ratio.[32] This alteration in hepatic redox potential reflects a disturbance in the cellular energy charge that may be associated with hepatic mitochondrial damage by toxic oxygen radicals and other inflammatory mediators.[33]

Protein Metabolism in Critical Illness

Protein synthesis is increased in the stressed state relative to that seen in starvation. Protein breakdown is markedly increased compared with the synthetic rate, thereby resulting in net protein catabolism and a rapid decrease in lean body mass.[30] There is a net efflux of amino acids from skeletal muscle as protein breakdown via the ubiquitin-proteosome pathway of protein degradation is accelerated by catecholamines, cortisol, and cytokines.[34–37] Amino acid uptake by skeletal muscle is impaired despite excess amino acids circulating in the bloodstream early in the course of stress metabolism; the situation deteriorates further as plasma concentrations of specific amino acids such as leucine begin to fall.[38] Decreased plasma glutamine is known to have deleterious effects on immune function and gastrointestinal barrier function.[39,40] Although it has long been thought that the accelerated protein catabolism associated with critical illness is unresponsive to the provision of amino acids or other fuel sources, the fact that muscle amino acid uptake is in part compromised by decreased plasma levels of specific amino acids suggests the possibility that protein catabolism during stress may be attenuated with the provision of appropriate nutrition support.[41]

Amino acids mobilized from skeletal muscle are redistributed to other areas of the body to support immune function, wound healing, and tissue repair, as well as for the hepatic synthesis of acute-phase proteins, presumably in an attempt to enhance survival. It has recently been demonstrated that endotoxemia induces significant increases in protein synthesis in the liver, spleen, kidney, jejunum, diaphragm, lung, and skin at the expense of skeletal muscle catabolism.[42] Amino acids such as alanine, glutamine, glycine, and serine are used as gluconeogenic substrate, and branched-chain amino acids (leucine, isoleucine, and valine) can be used as an oxidative fuel source, particularly in skeletal muscle. The net result of stress protein metabolism is a rapid decrease in lean body mass that exceeds that associated with bed rest or simple starvation, along with increased ureagenesis, azotemia, and increased urinary nitrogen excretion.

Indications for Nutrition Support

Nutrition support should be considered once hemorrhage has been controlled, devitalized tissue debrided, fractures stabilized, and the patient resuscitated from shock. Limited data are available regarding the appropriate timing for the institution of nutrition support, although there are suggestions in the literature that early enteral feeding, within 24 to 72 hours of admission, may help decrease postburn and postinjury hypermetabolism and reduce infectious complications. In general, nutrition support should be initiated in any patient who is malnourished on admission to the intensive care unit (ICU), for any patient who is likely to become malnourished during a long and complicated ICU stay, and for any patient who has not eaten for 5 to 7 days.

Goals of Nutrition Support

The goals of nutrition support in a critically ill patient are to minimize the effects of starvation to provide appropriate doses of macronutrients and micronutrients, to modulate the metabolic processes of the disease, to minimize complications of nutrition support, and to improve outcomes. More specifically, the goals of nutrition support in the critically ill or injured are to provide sufficient calories to meet the energy requirements of the hypermetabolic state while avoiding the complications associated with overfeeding, provide sufficient protein to attain nitrogen balance or minimize the nitrogen deficit, provide electrolytes to maintain normal levels while taking into account excessive losses or impaired excretion, and provide appropriate vitamins and trace elements with consideration of disease-specific requirements.

Nutrition Support in Critical Illness

Calories

In any metabolic state, energy requirements must be met to minimize the use of stored energy reserves and to decrease the loss of lean body mass. In the setting of adapted starvation, the protein-sparing effect of an adequate caloric intake is well recognized; however, in the stressed state, protein catabolism is only partially responsive to caloric intake and continues to a significant degree regardless of caloric intake.[30,41] Overfeeding is of particular concern in a critically ill patient because it can result in excess carbon dioxide production and ventilator dependence,[43] lipogenesis and fatty infiltration of the liver,[44–46] and hyperglycemia with its attendant hyperosmolar and infectious complications.[14,47–49]

The daily caloric requirement depends on total energy expenditure (TEE), which is the sum of basal energy expenditure (BEE), diet-induced thermogenesis (DIT), and activity energy expenditure (AEE). BEE is the caloric expenditure of a person in the recumbent position who has fasted for at least 10 hours. DIT is the energy expended to perform all aspects of food consumption, including eating and hydrolysis and absorption of nutrients, and may account for 15% to 40% of TEE. Resting energy expenditure (REE) is the energy expenditure of a recumbent person who is not fasting and is the sum of BEE and DIT. These relationships can be expressed by the following equations:

$$REE = BEE + DIT$$

$$TEE = REE + AEE$$

Caloric requirement can be estimated by using a number of formulas or can be measured with indirect calorimetry. Most commonly, BEE is estimated with the Harris-Benedict equations, which are based on sex, age, height, and weight and then multiplied by stress and activity factors to estimate caloric requirement. The Harris-Benedict equations are as follows:

For males:

$$\text{BEE} = 66.42 + (13.75 \times \text{Wt[kg]}) + (5.0 \times \text{Ht[cm]}) - (6.77 \times \text{Age[yr]})$$

For females:

$$\text{BEE} = 655.10 + (9.65 \times \text{Wt[kg]}) + 1.85 \times \text{Ht[cm]}) - (4.68 \times \text{Age[yr]})$$

Classically, REE is then estimated by multiplying the calculated BEE by a stress factor ranging from 1.0 in a stable, mechanically ventilated patient to 2.0 in a patient with a 50% total body surface area burn. Stress factors for patients with multiple trauma or sepsis fall somewhere between the two extremes. TEE is estimated by multiplying REE by an activity factor of 1.2 to 1.3 for ambulatory patients. The caloric requirement is decreased to varying degrees (6%–30%) in mechanically ventilated patients receiving narcotics or sedatives and is reduced by as much as 33% in chemically paralyzed patients.[50] In nonventilated postoperative patients or in patients with decreased lung compliance, energy expenditure related to the work of breathing may increase. Although estimation of energy expenditure is relatively accurate in healthy people, it is much less reliable in critically ill patients because of the heterogeneity of the metabolic response and variations in sedation, work of breathing, and physical activity. Most critically ill patients should receive calories to supply 100% to 120% of calculated BEE. Estimation of energy expenditure in obese patients is particularly difficult. If indirect calorimetry is unavailable, the provision of calories should be based on body mass index (BMI) and ideal body weight rather than on obesity-adjusted body weight.[51]

Indirect calorimetry can be used to measure REE and does not require the addition of estimated stress factors. REE is based on measured oxygen consumption and carbon dioxide production and is calculated according to the Weir equation:

$$\text{REE} = (3.94 \times \text{V}_{\text{O}_2}) + (1.1 \times (\text{V}_{\text{CO}_2}),$$

where V_{O_2} is oxygen consumption and V_{CO_2} is carbon dioxide production.

Even when not used routinely, indirect calorimetry can still be helpful in assessing the energy needs of obese patients, to rule out overfeeding in patients with seemingly excessive ventilatory demands, in severely malnourished patients, and in patients with apparently high levels of metabolic stress.

In general, critically ill patients should receive 25 to 30 kcal/kg per day, with sedated mechanically ventilated patients receiving closer to 25 kcal/kg per day. Chemically paralyzed patients generally require 20 kcal/kg per day.[50] In obese patients, hypocaloric feeding may induce some degree of weight loss and improve insulin sensitivity and may decrease ventilator days and length of ICU stay.[52] In patients with a BMI greater than 30, calories should not exceed 60% to 70% of target energy requirements or 11 to 14 kcal/kg actual body weight per day or 22 to 25 kcal/kg ideal body weight per day.[51]

Carbohydrate

Carbohydrate is usually the primary source of calories in human beings. The maximal rate of glucose oxidation is approximately 5 mg/kg per minute, or 7.2 g/kg per day.[53] In stressed patients, part of this maximally tolerated glucose load will be provided by glucose synthesized endogenously from amino acids via gluconeogenesis. In a severely hypermetabolic patient, gluconeogenesis may provide as much as 4 mg/kg per minute of glucose[54] and result in significant hyperglycemia when large exogenous glucose loads are administered. Insulin tends to be ineffective in controlling this hyperglycemia, in part because glucose oxidation may already be maximal, endogenous insulin levels are already high, and insulin-mediated glucose uptake in the liver and other tissues is suppressed in a septic and hypermetabolic patient.[17,18] Complications of excess glucose administration include hyperglycemia and its attendant hyperosmolar/infectious complications, excess carbon dioxide production and ventilator dependence, and hepatic steatosis. In general, glucose should initially be provided at a rate of 5 g/kg per day or approximately 20 kcal/kg per day. Carbohydrate should generally constitute 60% to 70% of nonprotein calories in a hypermetabolic patient (Table 78.2).

Fat

In a hypermetabolic patient, fat should constitute 15% to 40% of daily caloric intake, both to prevent essential fatty acid deficiency and to meet caloric needs in the face of a fixed capacity to oxidize glucose. In the starved state, as little as 2% to 5% of calories can be provided as fat, primarily to prevent essential fatty acid deficiency. Substituting lipid calories for carbohydrate calories

TABLE 78.2 Nutrition Support in a Hypermetabolic Patient

Nutrient	General Recommendation
Total calories	25–30 kcal/kg/day OR BEE × 1.2–2.0 OR REE by IDC
Glucose	5 g/kg/day OR 20 kcal/kg/day OR 60%–70% of calories
Fat	15%–40% of calories OR <1 g/kg/day
Amino acids or protein	1.2–2.0 g/kg/day
Trace elements and vitamins	RDA
Electrolytes	Maintain normal levels

BEE, Basal energy expenditure; *IDC*, indirect calorimetry; *RDA*, recommended dietary allowance; *REE*, resting energy expenditure.

can reduce carbon dioxide production, although avoiding excess calories in general is probably most important in minimizing carbon dioxide production and ventilator dependence. Complications of excess lipid administration, particularly when given parenterally, include hyperlipemia, immunosuppression, and hypoxemia as a result of both impaired oxygen diffusion and ventilation-perfusion mismatching. In general, a hypermetabolic patient should receive 15% to 40% of calories as fat, not to exceed 1.0 to 1.5 g/kg per day (see Table 78.2).[55]

Protein

Protein needs in a hypermetabolic patient are increased compared with those in a patient with simple starvation. Protein catabolism in a stressed patient has long been thought to be unresponsive to protein or amino acid administration or glucose infusion,[56] and attainment of nitrogen balance is thought to depend largely on the support of stress protein synthesis.[41] However, recent evidence suggests that protein catabolism may be attenuated by the provision of appropriate nutrition support.[42] Regardless of the specific mechanisms involved, lean body mass decreases during catabolic illness because of bed rest and inactivity. Amino acids are redistributed from skeletal muscle to support hepatic protein synthesis, the cellular inflammatory response, and gluconeogenesis and are used as oxidative fuel sources. The critically ill or injured patient may require 1.2 to 2.0 g/kg per day to promote nitrogen balance or at least minimize the nitrogen deficit. With the exceptions noted later, the provision of more than 2.0 g/kg per day of protein rarely promotes nitrogen balance and usually results simply in increased urinary nitrogen excretion (see Table 78.2).

To meet the protein requirements of the stressed state and at the same time avoid excess calories and the attendant complications, an injured or septic patient may require nutrition support with a nonprotein calorie-to-nitrogen ratio of 80:1 or 100:1, as compared with a patient with starvation metabolism, who may tolerate a nonprotein calorie-to-nitrogen ratio of 150:1 or higher. The higher protein needs of a patient with catabolic illness can be met with custom-compounded total parenteral nutrition (TPN) or with numerous commercially available enteral formulas specifically designed for such patients (Table 78.3).

In summary, most critically ill patients should receive 1.2 to 2.0 g/kg per day of protein. Obese patients with BMI 30 to 40 should receive at least 2.0 g/kg per day of protein, and patients with BMI greater than 40 should receive at least 2.5 g/kg per day in conjunction with hypocaloric feeding.[51] Critically ill patients with renal failure should generally receive 1.25 to 1.75 g/kg per day, and those requiring continuous renal replacement therapy (CRRT) may require up to 2.5 g/kg per day.[51]

Electrolytes, Vitamins, and Trace Elements

Fluid and electrolytes should be provided to maintain adequate urine output and normal serum electrolyte levels. Typical daily electrolyte requirements include sodium 60 to 100 mEq/day, potassium 60 to 100 mEq/day, magnesium 10 to 20 mEq/day, calcium 10 to 15 mEq/day, chloride 80 to 120 mEq/day, and phosphorus 20 to 30 mmol/day.[57] Intravenous amino acid formulations contain acetate, but more acetate can be added in the setting of metabolic acidosis. Particular attention should be paid to the intracellular electrolytes (potassium, phosphorus, and magnesium), which are required for attainment of nitrogen balance[58] and serum levels of which can fall precipitously when nutrition support is initiated.

The requirements for vitamins and trace elements in critical illness are largely unknown, and in general the recommended dietary allowance for both should be provided. Antioxidant vitamins (including vitamins E and ascorbic acid) and trace minerals (including zinc, copper, and particularly selenium) may improve outcome in burns, in trauma, and in critically ill patients requiring mechanical ventilation[59] and should be provided to all critically ill patients receiving specialized nutrition support.[51] Patients with prolonged diarrhea or large burns or those undergoing dialysis have increased trace element loss and vitamin requirements, and deficiencies can develop if intake is inadequate. Initial limitation of trace elements should be considered in patients with renal failure. Routine supplementation of vitamins is necessary in patients receiving TPN. Typically, one ampule of a standard multivitamin preparation is added to TPN daily. Vitamin K, which is light sensitive, must be added separately in a light-impermeable bag or given by another route once or twice weekly. Excessive doses of vitamin C should be avoided in renal failure because of the accumulation of oxalate. Vitamin A accumulates and should not be supplemented beyond the recommended dietary allowance.[60]

Route and Timing of Administration

Nutrition support can be delivered enterally (via the gastrointestinal tract) or parenterally (via the intravenous route). The preferred route has been the subject of considerable controversy during the past 40 years.

Both routes have advantages and disadvantages, and nitrogen balance can be achieved by either route. TPN does not require an intact or functioning gastrointestinal tract, it is convenient to use, and its use virtually guarantees that the nutrients prescribed will be administered and that these nutrients will appear in the bloodstream. Disadvantages of parenteral nutrition include cost, procedure (central venous catheter)-related complications, an increased likelihood of metabolic complications, including hyperglycemia, and an increased risk of infectious complications. Enteral nutrition is much less expensive, is more physiologic, is associated with fewer metabolic complications such as electrolyte abnormalities and hyperglycemia, and stimulates gut function and preserves mucosal integrity and barrier function better than parenteral nutrition does. Disadvantages of enteral nutrition include the requirement for an intact and functioning gastrointestinal tract, procedure (feeding tube placement)-related complications, pulmonary aspiration, malabsorption, feeding intolerance (pain, vomiting, bloating, diarrhea), and as a result, an inability to deliver the entire nutrient prescription.

The gastrointestinal tract is a major interface between the host and the environment and not only regulates the ingestion and absorption of nutrients but is also responsible for defending the host against noxious microorganisms and toxins.[61] Malnutrition impairs gastrointestinal barrier function,[62] as does the lack of luminal nutrients independent of general nutritional status.[63,64] Enteral nutrition has been shown to promote mucosal growth, improve absorptive capacity, alter digestive enzyme production, improve gut mucosal weight, generate DNA and protein synthesis, and improve the efficiency of nutrient utilization.[65] Enteral nutrition stimulates intestinal contractility; the release of trophic substances such as bile salts, gastrin, and motilin; and the release of secretory IgA.[66–69] Enteral nutrition supports commensal bacteria, which in turn degrade bacterial toxins and prevent gut colonization by pathogenic organisms.[66,70] Further, enteral nutrition stimulates gut blood flow and supports gut-associated lymphoid tissue.[66–69] Enteral

TABLE 78.3 Enteral Nutrition Formulas

Type	General Information	Sample Formulas	Concentration (kcal/mL)	Osmolality	Nonprotein Calorie/ Nitrogen Ratio	Protein (g/1000 kcal)	Carbohydrate (% kcal)	Fat (% kcal)

nutrition supports the processing of naive CD4 helper lymphocytes by exposure to bacterial antigens in the gut. These IgA-producing lymphocytes then migrate to distant organs such as lungs, liver, and kidneys, where they form mucosal-associated lymphoid tissue and produce secretory IgA.[66–69] T_H2 CD4 helper lymphocytes, the proliferation of which are stimulated by feeding, enter the circulation and have an antiinflammatory effect.[66,71,72] Enteral nutrients stimulate the proliferation of T_H1 and T_H3 lymphocytes,[71] which in turn release transforming growth factor β (TGF-β), resulting in a further downregulatory or antiinflammatory effect.[66,71]

Several randomized prospective trials in a variety of critically ill patient populations, including trauma, burns, head injury, major surgery, and acute pancreatitis, have documented the benefits of enteral compared to parenteral nutrition.[73–78] Few studies showed a beneficial effect on mortality rate, but most demonstrated reduced infectious morbidity, primarily pneumonia and central line infections. Several meta-analyses comparing enteral and parenteral nutrition have shown significant reductions in infectious complications with the use of enteral nutrition.[79–82]

Traditionally, it has been assumed that parenteral nutrition does not offer the benefits related to gut mucosal integrity and immune function mentioned earlier. Whether this is the primary reason for the increased infection risk associated with parenteral nutrition is less clear. In several of the studies mentioned in previous paragraphs, many of the patients managed with parenteral nutrition received significantly more calories and had a higher incidence of hyperglycemia[80] than did their enterally fed counterparts. In a study in which parenterally fed patients had a higher incidence of sepsis, twice as many patients receiving parenteral nutrition had hyperglycemia as enterally fed patients.[77] In a large prospective trial comparing tight glucose control with standard glucose control, patients with tight glucose control had significantly lower rates of morbidity, infectious complications, and mortality.[49] Further analysis of these data revealed that when glucose was tightly controlled, there was no difference in infection when patients were nourished parenterally rather than enterally.[83] Recently in a large multicenter, randomized, controlled trial involving 2400 critically ill patients who could be fed via either route, the patients were randomly assigned to receive either early enteral or early parenteral nutrition. Caloric intake was similar between groups. There was no difference in 30-day mortality, and secondary endpoints were largely similar with the exception of more vomiting in the enterally fed patients.[84] In a more recent meta-analysis of randomized controlled trials comparing early enteral and early parenteral nutrition, there was no difference in mortality. The incidence of infection was lower in the enterally fed group, but this difference was explained by the subset of trials in which the parenterally fed group received more calories and presumably had poor glucose control.[85] These data suggest that dose may be more important than the route by which nutrition is supplied. A potential explanation for this phenomenon is the suppression of autophagy. Autophagy is an important housekeeping process that is normally activated by cellular stress to remove cellular damage.[86] Overfeeding, as can result from the use of parenteral nutrition, particularly early in the ICU course, can suppress autophagy.[87–90]

In summary, because it is less costly and is associated with fewer metabolic complications and possibly a lower incidence of infection, the enteral route continues to be the recommended route for nutrition support.[91] That said, in as many as 15% of critically ill patients, enteral nutrition is either contraindicated or not tolerated, and parenteral nutrition remains a viable option, particularly when overfeeding is avoided and hyperglycemia is controlled.[91]

The timing for the initiation of nutrition support in critically ill patients has also been controversial. It has been suggested that enteral nutrition started early (within 24–72 hours of admission or the onset of the hypermetabolic insult) is associated with less gut permeability, release of inflammatory cytokines, and reduced systemic endotoxemia.[76] Further, the accumulation of an energy deficit early in the course of an ICU admission has been significantly associated with the occurrence of ARDS, renal failure, pressure ulcers, and the need for surgery[92] and with longer ICU length of stay and more days of mechanical ventilation.[83,93] In a meta-analysis by Heyland and associates, early enteral nutrition was associated with a trend toward reduced infectious morbidity and mortality rates.[76] A second meta-analysis by Marik and Zaloga demonstrated significant reductions in infectious morbidity and hospital length of stay with early enteral nutrition as compared to delayed feedings.[94] In patients who are hemodynamically stable, it is recommended that enteral nutrition be started within 48 hours of admission.[91]

The early use of TPN to supplement enteral nutrition and thus prevent a caloric deficit has been controversial.[76,78,88,93] In a recent prospective, randomized, multiinstitutional trial 2312 patients were randomly assigned to initiation of parenteral nutrition to supplement insufficient enteral nutrition within 48 hours of ICU admission (early initiation group) and compared to 2328 patients randomly assigned to receive supplementary parenteral nutrition no earlier than 8 days after ICU admission (late initiation group). All patients received early enteral nutrition by protocol and had insulin infused to maintain normoglycemia. The late initiation group was slightly more likely to be discharged alive from the ICU and from the hospital without evidence of decreased functional status. Further, patients in the late initiation group had significantly fewer infections, a significant reduction in the proportion of patients requiring more than 2 days of mechanical ventilation, a significant median reduction of 3 days in the duration of renal replacement therapy, and a mean reduction in health care costs of approximately $1600. These patients were considered to be at nutritional risk but not malnourished on admission based on BMI.[95,96] In the past 5 years, three additional large randomized controlled trials have examined the use of parenteral nutrition to supplement inadequate enteral nutrition during the first week of critical illness.[97–99] These results suggest that early parenteral nutrition, even when used to supplement enteral nutrition, is not beneficial and may be harmful and should be avoided unless the patient is chronically malnourished.[100]

Trophic Feeding

The subject of trophic or permissive hypocaloric feeding has received considerable attention recently. In a single-center study, Rice et al. randomly assigned 200 patients with acute respiratory failure to receive trophic or full enteral feedings for the first 6 days in the ICU. The patients receiving trophic feeds received low protein and calories. There was no difference in ventilator-free days between the groups and the fully fed group had more gastrointestinal intolerance.[101] The Trophic vs Full-Energy Enteral Nutrition in Mechanically Ventilated Patients with Acute Lung Injury (EDEN) trial, a subsequent multicenter randomized controlled trial, confirmed these findings in a larger population of 1200 patients.[102] Long-term follow-up at 1 year did not reveal any effect on mortality or physical or neurocognitive function.[103,104] A recent meta-analysis of randomized controlled trials comparing intentional hypocaloric to normocaloric feeding found no difference in outcome.[105] Together

these studies suggest that restricting calories during the acute phase of critical illness is safe and may even be superior to normocaloric feeding. The most recent Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient (Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition) suggest that patients at low nutritional risk with normal baseline nutritional status and low disease severity (Nutrition Risk Screening [NRS-2002] of ≤3, Nutrition Risk in the Critically Ill [NUTRIC] score ≤5[106]) who cannot maintain volitional intake do not require specialized nutrition support over the first week of hospitalization in the ICU.[91] On the other hand, these guidelines also suggest that for patients at high nutritional risk (NRS-2002 ≥5 or NUTRIC score ≥5) or severely malnourished should be advanced toward goal as quickly as possible over 24 to 48 hours, and that every effort should be made to achieve 80% of estimated or calculated goal energy and protein needs within 48 to 72 hours.[91]

Types of Nutritional Formulas

Parenteral nutrition is most commonly administered as a three-in-one solution of dextrose, lipid, and amino acids. TPN order forms typically allow the physician to order "standard" or custom solutions, fluid-restricted solutions, and in some cases, disease-specific solutions such as renal failure or hepatic failure solutions. Electrolytes can usually be added in standard stock concentrations or individually. Vitamins and trace elements are generally added in standard quantities but can be supplemented. Histamine 2 (H_2) blockers for stress ulcer prophylaxis and regular insulin can also be added.

Enteral formulas are usually premixed with a fixed nonprotein calorie-to-nitrogen ratio, and the needs of a specific patient are generally met by changing the formula. Protein and carbohydrate supplements can be added at the bedside to alter premixed formulas. Enteral formulas can be classified in numerous ways, including the form in which protein is provided (e.g., intact protein, hydrolyzed protein [chemically defined or peptide], or crystalline amino acids [elemental]), the quantity of protein contained, the caloric density of the formula, and the disease state for which they were designed. Examples of different formulas are shown in Table 78.3. More detailed information is available elsewhere.[107,108]

Intact protein solutions contain protein as caseinate or soy isolate–based products that are lactose-free, gluten-free, and low in residue. Such solutions contain 45% to 60% of calories as carbohydrate (oligosaccharides), 20% to 35% of calories as long-chain fats (e.g., linoleic acid), and 15% to 20% of calories as protein. Intact formulas are usually isosmotic and may contain 1 to 2 kcal/mL of solution. Some formulas contain fiber as a means to improve diarrhea or glycemic control. Hydrolyzed formulas provide protein as peptides or amino acids, are generally low in fat, and are designed for patients with gut dysfunction or malabsorption.[109] Elemental solutions contain protein exclusively as amino acids and are intended for similar indications. Controlled studies comparing hydrolyzed or elemental formulas with intact formulas have not demonstrated improved tolerance or outcomes.

High-protein formulas contain more than 45 g protein per 1000 kcal and are designed for patients with increased protein needs, such as patients with catabolic illness.

Calorie-dense formulas are designed for patients in whom fluid restriction is required. They are generally relatively low in protein and not ideal for a stressed patient.

Organ-Specific Enteral Formulas

Organ-specific formulas are products designed to meet the nutritional requirements of patients with specific organ failures. None has been consistently shown to improve outcomes when compared with conventional formulas.

Pulmonary failure formulas are designed for patients with acute respiratory failure associated with chronic lung disease. They contain at least 50% of calories as fat and thus reduce carbon dioxide production and decrease the work of breathing relative to high-carbohydrate formulas. Few data suggest a benefit with specific pulmonary formulas, and avoidance of overfeeding is more important in reducing ventilatory demand.[82,110] In the 2016 Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient, published jointly by the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition, it is recommended that these high-fat/low-carbohydrate formulas, designed to manipulate the respiratory quotient and reduce carbon dioxide production, not be used in critically ill patients.[91]

Hepatic failure formulas were developed for patients with encephalopathy. They contain high concentrations of branched-chain amino acids and reduced concentrations of aromatic amino acids. Although these solutions have been shown to correct the abnormal amino acid profile characteristic of patients with liver failure,[111,112] it is less clear that they actually treat hepatic encephalopathy.[112] Hepatic failure formulas should be reserved for the rare encephalopathic patient who is refractory to lactulose and luminal antibiotics.[51]

Renal failure formulas have reduced concentrations of electrolytes and decreased protein content to minimize nitrogenous waste in patients with renal failure. Patients with acute renal failure frequently have associated catabolic illness and as a result need more protein rather than less. Although these formulas may be useful in patients with electrolyte abnormalities not yet being dialyzed, they are inappropriate for patients with catabolic illness who are undergoing dialysis and particularly CRRT. Current recommendations for critically ill patients with acute renal failure are that standard recommendations for protein and calories should be followed, and that specialty formulas only be used for management of significant electrolyte abnormalities.[91] Patients receiving CRRT may require up to 2.5 g/kg per day of protein.[91]

Immunomodulating Enteral Formulas

Immunomodulating enteral formulas are supplemented with various combinations of specific nutrients, arginine, ω-3 polyunsaturated fatty acids, nucleotides, glutamine, and antioxidants aimed at improving immune function and reducing inflammation in critically ill patients.

Arginine is a nonessential amino acid that has both beneficial and deleterious effects. It is a secretagogue for anabolic hormones, supports T-cell function, detoxifies ammonia, and supports wound healing via metabolism to polyamine and proline.[113,114] An arginine deficiency may develop after trauma or major surgery that is mediated by pathologic release of arginase from granulocytes.[114–116] Arginine deficiency impairs the immune response, which may result in increased infections and in impaired wound healing.[114,115,117] Arginine is a precursor for the synthesis of nitric oxide, which in turn is a modulator of hepatic protein synthesis and vascular tone. This nitric oxide–induced vasodilation may be beneficial in some circumstances but in the setting of severe sepsis and hypotension may aggravate hemodynamic collapse. Further, nitric oxide is

metabolized to peroxynitrite,[114,118] which is a potent oxidizing and nitrating agent that may damage mitochondria, increase gut barrier permeability, and promote organ dysfunction.[114,118–123]

Omega-3 *fatty acids* are incorporated into the phospholipid fraction of cell membranes and converted to trienoic prostaglandins and pentaenoic leukotrienes, which are less "inflammatory" than their ω-6 counterparts. Omega-3 fatty acids have been shown to decrease prostaglandin E_2, TNF, and IL-1 production in rat Kupffer cells[124] and alter TNF and IL-1 production in human monocytes.[125] Furthermore, ω-3 fats have been shown to be beneficial in animal models of chronic inflammation and in humans with psoriasis[126] and rheumatoid arthritis.[127]

Glutamine is an important fuel for enterocytes and cells of the immune system. Considered a nonessential amino acid, glutamine may become conditionally essential when skeletal muscle stores and plasma levels become depleted during catabolic illness, thereby resulting in adverse effects on gut barrier and immune function.[128–130] Glutamine has been shown to improve nitrogen balance and decrease bacterial translocation in animals.[131–133] It also promotes the synthesis of glutathione, an important antioxidant. A meta-analysis of 14 randomized trials in which glutamine-supplemented nutrition was compared with standard nutrition demonstrated reduced infectious morbidity and mortality rates with glutamine supplementation, particularly in parenterally nourished surgical patients.[134] The addition of glutamine to an enteral formula not containing glutamine has been shown to reduce mortality in a small group of burn patients,[135] but analysis of aggregate data[136] from 5 randomized controlled trials involving 588 patients from burn, trauma, and mixed ICU populations has shown no benefit in terms of mortality, infections, or hospital length of stay.[135–141] Glutamine supplementation in enterally fed patients is not currently recommended.[91]

Antioxidant vitamins, including vitamins E and C, and trace minerals selenium, zinc, and copper offer the potential to reduce oxidant injury and may improve patient outcomes in burns, trauma, and critical illness requiring mechanical ventilation.[142–144] Aggregated results of 15 trials demonstrated that antioxidant and trace element supplementation was associated with a significant reduction in mortality, but no differences in infectious complications, length of stay, or duration of mechanical ventilation.[91,145–159] Current guidelines suggest that antioxidant vitamins and trace elements in doses known to be safe should be administered to patients receiving specialized nutrition support.[91] Numerous studies comparing immunity-enhancing enteral nutrition with conventional nutrition have produced contradictory results. In a 2001 meta-analysis of 22 studies (2419 patients) in which enteral nutrition supplemented with various combinations of arginine, ω-3 fatty acids, glutamine, and nucleotides was compared with conventional enteral nutrition, the supplemented patients had decreased infectious morbidity but no difference in mortality rates when compared with patients receiving the control diet.[160] The majority of studies demonstrating benefit involved elective surgery patients and not critically ill patients. In the subsequently published and largest (597 patients) randomized trial to date, immunonutrition had no benefit in terms of infectious morbidity, length of hospital stay, number of ventilator days, or mortality rate.[161] In retrospect, it appears that a number of factors may have been responsible for the conflicting results mentioned earlier. First, there was considerable heterogeneity in the patient populations studied (major elective surgery, burns, trauma, sepsis, and ARDS). Second, the immunomodulating enteral formulas studied contained varying combinations of arginine, ω-3 polyunsaturated fatty acids (fish oil), glutamine, and antioxidants. These differences were addressed in a 2008 meta-analysis of 24 studies by Marik and Zaloga in which studies were analyzed by patient type (ICU, burns, and trauma) and by the combination of immunomodulating nutrients in the subject study formula (fish oil, arginine, glutamine, fish oil plus arginine, fish oil plus arginine plus glutamine).[162] All enteral formulas contained antioxidants, primarily selenium, though in varying doses, and could not be studied separately. Overall, the immunomodulating diets had no effect on mortality rate but did demonstrate significant reductions in secondary infections. Mortality rates, infections, and length of stay were significantly reduced only in ICU patients with sepsis, systemic inflammatory response syndrome, and ARDS receiving a formula supplemented with fish oil alone.[163–165] Infection and length of stay were reduced in the 13 ICU studies, but this effect disappeared when the three fish oil studies were excluded.[162] The 2009 Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient recommended the use of an immunomodulating enteral formula supplemented with fish oil and antioxidants for patients with acute lung injury/ARDS.[82] In 2011 Rice et al., working with the NIH NHLBI ARDS Network, reported a randomized, double-blind, placebo-controlled trial of 272 patients with lung injury, comparing twice-daily supplementation of ω-3 fatty acids, γ-linolenic acid, and antioxidants with an isocaloric diet. The supplemented group had an eightfold increase in plasma eicosapentaenoic acid levels but fewer ventilator-free days, fewer ICU-free days, and fewer organ failure–free days. The adjusted 60-day mortality was 25.1% in the supplemented group compared to 17.6% in the control group ($P = 0.11$).[166] The 2016 Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient recommend that immune-modulating enteral formulas not be used in the medical ICU, but that such formulas may be appropriate in patients with head injuries and gastrointestinal surgical patients in the surgical ICU. Because of conflicting data, formulas containing ω-3 fatty acids and antioxidants are not currently recommended for patients with acute lung injury or ARDS.[91]

Nutritional Assessment and Monitoring

The history and physical examination remain the mainstay of nutritional assessment, although they are perhaps more useful in the ambulatory setting or in patients with chronic malnutrition.[167] Pertinent historical information includes height and weight, a history of recent weight change, genetic background, recent nutritional intake, and a history of disease that might affect nutrient intake, absorption, or tolerance. The physical examination might, on occasion, demonstrate abnormal end-organ function that reflects malnutrition, but more commonly it is useful for the assessment of body mass and detection of specific nutrient deficiencies. Signs and symptoms of selected vitamin and mineral deficiencies are presented in Tables 78.4 and 78.5.

Anthropometric measurements such as triceps skinfold thickness (SFT), midarm circumference, and arm muscle area, which is derived from SFT and midarm circumference, can be used to estimate fat mass and lean body mass.[168] Although serial measurements may be useful in certain patients over long periods, SFT measurements are less reliable in the elderly because of changes in fat distribution and skin compressibility associated with aging[168,169] and are inaccurate in patients with peripheral edema.[170] In general, these measurements are not practical for nutritional monitoring in a recumbent, critically ill patient.[171]

Visceral protein levels have long been used in nutritional assessment and monitoring and can be useful in the appropriate

TABLE 78.4 Selected Vitamin Deficiencies

Vitamin	Function	Signs of Deficiency
Niacin (vitamin B_5)	Component of the coenzymes NAD and NADP, which catalyze oxidation-reduction reactions and play a role in the oxidative catabolism of carbohydrates, proteins, and lipids and the biosynthesis of fatty acids	Pellagra, dermatitis, headaches, loss of memory, dementia, glossitis, diarrhea
Folate (vitamin B_9)	Transfer of single-carbon units; DNA synthesis	Megaloblastic anemia, diarrhea, glossitis
Cyanocobalamin (vitamin B_{12})	Maintains normal folate metabolism; coenzyme in reactions involving isomerizations and reductions; participates in the metabolism of fat, carbohydrate, and protein and in myelin synthesis	Pernicious anemia, glossitis, peripheral neuropathy, spinal cord degeneration
Thiamine	Carbohydrate metabolism coenzyme in oxidative decarboxylation	Paresthesias, impaired memory, nystagmus, congestive heart failure, Wernicke-Korsakoff syndrome
Riboflavin (vitamin B_2)	Electronic transport as flavin nucleotides	Mucositides, dermatitis, cheilosis, vascularization of the cornea, photophobia, decreased vision, lacrimation, impaired wound healing
Pyridoxine (vitamin B_6)	Coenzyme in transformations of amino acids	Neuritis, dermatitis, convulsions
Pantothenic acid	Precursor of coenzyme A (Krebs cycle)	Headache, fatigue, malaise, insomnia, vomiting, abdominal cramps
Biotin	Coenzyme for carboxylation reactions	As with other B vitamins (normally synthesized and absorbed from gut)
Ascorbic acid (vitamin C)	Reducing agent, wound healing, integrity of blood vessels, folate metabolism	Enlargement and keratosis of hair follicles, impaired wound healing, anemia, ecchymosis, lethargy, depression, bleeding
Vitamin A	Normal vision, mucopolysaccharide synthesis, protease release, entry of macrophages and leukocytes into an acute wound, immune stimulation, mucosal integrity	Dermatitis, keratomalacia, xerophthalmia, night blindness
Vitamin D	Calcium and phosphorus homeostasis	Rickets, osteomalacia
Vitamin E	Antioxidant	Hemolysis
Vitamin K	Clotting factors II, VII, IX, X	Bleeding

NAD, Nicotinamide-adenine dinucleotide; *NADP,* nicotinamide-adenine dinucleotide phosphate.

TABLE 78.5 Selected Mineral Deficiencies

Trace Element	Function	Signs of Deficiency
Chromium	Glucose tolerance; possible role in maintenance of normal serum lipid levels	Elevated serum lipids, insulin-resistant glucose intolerance
Copper	Metalloenzyme biochemical processes, component of ceruloplasmin, connective tissue metabolism, melanin formation	Anemia, neutropenia, leukopenia, depigmentation of skin
Iron	Constituent of hemoglobin, myoglobin, and the cytochrome enzymes	Microcytic hypochromic anemia, fatigue, faulty digestion, decreased serum iron
Zinc	Essential for the function of many enzymes and a component of lipid, protein, carbohydrate, and nucleic acid metabolism; cell replication and connective tissue synthesis	Dermatitis; impaired wound healing; alopecia; depressed cell-mediated immunity, taste acuity, and dark adaptation; sexual retardation; depressed visceral protein status
Cobalt	Biologic methylation	Pernicious anemia, methylmalonic aciduria
Manganese	Oxidative phosphorylation, fatty acid metabolism, protein and mucopolysaccharide synthesis	Growth retardation, bony abnormalities, central nervous system dysfunction

clinical setting. They are affected by a number of variables other than nutritional status, such as hydration state and gastrointestinal and urinary losses, and must therefore be used cautiously in a critically ill patient.

Albumin is contained in a large body pool (4–5 g/kg) and has a half-life of 20 days, so it is insensitive to acute changes and responds slowly to nutritional therapy. Serum albumin levels are decreased in nephrotic syndrome, enteropathies, hepatic failure, and dialysis (particularly peritoneal dialysis), as well as in the setting of acute volume expansion. Levels may be increased in the presence of dehydration, hypercortisolemia, and anabolic hormones, such as insulin, growth hormone, and estrogen. Although serum albumin levels are useful in predicting surgical mortality rate and monitoring nutritional status over the long term, they are much less useful in monitoring a critically ill patient.[172]

Transferrin is contained in a smaller body pool and has a shorter half-life than albumin does (8–10 days), so it is a more sensitive indicator of nutritional status. It is subject to the same influences as mentioned for albumin and, in addition, is affected inversely by serum iron levels.[173]

Retinol-binding protein is a specific carrier involved in vitamin A transport and is linked with thyroxine-binding prealbumin in a constant molar ratio.[174] It has a 12-hour half-life and is sensitive to synthesis and utilization rates. Levels rise in patients with renal disease[175] and with excess vitamin A administration and are reduced in patients with liver disease, cystic fibrosis, hyperthyroidism, and vitamin A deficiency.

Transthyretin (thyroxine-binding prealbumin) is involved in the transport of thyroid hormone and is a carrier for retinol-binding protein. It has a small body pool and a short half-life (2–3 days) and as such may be a sensitive indicator of nutritional status.[176,177] Levels are affected by the same variables that affect albumin and transferrin. Levels are low in patients with hyperthyroidism, cystic fibrosis, chronic illness, and acute stress. Because of its short half-life and ease of measurement, transthyretin is the visceral protein of choice for nutritional assessment and monitoring, although its use in a critically ill patient is controversial. During catabolic illness, hepatic protein synthesis is reprioritized, under the influence of cytokines, with increased synthesis of acute-phase reactant proteins and decreased synthesis of visceral proteins.[178–180] Transthyretin levels fall early in the course of catabolic illness and rise with the subsequent decrease in acute-phase reactant proteins as a result of reversal of the reprioritized hepatic protein synthesis. The association of this response with specific nutrients,[181–184] nitrogen balance,[52,185–188] and outcomes[78,187,189] has been variable. Whether transthyretin levels are reflective of appropriate nutrition support or simply a reflection of the course and severity of the inflammatory response is unclear. An initial transthyretin level lower than 50 mg/L or failure to increase by 40 mg/L per week has been associated with a poor prognosis.[177]

In general, because visceral protein levels are affected by a variety of nonnutritional factors, they are not recommended for the monitoring of nutritional status in critically ill patients.[51]

Nitrogen balance is the nutritional parameter most consistently associated with improved outcomes, and nitrogen balance studies are used routinely in many ICUs to monitor nutrition support. Ideally, positive nitrogen balance is the goal, but minimizing the nitrogen deficit in a critically ill patient is probably more realistic when one considers the fact that proteolysis in the skeletal muscle compartment, which constitutes 70% of body protein stores, is likely to exceed protein synthesis related to the inflammatory response and wound healing, simply because of the size of the compartments involved. Nitrogen balance is calculated as follows:

$$\text{Nitrogen balance (g)} = \text{Nitrogen intake (g)} - \text{Nitrogen output (g)}$$

$$\text{Nitrogen intake (g)} = \text{Protein or amino acid intake (g)}/6.25$$

$$\text{Nitrogen output (g)} = \text{Urinary nitrogen losses (g)} + 2\text{ g (stool and skin losses)}$$

Urinary nitrogen consists of several components, including urea, creatinine, uric acid, ammonia, and amino acids. In health, urea constitutes 90% of urinary nitrogen, whereas in catabolic states, urea may represent as little as 70% of urinary nitrogen. Measurement of total urinary nitrogen (TUN) is complex and not done in most hospitals, whereas urinary urea nitrogen (UUN) is measured routinely. When UUN is used in the calculation of urinary nitrogen excretion, an additional 20% of the UUN is added to account for nonurea nitrogen losses. In the absence of abnormal stool or skin losses, nitrogen output is calculated as

$$\text{Nitrogen output (g)} = \text{TUN (g/24 h)} + 2\text{ g (stool and skin losses)}$$

or

$$\text{Nitrogen output (g)} = \text{UUN (g/24 h)} + 20\%\text{ UUN} + 2\text{ g (stool and skin losses)}$$

Classically, measurement of urinary nitrogen excretion involves a 24-hour urine collection, but recent evidence suggests that a carefully collected 12- or even 6-hour urine collection can be obtained and extrapolated to a 24-hour period.[190] Nitrogen balance is usually calculated weekly.

Numerous techniques for assessment and monitoring of energy balance have been studied, including continuous whole-body calorimetry,[191] the doubly labeled water technique,[191] and nuclear magnetic resonance spectroscopy using phosphorus 31,[192] but no method is ideal. Although they are potentially useful, these methods are either cumbersome, expensive, or impractical for use in critically ill patients.

Indirect calorimetry is used to determine the heat produced by oxidative processes by measuring oxygen consumption and carbon dioxide production, which are then used to calculate REE via the abbreviated Weir equation.[193,194] Indirect calorimetry is widely used at the bedside, is convenient and relatively inexpensive, and accurately estimates REE when compared with standard predictive formulas.[195–201] Indirect calorimetry is performed on patients at rest and therefore does not account for energy expenditure during periods of activity. Many clinicians will increase caloric input by 20% to 25% above measured REE to account for physical activity, particularly in patients who are agitated, ambulatory, or involved in intense physical therapy.[202–204]

In addition to the nutrition-specific monitoring techniques mentioned, the usual laboratory values should be monitored for fluid and electrolyte composition, hepatic function, infection, and any coagulopathy that might reflect vitamin K deficiency. In a critically ill patient, serum electrolytes (sodium ions [Na^+], potassium ions [K^+], chloride ions [Cl^-], and bicarbonate [HCO_3^-]) should be determined daily and as needed. Special attention should be paid to the intracellular electrolytes (K^+, magnesium ions [Mg^{2+}],

and phosphate ions [PO_4^{2-}]), which are required for the attainment of nitrogen balance[80] and can fall precipitously when nutrition support, particularly glucose, is initiated. Rapid uptake into cells can result in dangerously low serum levels acutely. Intracellular electrolyte levels should be measured before starting nutrition support, 1 or 2 days after starting support, and at least weekly thereafter. Liver function and coagulation parameters should be evaluated weekly and as needed. Glucose should be measured every 6 hours initially and then as needed; it can be measured as often as every 2 hours when continuous insulin infusions are being used.

Complications of Nutrition Support

Complications of nutrition support include those related to the route of nutrition support and those related to nutrition support in general and are discussed in the following paragraphs. Perhaps the most important problem with nutrition support is failure to achieve therapeutic goals. Recommendations for appropriate doses of protein and calories, electrolytes, vitamins, and trace elements are discussed in previous text.

Complications of Enteral Nutrition Support

Complications specific to enteral nutrition support include mechanical or technical complications, gastrointestinal complications, and aspiration pneumonia.

Mechanical and technical complications of enteral nutrition include feeding tube misplacement, gastrointestinal perforation, sinusitis, otitis media, ulceration of the nasal septum, and obstruction of the feeding tube. Proper placement of feeding tubes in the gastrointestinal tract should be confirmed radiographically or with pH testing before feeding is initiated. Auscultatory techniques for confirmation of proper tube placement are unreliable.[205] Nasally placed feeding tubes are a potential cause of sinusitis or otitis media (or both), particularly when stiff, large-bore nasogastric tubes are used as feeding tubes. Soft, small-caliber tubes such as Miller-Frederick or Dobhoff tubes seem to cause sinusitis less frequently. In mechanically ventilated patients, feeding tubes may be placed orally to minimize the incidence of sinusitis.[206] Perforation of the esophagus or other parts of the gastrointestinal tract is a disastrous complication and seems to occur most frequently in the setting of stricture, obstructing tumor, or abnormal anatomy as a result of surgery. In these situations, tube placement under fluoroscopic guidance or endoscopic tube placement should be considered. Dislodgment of the feeding tube is a frequent and frustrating problem and can be disastrous when the tube dislodged is a recent, surgically placed tube such as a gastrostomy or jejunostomy tube. When a surgically placed tube has been present for longer than 1 to 2 weeks, the stomach or intestine should be adherent to the abdominal wall and the tube can usually be replaced through the existing tract, as long as the tube is replaced within a few hours before the tract begins to close. A radiograph with contrast enhancement should be used to verify replacement of the tube in the appropriate location. Dislodgment of a surgically placed tube within a week of placement can result in peritonitis from spillage of enteral formula or gastrointestinal contents into the abdominal cavity. Care should be taken to properly secure all feeding tubes either with sutures and tape or with commercially available fixation systems, and tubes should be protected with appropriate patient restraints and caregiver attention when the patient is being moved. Feeding tube obstruction occurs most frequently when tubes are not routinely flushed or when crushed medications are delivered through the tubes. Tubes should be flushed every 6 hours and after every medication dose. Numerous techniques have been used to clear obstructed tubes, including flushing with cola, pancreatic enzymes, cranberry juice, and streptokinase, although none is universally successful. Clearing a nasoenteric tube with a stylet or wire carries the risk of perforating the gastrointestinal tract and should be avoided unless done under fluoroscopic guidance to ensure that the stylet remains within the tube lumen.

Gastrointestinal complications such as abdominal distention, nausea, vomiting, diarrhea, and constipation occur in approximately 60% of critically ill patients receiving nutrition support.[207] Gastrointestinal motility is often decreased in these patients,[207,208] although gastric stasis and high gastric residual volumes occur more frequently than decreased small intestinal motility does.[208] Potential causes of gastroparesis include increased sympathetic tone, elevated intracranial pressure, opiates, benzodiazepines, dopamine, hyperglycemia, recent abdominal surgery, and pancreatitis. Prokinetic agents such as metoclopramide may restore gastric motility and allow gastric feeding.[209] Postpyloric feeding tube placement will often allow the continuation of enteral nutrition. Advancement of the feeding tube into the proximal jejunum facilitates enteral nutrition in patients with pancreatitis.

Diarrhea occurs in as many as 70% of critically ill patients.[207] Potential causes include antibiotics and other drugs, hyperosmolar formulas, infected solutions, hypoalbuminemia, chronic malnutrition and disuse mucosal atrophy, intolerance to lactose or other nutrients, pancreatic insufficiency, biliary fistula, and short-gut syndrome.

Clostridium difficile overgrowth is perhaps the most serious cause of antibiotic-associated diarrhea, and stool should be assayed for *C. difficile* toxin in every case of persistent diarrhea in the critically ill. *C. difficile* enterocolitis should be treated with appropriate antibiotics. Antibiotics may also cause diarrhea by eliminating the bacteria that ferment dietary fiber into short-chain fatty acids. Short-chain fatty acids are important for maintaining colonic mucosal integrity and enhance water and electrolyte absorption.[210] Enteral formulas should be replaced daily to avoid bacterial contamination of the solution.

A change in formula or more gradual institution of nutrition support can be used to overcome problems caused by nutrient intolerance, disuse atrophy, and short-gut syndrome. Semi-elemental or peptide formulas may reduce diarrhea in patients with mucosal atrophy. H_2 blockers can be used to decrease the contribution of gastric secretions to diarrhea in patients with short-gut syndrome. Drugs with the potential to cause diarrhea should be identified and eliminated if possible. Pancreatic insufficiency should be treated with commercially available pancreatic enzymes. Diarrhea secondary to a biliary fistula may be improved with reinfusion of bile into the intestine distal to the fistula. Once correctable causes of diarrhea have been identified and eliminated, bismuth subsalicylate (Kaopectate) can be given for symptomatic relief. Antiperistaltic agents such as loperamide (Imodium) or opiates should be avoided until infectious causes of diarrhea have been ruled out. Fiber may be used to thicken stool and lessen perineal irritation, but it may be associated with constipation and fecal impaction in critically ill patients. Intractable diarrhea may warrant the discontinuation of enteral nutrition and the initiation of parenteral nutrition.

Aspiration pneumonia is the major infectious complication of enteral nutrition. Bolus feeding carries a higher risk of aspiration than continuous feeding does. Gastric residual volume, which has traditionally been used to assess gastric feeding tolerance, does not appear to correlate with risk for aspiration.[211] Gastric feeding is

routinely used in many ICUs, but because a nasogastric tube is one of the leading causes of aspiration, gastric feeding should probably be done with a soft, small-caliber tube designed for feeding. The risk of aspiration associated with gastric feeding may be lower when done via a percutaneous gastrostomy tube,[211] which avoids compromising the function of the gastroesophageal junction and swallowing mechanics. Multiple studies have compared the risk of aspirating gastric versus postpyloric feedings, but the results have been contradictory.[78,212,213] In a recent meta-analysis of seven randomized trials, small bowel feeding was associated with a lower risk of aspiration pneumonia than was gastric feeding.[214] Nursing protocols for the bedside placement of postpyloric feeding tubes have been developed,[215,216] although placement under fluoroscopic guidance is more likely to be successful and is cost-effective.[217] The semirecumbent body position has been shown to significantly reduce aspiration pneumonia compared with the supine body position.[218]

Complications of Parenteral Nutrition Support

The primary complications of parenteral nutrition include mechanical or technical complications and infectious complications. Mechanical and technical complications are related to central venous catheter placement and include pneumothorax, arterial injury, hemothorax, hydrothorax, cardiac arrhythmia, and cardiac perforation with tamponade. The incidence of severe complications with subclavian vein catheterization is 1% to 3%, with an overall complication rate of 5%.[219] The incidence of complications with jugular venous catheterization ranges from 0.1% to 4.2%.[220] Jugular venous catheterization under ultrasound guidance is increasingly being recommended.[221–224] Jugular or subclavian vein thrombosis is a postprocedural complication that is manifested as neck or arm swelling and should be managed by catheter removal and anticoagulation; thrombolytics have also been recommended.[225]

Catheter infection and catheter-associated bloodstream infection are the major infectious complications of parenteral nutrition and occur in 2% to 8% of patients with central venous catheters. The most common infecting organisms are coagulase-negative staphylococci, *Staphylococcus aureus*, and *Candida* species. Infection is more likely when parenteral nutrition is administered through a multilumen catheter than through a single-lumen catheter,[226] although the incidence of infection may be reduced when parenteral nutrition is infused through a dedicated port.[227] Jugular and femoral catheters have higher rates of infection than do subclavian catheters.[228] Dedicated central line care teams and regular dressing change protocols may reduce the incidence of catheter infection.[227] Antibiotic-coated or antibiotic-impregnated catheters are expensive but appear to be effective in reducing catheter-related bloodstream infections.[229] Guidewire exchange is associated with a decreased incidence of technical complications but an increased incidence of catheter infections.[230] Although the possibility of catheter infection increases with time, routine catheter exchange is probably not indicated.[229] Catheters should be replaced, ideally at a fresh site, for obvious site infection, for the evaluation and treatment of fever of unknown origin, and after any positive blood culture. If guidewire exchange is used and the removed catheter proves to be infected, the new catheter often becomes infected during the exchange and should in turn be removed and replaced at a fresh site.

Metabolic Complications of Nutrition Support

Common metabolic complications of nutrition support include hyperglycemia, hepatobiliary complications, disturbances in water and electrolyte balance, and acid-base abnormalities. Although more common in patients receiving parenteral nutrition, metabolic complications can occur with either form of nutrition support.

Hyperglycemia occurs frequently in critically ill patients receiving nutrition support and is most common in diabetic patients and those with catabolic illness. Complications related to hyperglycemia include infection, hyperosmolarity, and osmotic diuresis. The first step in the control of blood sugar is avoidance of overfeeding, as discussed previously. Insulin, whether by intermittent dosing or continuous infusion, is the mainstay for maintenance of acceptable blood glucose levels. The appropriate glucose level has been the subject of controversy. In a large, prospective, randomized trial in critically ill surgical patients, tight glucose control (80–120 mg/dL) was associated with significantly decreased mortality rate, infection, neuropathy, and renal failure.[49] In medical ICU patients the same tight glucose control protocol was associated with decreased renal failure, ventilator days, and reduced ICU and hospital length of stay, but not improvements in mortality rate or infection.[231] Subsequently, the Normoglycaemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial compared tight glucose control to glucose levels less than 180 mg/dL and demonstrated similar infection and mortality rates and fewer episodes of dangerous hypoglycemia with more liberal glucose control.[232] Currently, most practitioners aim for blood glucose levels below 150 to 180 mg/dL. Symptomatic hypoglycemia has been reported in children after sudden withdrawal of TPN but is rare in adults, and weaning of TPN in adults is not usually necessary.[233]

Hepatobiliary complications of nutrition support include hepatic steatosis (fatty infiltration of the liver) and intrahepatic and extrahepatic cholestasis. Progression to chronic liver disease occurs in premature infants[234] but is rare in adults. Hepatic steatosis may develop after 7 to 21 days of parenteral nutrition and is characterized initially by elevated transaminases. Usually asymptomatic, fatty infiltration can, in severe cases, be accompanied by hepatomegaly and right upper quadrant abdominal pain. Histologically, mild cases are characterized by periportal fat infiltration and severe cases by centrilobular infiltration. Overfeeding, hyperinsulinemia, essential fatty acid deficiency, and carnitine deficiency may predispose to fatty infiltration. Cholestasis occurs later in the course of parenteral nutrition and is characterized by elevations in bilirubin and alkaline phosphatase. Histologically, periportal or pericentral canalicular bile plugging, bile staining of surrounding hepatocytes, and lymphocytic triaditis characterize cholestasis. Cholelithiasis has been linked to long-term TPN use. Gallstone formation is almost certainly related to the lack of enteral feeding and the resultant lack of neural and hormonal stimulation of gallbladder contraction. Other potential but unproven causes of cholestasis include overfeeding, the production of toxic bile acids by intestinal bacteria, hormones, endotoxin, and taurine deficiency.[31,235–238] Management of hepatobiliary complications is aimed at prevention. Overfeeding should be avoided. Cyclical TPN and enteral feeding, even if only partial, may help prevent cholestasis. A trial of oral neomycin and metronidazole may be helpful.[238]

Serum electrolyte levels should be monitored and electrolytes added to or eliminated from TPN as indicated, with consideration of excess losses or abnormal accumulation. Hypernatremia or hyponatremia can be managed by increasing or decreasing free water. Particular attention should be paid to the intracellular electrolytes potassium, magnesium, and phosphorus. In malnourished individuals, these electrolytes rapidly move intracellularly when nutrition support is initiated. In what is termed the refeeding syndrome, serum levels of these intracellular electrolytes fall precipitously, with

hypophosphatemia resulting in hemolysis, rhabdomyolysis, and heart failure with hypokalemia and hypomagnesemia leading to cardiac arrhythmias.[239,240] Serum levels of intracellular electrolytes should be corrected before and, in particular, 24 hours after the institution of nutrition support. Abnormally high levels of the intracellular electrolytes are of concern in renal failure and often need to be reduced or eliminated from TPN solutions. Hyperkalemia and hypomagnesemia may lead to weakness and cardiac arrhythmia, and hyperphosphatemia may result in hypotension, hypocalcemia, and metastatic calcification. Hyperphosphatemia is often treated with oral phosphate binders such as calcium carbonate.

Metabolic acidosis related to nutrition support is most commonly caused by excess chloride administration and resultant renal bicarbonate losses, but it can also occur as a result of thiamine deficiency with resultant lactic acidosis.[241,242]

Key Points

- Malnutrition is a significant contributor to morbidity and mortality rates in critically ill patients.
- Distinguishing stress metabolism from starvation metabolism is critical to the provision of appropriate nutrition support.
- Critically ill patients may require more energy but are less able to tolerate glucose than starved patients and require a significant portion of calories as fat.
- Critically ill patients require increased protein to achieve nitrogen balance.
- Enteral nutrition is less costly and more physiologic, is associated with fewer metabolic disturbances, and may be associated with fewer infections than parenteral nutrition and thus remains the preferred route for nutrition support.
- Parenteral nutrition is acceptable when enteral nutrition cannot be used, particularly if blood glucose is tightly controlled.
- Nutrition support should be closely monitored to avoid complications.

Review Questions

1. A patient weighing 75 kg on admission is recovering from sepsis and acute lung injury and is difficult to wean from the ventilator despite an improving chest radiograph. Minute ventilation is 15 L/min. Respiratory quotient (RQ) by indirect calorimetry is 1.15. He is receiving 3000 kcal/day (80% from carbohydrate and 20% from lipids) as total parenteral nutrition (TPN). Which of the following is the most appropriate nutritional modification?

a. Change to an enteral pulmonary failure formula.
b. Substitute protein calories for part of the carbohydrate calories.
c. Decrease total calories to 2250 kcal/day.
d. Increase the proportion of fat calories to 50% of total calories (1500 fat kcal/day).
e. Increase total calories to 4000 kcal/day.

Answer: c. It is recommended that critically ill patients receive 25 to 30 kcal/day. Overfeeding, which results in lipogenesis, would be expected to produce an increase in the RQ, whereas underfeeding, which promotes use of endogenous fat stores, would be expected to produce a decrease in the RQ. Marked increases in carbon dioxide production (VCO_2, with subsequent increases in RQ) in response to overfeeding may cause respiratory compromise in patients with limited pulmonary reserve. An RQ above 1.0 supports overfeeding. The RQ of 1.15 in this case suggests fat synthesis and thus overfeeding. Specialized pulmonary failure formulas contain 50% of calories as fat, which will decrease the RQ, but avoidance of overfeeding is more important.

2. A patient with multiple organ dysfunction syndrome including renal failure is receiving continuous renal replacement therapy (CRRT). Which one of the following represents the most appropriate nutritional prescription?

a. A specialized renal failure formula with low protein
b. A standard nutritional formula with a nonprotein calorie-to-nitrogen ratio of 150 : 1
c. A high-protein enteral formula and possibly the addition of a powdered or liquid protein supplement
d. A specialized immunomodulating enteral formula containing fish oil and supplemental arginine
e. "Standard TPN" with a nonprotein calorie-to-nitrogen ratio of 150 : 1

Answer: c. Although low-protein feeding may be appropriate for patients with chronic renal failure who are not acutely ill, any critically ill patient with acute renal failure needs a high-protein diet primarily because of the catabolic illness that caused the renal failure. Patients receiving CRRT actually need increased protein, usually 2.0 to 2.5 g/kg per day, to account for losses via the dialysis filter. Specialized renal failure formulas are generally not recommended for any critically ill patient with renal failure. Immunomodulating formulas are not currently recommended for critically ill patients with renal failure. Use of TPN is not recommended for patients tolerating enteral feeding.

3. A previously well-nourished patient develops undifferentiated shock and acute respiratory distress syndrome after a difficult coronary artery bypass procedure. The patient becomes hemodynamically stable within 48 hours but still needs ventilator support. Enteral nutrition via a nasojejunal tube is started. After another day, the patient is not tolerating full enteral feeds and continues feeding at 20% of goal rate. Which of the following is the most appropriate nutritional intervention at this point?

a. Discontinue enteral feedings and start TPN.
b. Use TPN to supplement the enteral nutrition to meet calorie and protein requirements.
c. Force enteral feedings, disregarding gastric residual volume, to achieve full enteral feedings.
d. Continue "trophic feedings" for up to a week before considering the addition of TPN.

Answer: d. Early TPN is not indicated in low-risk patients. In higher-risk patients such as this one, Casaer et al.[95] demonstrated in a large randomized controlled trial of ICU patients that late TPN supplementation (at 8 days), compared with earlier TPN supplementation of inadequate enteral feedings, reduced infections, renal replacement therapy and cost, and led to improved functional status. Although full enteral feedings are generally considered a "good thing," in a randomized controlled trial, Rice et al.[102] demonstrated that in patients with acute respiratory distress syndrome, full enteral feedings were no better than trophic feedings during the first 6 days of enteral nutrition support and were associated with fewer gastrointestinal complications. All critically ill patients should receive full feedings, by whatever route, after 6 to 8 days of critical illness.

4. A morbidly obese patient is admitted for multiple trauma 2 months after gastric bypass via Roux-en-Y gastrojejunostomy. The patient is intubated after multiple rib fractures, pelvic fractures, and lower extremity fractures. His family notes that he has been complaining of numbness in his hands and feet and on examination has what appears to be lateral nystagmus. He has multiple surgical procedures planned and will be intubated for an extended period. Which one of the following represents the most appropriate nutrition support prescription?

a. A standard enteral formula with supplemental vitamin D
b. Thiamine supplementation with 2.0 to 2.5 g/kg per day of protein and 11 to 14 kcal/kg per day
c. Thiamine supplementation with 1.5 g/kg per day of protein and 25 to 30 kcal/kg per day
d. Niacin supplementation with 2.0 to 2.5 g/kg per day of protein and 25 to 30 kcal/kg per day
e. Thiamine supplementation with 2.0 to 2.5 g/kg per day of protein and 25 to 30 kcal/kg per day

Answer: b. Patients undergoing gastric bypass for morbid obesity are at risk for Wernicke encephalopathy, which presents with stocking and glove neuropathy and lateral nystagmus, and thus thiamine supplementation is appropriate. The American Society for Parenteral and Enteral Nutrition and the Society of Critical Care Medicine recommend 2.0 to 2.5 g/kg per day of protein and 11 to 14 kcal/kg per day for the provision of nutrition support for the morbidly obese patient.
