Review Questions

1. Which one of the following is most correct regarding antimicrobial stewardship?
   a. Prolonged use of broad-spectrum antimicrobials is not associated with antimicrobial resistance or Clostridium difficile infection.
   b. Only a small proportion of antimicrobial use in the intensive care unit (ICU) is either inappropriate or unnecessary.
   c. Antimicrobial stewardship programs have been shown to improve infection cure rates, reduce treatment failures, increase frequency of correct antibiotic prescribing, and decrease antibiotic resistance and C. difficile infection.
   d. Prospective audits with intervention and feedback and formulary restriction and preauthorization are not core strategies of antimicrobial stewardship.

   Answer: c. Prolonged use of broad-spectrum antimicrobial therapy is associated with antimicrobial resistance and C. difficile. It is estimated that up to 50% of antimicrobial use in U.S. acute care hospitals is either inappropriate or unnecessary. Antibiotic stewardship is defined as coordinated interventions designed to improve the appropriate use of antibiotic agents by promoting the selection of the optimal antibiotic drug regimen including dosing, duration of therapy, and route of administration. Antibiotic stewardship programs have been shown to improve infection cure rates, reduce treatment failures, increase frequency of correct antibiotic prescribing, and decrease antibiotic resistance and C. difficile infection. Prospective audits with intervention and feedback and formulary restriction and preauthorization are core strategies of antimicrobial stewardship programs.
2. Which one of the following is associated with the highest rate of device-related bloodstream infections in the ICU?
   a. Arterial catheters
   b. Central venous catheters
   c. Hemodialysis catheters
   d. Pulmonary artery catheters

   Answer: c. The highest rates of bloodstream infections are seen with the use of hemodialysis catheter (10% of patients). Arterial catheters have rates of device-related bloodstream infection in the range of only 1%. Central vein catheters in the subclavian vein or internal jugular have rates of device-related bloodstream infections in the range of 3% to 5%. Swan-Ganz pulmonary artery catheter use is associated with a 1% to 3% risk of bloodstream infections. Infection rates are associated with the use of proper sterile technique at insertion time.
3. Which of the following is a recommended strategy to reduce catheter-associated urinary tract infection (CAUTI)?
   a. Use of systemic antimicrobials to prevent CAUTI
   b. Maintaining an open drainage system
   c. Use standard precautions, including the use of gloves and gown as appropriate, during any manipulation of catheter or collecting system
   d. Keep collecting bag at level of bladder at all times

   Answer: c. Use of systemic antimicrobials are not recommended to prevent CAUTI. Maintaining a closed drainage system is key; if a break in aseptic technique, disconnection, or leakage occurs, replace the catheter and collecting system. Use of standard precautions, including the use of gloves and gown as appropriate, during any manipulation of the catheter or collecting system is recommended. It is recommended to maintain an unobstructed urine flow, including keeping the collecting bag below the level of bladder at all times, keeping the catheter and collecting tube free from kinking, and emptying the collecting bag regularly.
4. Which one of the following has the strongest causative association with ventilator-associated pneumonia (VAP)?
   a. Oropharyngeal bacteria
   b. Gastric bacteria
   c. Nasal bacteria
   d. Skin bacteria

   Answer: a. Oropharyngeal bacteria are the major source of VAP, not gastric bacteria. It does not appear that nasal bacteria independently play a significant role in the development of VAP. Other sources exist exogenously, such as bacteria brought to patients from inadequately washed hands, inadequately disinfected respiratory therapy equipment, contaminated medication vials, and inadequately disinfected nebulizers shared among patients. Aspiration of oropharyngeal bacteria into the lower respiratory tract and reduced host-defense lung mechanisms are risk factors for the development of VAP.
5. A 40-year-old male with a history of alcoholism and injection drug use presents heavily intoxicated and requires intubation for airway protection. On day 3 of mechanical ventilation he develops fever, leukocytosis, new lung infiltrates as seen on chest x-ray, and increased tracheal secretions. Which of the following is correct?
   a. He does not have VAP as he likely aspirated before intubation and has community-acquired pneumonia.
   b. The most likely organisms causing VAP at any stage are either Streptococcus pneumoniae or Haemophilus influenza.
   c. The American Thoracic Society and Society of Critical Care Medicine recommends an invasive diagnostic approach such as bronchoalveolar lavage as it has been shown to decrease mortality.
   d. If results of Gram staining of deep tracheal aspirate are negative, then the patient is unlikely to have bacterial VAP

   Answer: d. Hospital-acquired pneumonia (HAP) is defined as pneumonia that develops more than 48 hours after hospitalization. VAP is a subset of HAP and is defined as pneumonia that occurs more than 48 to 72 hours after initiating mechanical ventilation.

   Microorganisms associated with early VAP within 4 days of intubation are Streptococcus pneumoniae and Haemophilus species. The microbial spectrum shifts to nosocomial agents the longer patient is supported by mechanical ventilation and is exposed to antibiotics. Invasive diagnostic approach failed to show improved 28-day mortality and the data are inconclusive. If initial result of a Gram stain of a deep tracheal aspirate is negative, the patient is unlikely to have a bacterial VAP.
6. Which one of the following statements is most correct with regard to the use of selective digestive decontamination (SDD) in ICU patients?
   a. It increases VAPs caused by gram-positive organisms.
   b. It increases ICU mortality.
   c. It decreases the incidence of VAPs caused by gram-negative organisms.
   d. It decreases the incidence of VAPs caused by Candida species.

   Answer: b. Selective digestive decontamination (SDD) has been shown in some randomized trials to reduce the incidence of

VAP, and in one large clinical trial has shown a decrease in mortality. SDD consists of scheduled applications of non-absorbable antibiotics with activity against aerobic bacteria and yeast, such as polymyxin, tobramycin, and amphotericin B. In addition, a broad-spectrum antibiotic is administered intravenously for the first 3 days of ICU hospitalization. SDD has been shown to reduce the rate of gram-negative bacilli and in one large trial, Staphylococcus aureus infection. There has been no proven reduction in Candida species with the use of SDD.

Right Dose

Right Duration

Antibiotic Stewardship in the Intensive Care Unit

Conclusions

As medicine advances it is commonplace for older drugs to be replaced by newer ones. Often, the newer drug may have more potency, a more desirable dosing schedule, or a better side effect profile. The usual scenario is that the "old" drug still works, but the "new" ones work better. This is not always the case with antibiotics; antibiotics often evolve because the old drugs cease to work—the microorganisms targeted by these agents evolve, often through repeated exposure, to evade the effect of these medications. The result of this frequent exposure of microorganisms to antibiotics, and the ability of the microorganisms to become resistant to the effects of these medications, has created a crisis in the field of infectious diseases—we cannot keep up with the pathogens' ability to evade our weapons. Indeed, the problem is in many ways self-inflicted, caused by misuse and overuse of antimicrobials. As Dr. Art Wheeler, the late director of the Vanderbilt Medical Intensive Care Unit (ICU) and pioneer in critical care medicine, once said while conducting rounds, "There are only two classes of drugs that, when you give them, have the potential to affect not only the patient you give them to, but also all of the other patients and providers that they will contact: radiotherapeutics and antibiotics." The intent of this chapter is to help readers develop an understanding of antibiotic resistance and provide the framework for an effective, responsible process for the use of this invaluable class of medications.

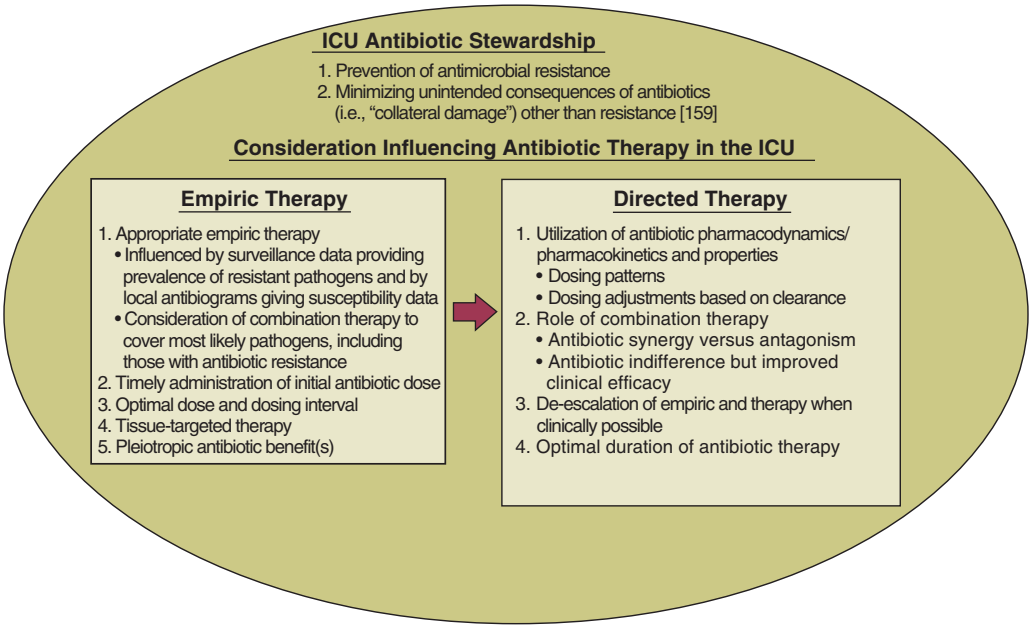
In the critical care setting, antibiotic selection typically entails a two-stage process: empiric therapy, followed by de-escalation to directed, definitive therapy upon identification of the pathogen. Fig. 48.1 illustrates this progression in antibiotic therapy and summarizes some principles that contribute to the goal of achieving optimal efficacy while attempting to preserve the antibiotic armamentarium—the components of antibiotic stewardship. A challenge for the critical care physician is to recognize that antibiotic therapy for the critically ill may ultimately affect that unit's microbiome. If antibiotic-resistant organisms or organisms with certain virulence factors are selected by a pattern of antibiotic use, those pathogens can become part of the ICU's ecology and affect other patients. The 2016 update[1] of the 2007 inaugural Infectious Diseases Society of America (IDSA) and the Society for Healthcare Epidemiology of America joint guideline for the development of an institutional program to enhance antimicrobial stewardship behavior[2] reiterates the challenge of coordinating interventions to improve and measure the appropriate use of antimicrobial agents.

Four focuses of antibiotic prescribing are of primary importance in both the clinical and public health context: the right drug, the right time, the right dose, and the right duration.[3] In acknowledgment of this mandate, this chapter focuses on the elements of antibiotic stewardship that pertain to antibiotic prescription in ICUs. Practitioners must combine antibiotics with infection prevention for it to be optimally effective. Such a combination of philosophical priorities results in an approach to antimicrobial therapy that is collaborative and multidisciplinary. Awareness of such factors is important in the development of the knowledge base regarding adequate antibiotic therapy and its effect on not only morbidity and mortality but also the hospital ecology.

Right Drug

A Clinical Dilemma

Often in clinical medicine, there are life-threatening infections for which there are not definitive data to guide the selection of optimal therapy. Representative examples are hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP), in which gram-negative bacteria are frequently the etiologic agents. The



• **Fig. 48.1** Considerations influencing forms of therapy in the intensive care unit *(ICU)*. Several principles influence antibiotic prescription for an individual patient, first in empiric and then in directed therapy. Antibiotic selection at all times occurs within the context of the entire intensive care unit, raising principles relevant to antibiotic stewardship that may conflict or compete with those influencing antibiotic prescription.

most recent iteration of the clinical guideline for treating HAP and VAP[4] acknowledged the varied treatment options for covering gram-negative bacteria. The authors identified 29 randomized controlled clinical trials comparing different gram-negative regimens for empiric treatment of VAP, including regimens that included carbapenems, cephalosporins, antipseudomonal penicillins, aminoglycosides, quinolones, aztreonam, and tigecycline, with these agents given either alone or in combination. Individually, none of these trials reported significant differences in clinical response or mortality rates between comparator arms with the exceptions of tigecycline[5] and doripenem,[6] which were both associated with worse outcomes. In the absence of definitive data from the trials, the authors performed a series of meta-analyses comparing each class of antibiotics against all other classes to determine whether any class of antibiotics might be superior to another. They reached no definitive conclusion about a gold standard antibiotic for the treatment of HAP or VAP. The absence of definitive data directing antibiotic therapy for these and many other serious infections in the ICU is emblematic of the challenge for the intensivist. Several variables influence decisions about selection of the "right drug," including the microbiology of antibiotic-resistant organisms and the pharmacology of the antimicrobial agents used to treat infections. A basic understanding of the mechanisms of resistance and the organisms that express them can lead to more effective empiric therapy and a more efficient de-escalation process.

Clinical Responses to Multidrug Resistance

Antibiotic resistance leads to delays in appropriate antibiotic therapy and subsequent treatment failure.[7] Furthermore, in studies addressing increased mortality rates associated with inadequate initial antimicrobial therapy for serious infections,[8–13] antimicrobial resistance is a frequent reason for initially selecting an ineffective antibiotic. Trouillet and colleagues evaluated the risk factors for resistance in patients with VAP[14]; the most important of those were use of antibiotics within the past 15 days and mechanical ventilation of at least 7 days. When these two parameters were used in subcategories to evaluate the predisposition for selecting resistant organisms, antibiotic use was a more influential factor than was mechanical ventilation. This fact highlights the dual role that antibiotics play in the ICU: (1) treatment of infection and (2) potential selection of resistant organisms. The challenge for the clinician is to achieve the appropriate degree of balance between these two opposing effects.

The understanding of the development of clinical resistance is evolving. Research has shown that intermittent antibiotic exposures lead rapidly to the evolution of tolerance—the ability to survive under treatment without developing resistance. Using in vitro evolution experiments, investigators have shown that tolerance usually precedes resistance, with mathematical population genetics modeling showing that tolerance boosts the chances for resistance mutations to spread in the population.[15] With these experiments has come a better understanding of the sequential role that antibiotics can have to first lead to tolerance mutations that then pave the way for the rapid subsequent evolution of resistance. Such knowledge provides insight into the impact of antimicrobial exposure on bacterial ecology. Clinical implications of this include the importance of minimizing unnecessary broadness and duration of antibiotic therapy.

Mechanisms of Action and of Resistance

Fig. 48.2 depicts the mechanisms by which bacteria become resistant to antibiotics[16]; Table 48.1 summarizes these mechanisms for specific classes of antibiotics.[17] Fundamentally, an antibiotic must bind to a target site to affect its action and kill the microorganism. As examples, β-lactams, which prevent synthesis of the bacterial cell wall, bind to penicillin-binding proteins (PBPs) located on the inner membrane of the cell wall, whereas fluoroquinolones, which

prevent replication of the genetic elements required for bacterial replication, bind to DNA gyrase located within the cytoplasm. To reach its target site, an antibiotic must penetrate the outermost part of the bacterial cell wall; thus impermeability precludes the drug from getting to its target site. Once an antibiotic enters the bacterial cell wall, but before it binds to its target site, there are two potential mechanisms by which the bacteria can prevent the antibiotic from achieving its effect: (1) enzymatic destruction of the antibiotic and (2) extrusion of the drug from the bacteria via efflux pumps. Because of the importance of enzymatic destruction and of efflux that leads to the drug resistance encountered in the critical care setting, these two mechanisms of action are discussed in some detail; however, it is important to consider the importance of target-site binding and of impaired penetration because both mechanisms of resistance have practical implications for the clinician.

Binding to a Target Site

Although there are multiple sites to which antibiotics bind and exert their action, probably the most relevant in clinical practice is the binding of β-lactam antibiotics to PBPs. PBPs are enzymes on the cytoplasmic membrane that play a role in the synthesis of the peptidoglycan cell wall. When bacteria have alterations in their PBPs such that antibiotics (typically a β-lactam) can no longer bind to that site, the organism demonstrates resistance to that antibiotic.

In clinical medicine, the two most important examples of resistance mediated via altered PBPs are methicillin resistance in *Staphylococcus aureus* (MRSA) and penicillin resistance in *Streptococcus pneumoniae*. The clinical significance of this mechanism is best represented by a relatively common practice. Assume that a patient has an infection presumed to be caused by *S. pneumoniae* that is unresponsive to penicillin. An uninformed practice pattern is the addition of a β-lactamase inhibitor like clavulanic acid to a drug like amoxicillin as the next agent used in an attempt to treat that infection. Because the resistance in penicillin-resistant *S. pneumoniae* is not via β-lactamase production but via altered PBPs, the β-lactamase inhibitor adds no benefit. Alternatively, a higher dose of penicillin might overcome the problem of decreased affinity of the PBPs and improve efficacy of the drug.

Although classically described with resistance in gram-positive bacteria, alterations in certain PBPs occur with some gram-negative bacteria, such as certain carbapenem-resistant strains of *Acinetobacter baumannii*.[18] The β-lactamase inhibitors (i.e., sulbactam, clavulanic acid, tazobactam, avibactam, and vaborbactam) rarely have primary activity against bacteria. The exception to this tenet is the intrinsic activity of sulbactam against *A. baumannii* that occurs on the basis of sulbactam binding to PBPs.[19] Even though the U.S. Food and Drug Administration (FDA) has not approved the compound for such use, some clinicians include sulbactam in certain antibiotic regimens in an attempt to provide coverage against resistant strains of *Acinetobacter*.

Penetration Through the Bacterial Cell Wall

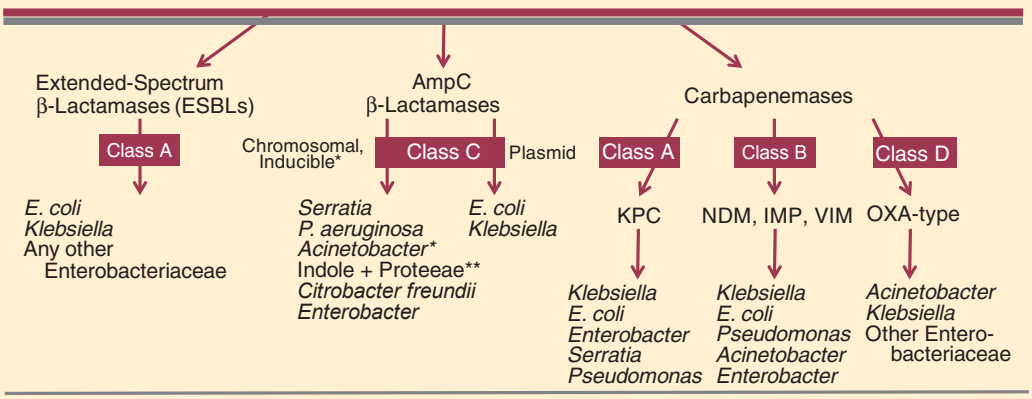
An antibiotic must penetrate the bacterial cell wall to reach its target binding site. Representative examples of resistance caused by altered permeability of the bacterial cell wall include the outer membrane impermeability of *Stenotrophomonas* to β-lactam antibiotics and the inner membrane impermeability that is the basis for aminoglycoside resistance.[20]

One route that can be used by certain antibiotics is through trimers of proteins in the cell wall referred to as porins. Normally a point of access for nutrients into the bacteria and excretory products out of the bacteria, antibiotics, most notably carbapenems, use porin channels as the route of entry. When an organism becomes deficient in these porins, the dependent antibiotics are not able to enter the bacteria, thus resulting in resistance to these agents. The most important example of resistance mediated by porin channel closure is the resistance of *Pseudomonas aeruginosa* to carbapenems.

Enzymatic Degradation

Enzymatic degradation of antibiotics is one of the most widespread and variable mechanisms of antibiotic resistance available to microorganisms. The classic example of resistance by enzymatic destruction is the cleaving—and subsequent inactivation—of β-lactam antibiotics by the β-lactamase family of enzymes. These enzymes are capable of cleaving the four-membered β-lactam ring that is common to all the β-lactam antibiotics (i.e., penicillins, cephalosporins, carbapenems and monobactams) as well as certain β-lactamase inhibitors (i.e., clavulanic acid, sulbactam, and tazobactam). This family of enzymes is large and diverse; Table 48.2 outlines a conceptual approach to this mechanism of resistance. Because countless β-lactamase enzymes exist, clinicians must use a clinically relevant classification system. The Ambler classification divides β-lactamase enzymes into four distinct classes (i.e., Ambler classes A, B, C, and D) based on their molecular structure.[21] In this scheme, classes A, C, and D have serine bases whereas class B has a metallobase. This system can be further simplified to consider three types of β-lactamases with

TABLE 48.2 A Clinical Approach to Gram-Negative Resistance Caused by β-Lactamases[a]



KPC, Kiebsiella pneumoniae carbapenemase; *NDM,* New Delhi metallo-β-lactamase; *IMP,* active on imipenem; *OXA*, oxacillinase; *VIM,* Verona integron-encoded.

[b]AmpC β-lactamase of *Acinetobacter* is not inducible and therefore is less important for resistance in *Acinetobacter*.

[c]The Proteeae tribe of Enterobacteriaceae is composed of three genera of gram-negative organisms: *Proteus* (*P. mirabilis*, *P. vulgaris*, and *P. myxofaciens*); *Morganella* (*M. morganii*); and *Providencia* (*P. rettgeri*, *P. stuartii*, and *P. alcalifaciens*). Of these indole-positive organisms, *M. morganii*, *P. rettgeri*, and *P. stuartii* produce inducible, chromosomal AmpC β-lactamase and have been described as causing systemic infections, including bacteremia. From Kim BN, Kim NJ, Kim MN, et al. Bacteraemia due to tribe Proteeae: a review of 132 cases during a decade (1991–2000). *Scand J Infect Dis.* 2003;35:98–103.

relevance to clinical medicine: (1) extended-spectrum β-lactamases (ESBLs), (2) AmpC β-lactamases (which are class C β-lactamases, also referred to as a type 1 enzyme), and (3) carbapenemases.

Extended-Spectrum β-Lactamases

An increasingly common problem facing clinicians and clinical microbiologists is the presence of ESBLs produced by such pathogens as *Klebsiella*, *E. coli*, *Enterobacter*, and *Proteus*. First described in the 1980s, these enzymes may occur on the basis of a change of only one amino acid in the β-lactamases these pathogens normally produce.[22] The use of any of several classes of antibiotics, notably third-generation cephalosporins and fluoroquinolones, appears to be a risk factor for selecting ESBLs.[23,24]

ESBLs are not chromosomal; rather, they are carried on large plasmids that may contain genetic material that conveys resistance to many classes of antibiotics. For example, the resistance genes for aminoglycosides may be located on the same plasmid as those encoding an ESBL. As a result, gentamicin and tobramycin resistance often occurs in ESBL producers.[25] With fluoroquinolones, multiple mechanisms may contribute to quinolone resistance in ESBL producers. Topoisomerase mutations (i.e., target modification) may be associated with decreased binding. The *qnr* gene codes for a protein that wraps around DNA gyrase, thereby preventing quinolones from attaching to target binding sites.[26,27] In addition, ESBL-producing organisms may possess efflux pumps, and because fluoroquinolones are subject to extrusion from bacteria by means of these pumps, efflux is a potential mechanism of quinolone resistance in ESBL producers.[28]

In the early years after their discovery, ESBL-producing organisms typically occurred in either hospitalized patients or in those who had been exposed to antibiotics. The early 2000s saw ESBL infections occurring in community hospital and antibiotic-naïve, patients,[29] with about 35% of infections caused by ESBL-producing organisms occurring in patients who had no previous health care contact.[30] With the awareness of community ESBL infections came increased identification of specific types of ESBLs (e.g., the enzyme CTX-M, which refers to a cefotaximase that was initially identified in Munich, Germany) occurring predominately in isolates of *Escherichia coli* from community urinary specimens.[31] Jacoby and Munoz-Price suggested an explanation for why infection with ESBL-producing pathogens might originate in the community setting in patients without the risk factors for either selective antibiotic pressure or person-to-person spread of the organism.[25] Genes for CTX-M–type enzymes are found on the chromosome of *Kluyvera*, a genus of rarely pathogenic commensal organisms found in the gastrointestinal tract. It was postulated that pathogenic organisms such as *E. coli* obtained CTX-M–type enzymes by plasmid acquisition from these commensals with which they have close proximity in an environmental reservoir (e.g., the gastrointestinal tract). The awareness of such a trend for community-acquired resistant pathogens may influence the initial empiric therapy of patients with either a gastrointestinal or urinary tract source of infection who present ill enough to require ICU admission.

Although infection with ESBL-producing organisms has been associated with significant clinical consequences, no definitive recommendations exist for how to optimally treat such infections, and, at the time of writing this chapter, no antibiotic on the market has an FDA-approved indication specifically for treating infections caused by ESBL-producing pathogens. The reviews by Jacoby and Munoz-Price[25] and by Paterson and Bonomo[22] list carbapenem as a drug of choice for infections caused by ESBL-producing pathogens. Influencing this recommendation are the facts that ESBL-producing pathogens are often resistant to fluoroquinolones and aminoglycosides and that carbapenems, although β-lactam agents, are paradoxically stable in the presence of ESBLs.

An unanswered question is whether noncarbapenem therapy might be appropriate for some patients, such as those with severe, community-acquired infections requiring ICU admission, for both empiric and definitive therapy. A Spanish post hoc analysis addressed this question using patients from six published prospective cohorts with bloodstream infections due to ESBL-producing strains of *E. coli*,[32] with most of these infections originating from the urinary tract. These results suggested amoxicillin/clavulanic acid and piperacillin/tazobactam to be suitable alternatives to carbapenems for treating patients with bloodstream infections caused by ESBL-producing *E. coli* if the isolate was susceptible in vitro to these agents. The review did not suggest an optimal management of ESBL-producing *E. coli* bloodstream infections originating outside the urinary tract and of infections caused by ESBL-producing pathogens other than *E. coli*.

A retrospective, propensity-matched analysis of monomicrobial bacteremia caused by ESBL producers at two medical centers between May 2002 and August 2007 compared outcomes of patients who received definitive therapy with cefepime to those who received definitive therapy with a carbapenem. All patients who received cefepime had sensitive isolates based on the Clinical and Laboratory Standards Institute (CLSI) breakpoint for cefepime that was current for the time (8 μg/mL). Using that susceptibility breakpoint, investigators found definitive therapy with cefepime to be inferior to carbapenem therapy for the primary endpoint of 30-day crude mortality.[33]

In 2010, which was subsequent to the publication of this article,[33] CLSI lowered the susceptibility breakpoint for cefepime to <2 μg/mL. After the breakpoint change, a clinical analysis compared the outcomes of therapy against ESBL-producing Enterobacteriaceae based on the pharmacokinetic/pharmacodynamic properties of cefepime and piperacillin/tazobactam.[34] The authors concluded that standard-dose cefepime was a reasonable option for the definitive therapy of invasive infections resulting from ESBL-producing *E. coli* and *Klebsiella* species with minimal inhibitory concentrations of (MICs) ≤2 μg/mL or less, which now defined susceptibility.

Based on the antimicrobial stewardship principle of heterogeneity as a means of minimizing the emergence of bacterial resistance and the lack of prospective data defining optimal therapy for infections caused by ESBL-producing organisms, many experts have focused on potential alternatives to carbapenems as "a drug of choice" for such infections.

In a perspective article, Harris et al. suggested potential roles for β-lactam/β-lactamase inhibitor combinations (BLBLIs) in the treatment of ESBL infections in the following settings: in the urinary tract, in a nonurinary site if the isolate has a low MIC, and when source control has been achieved.[35]

A multinational, retrospective cohort study by Gutiérrez-Gutiérrez et al. showed that BLBLIs, if active in vitro, appear to be as effective as carbapenems for empiric and definitive bloodstream infection caused by ESBL-producing Enterobacteriaceae, regardless of source and specific species, if used at appropriate doses.[36] Bassetti et al. proposed that the best alternative to carbapenems for the treatment of ESBL infections may be BLBLIs, specifically piperacillin/tazobactam, if the MIC of the ESBL-producing pathogen is 16.4 μg/mL or less.[37]

The conclusions of these studies suggesting a potential role for a noncarbapenem regimen for the treatment of infections caused by ESBL-producing organisms are consistent with the 2016

guidelines by the IDSA and the American Thoracic Society (ATS) for the management of adults with HAP and VAP.[4] In those guidelines the authors acknowledged that their synthesis of the evidence failed to identify an agent that is clearly preferable to others in the treatment of HAP/VAP caused by ESBL-producing gram-negative bacilli; the panel therefore did not recommend a preferred antibiotic regimen for patients with confirmed HAP/VAP caused by ESBL-producing gram-negative bacilli.

A concern is whether use of agents such as a penicillin combined with a β-lactamase inhibitor might select for patterns of resistance other than ESBLs. In a matched case-control study from Singapore in which 203 cases of carbapenem-resistant Enterobacteriaceae infection or colonization were matched with 203 controls, the most common resistance enzymes were New Delhi metallo–β-lactamase 1 (NDM-1, in 44.4% of isolates), *Klebsiella pneumoniae* carbapenemase (KPC, 39.9%), and oxacillinase-48 (OXA-48, 7.8%).[38] Penicillin antibiotics were among the risk factors demonstrated by multivariate analysis to be an independent risk factor for carbapenem-resistant Enterobacteriaceae colonization or infection. With the increasing prevalence of OXA-48 β-lactamases in carbapenem-resistant *K. pneumoniae*, it is important to be aware about whether one pattern of antibiotic use (for example, use of a carbapenem-sparing regimen to treat infection by ESBL-producing bacteria) might predispose to a different pattern of resistance (such as OXA-48–producing Enterobacteriaceae infection).

The MERINO trial was an international multicenter open-label non-inferiority randomized controlled trial of piperacillin-tazobactam versus meropenem for the definitive treatment of bloodstream infections caused by third-generation cephalosporin non-susceptible Escherichia coli or Klebsiella spp. The trial enrolled 378 patients from 32 sites in 9 countries. The study, in which the primary outcome was mortality at 30 days after randomization, was prematurely terminated based after the third interim analysis by the data safety monitoring board, and the preliminary findings were reported at the 2018 European Congress for Clinical Microbiology and Infectious Diseases.[38a] More than 50% of the enrolled patients had healthcare-associated infections. The urinary tract most common site (60.9% of patients), and E. coli was the most common organism (86.5% of patients). There was a statistically significant difference in mortality rate in patients treated with piperacillin-tazobactam (23 patients, 12.3%) compared with meropenem (7 patients, 3.7%). There was no difference between the two groups regarding subsequent infections of drug-resistant bacteria or C. difficile.

An alarming trend in the worldwide epidemic of antibiotic resistance has been the increasing prevalence of carbapenem-hydrolyzing β-lactamases that coexist with ESBLs. A clinical report described a group of infections caused by *Klebsiella* spp. in which 45% of *K. pneumoniae* strains produced ESBLs, with 3.3% of the strains carrying KPC-2 carbapenem-hydrolyzing enzymes.[39] To investigate this outbreak, the investigators studied the prior antibiotic exposure in the patients from whom these KPC-2 enzymes were isolated. Most had received a β-lactam or fluoroquinolone, but only 20% had received a carbapenem. These findings have clinical relevance not only because of shared risk factors for both ESBL- and carbapenemase-producing organisms but also because of the coexistence of multiple mechanisms of bacterial resistance in the same patient.

A clinically relevant consideration in the selection of therapy for infections caused by ESBL-producing bacteria is whether the antibiotic has activity against *Pseudomonas aeruginosa*, which is not an ESBL-producing pathogen. The antimicrobial principle in such a situation is to avoid the collateral damage that may result by selecting resistant strains of *P. aeruginosa*. To pursue such a pseudomonal-sparing strategy (which is not accepted by all infectious disease specialists as a means of preventing resistance), the clinician may divide the carbapenems into two categories: those that have activity against *P. aeruginosa* (i.e., imipenem, meropenem, doripenem) and the one that does not (i.e., ertapenem). Incorporating the data from Sanders and Sanders, the selection of resistant strains of *P. aeruginosa* occurs when a spontaneously mutated antibiotic-resistant colony proliferates because the antibiotic kills sensitive, nonmutant organisms.[40] Although numerous references regarding antibiotic selective pressure leading to drug-resistant *P. aeruginosa* have been published, two publications are representative of how a process might be favored by pseudomonal-active antibiotics.

In a 2-year case-control study of 2613 patients admitted to three ICUs in a large teaching hospital in Paris, France, prolonged receipt of antibiotics with specific antipseudomonal activity, most notably ciprofloxacin, was associated with the emergence of multidrug-resistant (MDR) *P. aeruginosa*.[41] The authors concluded that if treatment with an antibiotic active against gram-negative bacteria is needed, agents with little antipseudomonal activity should be preferred over those with specific antipseudomonal activity to limit the emergence of MDR *P. aeruginosa*. Using data from 779 isolates of carbapenem-resistant *P. aeruginosa*, Carmeli and colleagues showed by univariate analysis that the risk factors for isolation of carbapenem-resistant *P. aeruginosa* were receipt of group 2 carbapenems (imipenem, meropenem) ($P < 0.0001$), aminoglycosides ($P = 0.034$), or penicillins ($P = 0.05$).[42] They found no association between group 1 carbapenem (ertapenem) use and resultant imipenem-resistant *P. aeruginosa* ($P = 0.2$).

There have been theoretical concerns that use of an agent like ertapenem might select for strains of carbapenem-resistant *P. aeruginosa*. Ecologic studies conducted over the first 9 years that ertapenem was on the market specifically addressed this concern, and Nicolau et al. published those results in a review on the topic.[43] Results from the 10 clinical studies evaluating the effect of ertapenem use on the susceptibility of *Pseudomonas* to carbapenems uniformly showed that ertapenem use did not result in decreased *Pseudomonas* susceptibility to the antipseudomonal carbapenems.

AmpC β-Lactamases (Type 1)

The clinically representative list of organisms producing AmpC β-lactamase is included in Table 48.2. Unlike the plasmid-mediated ESBL, AmpC (sometimes referred to as type 1) β-lactamases are most often chromosomally mediated, with the product of the *ampC* gene (hence the term AmpC β-lactamases) being the prototypical enzyme. On occasion, however, AmpC β-lactamase production can be plasmid mediated. As acknowledged in Table 48.2, AmpC β-lactamase production is inducible in most of the bacteria capable of producing this enzyme; however, there are some bacteria (most notably, *Acinetobacter* as a producer of chromosomally mediated AmpC enzyme and *E. coli* as an example of plasmid-mediated AmpC enzyme) in which AmpC β-lactamase production is noninducible.[44] This latter fact explains why AmpC β-lactamase is not a classic mechanism of antibiotic resistance in *Acinetobacter*. According to data from the Centers for Disease Control and Prevention's National Nosocomial Infections Surveillance system, these organisms account for 13% to 40% of nosocomial infections involving blood, surgical site, urine, and lung.[45] Even though the listed pathogens do not always produce AmpC enzymes, the potential exists and the clinician must consider it when selecting empiric therapy.[46] Because AmpC β-lactamases have an affinity for cephalosporins

(and have therefore been referred to by some authors as cephalosporinases), third-generation cephalosporins are not predictably stable in the their presence.[47] Also lacking consistent stability are the BLBLIs (i.e., sulbactam, clavulanic acid, and tazobactam).

Exposure to specific antibiotics may influence a microorganism's ability to produce AmpC β-lactamases. Two mechanisms have been described by which this occurs: (1) induction and (2) the selection of spontaneous mutant strains (previously referred to as stable de-repression). Sanders and Sanders explored the property of induction when they performed an investigation in which they incubated an organism with the potential to produce AmpC β-lactamases overnight in the presence of antibiotic.[40] After this incubation, they performed an assay for AmpC β-lactamase. If they subsequently detected the enzyme, they described the process as induction. They identified cefoxitin, imipenem, and clavulanic acid as strong inducing β-lactams. Of note, upon removal of the inducing antibiotic, the β-lactamase production ceased before the next dose of drug was due to be given. The investigators thus described induction as a reversible in vitro phenomenon. Since the description of induction as an in vitro phenomenon, no definitive evidence has accumulated demonstrating that induction in gram-negative organisms leads to clinically significant resistance in patients; however, the *ampC* gene product can lead to alarming resistance patterns through another mechanism.

The selection of spontaneous mutant strains of bacteria has been proven to occur in the clinical setting. Organisms that possess the *ampC* gene possess complex regulatory mechanisms that prevent overexpression of the gene; however, a certain number of bacteria within clinical isolates (often in the 10^{-6} to 10^{-7} range) will have spontaneous mutation(s) that can allow them to overproduce AmpC β-lactamase.[40] Upon exposure to certain broad-spectrum antibiotics, the wild-type organisms die; however, the mutant strains proliferate to become the predominant organisms, clinically manifesting as a resistant strain. Most notable of the antibiotics described to select these "stably de-repressed" mutants are the third-generation cephalosporins.[48,49]

In the overwhelming majority of instances with gram-negative organisms, antibiotics do not cause induction of resistance, but rather certain antibiotics efficiently kill susceptible organisms while leaving resistant mutants to proliferate, thereby selecting the resistant microbes to flourish. This process of selection, not induction, is the basis for most of the resistance encountered in the clinical setting. Thus when clinicians suspect infection with organisms capable of producing AmpC β-lactamase, they should avoid certain antibiotics that are not only good substrate for the product enzymes but also efficiently select these mutants. In the critical care setting, two clinical lessons regarding AmpC β-lactamases are important.

In a five-center prospective trial that evaluated the therapy of *Enterobacter* bacteremia, the development of resistance of *Enterobacter* isolates during therapy with an extended-spectrum (i.e., third-generation) cephalosporin to which the organism was initially susceptible was 19%, in contrast to no significant development of resistance of those *Enterobacter* isolates treated with other β-lactam antibiotics.[48] This example of selection of resistance during therapy is representative of the concept that in vitro susceptibility is not always predictive of in vivo outcome. Resultant from this knowledge is the practice of avoiding third-generation cephalosporins for the treatment of *Enterobacter* bloodstream infections, even when the isolate is initially susceptible, because of the propensity of these antibiotics to select for strains of *Enterobacter* that have the spontaneous mutation that allows for their expression of AmpC β-lactamase.

A second example is *P. aeruginosa,* which possesses three chromosomally mediated mechanisms of resistance: (1) AmpC β-lactamases, (2) efflux pumps, and (3) outer membrane porin alterations.[50,51] Until recently, there was no single β-lactam antibiotic stable in the presence of all three of these mechanisms of resistance. Ceftolozane is a new cephalosporin that is structurally similar to ceftazidime but differs from it by a modification that allows increased antipseudomonal activity as well as activity against some extended-spectrum β-lactamase–producing strains. Importantly, ceftolozane is stable in the presence of all three of the chromosomally mediated resistance mechanisms in *P. aeruginosa.* For clinical use, ceftolozane is combined with tazobactam. Although the addition of the β-lactamase inhibitor does not increase the antipseudomonal activity of ceftolozane, it does significantly enhance the coverage of Enterobacteriaceae isolates that produce extended-spectrum β-lactamases.[52]

The randomized, double-blind, phase II trial (ASPECT-cUTI) compared a combination of ceftolozane and tazobactam with levofloxacin in the treatment of complicated urinary tract infections, including pyelonephritis.[53] In that trial, ceftolozane/tazobactam led to better responses than high-dose levofloxacin. Of the patients in the microbiologic modified intention to treat population, *P. aeruginosa* was the pathogen in only 23 (2.9%) of the 800 patients with pyelonephritic. Another prospective, randomized, double-blind, phase III trial (ASPECT-cIAI) compared ceftolozane/tazobactam given in combination with metronidazole to meropenem in the treatment of complicated intra-abdominal infections.[54] Treatment with ceftolozane/tazobactam plus metronidazole was noninferior to meropenem. Of the 806 patients in the microbiologic modified intention to treat population, 72 (8.9%) had infection with *P. aeruginosa*. Susceptibility rates of *P. aeruginosa* to ceftolozane/tazobactam and meropenem were 98.6% and 89.9%, respectively. At the present time, clinical trials are under way to assess the role, if any, that ceftolozane/tazobactam will have in pulmonary infections, including those that may cause critical illness.

Carbapenemases

Carbapenemase is the name used for those β-lactamases that have the ability to inactivate carbapenems, which is the broadest class of antimicrobial agents currently available. The name *carbapenemase* has the potential to be misleading. In an insightful discussion of carbapenemases, Queenan and Bush acknowledged that KPC carbapenemases hydrolyze β-lactams of all classes, with the most efficient hydrolysis observed for nitrocefin, cephalothin, cephaloridine, benzylpenicillin, ampicillin, and piperacillin.[55] The same enzyme also hydrolyzes the carbapenems imipenem and meropenem, as well as the β-lactam antibiotics cefotaxime and aztreonam, albeit 10-fold less efficiently than the penicillins and early cephalosporins. Simply stated, the carbapenemases have a broad hydrolysis spectrum that includes most β-lactam antibiotics.

The carbapenemases are as diverse in structure as they are in substrate, having members in three of the four Ambler classes of β-lactamases. An example from clinical practice of a class B metalloenzyme is the NDM found in certain Enterobacteriaceae. After the identification of metallo–β-lactamases, microbiologists began identifying serine-based β-lactamases capable of hydrolyzing carbapenems in Ambler group A (which is the same class in which the majority of ESBLs are found). These enzymes were produced by *K. pneumoniae* and were subsequently referred to as KPCs. Although there are also class D serine-based carbapenemases such as the OXA-type enzymes produced by organisms like Enterobacteriaceae and *Acinetobacter* species, the class A and class B

carbapenemases are most frequently discussed today in clinical practice. With this understanding, the clinician can begin to approach the role of antibiotics in selecting for organisms that produce carbapenemases.

A common assumption is that carbapenem antibiotics are the most likely to select for resistance owing to carbapenemase production. Although not definitively proven, multiple reports in the literature support the conclusion that several classes of antibiotics may result in subsequent infection with carbapenemase-producing bacteria. The most consistent risk factors that lead to the selection of carbapenemase-producing bacteria are not the class of antibiotics being used (since multiple classes of antibiotics other than carbapenems have been associated with the selection of carbapenemase-producing gram-negative bacteria); rather, it is the intensity of the antimicrobial therapy and the duration of therapy.[56,57]

In the absence of the identification of a specific class of antibiotics responsible for selecting carbapenemase-producing bacteria, efforts to identify other variables that contribute to the problem are underway. Two representative articles provide insight into the association between prior antimicrobial therapy and the subsequent identification of carbapenemase-producing bacteria. In a 4-year case-control study (n = 102), the only covariate independently associated with carbapenem-resistant Enterobacteriaceae in all multivariate analyses was the cumulative number of prior antibiotic exposures.[56] A study in which data were collected over 26 months in a tertiary care university hospital with an established endemicity of carbapenem-resistant ESBL-*Klebsiella pneumoniae* (ESBL-CRKP) demonstrated an interaction effect in which increased exposure to fluoroquinolones amplified the impact of exposure to carbapenems (and vice versa) on ESBL-CRKP infection risk.[58] In this study, the duration of prior treatment with fluoroquinolones was also associated with increased risk of infection with ESBL-CSKP, whereas prior receipt of carbapenems presented a protective effect against ESBL-CSKP infection. These data are consistent with previous reports that no particular class of antibiotic is the predominant predisposing factor for selection of carbapenemase production. In summary, after resistant pathogens colonize patients, any broad-spectrum antibiotic has the ability to kill the normal flora, thereby allowing the resistant strains to proliferate and to cause clinical disease.

Treating carbapenemase-producing bacteria is challenging, and there are neither definitive nor predictable recommendations that guarantee clinical success. In the absence of such data, the clinician is challenged to make clinically relevant deductions from the published literature. The findings from 15 studies and reports in treating infections caused by KPCs showed success rates of 75% with aminoglycosides, 73% with polymyxin combinations, 71% with tigecycline, 40% with carbapenems, and 14% with polymyxin monotherapy.[59] Antimicrobial agents accepted as having activity based on in vitro susceptibility are tigecycline, polymyxins, and aztreonam.[60] There are evolving data suggesting a potential role for carbapenems as a therapeutic option if the MIC of the infecting organism is 4 mg/L or less and the carbapenem is given in combination with another active agent.[61]

The response to the clinical problem of treatment for infections caused by carbapenemase-producing bacteria has included BLBLI combinations. A clinical approach to carbapenemases is represented in Table 48.2. Carbapenemases are serine-based (classes A and D) or metallo-based (class B).

In contrast to the traditional β-lactamase inhibitors (i.e., sulbactam, clavulanic acid, and tazobactam), all of which have the β-lactam ring as part of their structure, a new class of β-lactamase inhibitors that does not possess a β-lactam ring is now available. The initial member of this class of non-BLBLIs to make it to the antibiotic market in the United States is avibactam. In addition to being stable in the presence of most ESBLs and some AmpC β-lactamases, avibactam, when added to ceftazidime, has been shown to increase activity against KPCs. Of note, avibactam is unstable in the presence of metallo-based carbapenemases.[62]

Vaborbactam is a non-BLBLI that is given in combination with meropenem. Like avibactam, it is a potent inhibitor of KPCs; in contrast to relebactam, preliminary studies have not shown that it increases activity against *P. aeruginosa.*[63] Vaborbactam is not active against metallo–β-lactamases.

Relebactam is a non-BLBLI that is being studied in combination with imipenem. Like avibactam, it is active against KPC-producing gram-negative bacteria. Even though the addition of relebactam to imipenem does not increase activity against *A. baumannii,* there is enhanced activity against *P. aeruginosa*, including isolates with depressed oprD (porin) and increased AmpC (type 1) β-lactamase expression.[64] Metallo-β-lactamases are not susceptible to inhibition by relebactam.

Much more challenging than therapy for the serine-based KPCs is that for the NDM carbapenemases. Included as agents with potential activity are colistin as well as the investigational agents aztreonam/avibactam and ervacycline.[65] It is noteworthy that avibactam does nothing to enhance the efficacy of aztreonam as the active agent against NDMs. Because NDMs often occur in combination with other β-lactamases, the addition of avibactam allows the activity of aztreonam against NDMs to be detectable. As a component of combination therapy, fosfomycin may have a role.[66]

The examples of carbapenem resistance (whether on the basis of carbapenemase or other mechanism of resistance) in *Pseudomonas, Acinetobacter, Stenotrophomonas*, and *Klebsiella* underscore an important concept in antimicrobial therapy for the critical care clinician. When multidrug resistance occurs, the clinician cannot assume that such resistance results from exposure to the broadest class of antibiotic to which the organism is resistant. To accept such a flawed assessment could result in limited use of that class of antibiotic, which could then shift to increased use of the actual class of antibiotic that led to the pattern of resistance. The other clinically relevant observation in many of the recently described outbreaks is that inadequate infection control contributed to the spread of resistant strains that had been selected by antibiotics.[39,67,68]

Efflux Pumps

The importance of efflux as a mechanism of multidrug resistance in the ICU has been increasingly acknowledged.[69] Efflux pumps are three-component systems, contained within the bacterial cell wall, that allow bacteria to eliminate antibiotics that have entered the cell. Initially described in 1980 as a mechanism of resistance in tetracyclines, efflux was recognized in 1988 as a contributor to fluoroquinolone resistance.[70] In recent years, the contribution of efflux to clinical resistance has broadened, with important implications for treatment of serious infections. The composition of this system has been nicely detailed.[71,72] The pump itself (also referred to as the transporter) lies in the cytoplasmic membrane and is designated MexB, MexD, or MexF. It is attached via a linker lipoprotein (MexA, MexC, or MexE) in the periplasm to the third component, the exit portal (OprM, OprJ, or OprN), which lies in the outer membrane. These three components of the efflux pump are under repression and are therefore are not clinically active.

P. aeruginosa has several efflux systems, with MexAB-OprM and MexEF-OprN having particular clinical significance. The MexAB-OprM system contributes to both intrinsic and acquired resistance, and the MexEF-OprN system contributes only to acquired resistance.[73] The MexAB-OprM system is expressed constitutively in cells grown in standard laboratory media, where it contributes to intrinsic resistance to several antimicrobials, including fluoroquinolones, tetracyclines, piperacillin, cefepime, aztreonam, and certain carbapenems.[51] Of the β-lactams, only carbapenems appear to be poor substrates for MexAB-OprM; however, different carbapenems vary in susceptibility to efflux. Meropenem and doripenem are subject to efflux, and expression of the MexAB-OprM efflux system has been correlated with resistance to meropenem.[74] By contrast, imipenem, which is less amphipathic than meropenem, is not subject to efflux,[73] possibly owing to the need for efflux systems with MexAB-OprM to access their substrates within the cytoplasmic membrane.[74] Such a microbiologic property may explain why a gram-negative isolate may be susceptible to imipenem but resistant to meropenem.

Among the classes of antibiotics in which efflux becomes a predominant mechanism in the development of resistance, tetracyclines are noteworthy. This has clinical significance because *A. baumannii* has become a significant nosocomial pathogen, and tigecycline is one of the few therapeutic options for treating infections caused by this pathogen. To address the problem in increasingly reported tigecycline resistance, a study to assess the prevalence and characteristics of efflux-based tigecycline resistance in clinical isolates of *A. baumannii* was undertaken.[75] *A. baumannii* isolates, including 64 tigecycline-nonsusceptible *A. baumannii* and 10 tigecycline-susceptible *A. baumannii* isolates, were analyzed. The study showed that the active efflux pump AdeABC appeared to play important roles in the tigecycline resistance of *A. baumannii*.[75] Eravacycline is a fluorocycline in the tetracycline class. Compared with tigecycline, eravacycline generally has lower MICs against gram-negative organisms, including resistant pathogens such as *Acinetobacter*.[76] For *A. baumannii*, eravacycline MICs correlated with increased expression of the *adeB* efflux gene.[77]

Clinical Relevance for Understanding Antibiotic Resistance

An understanding of the mechanisms of antibiotic resistance is integral to understanding the emergence of MDR organisms. A common mistake in clinical practice is to assume that the major predisposition to a pattern of resistance is the overuse of the broadest category of antibiotic to which a pathogen is resistant; indeed, many examples illustrate that this is not the case. A classic example of multidrug resistance in gram-negative organisms is the resistance in *P. aeruginosa*. As previously noted, *P. aeruginosa* possesses three mechanisms of resistance regulated by genetic operons on the chromosome: (1) AmpC β-lactamases, efflux pumps, and outer membrane porin alterations.[50,51,78] Because the clinician will not have information at the time of empiric therapy regarding which of these mechanisms might be present in the *P. aeruginosa* being targeted, regimens for infections such as HAP often target more than one of these mechanisms of pseudomonal resistance.[79] For infections such as HAP and VAP, in which *P. aeruginosa* is a pathogen targeted with empiric therapy and for which fluoroquinolones are offered as an option in the initial regimen,[79–81] data on the risk of fluoroquinolones leading to multidrug resistance via efflux mechanisms become especially noteworthy. The fluoroquinolones may select certain *nfxc (mexT)* mutants.[50,71] In addition to resistance to fluoroquinolones, these mutants may have decreased susceptibility and even clinical resistance to carbapenems (e.g., imipenem, meropenem) that occurs on the basis of either closure of porin channels in the outer membrane of the bacterial cell wall or upregulation of an efflux pump. Such information may help explain patterns of carbapenem resistance in health care institutions with low rates of carbapenem usage.

The experience with carbapenem-resistant *A. baumannii* in Brooklyn, New York, provides another important insight into the problem of selection of resistance by one class of antibiotic to an entirely different class. In a study to evaluate the endemicity of *A. baumannii*, all unique patient isolates of this pathogen were collected from 15 Brooklyn hospitals over a 3-month period.[67] Antibiotic susceptibilities, ribotyping, and the relationship between antibiotic use and resistance rates were determined. Among the 224 carbapenem-resistant strains of *A. baumannii*, ribotyping demonstrated that one strain accounted for two-thirds of the isolates and was present in all 15 participating hospitals. The strongest predisposition to selection for this pathogen was cephalosporin use. Known *A. baumannii* resistance mechanisms include chromosomally associated β-lactamases and porin protein mutations,[82] so it can be assumed that this represents selection of carbapenem-resistant mutant strains by the cephalosporins.

A study in which the investigators collected data over 26 months in a tertiary care university hospital with an established endemicity of carbapenem-resistant ESBL-CRKP demonstrated an interaction effect in which increased exposure to fluoroquinolones amplified the impact of exposure to carbapenems (and vice versa) on ESBL-CRKP infection risk. In this study, the duration of prior treatment with fluoroquinolones was also associated with increased risk of infection with ESBL-CSKP, whereas prior receipt of carbapenems presented a protective effect against ESBL-CSKP infection.[57]

The evolving data about risk factors for the selection of organisms that produce carbapenemases suggest that the most important variables are not the class of antibiotics being used (since multiple classes of antibiotics other than carbapenems have been associated with the selection of carbapenemase-producing gram-negative bacteria) but rather the intensity and the duration of the antimicrobial therapy.[56,57]

Based on these examples, a principle of antibiotic therapy in the ICU should be that resistance may be selected by a class of antibiotics other than the agent to which the resistance is being reported (e.g., carbapenem resistance being selected by noncarbapenem antibiotics).

A second principle is that antibiotics without activity against certain pathogens may provide less risk of selecting for resistant strains than do antibiotics that do cover such pathogens. An important example might be *P. aeruginosa.* Because of the ability of *P. aeruginosa* to express multiple mechanisms of resistance, many experts recommend avoiding the use of traditional antipseudomonal agents (i.e., a pseudomonal-sparing regimen) when treating infections in which *Pseudomonas* is not a suspected pathogen, as the use of overuse these agents may result in the development of multidrug resistance in *Pseudomonas* isolates.[41]

Role of Combination Therapy

Synergy

The concept of synergy, in which antimicrobial combinations are assumed to be more effective than single agents, is one of the most frequently cited justifications for combination therapy. The best-recognized example of synergistic antimicrobial therapy is in treatment of enterococcal endocarditis, where treatment with

penicillin or ampicillin monotherapy has been associated with a high rate of relapse compared with combined therapy using penicillin or ampicillin plus streptomycin or gentamicin.[83,84] Discussions of combination therapy have raised the question of whether the use of multiple drugs in the treatment of an infection may result in improved clinical outcomes. One example is the treatment of bacteremia with *S. aureus* in which some clinicians advocate using a semisynthetic penicillinase-resistant penicillin (e.g., nafcillin or oxacillin) in combination with a brief course (3 to 5 days) of an aminoglycoside. This is based on data demonstrating more rapid clearing of bacteremia.[85] Unfortunately, clearance of organism was not correlated with a mortality reduction in nonaddicts with primarily left-sided endocarditis caused by *S. aureus* when compared to monotherapy nafcillin. The mechanism of synergy between antipseudomonal penicillins and aminoglycosides in *P. aeruginosa* infections is similar to aforementioned enterococci.[86] Despite this microbiologic observation, the presence or absence of synergy received less priority in an alternate trial assessing outcomes in patients with *P. aeruginosa* bacteremia; rather, combination therapy to prevent the emergence of resistance was explored.[87]

In contrast with the beneficial effect of synergy, a combination regimen may result in the detrimental effect of antagonism. The treatment of pneumococcal meningitis in the 1950s serves as the preeminent example. The mortality rate in patients who received penicillin alone was 21%, whereas combination therapy with penicillin (a bactericidal agent) plus chlortetracycline (a bacteriostatic agent) resulted in a staggering mortality rate of 79%.[88]

The clinical importance of antagonism has increased in the era of community-associated methicillin-resistant *S. aureus* (CA-MRSA). MRSA infection is an independent predictor of mortality, ICU length of stay, and overall cost of care.[89–92] Efforts have been made to identify the in vitro activity of antibiotic combinations with potential clinical benefit. A study using 10 different strains of *S. aureus* found an overall pattern of antibiotic indifference (no combination effect) in combinations of linezolid with fusidic acid, rifampin, or gentamicin. On the other hand, the combination of linezolid with ciprofloxacin or vancomycin resulted in slight antagonism and reduced bactericidal effect when investigators used these combinations against the same strains of staphylococci.[93] A subsequent study using the checkerboard broth microdilution method tested linezolid in combination with 28 different antimicrobial agents (including vancomycin and several fluoroquinolones) did not confirm the antagonistic effect.[94] Sahuquillo and colleagues reproduced the effect of antibiotic indifference with vancomycin, but they noted antagonism with levofloxacin in two of the five *S. aureus* isolates tested.[95]

Further investigations have evaluated 5-day treatment regimens of linezolid monotherapy, vancomycin monotherapy, and linezolid in combination with vancomycin in 40 rabbits with MRSA aortic valve endocarditis.[96] Treatment with vancomycin alone achieved the largest mean reductions in valvular vegetation bacterial counts ($P = 0.05$) as well as sterilization of aortic valve vegetations in three subjects. Linezolid monotherapy resulted in zero sterilized vegetations. In addition, combination therapy with linezolid and vancomycin resulted in a lower peak serum linezolid level than linezolid alone. Even though in vitro synergy testing revealed additive or indifferent activity between the two drugs, the rabbit model revealed in vivo antagonism. A potential explanation offered by the investigators for the observed antagonism was the effect of combining a bacteriostatic (linezolid) with a bactericidal drug (vancomycin). The observed reduction in peak serum linezolid levels suggests a role for additional mechanisms in the interaction between the two antibiotics. Unfortunately, the clinical significance of these findings is not yet known.

Several studies have evaluated the use of the semisynthetic penicillins (e.g., nafcillin) in combination regimens to treat infection with MRSA. In a pharmacokinetic/pharmacodynamic model evaluating the combination of nafcillin and vancomycin, Leonard found evidence of synergy in the treatment of heterogeneously vancomycin-intermediate *Staphylococcus aureus*, MRSA, and methicillin-sensitive *S. aureus*.[97] Subsequently, Leonard and Rolek found evidence of synergy between daptomycin and nafcillin for the treatment of VISA.[98] Interestingly, they noted a more pronounced synergistic effect as the daptomycin susceptibility decreased. Despite these findings, no clinical trials exist that have proven this in vitro phenomenon translates to the clinical setting.

In the absence of definitive data on optimal management of *S. aureus* infections in seriously ill patients, a pattern has emerged in some health care systems to prescribe combination therapy for this pathogen. The overall assessment of the data is that antibiotic indifference appears to best characterize the drug interaction profile of linezolid with vancomycin. Because some data, albeit unsubstantiated in controlled clinical trials, suggest caution in combination administration of linezolid with vancomycin[93] and the fluoroquinolones,[95] it is important for the intensivist to be aware of the potential unintended consequences. In summation, the role of combination therapy in the overall treatment of serious MRSA infection remains unclear.[99]

Enhanced Efficacy Against a Pathogen

The potential for combination therapy to result in increased efficacy against a pathogen via a mechanism other than synergy remains a common clinical question. In an attempt to decipher the answer, Paul et al. conducted a meta-analysis of 64 trials with 7586 patients comparing β-lactam monotherapy versus β-lactam plus an aminoglycoside in immunocompetent patients with sepsis.[100] No statistically significant advantage of combination therapy was identified among the 1835 patients with gram-negative infections for whom the data were analyzed. In contrast with the prior results,[87] the investigators observed no improvement in survival for the 426 patients who had infection caused by *P. aeruginosa*. Rates of resistance development did not differ between the two treatment groups; however, nephrotoxicity developed significantly more often with combination therapy.

Prevention of the Emergence of Resistance

Clinicians frequently use combination therapy for *P. aeruginosa* to prevent the emergence of resistance. Results of some clinical trials[101] and fear of the emergence of resistance have provided the basis for this practice habit. Despite the importance of this subject, no definitive data are available to prove that combination therapy will prevent the emergence of *Pseudomonas* resistance.[102]

In an effort to determine the impact of combination therapy on the risk of the overall emergence of antibiotic resistance, a meta-analysis of eight randomized controlled clinical trials comparing β-lactam monotherapy to β-lactam plus aminoglycoside combination therapy was performed.[103] Among initially antimicrobial-susceptible isolates in this analysis, combination therapy did not affect the development of antimicrobial resistance. Subsequently, a larger meta-analysis of 64 trials comparing β-lactam monotherapy versus β-lactam plus aminoglycoside combination therapy in immunocompetent patients with sepsis also failed to demonstrate a difference in the rate of development of resistance.[100]

Increased Opportunity to Achieve Appropriate Therapy

Even though clinicians frequently invoke the issues of synergy and of reduction in the emergence of resistance in discussions of combination therapy, the relevant data do not prove consistent benefits. In patients in the intensive care setting, an important advantage of combination therapy is that it provides the clinician with broader antibacterial coverage for potentially MDR microorganisms.[104] Additionally, because inappropriate initial therapy may result in increased mortality, a combination of antibiotics has the potential benefit of providing coverage against a pathogen that may not be the most likely on a statistical basis but is a reasonable consideration in life-threatening clinical settings confronting the critical care physician. The use of antibiotic combinations for empiric therapy increases the probability that at least one of the agents will have activity against the causative organism; however, once the clinician identifies the organisms, de-escalation to monotherapy, where possible, should become a priority.

Properties of Antibiotics That Affect Their Usefulness in the Clinical Setting

Immunomodulating Effect of Antibiotics

Although most classification schema group antibiotics by their chemical structure and spectrum of coverage, certain antibiotics may possess additional properties that have important clinical implications. The interaction of antibiotics with host immune response, bacterial population kinetics, and bacterial gene expression for exotoxin production are examples of the pleiotropic, or "off-target," properties of antibiotics. This is especially relevant in the treatment of life-threatening infections caused by gram-positive cocci and may provide a basis for combination therapy in the treatment of these infections.

Streptococcal toxic shock syndrome is a clinical infection in which bacteria produce exotoxins that act as host superantigens, precipitating shock, multiple organ failure, and death. Although *Streptococcus pyogenes* demonstrates exquisite in vitro sensitivity to penicillin, experimental studies of infection by this pathogen have demonstrated reduced efficacy against organisms in the stationary phase of bacterial growth. This phenomenon has been termed the Eagle effect, whereby high organism population density and slow organism division make treatment with an antibiotic dependent on cell wall synthesis ineffective.[105] Some cite the Eagle effect as a justification for use of the bacteriostatic antibiotic clindamycin in the treatment of toxic shock syndrome. Clindamycin inhibits bacterial protein synthesis independent of the stage of bacterial growth, resulting in the inhibition of bacterial exotoxin production. Finally, clindamycin facilitates the phagocytosis of *S. pyogenes* by inhibiting M protein synthesis and suppresses the production of PBPs.[106] In addition to its effects on microbes, evidence demonstrates that clindamycin has immunomodulatory effects, suppressing monocyte synthesis of tumor necrosis factor-α.[107,108] All of these pleiotropic qualities have resulted in the recommendation for clindamycin use in necrotizing skin or soft tissue infections and toxic shock syndrome caused by *S. pyogenes*.[106]

The dramatic increase in the worldwide incidence of highly virulent, community-acquired infection with CA-MRSA has resulted in increasing reports of necrotizing skin and soft tissue infections as well as necrotizing pneumonia confronting the critical care physician.[109–111] CA-MRSA virulence has been attributed to expression of several virulence factors: α-hemolysins, toxic shock syndrome toxin-1 (TSST-1), staphylococcal enterotoxin B, and Panton-Valentine leukocidin (PVL). The association of staphylococcal virulence with the current CA-MRSA epidemic prompted Stevens and colleagues to investigate the impact of antibiotics on the expression of virulence-associated exotoxin genes.[112] Both clindamycin and linezolid demonstrated markedly suppressed in vitro production of staphylococcal toxin genes. In fact, no PVL production up to 12 hours after antibiotic administration was observed. In contrast, subinhibitory concentrations of nafcillin resulted in increased toxin production. These findings led the investigators to conclude that the inhibition of protein synthesis is an important consideration in the selection of antimicrobial agents for treatment of serious infections caused by toxin-producing gram-positive cocci.[112]

The inflammatory response to pneumococci is one of the most potent in medicine.[113] Macrolides induce an immunomodulatory effect that attenuates the production of inflammatory cytokines,[114] including suppression of harmful interleukin host responses and inhibition of neutrophil oxidant burst and degranulation.[115–117] A growing body of evidence exists to support the benefit of macrolide therapy for bacteremic pneumonia caused by *S. pneumoniae*.[115–123] Although there are multiple proposed explanations, efficacy appears to extend beyond the drug's spectrum of antimicrobial activity. In a review of critical illness in asplenic patients, it was acknowledged that macrolide therapy has not been specifically studied in the splenectomy population; however, consideration for use of empiric macrolide therapy in combination with a β-lactam antibiotic owing to the pleiotropic antiinflammatory effects was raised.[124] Such pleiotropic effects have received an increasing focus of attention and further illustrate how immune modulation influences recommendations for therapy in the intensive care setting.

Penetration at the Site of Infection: Tissue-Targeted Therapy

Clinicians now understand the importance of pharmacokinetic properties of antibiotics in the treatment of pneumonia caused by MDR gram-positive cocci. Understanding the relevance of pharmacokinetic properties will also assist the critical care physician navigate through the recent published literature for these infections.

Pulmonary pharmacokinetics specifically address the tissue penetration and distribution of antibiotics within the lung.[125] Early studies investigating antibiotic penetration in pulmonary infections in the critically ill included aminoglycosides and fluoroquinolones. Although aminoglycosides reach acceptable levels in the interstitium of the lung, levels in pulmonary secretions reach a mean of only about 20% of the concomitant serum level.[126] By contrast, the concentrations of quinolones in lung tissue and bronchial secretions exceed the concomitant serum concentrations.[127] Even though quinolones have better penetration into bronchopulmonary secretions and less potential for nephrotoxicity than aminoglycosides, available data show a trend toward improved survival in patients with VAP treated with an aminoglycoside-containing combination as opposed to one containing a quinolone.[128] A concern with fluoroquinolones in combination therapy directed against gram-negative organisms is the selection of resistance. This is of particular importance in treatment of *P. aeruginosa* where the resultant resistance may involve multiple classes of antibiotics.[129] To maximize clinical efficacy and limit nephrotoxicity with aminoglycosides,

some investigators have suggested, based on clinical trials, discontinuation of the aminoglycoside after 5 days if the patient's condition is improving.[130]

Existing pharmacokinetic evidence highlights the extremely poor lung tissue penetration of vancomycin. Cruciani and associates investigated vancomycin pharmacokinetics in 30 human lung tissue sections after administration of a 1-g dose over 1 hour.[131] They used a comparison of serum-to-tissue concentration over the dosing interval to generate a graph to determine a concentration ratio. Overall, the lung tissue concentration reaches 21% of serum levels. Not surprisingly, investigation has confirmed even poorer penetration into epithelial lining fluid.[132] These data raise concern that the traditional dosing regimens of vancomycin (1 g given intravenously every 12 hours) and low target serum trough concentrations (5–10 μg/mL) will generate lung tissue concentrations below the MIC for *S. aureus*. The issues surrounding suboptimal vancomycin dosing are reflected in the 2005 published ATS/IDSA guidelines for treatment for adults with HAP, VAP, and health care–associated pneumonia, which noted that retrospective pharmacokinetic modeling suggested that vancomycin failures may be related to inadequate dosing. Because of these concerns the authors recommended achieving trough levels for vancomycin of 15 to 20 μg/mL.[79] A joint vancomycin clinical guideline for the treatment of all complicated infections caused by MRSA recommended intensified vancomycin dosing.[133]

In contrast to the poor pulmonary pharmacokinetic properties of vancomycin, several studies of linezolid confirm excellent lung penetration in healthy volunteer subjects and in vitro modeling.[134–136] These improved levels appear to correlate with observed improved clinical outcomes with linezolid over vancomycin.[137–140] Boselli and coworkers investigated the steady-state plasma pharmacokinetic variables and epithelial lining fluid concentrations of linezolid administered to critically ill patients with VAP.[141] Epithelial lining fluid concentrations of linezolid approximated 100% of corresponding plasma values, with drug concentrations that exceeded the susceptibility breakpoint (4 μg/mL) for *S. aureus* throughout a majority of the dosing interval.

A retrospective analysis of two multinational, double-blind, randomized studies suggested linezolid to be superior to vancomycin in traditional dosing regimens for treating MRSA pneumonia.[140] A subsequent randomized, controlled clinical trial of linezolid versus vancomycin in the treatment of nosocomial pneumonia favored linezolid; furthermore, a subgroup analysis of this investigation did not suggest a benefit in those patients with vancomycin troughs of 15 μg/L or higher on day 3.[142] In patients with HAP and VAP, there is a lack of data to inform the definitive choice for optimal therapy between different agents active against MRSA. Vancomycin and linezolid have been best studied. In the most current iteration of the HAP and VAP guideline,[4] variability in individual studies comparing vancomycin and linezolid are noted. This led the authors to conduct meta-analyses of the four trials, in which no difference in mortality was found when the data were analyzed using an intention-to-treat strategy or a modified intention-to-treat strategy. They also found no difference in the clinical cure rate in an intention-to-treat analysis; however, there was improvement of the clinical cure rate among patients who received linezolid in a modified intention-to-treat analysis. Linezolid and vancomycin appeared to confer no clear difference in nephrotoxicity, thrombocytopenia, serious adverse events, or need for treatment discontinuation owing to an adverse event. The authors subsequently concluded that "The choice between vancomycin and linezolid may be guided by patient-specific factor such as blood cell counts, concurrent prescriptions for serotonin-reuptake inhibitors, renal function, and cost."[4]

Because of the difficulty in achieving adequate drug levels in pulmonary tissue and secretions, many clinicians consider the use of topical, aerosolized antibiotics to deliver drug directly to the site of infection.[143] For patients receiving mechanical ventilation, aerosolized antibiotics delivered via an efficient system may achieve airway-drug concentrations 100- to 300-fold higher than the MIC of most bacteria, including MDR pathogens. Potential theoretical benefits include both reduced systemic toxicity and reduced pressure for selection of resistant organisms.[144,145] In a double-blind, placebo-controlled study in 42 ICU patients requiring prolonged mechanical ventilation who were colonized and/or infected with potentially difficult-to-treat pathogens (e.g., MRSA and nonfermenting gram-negative bacteria), aerosolized antibiotics successfully eradicated the existing MDR organisms and reduced the pressure for new resistance.[146] Technical issues associated with the adequate delivery of nebulized antibiotics have been reviewed.[147]

Despite studies of several antibiotics administered as aerosolized agents, none has established efficacy and dosing. Most of the evidence supporting nebulized tobramycin originates from small studies and meta-analyses assessing its utility in the management of chronic respiratory disease such as cystic fibrosis, not in the treatment of acute infection.[148] Although the risk of toxicity appears lower with the administration of nebulized (rather than intravenous) tobramycin, certain populations, such as those with renal insufficiency, may be at risk.[149] A meta-analysis of 12 studies using nebulized antibiotics showed improved clinical cure rates in VAP, but this effect did not persist after trial sequential analysis. There was no effect on microbiological cure, lengths of stay, or mortality.[150] Owing to the increasing prevalence of MDR gram-negative organisms such as *A. baumannii* and *P. aeruginosa*, clinicians increasingly face the need to administer colistimethate via intravenous (IV) infusion,[151] with some giving consideration to aerosolization,[152,153] as therapy for VAP and HAP. Although the quality of the evidence was considered poor, a recent meta-analysis of studies suggested that addition of aerosolized colistin in VAP was associated with improved clinical and microbiologic response rates but had no effect on mortality.[154]

Special Pharmacologic Properties

As the focus of antibiotic research has expanded beyond the in vitro properties, the importance of antibiotic performance at the in vivo target tissue level is becoming increasingly recognized. With the 2003 introduction of daptomycin for treatment of infections caused by resistant gram-positive cocci the concept of "organ-specific deactivation" arose.[155] Daptomycin is an IV cyclic lipopeptide with rapid, concentration-dependent killing and bactericidal activity against a broad spectrum of gram-positive cocci.[156–158] It demonstrates a unique mechanism of action, with calcium-dependent insertion into the phospholipid bacterial cell membrane. This results in cell depolarization via potassium efflux, causing disruption of DNA, ribonucleic acid (RNA), and protein synthesis.[159]

As a result of two multicenter, randomized, controlled trials comparing it with penicillinase-resistant penicillin or vancomycin,[160] daptomycin, at a daily dose of 4 mg/kg (for patients with creatinine clearance greater than 30 mL/min), received FDA approval for the treatment of complicated skin and soft tissue infections. A subsequent randomized, open-label trial investigated the use of daptomycin in *S. aureus* bacteremia and endocarditis.[161] This trial

prompted FDA approval of daptomycin for treatment of *S. aureus* bacteremia, including right-sided endocarditis, at a daily IV dose of 6 mg/kg.

Phase III clinical trials explored treatment of community-acquired pneumonia in hospitalized patients. Despite daptomycin's potent in vitro bactericidal activity against *S. pneumoniae*, clinical outcomes were disappointing and inferior to those with the comparator, ceftriaxone. Although daptomycin is known to exhibit poor penetration into epithelial lining fluid, the reason for treatment failure was not fully elucidated until Silverman and colleagues described a unique organ-specific inactivation process.[155] Investigators linked daptomycin's inactivation to its mechanism of bactericidal action: calcium-dependent membrane lipid binding.[155,159,162,163] Using a mouse model, they demonstrated drug sequestration and inactivation by binding to phospholipid vesicles that are found in pulmonary surfactant.[155] Because of the presence of surfactant in the target tissue, daptomycin is not an appropriate therapeutic agent for treatment of pneumonia. This phenomenon appears to be unique to daptomycin,[155] but it does raise the question of unrecognized organ-specific inactivation for other classes of antibiotics and other target organs.

Unintended Consequences of Antibiotic Therapy

Traditional teaching about antibiotics focused on three classic parameters: efficacy, safety, and cost-effectiveness. With respect to safety, the major considerations were allergic reactions and adverse effects. Within the pandemic of antibiotic resistance, clinicians must consider an important safety issue: unintended consequences of antibiotic therapy. An insightful report termed such unintended consequences as the "collateral damage" of antibiotics encompassing the selection of drug-resistant organisms and development of colonization or infection with MDR organisms.[164]

The increasing prevalence of MRSA infections in critically ill patients has required an ongoing evaluation of factors that propagate and sustain this pattern of resistance. The role of inadequate handwashing in the spread of nosocomial MRSA in hospitals has been well known for many years.[165] As rates of MRSA have increased in infections such as HAP,[166] other variables that may serve as risk factors for MRSA infection are targeted.

Infection by strains of *Clostridium difficile* with increased levels of toxin production and the resultant complications of toxic megacolon, bowel perforation, and death is a problem that has gained attention in recent years.[167] A postulated cause for this increase in toxin production is hypermutation. Spontaneous mutations that lead to bacterial resistance typically occur with a frequency of 10^{-6} to 10^{-8}. Hypermutation refers to a situation in which the mutation rate exceeds the rate of spontaneous mutations.[168] Certain factors may lead to an increase in the potential for a mutation that can lead to resistance. Antibiotics that have an effect on DNA have been shown with in vitro experiments to contribute to this predisposition to resistance.[168]

To better understand outbreaks of clinical disease caused by toxin-producing strains of *C. difficile*, researchers explored the genetics of epidemic strains.[169,170] In these studies, investigators noted an 18-base-pair deletion in the *tcdC* gene, which normally downregulates production of toxins A and B. The presence of binary toxin genes was an additional finding. Investigators postulated that these contribute to the hyperproduction of toxin expressed in clinical outbreaks. The epidemiologic analysis of these outbreaks identified fluoroquinolone therapy as a risk factor in some *C. difficile* outbreaks.[169–171] These observations challenge the critical care clinician to consider the potential of unintended antibiotic consequences in the selection of empiric antibiotic therapy in seriously ill patients.

In addition to *C. difficile,* the effect of antibiotics on toxin production has been studied in gram-positive organisms. In a study investigating the effects that cell wall–active antibiotics and protein synthesis inhibitors have on transcription and translation of genes for PVL, α-hemolysin, and TSST-1, Miller et al. demonstrated that subinhibitory concentrations of nafcillin both induced and prolonged messenger RNA (mRNA) expression for PVL, α-hemolysin, and TSST-1.[111] The investigators suggested that inadvertent use of β-lactam antibiotics to treat MRSA infections may contribute to worse outcomes.

When approved for clinical use in 1958 as the first glycopeptide antibiotic, impurities in vancomycin, often referred to as "Mississippi Mud," resulted in nephrotoxicity. Since that time, the incidence of all vancomycin toxicities has reduced owing to the improvement in vancomycin purity from 70% to almost 95% with improved fermentation methods.[172] After three decades of use, the issue of vancomycin and kidney injury was addressed by Moellering with the following editorial comment:

> Although vancomycin was originally thought to be ototoxic and nephrotoxic, recent studies of animals have failed to confirm either the ototoxicity or the nephrotoxicity of vancomycin administered alone. Definitive data proving that vancomycin is ototoxic or nephrotoxic in humans are likewise difficult to find in the literature. One area in which considerable controversy remains, however, relates to the possibility that vancomycin may produce synergistic or enhanced nephrotoxicity in patients receiving concomitant aminoglycosides.[173]

A consensus review of therapeutic monitoring of vancomycin in adult patients by the American Society of Health-System Pharmacists, the IDSA, and the Society of Infectious Diseases Pharmacists noted that data derived from more recent studies appear to suggest that vancomycin has little potential for nephrotoxicity or ototoxicity when used at conventional dosages (e.g., 1 g every 12 hours [15 mg/kg every 12 hours]), unless it is used concomitantly with known nephrotoxic drugs or at very high dosages.[133] The authors suggested a case definition of vancomycin-induced nephrotoxicity to be multiple (at least two or three consecutive) high serum creatinine concentrations (increase of 0.5 mg/dL or 50% or higher increase from baseline, whichever is greater) documented after several days of vancomycin therapy in the absence of an alternative explanation.

Over the ensuing two decades since the Moellering editorial, research has identified several contributing factors to the development of vancomycin-associated nephrotoxicity, including patients who receive daily doses in excess of 4 g, where toxicity rates may be as high as 34.6%.[174] Other risk factors for vancomycin-associated nephrotoxicity include increased body weight, extended duration of therapy, history of kidney disease, higher severity of illness, hypotension, elevated trough concentrations, and receipt of concomitant nephrotoxic medications including other antimicrobials.[172,175–177]

Certain β-lactam antibiotics may also contribute to nephrotoxicity owing to acute interstitial nephritis.[178] Because of the high frequency combination therapy in the ICU, one of the important considerations for synergistic nephrotoxicity is the concomitant use of vancomycin with piperacillin/tazobactam.

A retrospective, matched, cohort study of 558 patients compared the risk of acute kidney injury in patients receiving concomitant vancomycin plus piperacillin/tazobactam versus those using vancomycin and cefepime.[179] The investigators matched subjects for severity of illness, ICU status, duration of combination therapy, vancomycin dose, and number of concomitant nephrotoxins. In multivariate analysis, therapy with vancomycin plus piperacillin/tazobactam was an independent predictor of acute kidney injury (hazard ratio 4.27; 95% confidence interval [CI] 2.73–6.68). Among patients who developed acute kidney injury, the median onset was more rapid in the group receiving vancomycin plus piperacillin/tazobactam compared with the vancomycin plus cefepime group (3 vs. 5 days $P \leq 0.0001$).

In a registered meta-analysis (PROSPERO: CRD42016041646) using 14 observational studies with a total of 3549 patients, concomitant vancomycin and piperacillin/tazobactam was associated with acute kidney injury in unadjusted odds ratio (OR 3.12; 95% CI 2.04–4.78) and in adjusted odds ratio (OR 3.11; 95% CI 1.77–5.47) analyses.[180] The clinical observation of increased development of acute kidney injury owing to synergistic nephrotoxicity with dual-therapy vancomycin and piperacillin/tazobactam should be taken into consideration when determining either empiric or definitive therapy in ICU patients at risk for renal dysfunction. Identification of risk that prevents homogenous prescribing habits may eventually lead to a goal of antibiotic stewardship: greater heterogeneity in antibiotic choices in ICU medicine.

Right Time

The adequacy of initial empiric antibiotic therapy influences outcomes of clinical infections in the critically ill. For many years, clinicians adjusted antibiotic therapy on hospital day 2 or 3 after either bacterial susceptibility was known or the clinical course of the patient had been defined. This practice was based on the assumption that neither morbidity nor mortality would be negatively affected by such delays. The 1990s saw the publication of several reports challenging this tenet in the infectious disease processes of sepsis and VAP.[8–13,181] In these reports, investigators used the term *inadequate* to describe situations in which the organism causing an infection was not sensitive to antibiotic therapy as indicated by in vitro susceptibility. The published studies exhibited variability in sample size, inconclusiveness regarding whether isolated organisms were pathogens or colonizers, and lack of consistent identification of confounders that contributed to mortality; thus it was not possible to prove that such inadequate therapy affected mortality. Nevertheless, the consensus of multiple studies was that initial inadequate therapy had the potential to contribute to mortality.[182]

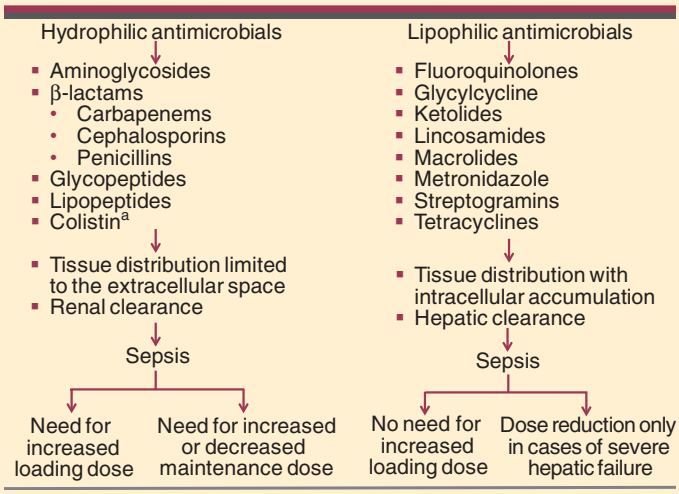
Shortly after the reports emphasizing the importance of initial, adequate therapy, there was a growing awareness of other important variables that influenced clinical outcomes in the critically ill. In a 2005 joint guideline for management of patients with HAP, VAP, and health care–associated pneumonia, the ATS and the IDSA modified definitions for the terms used in the selection of antibiotic therapy.[79] *Inappropriate* replaced the term *inadequate;* furthermore, the authors adopted *adequate* to refer to therapy that included not only the correct antibiotic based on the susceptibility of the organism but also optimal dose, correct route of administration, and use, if necessary, of combination therapy.[79] A contemporary definition of adequate therapy has now evolved to include that antimicrobial therapy (1) should be initiated as soon as possible after the onset of sepsis (with this usually occurring before the causative pathogen is known), (2) should be broad enough when given empirically to cover the potential causative microorganisms, and (3) embody appropriate antimicrobial dosing to maximize microbial killing, minimize the development of multidrug antimicrobial resistance, and avoid concentration-related adverse drug reactions.[183]

Multiple studies have addressed the impact of the timing of antibiotic therapy for patients in the ICU. In an analysis based on 107 consecutive patients receiving mechanical ventilation and antibiotic treatment for VAP, Iregui and colleagues noted that 30.8% (33 of 107) received antibiotic treatment that was delayed for 24 hours or more after initially meeting diagnostic criteria for VAP. These patients were classified as having initially delayed appropriate antibiotic therapy (IDAAT).[184] Two major variables were identified in these patients with IDAAT: (1) a delay in writing an antibiotic order (in 75.8% of the cases), and (2) the presence of a bacterial species resistant to the initially prescribed antibiotic regimen (in 18.2%). The investigators found that the hospital mortality rate was 69.7% for the patients with IDAAT, in contrast to only 28.4% for the patients without IDAAT ($P < 0.01$). An earlier study noted that modification of the antibiotic regimen to cover pathogens based on the susceptibility report did not eliminate the increased mortality associated with inadequate empiric therapy in patients with VAP.[11] This finding formed the basis for the statement that secondary modifications of an initially failing antibiotic regimen do not substantially improve the outcome for critically ill patients.[185] These results challenge the clinician to promptly order antibiotics that cover the involved pathogens even before culture results are available.

The IDSA practice guidelines for management of adult patients with meningitis note the lack of prospective clinical data on the relationship of the timing of administration of antimicrobial agents to clinical outcome in patients with bacterial meningitis.[186] Data from a retrospective cohort study of 269 adult patients with community-acquired bacterial meningitis provide some insights into the timing of antibiotic therapy in the absence of definitive recommendations.[187] Using these and other data, the IDSA acknowledged that evidence for definitive recommendations is inadequate and concluded that a reasonable assumption is to administer treatment for bacterial meningitis before the infection advances to a high level of clinical severity.[186] Referring to meningitis as a "neurologic emergency," the guideline recommended that appropriate therapy for meningitis be initiated as soon as possible after the diagnosis is considered to be likely. In support of the importance of prompt timing, this document also noted the potential in certain patients for administration of antibiotics before hospital admission if the patient initially presents outside the hospital.

For the critical care clinician, sepsis is a clinical entity in which appropriate timing of antibiotic therapy has been associated with improved clinical outcomes.[8,9,13,104,181] A sentinel retrospective cohort study of 2731 patients with septic shock–related recurrent or persistent hypotension in 14 North American ICUs demonstrated an associated increase in mortality rates with delayed antibiotic delivery. Survival rates decreased from 79.9% to 70.5% if administration of antibiotics administration was delayed from within the first hour to the second hour after hypotension development. In the 6 hours after onset of hypotension, the survival rate decreased by an average of 7.6% for each hourly delay in drug delivery.[188] A later larger study in 165 international ICUs involving 28,150 patients with sepsis and septic shock further evaluated the link between antibiotic timing and outcomes. Results demonstrated a positive relationship between the earlier administration of antibiotics and mortality in patients with severe sepsis and septic shock, even

TABLE 48.3 Effects of Pathophysiology on Pharmacokinetics in Critically Ill Patients



[a]Roberts JA, Lipman J. Pharmacokinetic issues for antibiotics in the critically ill patient. *Crit Care Med.* 2009;37:840–851.

Adapted from Blot SI, Pea F, Lipman J. The effect of pathophysiology on pharmacokinetics in the critically ill patient—concepts appraised by the example of antimicrobial agents. *Adv Drug Deliv Rev.* 2014;77:3–11.

when stratified by location of sepsis diagnosis.[189] Although a more recent meta-analysis has questioned the validity of the initial observations[190] regarding mortality benefit, the meta-analysis suffered from inclusion of studies with negative results with significant flaws characterized by small study sample sizes and large variations in index timing. Thus the 2016 Surviving Sepsis Campaign guidelines continued to recognize the importance of prompt therapy in influencing clinical outcomes. The guidelines specifically provide a strong recommendation citing a moderate quality of evidence to initiate administration of IV antimicrobials as soon as possible after recognition of sepsis and septic shock and within 1 hour.[191] Consistent with the 2008 guidelines, appropriate routine microbiologic cultures, including blood cultures, should be obtained before initiating antibiotic therapy but should not prevent prompt administration of antimicrobial therapy.[192]

Right Dose

As the literature regarding the treatment of infections in the ICU has evolved over the years, studies have identified several elements that influence the optimal dose of an antibiotic. The manner in which antibiotics kill bacteria varies among different classes of drugs, but the two major pharmacodynamic categories of killing are *time-dependent* killing and *concentration-dependent* killing.[193] In time-dependent killing, also referred to as *concentration-independent* killing, maximum bacterial killing occurs when the drug concentration remains above the MIC. Examples of antibiotics that demonstrate time-dependent killing include β-lactam antibiotics (i.e., penicillins, cephalosporins, carbapenems, and monobactams) and vancomycin. Conversely, in concentration-dependent killing, maximum bacterial killing occurs when the peak drug concentration is approximately 10 times the MIC. Examples of agents with concentration-dependent killing are fluoroquinolones and aminoglycosides. Several studies have demonstrated the relevance of these properties in the management of patients with serious infections.

In recent years, the focus on discussing antibiotic properties has moved toward the characterization of antimicrobial agents as being either hydrophilic or lipophilic. The knowledge of these properties may affect dosing strategies. A summary of these physicochemical properties of antibiotics and their effects on dosing strategy is included in Table 48.3.[183,194] Noteworthy is the lack of uniform consistency between time-dependency and hydrophilicity and between concentration-dependency and lipophilicity (e.g., aminoglycosides and lipopeptides [daptomycin], which are hydrophilic but concentration dependent). It is important to understand these pharmacologic properties and the variations that occur with hydrophilic antibiotics in the presence of sepsis. Most relevant are (1) the significant antibiotic dilution that might occur with hydrophilic antibiotics when intravascular fluid escapes into tissues and (2) the fluctuations of renal function that often occur in patients with sepsis and result in increasing or decreasing elimination rates. In contrast to hydrophilic antibiotics, lipophilic antimicrobials are less affected in their pharmacokinetic behavior by the pathophysiology of sepsis, as they are normally distributed in the intracellular and extracellular spaces.[183] This distribution means that retrodiffusion from the intracellular reservoir to the extracellular space may prevent antibiotic dilution whenever intravascular fluid escapes into tissues. Also, most of these agents are cleared through the liver, whose function is often less significantly compromised during sepsis, with the result that elimination rates are frequently similar to those observed in stable patients.

Ultimately, hydrophilic antibiotics often need higher loading dosages and increased or decreased maintenance dosages in critically ill patients with sepsis compared with noncritical stable patients. On the contrary, similar concentration-time profiles are observed for lipophilic agents in critically ill as well as noncritically ill patients.

As summarized by Blot and colleagues,[183] the following characterizations of antibiotics are relevant: (1) time-dependent

antibiotics (i.e., cumulative percentage of time over a 24-hour time [i.e., T] period that the free [*f*, or unbound] antimicrobial concentration exceeds the MIC [*f*T > MIC]: β-lactam antimicrobials); (2) concentration-dependent antibiotics (i.e., peak concentration in a dosing interval divided by the MIC), with the usual maximum concentration (C_{MAX}/MIC target exceeding 8–10): aminoglycosides and daptomycin; and (3) concentration-dependent with time-dependence (i.e., defined by the area under the curve over a 24-hour period [$AUC_{0–24h}$] divided by the MIC [$AUC_{0–24h}$/MIC]): fluoroquinolones, tigecycline, linezolid, and glycopeptides.

An unresolved issue is whether vancomycin is only time-dependent[195] or whether it is a combination of concentration-dependent with time dependence.[183] Because vancomycin exhibits time-dependent killing,[195] the length of time that concentrations of vancomycin stay above the pathogen's MIC is important to bacterial eradication. As drug levels decline, organisms have the potential to regrow, increasing the chance of clinical failure. This pharmacologic principle is influential in the practice patterns of more frequent (every 6 hours) or of continuous infusion vancomycin dosing for infections like pneumonia in which vancomycin penetration to the target site may not be optimal. Those who embrace vancomycin as having concentration-dependent with time-dependence properties do not usually advocate for continuous infusion.

Because a goal with time-dependent antibiotics such as β-lactams is to maintain antibiotic levels above the MIC of the organism for as long as possible during the dosing cycle, it is important to be aware of inadequate concentrations of these agents in patients with sepsis when standard dosage regimens are administered. This is particularly noteworthy when infection is caused by difficult-to-treat organisms such as *P. aeruginosa*.[196,197] On a theoretical basis, administration of β-lactams at increased doses, with increased frequency, or by an extended or continuous infusion can result in improvement in obtaining pharmacodynamic target attainment. Among these options, clinicians have used continuous infusions in critically ill patients, and this strategy achieves higher steady-state β-lactam concentrations compared with trough concentrations with standard intermittent regimens.[198] Despite such an advantage, continuous infusion β-lactam therapy may still result in concentrations below the MIC for difficult-to-treat pathogens, especially in patients with a high creatinine clearance and high renal drug elimination.[199] Because of such variables, enhanced clinical efficacy of continuous infusions of β-lactam antibiotics has not been consistently demonstrated.[194] As research explores new approaches to drug administration, it is important to be aware of the potential for neurotoxicity such as progressive neurologic deterioration with high-concentration β-lactam antibiotics.[147]

The postantibiotic effect, in which microbial killing persists despite clearance to undetectable serum levels, complements the concentration-dependent killing of gram-negative bacilli exhibited by aminoglycosides. These two properties may serve as the basis for once-daily aminoglycoside therapy.[200] Giving the same total dose in larger concentration less often may result in better killing, longer postantibiotic effect period, and reduced aminoglycoside toxicity.

In such a dosing schedule, clinicians administer single doses of gentamicin or tobramycin of 5 mg per kg to 7 mg per kg of body weight. Nicolau et al. reported their experience with once-daily therapy using 7 mg per kg in 2184 adult patients.[201] After exclusion of patients with end-stage liver disease with ascites, burns involving greater than 20% total body surface area, pregnancy, end-stage renal disease requiring dialysis, and enterococcal endocarditis, it was deemed unnecessary to draw standard peak and trough samples. Monitoring was completed by obtaining a single random blood sample between 6 and 14 hours after the start of an aminoglycoside infusion. The treating clinician could subsequently adjust the dosing interval in accordance with a provided nomogram. The authors made several important observations in this large group of patients. (1) Despite the prolonged drug-free period, bacterial regrowth was not clinically evident. (2) No increase in either ototoxicity or nephrotoxicity was found. (3) Efficacy was promoted in a cost-effective manner.[201] Supporting this strategy, a meta-analysis evaluating the safety and efficacy of once-daily aminoglycosides in 1200 patients from 16 trials found no difference concerning efficacy and safety between single-dose and multiple-dose regimens.[202]

Despite the role that colistin plays in the treatment of infections caused by carbapenemase-producing bacteria, there are no consistent recommendations regarding the dosing of this antibiotic. A comparison of U.S. FDA and European Medicines Agency colistin dosing strategies used pharmacokinetic data from 162 adult critically ill patients with creatinine clearances ranging from 5.4 to 211 mL/min to determine the average steady-state plasma colistin concentration.[203] In this study, there was variability in susceptibility breakpoints for *P.* and *Acinetobacter*, with the Clinical Laboratory Standards Institute breakpoints of 2 mg/L or less and 2 mg/L less, respectively, and with the European Committee on Antimicrobial Susceptibility Testing breakpoints of 4 mg/L or less and 2 mg/L or less, respectively. Based on these analyses, there has been variability in colistin dosing. The FDA recommended body weight–adjusted doses, whereas the European Medicines Agency recommends dosing in million international units.

To achieve optimal clinical benefits while minimizing the unintended consequences of selecting resistant bacteria, clinicians must simultaneously consider multiple variables when using concentration-dependent drugs in the treatment of serious infections. In a study of lower respiratory tract infections caused by *P. aeruginosa*, clinicians administered ciprofloxacin intravenously at a dose of 200 to 300 mg every 12 hours.[204] Resistance emerged at a rate greater than 70% during therapy, similar to the 75% rate predicted by a pharmacodynamic study.[205] By contrast, a randomized comparison of imipenem and ciprofloxacin for treatment of nosocomial pneumonia used a ciprofloxacin regimen of 400 mg given intravenously every 8 hours and noted emergence of resistance during therapy in 33% of cases in which *Pseudomonas* was the causative pathogen.[101] This rate was similar to the 38% predicted by the pharmacodynamic study previously cited.[205] These data emphasize the importance of considering not only the dosing interval but also the dose of antibiotic administered when using concentration-dependent antibiotics to treat infections in the critically ill.

In addition to dose and interval, antibiotic clearance plays an integral role in adequacy of antibiotic therapy. While it is routinely accepted that reductions in antibiotic dosing are appropriate in advancing acute kidney injury,[206] clinicians may fail to escalate drug administration in the increasingly reported clinical phenomenon of augmented renal clearance (ARC).[207] ARC is defined as the enhanced renal elimination of circulating solutes owing to an increased creatinine clearance (CrCl >130 mL/min per 1.73 m^2). Prevalence of ARC is higher in burn,[208] major trauma,[209] traumatic brain injury,[210] and febrile neutropenic[211] ICU patients; however,

it is difficult to traditionally recognize as derived estimates of glomerular filtration, such as the modification of diet in renal disease equation and Cockcroft-Gault formula are less accurate than direct measurement.[212] In 48 ICU patients with measured CrCl, Udy and colleagues demonstrated that CrCl values greater than or equal to 130 mL/min per 1.73 m^2 were associated with initial trough concentrations of β-lactams less than MIC in 82% ($P < 0.001$). Moreover, CrCl remained a significant predictor of subtherapeutic concentrations after multivariate analysis.[213] ARC has importance in vancomycin dosing as well. Baptista et al. performed a prospective, single-center, observational cohort study of 93 consecutive septic patients in the ICU treated with vancomycin by continuous infusion after a weight-based loading dose. Investigators compared patients with and without ARC. A statistically significant correlation between subtherapeutic vancomycin serum concentration and ARC was observed in the first 3 days of treatment.[214]

An interaction between renal clearance and hypoalbuminemia also plays a prominent role in pharmacokinetics. Ulldemolins and colleagues demonstrated that in critically ill patients with hypoalbuminemia, unbound flucloxacillin concentrations fell below concentrations necessary for treatment of methicillin-susceptible *S. aureus* 4 hours after standard bolus infusions.[215] The combination of increased volume of distribution owing to hypoalbuminemia combined with ARC presents a daily situation where lower achieved antibacterial exposures could result in subtherapeutic dosing, particularly for time-dependent antibiotics.[216] Because accurate and timely drug exposure is necessary for optimal clinical benefit,[9] clinicians must identify ARC and associated factors like hypoalbuminemia to prevent subtherapeutic pharmacologic treatment.

Right Duration

Given that antibiotic exposure may be a risk factor for resistance,[14] it is important in the process of antibiotic stewardship to identify opportunities to minimize exposure to these therapeutic agents. The concept of de-escalation therapy incorporates the dual goals of (1) initially attempting to decrease mortality by selecting the appropriate antibiotic for empiric therapy but (2) decreasing the time that a patient is exposed to the broad-spectrum therapy that might be necessary to correctly obtain administration of initial therapy.

Classically there have been three ways that de-escalation can occur. The most intuitively understood is changing from a broad-spectrum agent to a narrower-spectrum agent based on culture and sensitivity data. As is well known to those who practice in the intensive care setting, culture data are often negative in the sickest patients and the option of de-escalating based on culture data is often not available.

The de-escalation process becomes less clear when diagnostic studies do not yield an obvious pathogen. Perhaps an appropriate manner of using the information gained by a negative culture is to allow the nonrecovery of certain organisms to influence the alteration of an existing regimen. HAP, including VAP, provides a clinically applicable example of this concept. To minimize mortality, patients with HAP typically receive a three-drug empiric regimen that includes coverage against MRSA and *P. aeruginosa*. ATS/IDSA guidelines for HAP have suggested that clinically improving patients not receiving antibiotics when cultures are obtained may have therapy against MRSA and *P. aeruginosa* stopped if sputum cultures are negative for these pathogens.[79]

The third possibility for achieving de-escalation therapy is by decreasing the duration of therapy to the shortest time length necessary to achieve an optimal clinical outcome.[217] Often the decisions regarding traditional durations of therapy find their basis not in controlled trials or prospective studies, but rather in expert opinion. Although certain infections, such as *S. aureus* bacteremia, require well-defined and often prolonged durations of IV therapy,[218,219] trials in VAP have challenged some of the classic tenets and resulted in recommendations for shorter durations of therapy.

Dennesen and coworkers[220] evaluated the response to antimicrobial therapy administered according to ATS guidelines in 27 patients diagnosed with VAP. The diagnosis was made via bronchoalveolar lavage in conjunction with clinical parameters to confirm the diagnosis of VAP. Semiquantitative tracheal aspirates were used for subsequent microbiologic surveillance and all patients received appropriate antibiotic therapy. After initiation of antimicrobials, T_{max} (maximal temperature over a 24-hour period), partial pressure of arterial oxygen/fraction of inspired oxygen (the ratio used to quantify impairment of oxygen gas exchange in the lung), white blood cell count, and semiquantitative cultures of endotracheal aspirate were monitored. Resolution of clinical parameters occurred primarily within the first 6 days of therapy. Using cultures of endotracheal aspirates, the investigators found that colonization with *P. aeruginosa* persisted throughout the duration of treatment, whereas colonization with *S. aureus, Haemophlius influenzae*, and *S. pneumoniae* resolved shortly after initiation of therapy. Acquired colonization, predominantly with resistant pathogens such as *P. aeruginosa* or members of the Enterobacteriaceae family, usually occurred in week 2 and frequently preceded a recurrent episode of pneumonia. Based on these data, 7 days were suggested to be an appropriate duration of therapy for patients with VAP.

Ibrahim and colleagues evaluated a clinical guideline for the treatment of VAP using 7 days of therapy.[221] A total of 102 patients were prospectively evaluated, 50 before institution of the guidelines and 52 after institution. In addition to more frequent choice of adequate initial antibiotic treatment after implementation of the clinical guideline, patients also had shorter antibiotic courses when treated under the guideline. Investigators noted no mortality difference between the two groups. As was the case with the study by Dennesen and coworkers,[220] a second episode of VAP was more likely to occur in the patients receiving the longer, traditional duration of therapy.

Chastre and associates conducted a prospective, multicenter, randomized, double-blind study of 401 patients with VAP confirmed by quantitative cultures obtained by bronchoscopic protected specimen brush, bronchoalveolar lavage, or both.[222] Only patients who had received initial appropriate antibiotic therapy were included. Investigators divided therapy into two categories: short course, which was given for 8 days in 197 patients, versus long course, which was given for 15 days in 204 patients. Clinical efficacy was similar between the short course and long course groups. Because slightly more patients with nonfermenting gram-negative bacilli (e.g., *P. aeruginosa* and *A. baumannii*) assigned to the 8-day regimen had pulmonary infection recurrences, the investigators were unable to demonstrate the noninferiority of the 8-day regimen for infection by such pathogens compared to the 15-day course of therapy. Multiresistant pathogens more frequently caused recurrences in patients who received the 15-day regimen. Even though the findings from this study do not definitively prove that therapy for HAP or VAP can be limited to 7 days, they lend support to the findings by Dennesen[220] and Ibrahim[221] and their colleagues.

The previously cited trials formed the initial basis for the move to shorter durations of therapy for both HAP and VAP. There have been several additional trials along with meta-analyses and systemic reviews of the topic that have been nicely summarized in the 2016 guidelines by the ISDA and the ATS for the management of adults with HAP and VAP.[4] These guidelines recommend that therapy both for HAP (non-VAP) and for VAP is a 7-day course of antimicrobial therapy, with the acknowledgement that there exist situations in which a shorter or longer duration of antibiotics may be indicated depending on the rate of improvement of clinical, radiologic, and laboratory parameters.

The option for a shorter duration of therapy extends beyond pneumonia. In a randomized clinical trial of 518 patients with complicated intra-abdominal infection who had undergone an adequate source-control procedure, the outcomes after fixed-duration antibiotic therapy (approximately 4 days) were similar to those after a longer course of antibiotics (approximately 8 days) that extended until after the resolution of the physiologic abnormalities of fever, leukocytosis, and ileus.[223] The IDSA and European Society for Microbiology and Infectious Diseases collaborated in the development of an international clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women.[224] Those guidelines recommend the option of a 7-day course of oral fluoroquinolone therapy in women with uncomplicated pyelonephritis. Unfortunately, at the present time, there are no guideline recommendations for the duration of therapy in complicated urinary tract infection.

Adding to the decision-making process for reducing duration are advances in biomarker technology. The Stop Antibiotics on Procalcitonin (PCT) Guidance Study (SAPS)[225] was a prospective multicenter, randomized control trial open-label trial in 15 medical centers in the Netherlands involving 1546 ICU patients. Patients were randomly assigned to PCT-guided or standard of care antibiotic discontinuation strategies. Nonbinding advice was provided to the PCT-guided group to discontinue antimicrobial therapy if the PCT concentration had reduced by at least 80% of its maximum value or to less than 0.5 mg/L. The median duration of treatment was shorter in the PCT-guided group. Another interesting result of the trial was the associated reduction in 28-day mortality from 25% in the standard group to 20% in the PCT group. Given improving results in serial measurements of biomarkers, clinicians in ICUs with suboptimal culture collection results or techniques may consider the use of PCT to assist in safely discontinuing antibiotic therapy.

Antibiotic Stewardship in the Intensive Care Unit

To protect the finite resource of antibiotics that are available in clinical practice, it is important for the clinician to use antibiotics judiciously so that currently available agents are active for as long as possible. Several approaches toward achieving this goal have been described.

In a study of international collaboration by five different countries (United States, South Africa, Colombia, Australia, and the United Kingdom), it was shown that individual efforts can positively affect local and national antimicrobial stewardship programs. Based on this finding, the collaborative recommended that antibiotic stewardship models evolve from infection specialist–based teams to those that use cadres of health care professionals, including pharmacists, nurses, and community health workers, to meet the needs of the global population.[226] An implication from this study is that ICU-specific stewardship programs may have merit.

For many years, the standard approach to antibiotic prescribing occurred in a homogeneous manner in which a single or limited numbers of antibiotics were used as the "workhorse" agent(s) in empiric therapy.[227] Such an approach to antibiotic prescribing often resulted in restricted formularies, in the hope that limiting broad-spectrum agents might prevent the emergence of resistance. Unfortunately, this approach did not take into consideration that inadequate therapy in seriously ill patients might not be reversible when clinicians changed initial antibiotics to the correct agents once susceptibilities returned. In addition, it was during this era of restricted formularies that the proliferation of bacterial resistance began to occur. Because an inherent risk with homogeneous antibiotic use is the selective pressure that can lead to resistance, clinicians must consider other approaches.

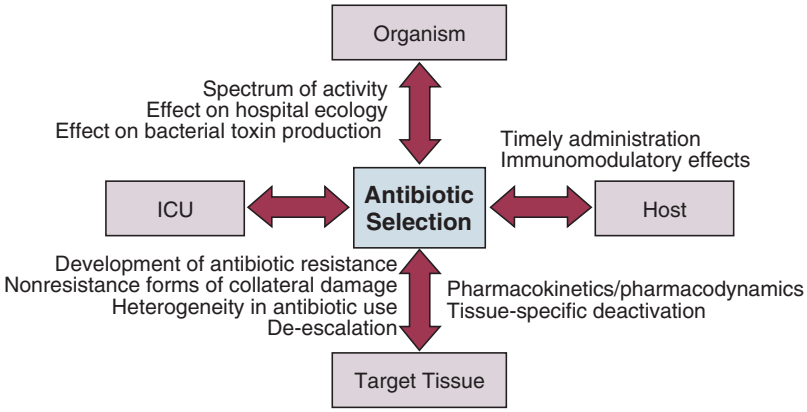
Heterogeneous antibiotic use, in which antibiotic selection is based not on hospital mandates but rather on issues related both to the patient and the pathogens involved in the infectious process, may decrease selective pressure.[228] Clinicians can achieve heterogeneity in any of several ways. A strategy by which multiple or all classes of antibiotics are available for use (i.e., antibiotic heterogeneity) has been suggested as part of a broader effort aimed at curtailing antibiotic resistance within ICUs. A mathematical model was developed to compare antibiotic cycling to the process of mixing, in which antibiotic variation is random as opposed to the regulation that occurs with a process like antibiotic cycling.[229] The premise for such a comparison is that mixing imposes greater fluctuation in selective conditions, thereby yielding greater heterogeneity than occurs with cycling. A simple ecologic explanation led to the conclusion that cycling is unlikely to be effective and may even hinder resistance control. Mixing may yield more favorable results toward the goal of preserving antibiotic susceptibility.

In contrast with homogeneous antibiotic use, which was developed to control resistance, heterogeneous use is aimed at managing resistance.[228] Because resistance at some level is an inevitable part of medical practice, the latter approach seems more insightful.

Conclusions

At a time when bacterial resistance is becoming more prevalent and antibiotic development is not as robust and rapid as necessary, the critical care clinician is faced with the daunting challenge of achieving clinical efficacy without compromising the antibiotic armamentarium that exists at present. For this to be accomplished, the interplay of several important concepts drives the decision process. As depicted in Fig. 48.3, these considerations include the organism, the host, and the targeted tissue, as well as specific issues related to the ICU itself.

Armed with the knowledge of these variables, health care providers now have the foundation for achieving a major goal of antibiotic stewardship: education.[1,2] As noted in the initial guideline for antibiotic stewardship, it was acknowledged that education alone, without incorporation of active intervention, is only marginally effective at changing antimicrobial prescribing practices and has not demonstrated a sustained effect.[2] An understanding of the principles governing antimicrobial selection in the ICU should better position critical care clinicians for practicing the art of antibiotic prescribing in a manner that both achieves efficacy for optimal outcome and preserves the integrity of the antibiotics available for this task.



• **Fig. 48.3** The interplay of antibiotic selection with principles relevant to host, organism, intensive care unit *(ICU)*, and target tissue. Adequate antibiotic therapy is dictated by more than matching the spectrum of antibiotic activity with a pathogen's in vitro susceptibility.

Key Points

- Initial appropriate antibiotic therapy (defined as matching antibiotic to pathogen susceptibility), with early dose administration, reduces mortality in the treatment of serious infections.
- Optimal antibiotic therapy takes into consideration more than the spectrum of activity and also includes dose optimization, ensuring target tissue penetration, and consideration of combination therapy.
- Empiric and directed antibiotic regimens for the individual patient also are influenced by factors that the critical care physician must recognize: time-dependent versus concentration-dependent killing, synergy versus antagonism, immunomodulatory antibiotic properties, inhibition of bacterial protein synthesis, and organ-specific deactivation.
- In selecting antibiotics for serious infections, the clinician should consider not only the individual therapeutic efficacy but also the potential for unintended antibiotic consequences, such as selection of resistant microorganisms.
- Antibiotic therapy is a risk factor for selecting resistant microorganisms and should not be broader in coverage, or given longer in duration, than necessary in clinically stable patients.
- Stratification based on severity of illness plays an important role in clinical decisions about how broad initial antibiotic therapy should be.
- When possible, initial broad and aggressive antibiotic therapy should be rapidly de-escalated as soon as the clinical situation might allow.
- It is important to recognize that resistance to a class of antibiotics may be selected by therapy with an entirely different class of antibiotics.
- With the increasing prevalence of community-acquired mechanisms of resistance such as ESBL production, it is important to stratify initial therapeutic options based on severity of illness.
- Informed decisions concerning initial antibiotic selection must take into consideration surveillance data that reveal patterns of resistance that occur within a practice setting. Timely antibiograms, which when possible are unit-specific, increase the ability to make strategic decisions about initial antibiotic therapy.
- Knowledge of the mechanisms by which antibiotic-resistant bacteria are selected can lead to more judicious patterns of antibiotic use that may ultimately help to manage the evolving global patterns of resistance.

Review Questions

1. For optimal clinical outcome when selecting empiric antimicrobial therapy, which of the following choices is correct?
- **a.** The clinician should adjust antimicrobial therapy on day 2 or 3 of the clinical course.
- **b.** Timing of initial dosing is key.
- **c.** Optimal dose and dosing interval do not make a difference in outcome.
- **d.** Tissue-targeted therapy has no role in managing infection.

Answer: b. Intensive care unit (ICU) antibiotic stewardship focuses on prevention of antimicrobial resistance and unintended consequences of antibiotics other than resistance. Empiric therapy should be adequate not only for the correct antibiotic based on susceptibility of the organism but also for optimal dose/dose interval, correct route of administration, and use of combination therapy if needed. Other variables playing a role in optimal clinical outcome include time of administration and pharmacologic properties of the agent (i.e., suppressed toxin production with clindamycin in group A streptococcus infection). Another point to consider is the potential for selection of antibiotic resistance (i.e., quinolones and multidrug-resistant *Pseudomonas*).

2. Which one of the following antibiotics would be effective in treating an infection caused by an extended-spectrum β-lactamase–producing strain of *Klebsiella* species?
- **a.** Piperacillin/tazobactam
- **b.** Meropenem
- **c.** Ampicillin/sulbactam
- **d.** Ceftazidime

Answer: b. The resistance that occurs with extended-spectrum β-lactamase (ESBL) producers is of importance in initial antibiotic selection in two regards. Even antibiotics that are stable in the presence of β-lactamases may not have a predictable activity. Inferior outcomes have been seen with cefepime and piperacillin/tazobactam. There is no antibiotic presently on the market with FDA approval to treat infections caused by an ESBL-producing organism. The data extrapolated from medical literature suggest that carbapenems are the drug of choice to treat such infections.

3. Which antibiotic should be avoided while treating an *Enterobacter* infection if laboratory data suggest susceptibility?
- **a.** Levofloxacin
- **b.** Bactrim
- **c.** Ceftriaxone
- **d.** Cefepime

Answer: c. Type 1 β-lactamases (ampCs) are chromosomally mediated product from *ampC* genes. Common β-lactamase–expressing organisms are SPICE or SPACE organisms (*Serratia*, *Pseudomonas aeruginosa*, indole-positive Proteeae, *Citrobacter*, *Enterobacter*) with some authors replacing the "I" for "A" of *Acinetobacter*. Those pathogens do not always express *ampC* genes but they have the potential of doing so. As type 1 β-lactamases have affinity for cephalosporins, third-generation cephalosporins are not predictably stable.

4. The concept of synergy is best described in which of the following?
- **a.** Use of penicillin or ampicillin with gentamicin in enterococcal endocarditis
- **b.** Combination of linezolid and vancomycin to treat methicillin-resistant *Staphylococcus aureus* (MRSA) endocarditis
- **c.** Use of β-lactam and an aminoglycoside as empiric therapy for sepsis
- **d.** Combination of ciprofloxacin and linezolid to increase the in vitro bactericidal effect of ciprofloxacin against MRSA

Answer: a. The role of combination therapy has received increased interest. The most frequently cited effect is synergy, which has been well described with penicillin and ampicillin with gentamicin in treatment of enteroccocal endocarditis. In vitro studies of combinations of linezolid and vancomycin or ciprofloxacin with MRSA revealed some slight antagonism with decreased bactericidal activity. Data failed to show that combination of a β-lactam with aminoglycoside has a clinical advantage over monotherapy. Combination therapy has failed to show an advantage in prevention of resistance when treating *Pseudomonas* infection. In the intensive care unit an important advantage of using combination therapy is that it increases the chance of adequate therapy when dealing with multidrug-resistant organisms.

Antifungal and Antiviral Therapy

LUIS OSTROSKY-ZEICHNER AND MOHANAD AL-OBAIDI

CHAPTER OUTLINE

Systemic Antifungal Agents
- Polyenes
- Flucytosine
- The Azole Antifungal Agents
- Echinocandins

Specific Indications and Uses for Antifungals

***Candida* Infections**
- Mucosal Infections and Colonization
- Cryptococcosis
- Aspergillosis
- Histoplasmosis
- Mucormycosis
- Other Fungal Infections

Areas of Controversy in Antifungal Therapy
- Empirical Antifungal Therapy for the Febrile ICU Patient
- Antifungal Prophylaxis in the ICU
- Measurement of Drug Levels
- Susceptibility Testing

Antiviral Agents
- Acyclovir, Famciclovir, and Valacyclovir
- Ganciclovir and Valganciclovir
- Cidofovir
- Foscarnet
- Amantadine and Rimantadine
- Ribavirin
- Oseltamivir
- Zanamivir
- Peramivir
- Other Antivirals

Specific Indications and Uses for Antivirals
- Herpes Simplex Virus and Varicella-Zoster
- Cytomegalovirus
- Influenza
- Other Viruses

Over the past two decades, fungal and viral diseases have become progressively more important to the critical care specialist. Increasing populations of immunocompromised hosts with serious fungal and viral infections often require critical care, and patients hospitalized in critical care units are also susceptible to these infections. Effective management of these conditions not only requires use of the appropriate anti-infective agents, but in-depth knowledge of their pharmacodynamic/pharmacokinetic properties, as well as awareness of their physiologic effects, toxicities, and drug interactions. Recent years have also brought important antifungal and antiviral drug developments, giving the clinician an ever-increasing arsenal of therapeutic choices.

Systemic Antifungal Agents

This chapter focuses on systemic antifungal therapy as it is relevant to the critical care setting. Topical therapy of candidiasis and therapy of other systemic fungal infections are omitted or only briefly reviewed. The interested reader is referred to the Infectious Diseases Society of America guidelines on the topic.[1]

Polyenes

Polyenes act by binding to ergosterol in the fungal cytoplasmic membrane, forming pores that causes ionic leakage and osmotic unstability.[2,3] In addition, they were found to cause oxidative damage to *Candia albicans*.[2] Polyenes are fungicidal in most settings and the most prominent members of the family are amphotericin B and nystatin. Both drugs have important toxic effects that often limit their use in patients with organ/system failure. Newer formulations of the drugs have been developed to reduce this limitation.

Amphotericin B and Its Lipid Formulations

Amphotericin B is produced by *Streptomyces nodosus* and is one of the oldest and most widely used antifungal agents. There is much

experience with its use in mycoses and hosts, and it is usually the comparison standard for new therapies.[3] Because of significant acute and chronic toxicities, there is an extensive anecdotal literature describing ways to ameliorate these toxicities, as well as limitations of all these strategies.[4] The advent of lipid-based formulations of amphotericin B has enhanced our ability to limit toxicities and provide adequate courses of therapy.[5]

Amphotericin B has in vitro and vivo activity against most isolates of *Candida* spp., *Cryptococcus neoformans, Histoplasma capsulatum, Blastomyces dermatitidis, Mucorales, Coccidioides immitis, Paracoccidioides brasiliensis, Aspergillus* spp., *Fusarium* spp., and *Sporothrix schenckii.*[6] The activity of amphotericin B is so broad that it is almost easier to think of this in terms of the few species that are consistently less susceptible or actually resistant to amphotericin B: *Aspergillus terreus,*[7] *Trichosporon* spp.,[8] and *Pseudallescheria boydii (Scedosporium prolificans).*[9] One species of *Candida, C. lusitaniae*, readily becomes resistant to the polyenes.[10] Resistance among isolates of *Candida* is otherwise rare.[11,12]

Amphotericin B is hydrophobic and combined with deoxycholate to permit intravenous (IV) administration in an aqueous solvent. Once in the bloodstream, it dissociates and binds to plasma proteins and lipoproteins. It is stored in the liver and other organs and slowly eliminated. Drug metabolism is complex and not affected by renal or liver failure.[3] Neither hemodialysis nor peritoneal dialysis removes the drug. Measuring drug levels is possible[13] but not of obvious clinical relevance. Cerebrospinal fluid (CSF) penetration is poor. Although amphotericin B is primarily used in IV infusions, it can also be used topically for localized gastrointestinal or urinary infections or instilled directly to treat central nervous system (CNS) infections.

The most common toxicity is the systemic reaction associated with IV infusion, thought to be caused by release of inflammatory mediators from monocytes and macrophages and producing fever, hypotension, and on occasion severe dyspnea. Two forms of renal toxicity are seen. First, a very acute form of renal dysfunction appears to be related to amphotericin B–induced renal arteriolar constriction.[14] Second, cumulative dose-dependent tubular damage is almost invariably seen if significant doses are given. The tubular injury is characterized by potassium/magnesium wasting and azotemia. It is generally reversible when the drug is stopped but it is also particularly aggravated if the patient is volume depleted or given other nephrotoxic drugs. The renal injury also reduces erythropoietin production[15] and thus causes a mild anemia during chronic therapy (the hematocrit typically falls to about 30%). Finally, amphotericin B may precipitate cardiac arrhythmias, especially if the patient is already hypokalemic and hypomagnesemic.[16–19] The deoxycholate formulation of amphotericin B is given intravenously at 0.5 to 1.0 mg/kg per day, but it can also be administered every other day by doubling the dose. To avoid producing a precipitate, it must be diluted in an electrolyte-free solution at no more than 0.1 mg/mL. It should be administered over no less than 1 hour and most authorities prefer a 2- to 3-hour infusion.[20] Because the occasional patient reacts violently to the drug, an initial test dose of 1 mg of the drug may be given before infusing the entire first dose; however we prefer just starting a slow infusion of the first dose. Premedication with acetaminophen, diphenhydramine, and steroids may be used if the patient develops reactions to the infusion. Volume loading appears to reduce nephrotoxicity, and many authorities give (if possible) 500 to 1000 mL normal saline solution just before each dose of amphotericin B. Administration via a central line is advisable as peripherally given amphotericin B often produces phlebitis.

Treatment goals have been traditionally and arbitrarily cumulative (such as 1 or 2 total g), but a time-based approach is increasingly used for some diseases (e.g., for candidemia, where 2 weeks of therapy at 0.6 to 0.7 mg/kg after the last positive blood culture has been shown to produce a late relapse rate of about 1%).[21] Although the importance of therapy in the typical patient is unclear,[22,23] candiduria is sometimes treated with amphotericin B bladder washes. A typical dose is 50 mg of amphotericin B diluted in 1000 mL of water and irrigated over 24 hours. A small number of intracranial fungal infections benefit from intrathecal dosing at 0.1 to 0.5 mg 3 times per week, but expert advice should be sought if this therapy is considered. Intraperitoneal amphotericin B is contraindicated, as it may cause excruciating pain and peritoneal fibrosis.

There are three lipid-based formulations of the drug: amphotericin B colloidal dispersion (ABCD, marketed as Amphotec and Amphocil), amphotericin B lipid complex (ABLC, marketed as Abelcet), and liposomal amphotericin (L-AmB, marketed as AmBisome). The names of these compounds are often confusing. Only one of the drugs (L-AmB) is a true liposome. However, it is not uncommon for physicians to refer to therapy with these compounds in general as therapy with "liposomal amphotericin B." The preferred terminology is "lipid-associated formulation of amphotericin B" (LFAB).[5] When speaking of specific compounds, we find that use of the names ABCD, ABLC, and AmBisome minimizes confusion.

All three LFABs have comparable efficacy among themselves and when compared to regular amphotericin B, but significantly less nephrotoxicity.[5,24] They are also thought to be concentrated and distributed in the reticuloendothelial system, theoretically achieving higher tissue delivery and concentration. The lipid carrier does, however, dramatically change the pharmacology and delivery of these compounds and higher doses than is typical for amphotericin B are both safe and necessary for optimal activity: the licensed doses are 5 mg/kg per day (ABLC), 3 to 6 mg/kg per day (ABCD), and 3 to 5 mg/kg per day (AmBisome). The optimal dose of these compounds is unclear and the agents appear generally equipotent. Dosages of ~3 mg/kg per day would appear suitable for treatment of most serious *Candida* infections. Doses of at least 5 mg/kg per day are used for mold infections, with some authors recommending even higher doses.[25–27] However, it was shown no advantage to using 10 mg/kg per day over 3 mg/kg per day for invasive aspergillosis and other invasive mold infections.[28]

All three LFABs appear active against the same range of fungal infections that can be treated with amphotericin B. The compounds do differ in their relative toxicities.[24] ABCD appears to have significant administration-related toxicity and is not often used. AmBisome and ABLC are both well tolerated, but AmBisome has been associated with somewhat less nephrotoxicity in some patient settings.[29] Some patients will tolerate one formulation better than another.[30,31]

Because of the cost of the LFABs, there has been great interest in the concept of making a pseudo-LFAB by suspending amphotericin B deoxycholate in commercially available lipid emulsions.[32–34] This practice does not, however, consistently reduce toxicity.[35] This may be due to preparation-dependent precipitation of the amphotericin B noted by some[36,37] but not all[38] authors. Most authorities have concluded that further work with this approach should be undertaken as part of a controlled clinical trial that addresses these issues.[39] A meta-analysis on the use of these formulations has been published, but because of heterogeneity, the results are inconclusive.[40]

The cost of the LFABs is significant, but the counterbalancing reduction in nephrotoxicity is also valuable and should be considered when choosing an LFAB versus a conventional amphotericin B.[41] A recent study of the impact of nephrotoxicity of amphotericin B deoxycholate in patients with invasive aspergillosis suggested that this patient population had significant morbidity owing to the amphotericin B itself.[42] Use of amphotericin B deoxycholate produces significant nephrotoxicity in about 30% of patients, increasing hospital length of stay and hospitalization costs by nearly $30,000.[43,44] Nevertheless, the context of amphotericin B–induced toxicity should also be considered. A rise of the creatinine to 3 mg/dL in an otherwise well patient who is being treated with amphotericin B for (say) osteoarticular sporotrichosis may be clinically imperceptible because the patient has no other acute medical problems. On the other hand, a rise in creatinine from 1 mg/dL to 2 mg/dL may be disastrous in a surgical patient who also has nosocomial pneumonia and cardiac insufficiency. No firm guidelines in this area have yet to emerge. We currently believe that an LFAB are the formulations of choice when available.

Flucytosine

Flucytosine (also known as 5-fluorocytosine [5-FC]) is the fluorine analog of cytosine.[45] It was originally synthesized as an antineoplastic agent, but poor antitumor activity and discovery of its antifungal properties led to its further development as an antifungal agent. It acts by deamination to 5-fluorouracil and then conversion to a noncompetitive inhibitor of thymidylate synthetase that interferes with fungal DNA and ribonucleic acid synthesis. It has been demonstrated to be effective in cryptococcosis, candidiasis, and chromomycosis. Drug resistance in vivo develops quickly, so the standard practice is to combine it with another agent.[46,47] 5-FC is water-soluble and has high bioavailability. Protein binding is negligible and approximately 90% is excreted in urine. CSF penetration is good, and both hemodialysis and peritoneal dialysis remove it. It is teratogenic in rats and therefore is contraindicated in pregnancy. Adverse effects include rash, diarrhea, and hepatic dysfunction. High blood levels (>100 μg/mL) are associated with profound leukopenia and thrombocytopenia.[48] This has prompted the recommendation of monitoring drug levels, renal/liver function, and blood counts in patients receiving 5-FC. Doses of 150 mg/kg per day divided in four doses have usually been suggested, but in vivo[49] and human experience[50] suggest that doses of 100 mg/kg per day (again, divided into four doses) may be as effective and better tolerated. Renal failure requires dose adjustment to half the dose if creatinine clearance (CrCl) is 25 to 50 mL/min and a quarter of dose if it falls below 25 mL/min. Patients receiving hemodialysis should be given the latter dose above after dialysis. Combination with amphotericin requires constant monitoring of toxicity parameters and dose adjustment. The target blood level is approximately 50 μg/mL. Most experts would discontinue use of this agent if blood counts start dropping, regardless of the blood levels. The use of 5-FC is currently limited as availability has become extremely limited in certain regions of the world.

The Azole Antifungal Agents

The introduction of this class of drugs was a major advance in antifungal therapy, because they offer both IV and oral (PO) formulations for the treatment of systemic mycosis. Their widespread use has also prompted the emergence of resistance. Azoles act by blocking the activity of lanosterol demethylase, a cytochrome enzyme in both fungal and mammalian cells. Fungal cell membrane synthesis of ergosterol is inhibited and other sterol intermediates are substituted in the membrane, resulting in a nonviable cell. This effect is much slower than that of amphotericin, so these drugs are generally regarded as fungistatic. Because these drugs reduce production of the ergosterol to which polyenes must bind to produce their effect, there is a potential for the azoles and polyenes to appear antagonistic. However, these effects are drug-, organism-, and model-dependent and a range of effects may be seen. This area is complex and has recently been reviewed.[51,52] All of the azoles have the ability to interfere with mammalian sterol synthesis. This was most notable with ketoconazole, which can produce gynecomastia and adrenal insufficiency.[53,54] Subsequent azoles have been selected for lack of such effects. All of the azoles can, however, produce hepatic dysfunction. The most common pattern is that of increased transaminases. However, any form of dysfunction may be seen. This can be life-threatening if not recognized. The hepatic dysfunction is usually reversible upon discontinuation of the offending azole.

Another concern with azoles is drug interactions. This becomes particularly important in the critical care setting where many drugs are being used concomitantly. Table 49.1 summarizes the most important drug interactions that have been reported. The critical interactions are generally related to drugs cleared by the liver. Some agents (e.g., rifampin and phenobarbital) induce the enzymes that clear the azoles. In other cases, the azole interferes with clearance of another agent (e.g., the azoles predictably increase blood levels of cyclosporine). It is not possible to list all of the known interactions. Consultation with a pharmacy specialist is suggested when using azoles in the setting of polypharmacy, particularly in the critical care setting and when caring for patients with multiple comorbidities.

Fluconazole

Fluconazole is a triazole with in vitro and in vivo activity mainly against yeast, such as *Candida* spp. and *C. neoformans*. It also has efficacy against *C. immitis*, *H. capsulatum, and B. dermatitidis.* Unfortunately, resistance (mediated by increased production of target enzymes, efflux pumps, and mutations in the target enzyme) has become a problem, particularly in *C. albicans* (mutation to resistance is seen), *C. glabrata* (has intrinsically lower susceptibility and may become highly resistant), and *krusei* (intrinsically highly resistant).[55,56] Nevertheless, fluconazole is still very active against most strains causing invasive candidiasis and higher doses can be used for organisms that have "dose-dependent susceptibility." Fluconazole is water-soluble and is available in oral and IV preparations that can achieve similar blood levels as it has excellent bioavailability and it is well absorbed regardless of the gastric contents. It has a long half-life and can be administered in a single daily dose. It exhibits little binding to serum proteins and is widely distributed in all body fluids. CSF penetration is particularly high, making it very useful in the treatment of CNS infections such as cryptococcosis and coccidioidomycosis. Fluconazole is excreted by the kidneys and dosing should be adjusted in proportion to the CrCl. The most common adverse effects are nausea and vomiting; skin rash is infrequent but can be severe and hepatitis has also been reported. The usual dose is 400 to 800 mg (or 6–8 mg/kg) per day PO or IV, but doses as high as 2 g/day have been tolerated.[57]

Itraconazole

Itraconazole is a triazole antifungal agent with a wider spectrum than fluconazole. It has in vitro and in vivo activity against *Candida*

TABLE 49.1 Selected Azole-Drug Interactions[a]

Azole Drug	Azole Alters Levels of:	Azole Levels Altered by:
Fluconazole	Cisapride Cyclosporine Diazepam Glipizide Glyburide Midazolam Phenytoin Rifabutin Sulfonylureas Tacrolimus Terfenadine Warfarins and coumarins Amitriptyline, nortriptyline Carbamazepine Celecoxib Fentanyl HMG-CoA reductase inhibitors Saquinavir Quinidine	Rifampin
Itraconazole	Astemizole Cisapride Cyclosporine Diazepam Digoxin Dihydropyridines Lovastatin Methylprednisolone Midazolam Phenytoin Quinidine Ritonavir Sulfonylureas Terfenadine Vinca alkaloids Warfarins and coumarins	Carbamazepine DDI H2-blockers Phenobarbital Phenytoin Proton pump inhibitors Rifabutin Rifampin Sucralfate Ritonavir
Voriconazole	Sirolimus Rifabutin Efavirenz Ritonavir Terfenadine Astemizole Cisapride Pimozide Quinidine Cyclosporine Methadone Tacrolimus Phenytoin Warfarin Omeprazole Fentanyl Oxycodone Oral contraceptives (containing ethinyl estradiol and norethindrone)	Rifampin Efavirenz Rifabutin Ritonavir Carbamazepine Phenytoin
Posaconazole	Sirolimus Tacrolimus Cyclosporine Pimozide Quinidine Simvastatin Ergot alkaloids Midazolam Ritonavir Atazanavir Vinca alkaloids Calcium channel blockers Digoxin Glipizide HMG-CoA Reductase inhibitors	Efavirenz Rifabutin Phenytoin Cimetidine Esomeprazole Metoclopramide
Isavuconazole	Bupropion Lopinavir/ritonavir Sirolimus Tacrolimus Cyclosporine Mycophenolate mofetil Digoxin Atorvastatin Midazolam Colchicine Dabigatran	Lopinavir/ritonavir Rifampin Carbamazepine Long-acting barbiturates St. John's wort

[a]Generally, azoles tend to increase the levels of other drugs, whereas other drugs tend to decrease the level of the azole. This list is not meant to be comprehensive and the prescriber should consult the full prescribing information. Consultation with a pharmacy specialist is recommended when azoles are to be used in complex polypharmacy situations.

spp., *Aspergillus* spp., *Histoplasma* spp., *B. dermatitidis, S. schenckii, Trichophyton* spp., *C. neoformans, C. immitis,* and *P. brasiliensis*.[58,59] The resistance issues observed for fluconazole are also an issue with itraconazole.[56] Itraconazole was initially available only in a capsule form with unpredictable bioavailability. Absorption of the capsule formulation is optimized by ingestion with food.[60] Two formulations were later introduced. First, there is the cyclodextrin solution formulation for oral administration that significantly enhances bioavailability and is now preferred over the capsule for producing maximal blood levels.[61] Second, an IV formulation (in a cyclodextrin carrier) was developed and it has been shown to quickly and reliably produce significant blood levels.[62–64] However, the IV formulation later became unavailable in the United States.[65] Itraconazole is highly protein-bound and has a prolonged half-life. CSF penetration is negligible, so it is not generally used for CNS infections. Itraconazole is metabolized by the liver and dosing does not need to be modified in renal failure. However, the cyclodextrin carrier used in the IV formulation is cleared by the kidneys and its behavior in patients with renal dysfunction is not known. Thus this formulation of itraconazole should not be used in patients with a CrCl below 25 mL/h. IV itraconazole was shown to cause transient decrease in cardiac contractility in experiments involving dogs and is contraindicated in patients with congestive heart failure.[65]

Adverse effects are mainly gastrointestinal, with nausea, vomiting, and abdominal pain occurring in up to 10% of patients. Hepatitis is uncommon but liver enzyme monitoring is recommended. Because

itraconazole and its major metabolite hydroxyitraconazole are inhibitors of cytochrome P450 3A4 (CYP 3A4), drug interactions are a major issue and the most common ones are summarized in Table 49.1.[65]

The usual oral dose is 100 to 400 mg/day and the oral solution formulation is now preferred. Giving the daily oral dose as two divided doses appears to maximize blood levels. IV dosing is 200 mg twice a day for 2 days and then 200 mg IV daily for a maximum of 14 days. Efficacy is plasma concentration-related and serum levels can be obtained from national reference laboratories. Such testing is warranted if oral itraconazole is being used to treat a serious fungal infection. Although minimal efficacious blood levels have not been defined, the point of testing is to ensure that at least some level is being obtained. Levels of at least 250 ng/mL are desirable.[61,65,66]

Voriconazole

Voriconazole is licensed for the treatment of invasive candidiasis and invasive aspergillosis, as well as for the treatment of *Fusarium* and *Scedosporium* infections. It is considered the treatment of choice for invasive aspergillosis.[67] Voriconazole was not inferior to amphotericin B followed by fluconazole in a large clinical trial, but it is unknown if it has any advantages over fluconazole or the echinocandins for treating infections by fluconazole-resistant *C. glabrata*.[68,69] Although it has activity against the endemic mycoses, data are limited at this point, so it is not recommended for routine use in these infections at this time.[70,71]

A relevant gap in its activity is for the Zygomycetes (such as *Mucor* spp., *Absidia* spp., and *Rhizopus* spp.). Moreover, there have been multiple reports of breakthrough Zygomycetes infections in patients receiving voriconazole prophylaxis or treatment, but a causal relationship has not been established.[72,73] Nevertheless, clinicians should be aware that this drug does not have activity against these organisms; thus it should not be used for empirical therapy of mold infections if Zygomycetes are in the differential diagnosis.

Voriconazole is available in oral (tablets and suspension) and IV formulations, with 96% bioavailability. The usual dosing is 4 to 6 mg/kg IV every 12 hours or 200 to 400 mg PO every 12 hours. Voriconazole has nonlinear pharmacokinetics; thus increasing the dose does not necessarily increase blood levels. Routine blood level measurement to document absorption is now recommended, although blood levels associated with specific efficacy and safety margins have not been established. In addition, voriconazole is metabolized by the human hepatic cytochrome P450 enzymes, CYP 2C19, CYP 2C9, and CYP 3A4, and has extensive drug interactions with many drugs commonly used in the critical care setting. Certain patients were identified as rapid metabolizers and others as slow metabolizers (15% of Asian descent), and proper levels monitoring is warranted.[66] Consultation with a pharmacy specialist is recommended for patients receiving multiple drugs. Like itraconazole, the IV formulation is prepared in a cyclodextrin-based formulation; thus it is not recommended for use in patients with CrCl below 50 mL/min. In contrast, in this patient population, the oral formulation may be safely used. Adverse events include self-limited visual disturbances and hallucinations (usually in higher levels >5.5 μg/mL), infrequent reports of hepatic insufficiency, skin photosensitivity, increased incidence of skin cancers with long term use,[74,75] painful periostitis,[76,77] and as with the other azoles, rare reports of arrhythmias and QT prolongation. Also to be kept in mind is that monitoring of liver enzymes is recommended during voriconazole therapy.[78–80] Trough levels above 0.5 μg/mL are recommended for prophylaxis, whereas levels below 1 to 2 μg/mL achieve therapeutic effect.[66]

Posaconazole

Posaconazole is a triazole licensed primarily for prophylaxis of fungal infections in high-risk patients,[81,82] and has promising activity against mold infections, particularly infections by the Zygomycetes and *Fusarium*.[83] It has also shown excellent in vitro and in vivo activity against *Candida* spp. with demonstrated efficacy in esophageal disease. Posaconazole has high protein binding (~99%). It is available in an oral formulation and recently in IV form.[84–86] A new formulation of tablets (delayed-release) has a better profile with regard to achieving steady-state levels at faster rates compared to the oral solution; it can be given without food and once daily in cases of antifungal prophylaxis.[86] Similar to other triazoles, posaconazole can lead to adverse effects such as elevated liver enzymes, gastrointestinal symptoms, and QT prolongation. There is no dose adjustment in renal failure except for the IV formulation (cyclodextrin-based formulation), which is not recommended to be given to patients with CrCl below 50 mL/min. The goal level of prophylaxis is above 0.7 mg/L with levels above 1 mg/L for therapy.[87]

Isavuconazole

Isavuconazonium sulfate is the most recent U.S. Food and Drug Administration (FDA)-approved triazole for the treatment of invasive aspergillosis and mucormycosis. Isavuconazonium sulfate is the prodrug for isavuconazole; we refer to it by the latter. Isavuconazole acts by inhibiting CYP 450–dependent enzyme lanosterol 14-α-demethylase and leads to the accumulation of methylated sterol precursors and depletion of ergosterol from the fungal cell wall.[88]

Isavuconazole comes in oral and IV formulations. Both have excellent tissue distribution; however, they are 99% bound to serum proteins, mainly albumin. The oral formulation has great bioavailability (98%). No dosage adjustment is needed in patients with renal or hepatic dysfunction.

Isavuconazole has been shown to affect L-type calcium (Ca^{++}) cardiac channels, and in contrast to other triazoles, it has been shown to cause QT shortening. Although no serious arrhythmogenic effect has been linked to QT interval shortening, it is advisable to avoid isavuconazole in cases of a familial short QT period.[89–91] In a noninferiority trial comparing voriconazole to isavuconazole in immunocompromised patients with invasive aspergillosis (IA), isavuconazole was shown to be as effective as voriconazole with lower rates of adverse events (elevated hepatic enzymes, visual disturbance, and skin reactions).[90] In a limited study, isavuconazole was also shown to be effective in patients with mucormycosis who could not tolerate primary amphotericin B–based therapy or in those in whom such therapy failed when compared to historical controls.[91] Isavuconazole dosage is 372 mg IV or PO every 8 hours for 2 days (loading dose) and then daily.

Echinocandins

The echinocandin antifungal agents represent an entirely new class of antifungal drugs. There are three echinocandins on the market at this time: caspofungin, micafungin, and anidulafungin. These agents are cyclic lipohexapeptides that act via inhibition of glucan synthesis.[92] Preclinical studies have shown efficacy against all species of *Candida*, *Aspergillus* spp., and selected other fungi.[93,94] Although the target enzyme is present in most fungi, the echinocandins are not active against *C. neoformans* and molds other than *Aspergillus*.

The echinocandins appear to be rapidly fungicidal for *Candida* spp., but their activity against *Aspergillus* may be better described as fungistatic.[95] Nonetheless, they are quite active in animal models of both candidiasis and aspergillosis.[96,97] The drugs have a long half-life, permitting once-daily dosing, and are excreted in the liver. They do not interfere with the cytochrome system and are not known to be nephrotoxic, having otherwise remarkable safety profiles. At this time, differences between the three drugs appear to be subtle, requiring further study. Echinocandins are found to have better survival benefit in patients with invasive candidiasis and they should be considered as the first-line therapy for this disease.[98,99]

Caspofungin

Caspofungin was the first candin in the market. It has excellent in vitro and in vivo activity against *Aspergillus* and *Candida* spp. It has demonstrated efficacy for the treatment of invasive candidiasis, invasive aspergillosis, and empirical therapy of fungal infections in the setting of febrile neutropenia.[100–102] The usual dosing includes loading with 70 mg IV, followed by 50 mg IV every 24 hours. The safety profile is good with mild elevation of liver enzymes. Patients with hepatic insufficiency (Child-Pugh class B or C) require dosage adjustment to 35 mg/kg IV every 24 hours.[71,103,104] Drug interactions are infrequent, but monitoring cyclosporine levels in patients receiving caspofungin is recommended.[105] In a clinical trial, higher doses of caspofungin (100 mg/day) are well tolerated but do not necessarily translate into additional clinical benefits.[106]

Micafungin

Micafungin is approved by the FDA for the treatment of esophageal candidiasis, prophylaxis of *Candida* infections in stem cell transplant patients, and treatment of candidemia. Although micafungin has excellent in vitro and in vivo activity against *Aspergillus* and *Candida* spp., clinical data on invasive aspergillosis is limited.[107–109] Micafungin has demonstrated efficacy both for the treatment of invasive candidiasis and as a prophylactic agent for fungal infections in allogeneic stem cell transplant recipients.[109–111] The prophylactic dose is 50 mg IV every 24 hours, and the therapeutic dose for invasive candidiasis is 100 IV every 24 hours. As with the other echinocandins, the most frequent adverse event is mild elevation of liver enzymes. No dosage adjustment is required in the setting of renal insufficiency or moderate hepatic insufficiency. The European package insert for this drug mentions an increased incidence in hepatic tumors in animals with very prolonged high-dose exposure.[112] This finding has not been observed in humans. Mild drug interactions have been reported with concomitant use of sirolimus and nifedipine.

Anidulafungin

As with the other candins, anidulafungin has excellent in vitro and in vivo activity against *Aspergillus* and *Candida* spp.[113] It is currently indicated for the treatment of invasive candidiasis, having demonstrated noninferiority, and perhaps superiority, in a clinical trial versus fluconazole.[114] The usual dosing includes a loading dose of 200 mg IV followed by 100 mg IV every 24 hours. Anidulafungin does not require dosage adjustment for patients with renal or hepatic failure and no significant drug interactions are reported.[113,115,116]

Specific Indications and Uses for Antifungals

Although the precise diagnosis of a fungal infection may be laborious, time-consuming, and delayed, therapy should never be withheld in a critically ill patient with suspected or confirmed fungal infection. Empirical therapy is often started with an echinocandin or amphotericin B (typically one of its lipid preparations) and then tailored according to the final identification of the organism. This section presents generally accepted treatment recommendations for the most commonly encountered fungal infections in the critical care setting. Infections by less common fungi may be particularly severe and rapidly progressive and require consultation with an infectious diseases specialist for appropriate treatment. Table 49.2 summarizes the most often encountered fungal diseases in the critical care setting with their generally accepted treatment options. Fig. 49.1 presents our approach for the critically ill patient with fungemia.

Candida Infections

Although *C. albicans* remains the most common pathogen in oropharyngeal and cutaneous candidiasis, non-*albicans* species of *Candida* are increasingly frequent causes of invasive candidiasis.[117] Guidelines and reviews for therapy of candidiasis in the intensive care setting have recently been published.[99] These guidelines are extensive and are not repeated in detail. Rather, the text focuses on several clinical situations in which candidal infections are particularly challenging for the critical care specialist.

Candidemia and Disseminated Candidiasis

The diagnosis of disseminated candidiasis is always a challenge.[118] There is no single tool that conclusively makes this diagnosis. Isolation of *Candida* from the bloodstream is simply the most obvious form of disseminated candidiasis, but clinical experience makes it obvious that disseminated candidiasis can occur in the absence of detectable fungemia.

Candidemia may be treated initially with echinocandins, fluconazole, voriconazole, or amphotericin B (or its lipid preparations). In the critically ill and unstable patient, echinocandins are preferred because of their broader spectrum of activity and more rapid onset of action.[119,120] Both the anidulafungin study and recent patient-level meta-analysis of the candidemia clinical trials suggest that initial therapy with echinocandins may be superior to initial therapy with azoles.[98,114]

The susceptibility of *Candida* to the currently available antifungal agents can generally be predicted if the species of the infecting isolate is known.[10,12,117,121–129] Bloodstream isolates of *C. albicans*, *C. tropicalis*, and *C. parapsilosis* are generally susceptible to fluconazole and amphotericin B. Isolates of *C. glabrata* and *C. krusei* are often (if not always, as is the case with *C. krusei*) resistant to fluconazole. Isolates of *C. lusitaniae* may be resistant to amphotericin B. Antifungal susceptibility testing is becoming increasingly important as a guide in the treatment of these infections.[130] In particular, detection of fluconazole resistance is very valuable, as it provides support for continued use of candins or polyenes. An emergent pathogen in intensive care units (ICUs) throughout the world, *C. auris*, may exhibit multidrug resistance, including nonsusceptibility to azoles, echinocandins, and amphotericin B.[131,132]

Although all *Candida* spp. are generally considered to be susceptible to echinocandins, *C. parapsilosis* has higher minimal inhibitory concentrations than the other *Candida* spp. This, however, has not translated into reduced activity in clinical trials.[100,133] Once the organism is identified, or if the prevalence of more resistant species is low, therapy may be switched to fluconazole 5 to 7 days after initiation of an echinocandin. Fluconazole has been demonstrated to be as effective as amphotericin B in clearing candidemia in immunocompetent hosts. The duration of treatment is 14 days after the last positive culture,[21] and if a central line is present removal is highly recommended.[98] Patients with candidemia are at risk of developing *Candida* endophthalmitis (1%–5%)[134,135]; thus performing

TABLE 49.2 Summary of Therapeutic Choices for Fungal Diseases Most Commonly Encountered in the Critical Care Setting

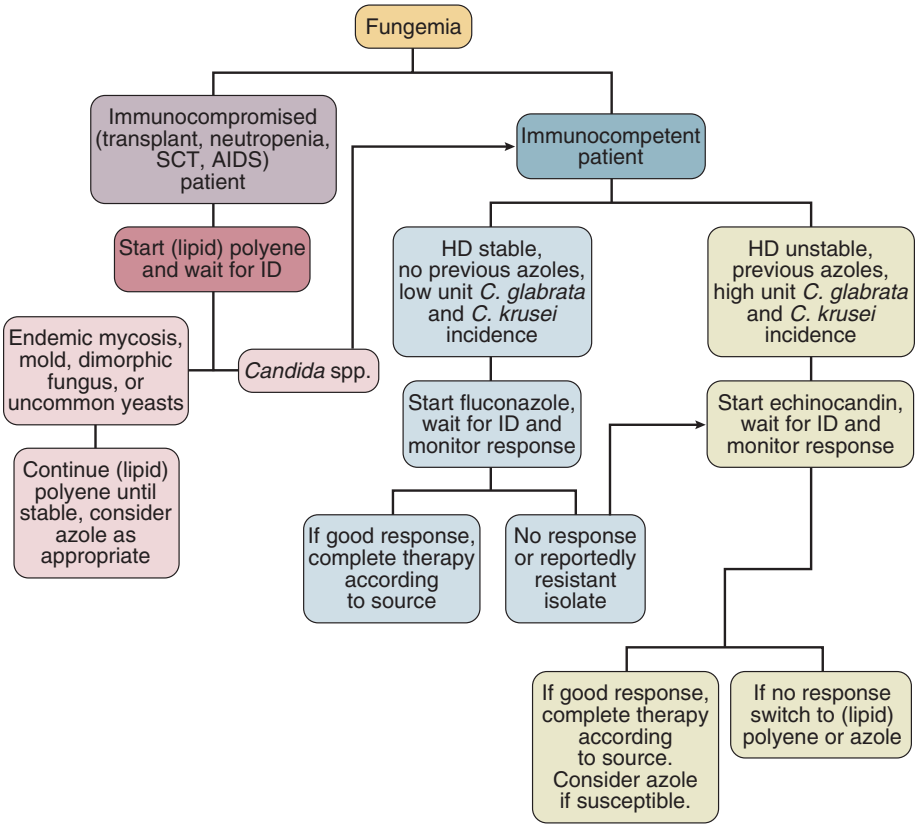
Fungal Disease	Therapy of Choice	Alternative Therapy	Duration of Treatment	Comments
Candidiasis				
Oral candidiasis	Fluconazole 200 mg single dose or 100 mg PO per day	Nystatin 200,000-U lozenges qid or 500,000-U swish and swallow qid	7–14 days	
Mucosal nonoral candidiasis	Fluconazole 200 mg first dose and continue 100 mg/day		7–14 days	
Candidemia and most forms of disseminated candidiasis	Caspofungin 50 mg/day (loading dose with 70 mg on day one); anidulafungin 100 mg/day (loading dose with 200 mg on day one); or micafungin 100 mg/day; fluconazole 400 mg qd, voriconazole 4–6 mg/kg/q12 hr, amphotericin B 0.5–0.6 mg/kg per day, lipid preparation of amphotericin B 3 mg/kg per day,		14 days after bloodstream clearance for uncomplicated candidemia; until resolution of sites of infection if disseminated	Central line removal is recommended. Assess for dissemination. An echocandin or lipid amphotericin B is usually preferred as initial therapy if the patient is unstable or infected with a non–*albicans* species. Loading doses recommended for caspofungin and anidulafungin
Urinary candidiasis	Fluconazole 200 mg first day and then 100 mg/day or amphotericin B 0.3 mg/kg IV single dose	Amphotericin B bladder washes, 50 mL/1000 mL H_2O in continuous irrigation for 2 days	7–14 days	Asymptomatic funguria does not require treatment. However it may be a sign of dissemination in immunocompromised hosts. Urinary catheter removal is very useful
Peritonitis	As for disseminated candidiasis			Removal of dialysis catheter is helpful. Surgical debridement if abscess present
Aspergillosis	Voriconazole 4–6 mg/kg per q12h (loading dose with 6 mg/kg IV q12hrs for 2 doses) Isavuconazole 372 mg daily (loading dose with 372 q8hrs for 6 doses)	Lipid preparation of amphotericin B 3 mg/kg per day	Until resolution of the clinical process and of any associated immunosuppression	May require surgical treatment. Isavuconazole and voriconazole can be administered orally or intravenously.
Histoplasmosis	Amphotericin B 0.5–1 mg/kg per day or liposomal amphotericin B 5 mg/kg per day	Itraconazole 200–400 mg/day 200 mg TID for 3 days then 200 mg BID	3–12 months	Lifelong suppression needed in HIV-infected patients
Cryptococcosis (in HIV-infected patients)	Amphotericin B 0.5–0.7 mg/kg per day or lipid preparation of amphotericin B 3–5 mg/kg per day + 5-FC induction 25 mg/kg q6h, fluconazole 400 mg per day during consolidation period	Induction with fluconazole 400 mg/day in stable patients	Managed very differently in HIV-infected (lifelong therapy needed) and uninfected patients (cure is possible). Expert consultation advised.	Consider frequent LP to relieve intracranial pressure. V-P shunts may be necessary.
Zygomycosis	Amphotericin B 0.8–1.5 mg/kg per day or lipid preparation of amphotericin B 5 mg/kg IV per day + surgical debridement + metabolic control	Isavuconazole or consider polyene + caspofungin. Limited experience with posaconazole		Surgical debridement is critical

5-FC, Flucytosine; *HIV,* human immunodeficiency virus; *LP,* lumbar puncture; *V-P,* ventriculoperitoneal.

a dilated eye examination is necessary to avoid catastrophic sequelae. Cases of proven *Candida* endophthalmitis should be evaluated and managed by an ophthalmologist, and systemic and topical antifungal therapy should be considered for a duration of 4 to 6 weeks. If evidence of disseminated candidiasis is found, therapy should be prolonged to at least 4 weeks to ensure proper organ clearance.[99]

The Intravenous Catheter in Patients With Candidemia

Although long an area of contention, current data strongly suggest that candidemia is often related to (if not primarily propagated by) a central venous catheter. Central venous catheters in particular



• **Fig. 49.1** Treating the critically ill patient with fungemia. *AIDS,* Acquired immunodeficiency syndrome; *HD,* hemodynamically; *ID,* identification to species level; *SCT,* stem cell transplant. (Modified from Ostrosky-Zeichner L, Pappas PG. Invasive candidiasis in the intensive care unit. *Crit Care Med.* 2006;34: 857–863.)

have been found to be both risk factors for developing candidemia[136–139] and associated with persistent fungemia.[137] Removal of the catheter has been associated with shorter duration of subsequent candidemia[140] and improved patient outcomes.[98,141,142] Unique to the species of *Candida*, candidemia with *C. parapsilosis* is almost always due to a catheter.[143,144] The situation may be different for neutropenic patients, particularly those who have permanent, lower-risk catheters such as Hickman catheters. Such catheters may of course become infected, but these patients may also have candidemia owing to gut translocation. This concept is supported by demonstrations that *Candida* can enter the bloodstream from the gut,[145] by the relative lack of effect of catheter removal in a large cohort of cancer patients,[143] and by the frequent demonstration of gut wall invasion in patients who die with disseminated candidiasis.[146,147] Unfortunately, there is no convincing way to tell if a given catheter is involved. Differential quantitative blood cultures through the line and from a peripheral site have been suggested to be one approach to resolving this problem,[148] but this technique remains controversial.[149] On a practical basis, lines should be removed if possible, and serious consideration of line removal should be given if fungemia persists for more than a few days. A recent patient level meta-analysis of the major candidemia clinical trials has confirmed a mortality and microbiologic cure benefit for this approach.[98]

Mucosal Infections and Colonization

Although there are many risk factors for development of disseminated candidiasis, colonization at one or more nonsterile sites represents an unusually strong risk factor.[150] As discussed earlier, local oral and mucosal candidiasis should thus be considered as a predictor of possible invasive disease in the critically ill or immunocompromised host.[151,152] Esophageal candidiasis does require systemic treatment. Fluconazole is generally preferred here, although amphotericin B and the echinocandins can also be used.

Candiduria

Treatment of asymptomatic candiduria produces only temporary clearing of the urine and is probably not indicated.[22,23] However, candiduria should probably be treated in symptomatic patients, immunocompromised patients, low–birth-weight infants, renal transplant patients, and patients undergoing urologic manipulation or surgery.[99] If treatment is indicated, systemic therapy with amphotericin or fluconazole is preferred and amphotericin bladder washes should be reserved for patients with renal insufficiency and low renal clearance. Removal of the urinary catheter is by itself a useful intervention and should always be considered.

Other Forms of Invasive Candidiasis

There are many other possible forms of invasive candidiasis: meningitis, endocarditis, and osteomyelitis, just to name a few. This area has recently been reviewed[99] and for most forms of this disease there are very few specific data regarding therapy. The largest body of data will always be anecdotal reports of use of amphotericin B, and for essentially every form there are at least a few reports of successful therapy with fluconazole. In general, LFABs are preferred when the infection is most acute, when data

on the nature of the infection are still being generated in the laboratory, or when the patient has previously received azole therapy. Fluconazole provides a good way to step down to an oral agent to complete therapy of infections caused by susceptible isolates. Data for the echinocandins are starting to accumulate for these chronic infections.[153] Removal of foreign body and surgical drainage are often key as well. An excellent example of the need to remove foreign bodies is found in treatment of dialysis catheter–related peritoneal candidiasis in which catheter removal is important. Surgical drainage is of course important in candidal peritonitis related to gut injury and fecal spillage.

Cryptococcosis

Treatment of cryptococcosis has previously been reviewed.[154,155] Cryptococcal meningitis in non–human immunodeficiency virus (HIV)-infected adults continues to be seen sporadically. The majority of the published experience on treatment is with amphotericin B given for 4 to 6 weeks.[156,157] This therapy is curative in approximately two-thirds of patients; thus this approach is warranted. Expert consultation is also appropriate for this relatively uncommon infection.[158,159]

On the other hand, cryptococcal meningitis in the HIV-infected patient is a well-established and common problem. Meningeal cryptococcosis in this setting should be treated with a 2-week course of IV amphotericin or its lipid preparations,[155,160,161] followed by suppression with fluconazole until CD4 cells recover.[162,163] Current trends favor also using 5-FC unless there is a contraindication to same.[50] High-dose fluconazole (up to 1200 mg/day) combined with 5-FC has shown to be effective in cryptococcal meningitis in HIV patients when amphotericin B is not available or not tolerated.[164] Although itraconazole does not penetrate the CSF, anecdotal evidence reported that it may be useful in treating CNS disease; however, it is apparently less potent as a long-term therapy.[165]

For all forms of cryptococcal meningitis, intracranial hypertension should be aggressively treated with repeated lumbar punctures or a CSF shunt.[166,167] The addition of steroids and other immune-modulating agents to antifungal therapy has shown promising results in animal models[168] and clinical trials are being conducted. The immune reconstitution syndrome plays a major role in cryptococcal-related morbidity in HIV patients and the current recommendation is to delay antiretroviral therapy for a few weeks after treatment for cryptococcosis is started.[155]

Aspergillosis

Treatment of aspergillosis has been extensively reviewed.[169–171] Invasive aspergillosis should be considered in any severely immunocompromised patient with an unexplained pulmonary or sinonasal process. Biopsy is normally required for definitive diagnosis, although a new generation of galactomannan-based serodiagnostic tests may prove useful as adjuncts to diagnosis.[172,173] Although amphotericin B has classically been the initial treatment of choice for invasive aspergillosis, the current treatment of choice is voriconazole,[67,80] isavuconazole,[90] or a lipid preparation of amphotericin B.[170] Aggressive surgical management is necessary and curative in some cases.[118,174] Itraconazole is also approved for the treatment of aspergillosis in patients who are intolerant or refractory to amphotericin B.[175] Overall, the outlook for invasive aspergillosis is critically dependent on recovery of immune function. Without this, the prognosis is usually dismal. Of note, recent studies have documented an increase in the incidence of invasive aspergillosis in nonhematology, nontransplant patients seen in the ICU such as chronic obstructive pulmonary disease and autoimmune diseases,[176,177] and in hospitalized ICU patients with influenza.[178] This trend should be monitored and the critical care specialist should be suspicious when cultures *Aspergillus* from a bronchoalveolar lavage or diagnostic markers such as galactomannan are positive.[179]

Histoplasmosis

The initial treatment of choice for severe acute histoplasmosis is an amphotericin B preparation.[180,181] Noncritical cases may be treated with itraconazole 200 to 400 mg/day. Fluconazole is only moderately effective and should not be used as primary therapy.[182] Successful treatment results in a decrease of serum and urine *Histoplasma* antigen.[183] The duration of therapy is a function of disease form and underlying immune status. HIV-infected patients with disseminated disease should be treated as acute histoplasmosis and maintained with lifelong suppression with itraconazole. Liposomal amphotericin B has shown excellent efficacy in this setting.[184] Non–HIV-infected patients may require from 3 to 12 months of therapy, and expert consultation is generally advised.

Mucormycosis

The treatment of choice for mucormycosis (infections typically caused by *Mucor* spp., *Rhizopus* spp., and *Absidia* spp.) is aggressive surgical debridement and prompt start of high-dose amphotericin B or a lipid preparation.[185] Follow-up therapy with active triazole therapy may be warranted, and expert consultation is advised. Isavuconazole has been recently approved for mucormycosis therapy for patients unable to tolerate amphotericin B therapy or those in whom such therapy has failed.[91] Posaconazole has also shown efficacy in this setting.[85] Meanwhile, despite the in vitro lack of activity of echinocandins against these agents, investigators have shown in vitro synergy and excellent clinical outcomes with the combination of amphotericin B and caspofungin.[186] Correction of metabolic abnormalities (acidosis, iron overload, and hyperglycemia) should also be pursued aggressively.

Other Fungal Infections

Other fungal infections, such as blastomycosis, fusariosis, and infections by *Trichosporon* spp., *C. immitis, Malassezia furfur,* and *Penicillium* spp., may be occasionally encountered in the critical care setting, particularly when caring for immunocompromised hosts. Although amphotericin B or an LFAB is probably the best empirical drug for any uncharacterized suspected fungal infection, it is not very effective against some of these pathogens. Guidelines for treating some of these infections have recently been published.[1] Expert consultation should be promptly obtained.

Areas of Controversy in Antifungal Therapy

Empirical Antifungal Therapy for the Febrile ICU Patient

Fever in the ICU patient is a complex problem that requires prompt evaluation for many possible sources, including infection, atelectasis, pulmonary embolism, drug fever, thermoregulatory dysfunction, and many more.[187] Infection by *Candida* should be suspected when the patient has risk factors such as immunocompromised,

broad-spectrum antibiotic therapy, central venous line, mechanical ventilation, parenteral nutrition, steroids, surgery (especially if the gut wall is compromised), urinary catheters, and burns.[188–191]

Unfortunately, making a diagnosis of invasive candidiasis is difficult. In the most straightforward scenario, the patient is febrile and has positive blood cultures for *Candida*. On other occasions, biopsy or aspiration is used to make a clear-cut diagnosis of a localized abscess caused by *Candida*. These situations are, however, the exception. Far more common is the scenario of a persistently febrile ICU patient with a combination of the above-mentioned risk factors. The presence of *Candida* colonization in different nonsterile body parts has been implemented in some ICU risk assessment scoring systems.[192,193] Positive cultures from the urine are also considered in this context (even though that is normally a sterile site). Candiduria in the afebrile patient is generally a clinical non-event that does not require therapy,[22,23] but candiduria in the febrile ICU patient at the very least represents colonization and increased risk of invasive disease and at the worse represents actual upper urinary tract infection. A similar logic applies to *Candida* in the sputum. Pneumonia caused by *Candida* occurs but is generally clinically inapparent.[194] The presence of *Candida* in the sputum more often originates from the gut, and thus the patient is colonized. This, in turn, is a risk factor as discussed earlier. Such a risk factor was devised as part of a scoring system, the Candida colonization index, which requires culturing several nonsterile sites to calculate. However, its benefits are controversial.[191,195]

It has been shown that the delay in starting appropriate antifungal therapy in ICU patients with invasive candidiasis is associated with increased mortality.[196] Infectious Diseases Society of America guidelines recommend empirical antifungal therapy in critically ill patients who are deemed to be high risk for the infection based on a variety of recently available risk scoring assessment strategies and scores.[99,191,197,198] However, there is a multicenter study with negative results that failed to show a benefit to fluconazole in this setting.[199]

Antifungal Prophylaxis in the ICU

Prevention is always preferred to therapy, and this is certainly true for invasive candidiasis. Although prevention of mucosal disease can be achieved with almost any regimen, prevention of invasive disease has consistently required systemic therapy. Both fluconazole and amphotericin B are effective in the right setting. The key is to select patient populations with a meaningful chance of contracting invasive candidiasis. The value of prophylaxis has been shown convincingly for bone marrow transplantation patients[200,201] and selected liver transplant patients.[202–205] Studies of patients receiving standard chemotherapy for leukemia have shown a trend favoring prophylaxis,[206,207] but the lower rates of disease in the control group reduced the statistical power of the studies. To further confuse matters, even a group that sounds homogeneous (e.g., allogeneic bone marrow transplant recipients) really is not—different forms of chemotherapy and degrees of graft-versus-host disease produce different levels of risk. This point was driven home in an editorial emphasizing the range of variation within the category of "neutropenic patient."[208]

In practical terms, multiple studies have demonstrated benefits to prophylaxis of invasive candidiasis in the ICU. [209–212] Although survival benefit is shown in one meta-analysis in surgical ICU patients,[213] most studies and meta-analyses have shown no benefits in terms of mortality.[214–218] Most experts would agree with the fact that routine use of antifungal prophylaxis should be reserved for units with a high incidence of invasive candidiasis (>5%–10%) or for carefully selected patients at the highest risk.[99,219]

Measurement of Drug Levels

Drug level monitoring is theoretically justified to ensure efficacy and avoid toxicity. However, drug level monitoring during antifungal therapy is relatively new and should not be carried out routinely because there is a lack of information on its clinical correlation and meaning. Situations in which drug level monitoring has proven useful are itraconazole levels to verify adequate absorption when using the oral forms of this compound, 5-FC levels to watch for possible myelotoxicity, and voriconazole/posaconazole levels to document absorption of the drugs when given orally.[220–222]

Susceptibility Testing

The Clinical Laboratory Standards Institute has published a guideline for standardized antifungal susceptibility testing that has been widely adopted[223] and subsequently revised. This methodology is recommended for testing *Candida* and *Cryptococcus* spp., and breakpoints as well as epidemiologic cutoff values have been developed.[224] Antifungal susceptibility testing is now widely available and should be considered when treating serious *Candida* infections, when treatment failure occurs, or when toxicity or side effects limit the use of a particular drug. It should also be remembered that pharmacology, safety, published experience, and drug interactions must be considered along with susceptibility when selecting a therapy.[99] Mold susceptibility has also been standardized, but is not routinely recommended.

Antiviral Agents

Antiviral chemotherapy has made great advances in the past two decades. Before then a diagnosis of a life-threatening viral infection meant mostly supportive therapy and patience. Although still limited, today we have a host of several treatment options for herpetic infections; upper and lower respiratory tract illness by influenza, cytomegalovirus (CMV), and respiratory syncytial virus (RSV); and some relatively exotic systemic diseases. Therapy for HIV, hepatitis B, and hepatitis C infection has also made gigantic leaps, but it is usually not undertaken in the critical care setting and is therefore beyond the scope of this chapter. Table 49.3 summarizes the currently available non–HIV-specific antiviral drugs and their general spectrum.

Acyclovir, Famciclovir, and Valacyclovir

Acyclovir is a nucleoside analog of guanine that has in vitro and in vivo activity against several viruses in the herpes virus family, particularly against herpes simplex virus type 1 (HSV-1), HSV-2, varicella-zoster virus (VZV), and Epstein-Barr virus. High concentrations also inhibit CMV. It inhibits DNA polymerase, causing DNA chain termination.[225–227] Acyclovir is the treatment of choice for severe herpetic infections in immunocompetent and immunocompromised host. Resistance owing to viral thymidine kinase mutations or, less often, DNA polymerase mutations, may emerge in severely immunocompromised patients such as transplant recipients and those with advanced HIV infection during treatment of HSV and VZV infections.[228–230] Acyclovir has also been used for CMV prophylaxis in transplant patients.[231,232] Acyclovir is

TABLE 49.3 Spectrum of Antiviral Agents

Susceptible Virus	Acyclovir/Valacyclovir/ Famciclovir	Ganciclovir/ Valganciclovir	Foscarnet	Cidofovir	Amantadine/ Rimantadine	Ribavirin	Oseltamivir/Zanamivir/ Peramivir
HSV-1	++[a]	++	++	++	0	0	0
HSV-2	++[a]	++	++	++	0	0	0
VZV	++[a]	++	++	++	0	0	0
CMV	±[a]	++[a]	++	++	0	0	0
EBV	+	++	++	++	0	0	0
Influenza A	0	0	0	0	++[a]	+	++[a]
Influenza B	0	0	0	0	0	+	++[a]

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *VZV,* varicella-zoster virus.
Notes: 0, no known activity; ±, active under specific circumstances; +, active; ++, very active.
[a]Resistant strains reported.

available in oral, IV, and topical forms. Bioavailability of the oral form is poor (15%–21%), thus the requirement of high/frequent doses. Protein binding is less than 20%. CSF penetration is low, but acyclovir is active for CNS infections. The topical form is virtually unabsorbed. The half-life is short and the drug is cleared by the kidneys, so dosage adjustment in renal failure and hemodialysis is required. Supplementation is not needed in peritoneal dialysis. Side effects are uncommon.[233] The main concern with acyclovir therapy is the crystallization of the drug in the renal tubules, leading to renal failure, which fortunately is reversible. Aggressive hydration and monitoring of renal function are recommended during IV acyclovir therapy. Oral acyclovir may cause nausea and vomiting. The usual oral dose is 200 to 800 mg q4h. The IV dosing range for severe infections is 8 to 12 mg/kg IV every 8 hours. Proven encephalitis is treated with 10 to 12 mg/kg every 8 hours for 14 to 21 days. Doses of up to 20 mg/kg may be more effective in premature infants.[234]

Famciclovir, the prodrug of penciclovir (a guanosine analog),[235,236] is a well-absorbed oral agent that has shown excellent activity against first-episode or recurrent genital herpes and HSV/VZV infection in both HIV and immunocompetent hosts.[237–239] A dose of 500 mg PO three times a day was shown to be as effective as acyclovir for treatment of herpes zoster.[240]

Valacyclovir, an analog of acyclovir with a similar profile of side effects, is available in oral formulations with the advantage of longer dosing intervals. It appears comparable to acyclovir for treatment of mucocutaneous HSV infections, but it is more effective in herpes zoster. It is also effective orally for prophylaxis of CMV in renal transplant patients.[241] The dosing range is 500 to 1000 mg PO two to three times a day.[242–245] Although absorption is excellent, there are few data to support treating invasive disease, such as CNS disease, with this drug. It is currently the drug of choice to treat patients who can be treated with oral regimens.

Ganciclovir and Valganciclovir

Ganciclovir is another nucleoside analog of guanine with a slightly wider antiviral spectrum than acyclovir. It is highly active against CMV, as well as HSV-1, HSV-2, and Epstein-Barr virus. Like acyclovir it acts by interference with DNA polymerase, but it is not an obligate chain terminator. Resistance to ganciclovir by CMV and HSV is increasingly reported. HSV isolates that are thymidine kinase–deficient and thus resistant to acyclovir will be also resistant to ganciclovir.[229,245] It is mainly indicated in prophylaxis, treatment, and suppression of CMV syndromes in immunocompromised patients.[232,246–250] Ganciclovir is available in oral, intraocular, and IV forms; the first two are useful in chronic suppression of CMV disease. Once ganciclovir reaches the bloodstream it has body-wide distribution, low protein binding, and low CNS penetration. Excretion is renal and dosage adjustment is required in renal failure. Ganciclovir is removed by hemodialysis; therefore it should be administered after dialysis. Side effects of IV ganciclovir include severe neutropenia (40%), thrombocytopenia (20%), phlebitis, rash, increased liver enzymes, and azotemia. The nephrotoxicity is potentiated by concomitant use of nephrotoxic agents and acyclovir. Ganciclovir should not be used in pregnant women because it is known to be teratogenic. The usual dose in acute infection is 5 mg/kg every 12 hours. Maintenance therapy at 5 mg/kg IV daily should be continued as long as the patient is immunocompromised. Discontinuation of therapy in AIDS patients appears feasible after immune reconstitution.[232,246,251,252] An intraocular delivery system is also available as an adjunct to the treatment of CMV retinitis.

Valganciclovir is an L-valyl ester of ganciclovir with significantly increased bioavailability over previous oral formulations of ganciclovir, resulting in levels previously unattainable with the traditional formulations. It allows for prophylaxis and treatment of CMV infections with an oral alternative. The usual dose for prophylaxis is 900 mg PO every 24 hours, and for treatment the recommended induction dose is 900 mg PO every 12 hours, followed by a maintenance dose of 900 mg PO every 24 hours. This drug requires adjustment for patients with renal impairment.[253,254]

Cidofovir

Cidofovir is a nucleotide analog with activity against most herpesviruses. Its activation is not virus enzyme–dependent, and thus it has activity against most acyclovir-resistant HSV and ganciclovir-resistant CMV. Resistant strains have also been reported and synergy with ganciclovir and foscarnet has been reported. Oral bioavailability

is very low. It is 6% protein bound and is excreted by the kidneys.[255,256] Its side effects include neutropenia and nephrotoxicity, which can manifest as proteinuria, azotemia, and a Fanconi-like renal syndrome. It has been shown to be teratogenic and mutagenic and is contraindicated in pregnancy. It is currently licensed for CMV retinitis in HIV but has also shown activity against acyclovir-resistant HSV.[257,258] The usual dose is 5 mg/kg every week for 2 weeks, then 5 mg/kg every other week.

Foscarnet

Foscarnet is a pyrophosphate analog with antiviral activity against the herpesviruses, HIV, and hepatitis B virus. Its mechanism of action is interference with DNA polymerase or reverse transcriptase to block effective viral replication. Viral isolates that are resistant to ganciclovir or acyclovir are often susceptible to foscarnet, but primary resistance to foscarnet has also been described, particularly in HIV-infected patients.[228,230,259–261] The main therapeutic indication of foscarnet is ganciclovir-resistant CMV disease. Foscarnet is only available in IV formulations and has body-wide distribution. Protein binding is 15% and it has good CNS and retinal penetration. The drug is excreted almost intact by the kidneys and requires very careful dosage adjustment in renal failure. Foscarnet is removed by hemodialysis but should be avoided in patients with severe renal dysfunction. Its main side effect is nephrotoxicity, which occurs in most patients but is reversible when therapy is stopped.[262,263] Dosage adjustment should be made by following the creatinine clearance closely. Hypocalcemia and hypercalcemia as well as phosphate abnormalities are common, so monitoring of electrolytes is also recommended. The usual dose is 60 mg/kg every 8 hours for CMV infections and 40 mg/kg every 8 hours for treating acyclovir-resistant HSV infections.

Amantadine and Rimantadine

Amantadine is a tricyclic amine inhibitor of influenza A virus. Its mechanism of action involves inhibition of the transmembrane domain of the viral M2 protein, thus preventing viral uncoating during early stages of replication. It has activity against influenza A but no clinical activity against influenza B.[264–267] Resistant strains can be developed in vitro and are also seen in household and nursing home contacts exposed to persons treated for acute influenza. It is indicated in influenza A prophylaxis and treatment and also for management of Parkinson disease and drug-induced extrapyramidal reactions. It is well absorbed orally and has body-wide distribution. It is 67% bound to plasma proteins and excreted unchanged in the urine by glomerular filtration and tubular secretion. The usual adult dosage for both prophylaxis and treatment is 100 mg twice a day. The dosage must be reduced in elderly patients and patients with renal insufficiency. In individuals 65 years of age or older, the dose should be reduced to 100 mg every day. The dose for a CrCl less than 10 mL/min is 200 mg/week. The most common adverse events are related to the CNS and correlate directly with high levels. Patients may present with confusion, seizures, hallucinations, and coma. Amantadine also causes gastrointestinal upset.

Rimantadine is another tricyclic amine with similar properties, spectrum, and indications as amantadine.[268,269] The main difference lies in its extensive metabolism by the liver and its minimal renal clearance, but it also requires dosage adjustment in advanced liver and kidney insufficiency (CrCl <10 mL/min) as well as in the elderly. Its major advantage is less frequent CNS toxicity. Dosage is 100 mg twice a day.

Ribavirin

Ribavirin is a triazole nucleoside analog with broad-spectrum antiviral activity. It is effective in vitro against RSV, influenza A and B, HSV, HIV, HCV, and viruses causing hemorrhagic fevers.[238,270–272] Its currently approved clinical indications are treatment of pediatric patients with severe RSV infection and in combination with injected interferon alfa and ribavirin capsules is approved for treatment of chronic hepatitis C.[273,274] The IV form has been shown to reduce mortality in Korean/Asian hemorrhagic fever with renal syndrome.[275] Its mechanism of action is not fully understood and intrinsic resistance has not been reported. It is available in oral, aerosolized, and IV formulations. It has high bioavailability through the oral or aerosolized forms and it is metabolized by the liver. Toxicity in the aerosolized formulation consists primarily of severe bronchospasm and cardiac rhythm abnormalities. The IV formulation also causes hemolytic anemia. Use in ventilated patients requires experienced personnel because environmental leaking and diffusion are common.[276] The recommended dosage is 6 g of ribavirin administered by continuous aerosolization for 18 hours/day for 3 to 7 days, which is FDA approved for pediatric patients. However, it was found effective in RSV-infected hematopoietic stem cell transplant recipients as it is also studied in a different dosage of 2 g aerosolized over 3 hours every 8 hours for 5 to 10 days; interestingly the latter intermittent dosing showed better outcome and ease to use in such a population.[277]

Aerosolized ribavirin should not be combined with other aerosolized medications. Induction of bronchospasm is common, and scheduled use of a bronchodilator may be required during ribarvirin therapy. It is also teratogenic and pregnant women should avoid exposure.

Oseltamivir

Oseltamivir is a sialic acid neuraminidase inhibitor that has recently become available for the treatment of both influenza A and B.[278–280] Its mechanism of action is inhibition of the viral neuraminidase, causing in turn inhibition of virus release from infected cells and spread in the respiratory tract. Drug resistance has already been reported in vitro in strains with mutations that cause changes in the viral neuraminidase or hemagglutinin. In clinical studies of adults, only 1% to 2% of posttreatment strains showed evidence of mutations with decreased neuraminidase susceptibility. Recent reports have mentioned infrequent resistance in avian-influenza and H1N1 strains.[281–283] Cross-resistance between oseltamivir and zanamivir, the other member of the class, has also been observed in vitro. It is indicated for the prevention and early treatment of uncomplicated acute influenza A and B.[284] Major clinical trials have demonstrated that oseltamivir reduces the duration, severity, and rate of complications requiring antibiotic use.[279] Its role in complicated cases such as those seen in the critical care setting is unclear at this time; however, the 2009 H1N1 epidemic contributed a wealth of data related to the use in critically ill patients.[285,286] Oseltamivir is available in an oral form, which has greater than 75% bioavailability. Protein binding is 3% to 42%. The drug is converted to oseltamivir carboxylate that is eliminated unchanged in the urine. Less than 20% of the dose is eliminated in feces. Dose adjustment is recommended for renal failure and geriatric patients when CrCl is less than 60 mL/min.[287] If CrCl 30 to 60 mL/min dose is 75 mg PO daily, CrCl 10 to 30 mL/min 30 mg PO daily, and in hemodialysis first dose of 30 mg then give one

dose after dialysis. Clinically relevant drug interactions have not been identified. Side effects include nausea, vomiting, and abdominal pain, which are usually mild. The recommended dosage is 75 mg PO twice a day for 5 days and it is recommended that treatment is begun within 2 days of symptom onset.

Zanamivir

Zanamivir is another sialic acid analog neuraminidase inhibitor that is also approved for the treatment of both influenza A and B.[288,289] Much like oseltamivir, its mechanism of action is by neuraminidase inhibition with subsequent inhibition of viral release and spread. Resistant strains have also been identified in vitro, and a resistant strain was also recovered from an immunocompromised patient with influenza B after 2 weeks of nebulized treatment.[290,291] It is indicated in acute cases of influenza with early onset of treatment.[278,284,292,293] Trials in patients with more severe disease are ongoing.[294,295] Experience is also building with its use in prophylaxis.[264,296,297] Zanamivir is available in a powder form for oral inhalation. It is also available as an IV investigational forumation.[298,299] Approximately 4% to 17% of the dose is absorbed and less than 10% of the drug is protein bound. It is excreted unchanged in the urine and unabsorbed drug is cleared in the feces. No dosage adjustment in renal or hepatic failure is recommended at this time but experience is limited. Zanamivir does not have significant drug interactions.[300,301] Bronchospasm may be precipitated. particularly in patients with underlying lung disease.[302] The recommended dose is 10 mg (two inhalations) twice a day for 5 days.

Peramivir

Peramivir is a neuraminidase inhibitor approved for the treatment of acute mild to moderate influenza A. It is also been shown to have activity against influenza B. It is available in IV formulation as one dose of 600-mg (CrCl >50 mL/min), 200-mg (CrCl 30–49 mL/min), or 100-mg (CrCl <30 mL/min) therapy. In a randomized clinical trial that recruited healthy nonpregnant adults older than 18 years with mild to moderate influenza, peramivir showed better efficacy compared with placebo by decreasing the median time to alleviation of symptoms.[303] In a Japanese multinational, randomized, double-blinded trial, peramivir was shown to be noninferior compared to oral oseltamivir.[304] However, benefits of IV peramivir have not been clearly established in hospitalized patients.[305,306]

Other Antivirals

Palivizumab is a monoclonal antibody that inhibits respiratory syncytial virus F protein. It is currently FDA approved for the prevention of RSV infection in children.[307] There are no data to support its use in adults.

Brincidofovir is a lipid conjugate of cidofovir that is available in IV and oral formulations. It has broad-spectrum activity against adenovirus, CMV, HSV, and other double-stranded DNA viruses. Although it has shown virologic efficacy, it had a significant gastrointestinal adverse effect profile. Nonetheless, it has lesser nephrotoxicity than cidofovir.[308,309]

Letermovir, a novel antiviral that interferes with the viral pUL56, has been shown effective for CMV prophylaxis in stem cell transplant patients, but it has not been explored as a therapeutic agent or for prophylaxis in other populations such as solid organ transplant patients.[310,311]

Specific Indications and Uses for Antivirals

Herpes Simplex Virus and Varicella-Zoster

Acyclovir, famciclovir, and valacyclovir are the treatment of choice for virtually all severe herpetic infections.[225,226,238,312–319] The greater oral bioavailability of famciclovir and valacyclovir makes these agents very attractive, especially for treatment of VZV. Although primary HSV-1 and HSV-2 infections can be treated orally, immunocompromised patients or severely ill patients will require IV therapy. A high index of suspicion for dissemination should be maintained in immunocompromised patients—mild, localized, or atypical disease may progress to fulminant disease. Duration of therapy in this setting is usually 7 to 14 days.

Herpetic encephalitis has had a substantial decrease in morbidity and mortality since acyclovir was introduced. As one of the few forms of viral encephalitis for which there is a treatment, empirical use of the drug is justified when viral disease is suspected and until it is ruled out. HSV polymerase chain reaction of CSF is a very sensitive and specific test for the diagnosis of this disease. The usual dose is 10 to 12 mg/kg every 8 hours for 14 to 21 days. Visceral infections, including esophagitis, hepatitis, pneumonia, and disseminated disease, are frequent in immunocompromised patients and should be treated with 5 to 10 mg/kg every 8 hours for 14 to 21 days. HSV may also cause aseptic meningitis without encephalitis in the setting of primary or recurrent genital HSV infection. Unlike the focal necrotizing disease seen with HSV encephalitis, this form of the disease is a mild, self-limited aseptic meningitis with a good prognosis.

Finally, acyclovir-resistant HSV infections, which are an increasing problem in the immunocompromised population,[229,230,320,321] can be treated with foscarnet or cidofovir.

Primary VZV infection (chickenpox) should be treated in all adults, especially in the immunocompromised.[312,315,319,322,323] Reactivation (shingles) should be treated because treatment has been shown to decrease duration and intensity of symptoms.[324,325] Mild cases may be treated with oral famciclovir or valacyclovir. Severe cases (disseminated, immunocompromised patients with involvement of more than one dermatome, or ophthalmic involvement) should be treated with IV acyclovir. It is important to remember that these patients are contagious and should be suitably isolated using airborne precautions. As with HSV, resistant strains may be treated with foscarnet.[326,327]

Cytomegalovirus

CMV infections require treatment in immunocompromised patients. Populations at increased risk of the disease are HIV-infected patients and transplant recipients. In HIV patients, both retinal and visceral involvement are initially treated with IV ganciclovir at 5 mg/kg every 12 hours for 2 weeks.[232,246,247] Valganciclovir is a suitable PO formulation for the treatment of this infection. Various maintenance options are increasingly available (including ganciclovir ocular implants) but are beyond the scope of this chapter. Resistant cases may be treated with foscarnet 60 mg/kg every 8 hours for 2 weeks[251,259] or cidofovir 5 mg/kg once weekly. Clinical and laboratory monitoring while either of these drugs is used is essential to avoid therapy-related complications. Refractory cases may be treated with cidofovir.

In the transplant patient, the combination of ganciclovir and IV immunoglobulin is now the treatment of choice for CMV pneumonia.[246,328–330] High doses of acyclovir are useful as prophylaxis

of CMV in the transplant patient but not in the HIV setting. Ganciclovir-resistant strains should be treated with foscarnet.[331]

Influenza

Clear benefit in the treatment of influenza is consistently seen only when patients are treated early in the course of the disease.[289,332–335] Therapeutic options (which can also be used prophylactically) include oseltamivir, peramivir, zanamivir, and amantadine/rimantadine.[289,306,336–340] In patients who present later in the course of the disease, the benefits of therapy are unstudied. Prevention of complications has not been clearly demonstrated. Further trials are required to demonstrate whether one class of drugs is superior to the other and whether they have a role in the critically ill patient. Rapid diagnosis of influenza is now available through different techniques that detect viral components in upper respiratory tract samples. These techniques are useful in detecting and treating infected hospitalized patients early and in regional surveillance of influenza. However, a negative test result does not completely rule out influenza and empirical therapy of ambulatory patients with a clinical syndrome strongly suggesting influenza is probably appropriate.

Avian and pandemic influenzas have received much attention from the scientific community and the media in the past 2 years. Considerable efforts are being carried out for surveillance, prompt detection, and containment of these diseases.[341–344] Critical care specialists should have increased awareness and involve infection control and public health authorities in patients with particularly severe forms of influenza with the appropriate epidemiologic background. Airborne precautions should be used in suspected and confirmed cases. As mentioned earlier, although there are few reports of neuraminidase inhibitor resistance in some avian influenza strains, these viruses appear to be generally susceptible to oseltamivir and zanamivir.[281,282]

The 2009 H1N1 epidemic virtually changed how we manage influenza in critically ill patients. During this epidemic oseltamivir and zanamivir were frequently used late in the disease and at high doses, also in the setting of extracorporeal membrane oxygenation, with variable results.[285,295,345–347] At this point the true value of these agents is still unknown, although most experts agree that at the very least they may decrease viral shedding and transmission. In retrospective studies survival rates are shown to be higher in critically ill patients with influenza infections who received neuraminidase inhibitors up to 5 days of start of symptoms; the survival rate is the highest with earlier therapy.[348,349]

An important consideration is vaccination and postexposure prophylaxis in health care personnel working in acute and chronic care facilities. Appropriate vaccination and influenza control measures in both health care personnel and patients have proven effective in decreasing disease and even mortality in patients.[350–352]

Other Viruses

Other potentially treatable viral infections that may be encountered in the critical care setting include parvovirus, for which treatment with IV immunoglobulin has shown some beneficial effects[353–355]; enterovirus, for which a new drug called pleconaril showed only marginal benefits in the setting of meningitis[356,357]; and hemorrhagic fevers and hantavirus, for which ribavirin may be considered despite definitive proof of efficacy.[270] Dengue and yellow fever can be particularly severe and are most effectively managed with aggressive supportive care. The Ebola epidemic accelerated the development and investigational use of several antivirals and monoclonal antibodies.

Key Points

- Amphotericin B and its lipid preparations are the treatment of choice for all critically ill patients with an undiagnosed fungal infection. Once diagnosis is made, other therapeutic options may be considered.
- Fluconazole has excellent antifungal activity, mainly against most yeasts, but resistance is possible and clinically relevant.
- Echinocandins comprise a class of antifungal agents with activity against *Candida* and *Aspergillus* with proven efficacy and remarkable safety profiles. They are now considered the treatment of choice for candidemia in critically ill patients.
- Combinations of antifungals should be approached carefully as they are clearly beneficial only in selected entities such as CNS disease and endocarditis.
- Empirical antifungal use and antifungal prophylaxis in the ICU setting remain controversial and should be reserved for carefully selected units and patients.
- Uncommon and serious mycoses require expert consultation.
- Acyclovir or its analogs are the drugs of choice for treatment of HSV and VZV infections. The new oral formulations (famciclovir and valacyclovir) have greater bioavailability and are preferred in ambulatory patients.
- Ganciclovir is the drug of choice for treatment of CMV disease in immunocompromised hosts. Immunoglobulin therapy is added to this in transplant patients with pneumonia.
- Critical care specialists should have a high index of suspicion for avian and pandemic influenza. Suspected or confirmed cases should have airborne precautions in place and be treated with neuraminidase inhibitors.
- Resistance is an increasingly real problem in both antifungal and antiviral therapy.

Review Questions

1. A 45-year-old female with a history of newly diagnosed rheumatoid arthritis has been taking 20 mg oral prednisone for the past 30 weeks. She is admitted to the intensive care unit (ICU) for necrotizing pancreatitis, which is thought to be secondary to biliary calculus. She underwent surgical debridement and placement of multiple intraabdominal drains. She started intravenous (IV) antibiotics empirically. The patient began IV caspofungin empirically as she continued to have fever and leukocytosis even though she has been taking vancomycin and meropenem for 12 days. Steroids therapy was continued during her ICU stay. On day 17, the laboratory reported that the blood culture is growing yeast. What is the most appropriate measure to do next?

a. Exchange the central line, and switch caspofungin to micafungin.
b. Exchange central venous lines, and switch caspofungin to fluconazole.
c. Switch caspofungin to liposomal amphotericin B.
d. Continue same management and consider the culture is a contaminant.

Answer: c. Answer a is incorrect because the spectrum of antifungal activity is the same among the currently approved echinocandins (caspofungin, anidulafungin, and micafungin). Although answer b is considered correct in cases of line-related *Candida* infection, given that breakthrough fungemia is worrisome for resistant *Candida*, and most likely in this case cryptoccocal infection, which we will need to rule out meningitis. Answer d is clearly incorrect. Answer c is correct because breakthrough fungemia while the patient is receiving echinocandin should make us think of mainly *Cryptococcus*, *Malassezia*, or *Trichosporon* spp. Once identification is completed, a line exchange is warranted for the latter two organisms and switching to triazole therapy. This case shows a patient with the risk factor of cryptococcal infection and liposomal amphotericin B is warranted until meningitis is ruled out.

2. A 61-year-old male with a history of refractory acute myeloid leukemia status multiple chemotherapy regimens and prolonged neutropenia. The patient has started ciprofloxacin, acyclovir, and voriconazole as a prophylaxis regimen for prolonged neutropenia. The patient is known to have multiple lung nodules that are thought to represent invasive pulmonary aspergillosis per a galactomannan-positive test result from bronchoalveolar lavage. The patient is admitted to the ICU for septic shock and on the second day, blood cultures grow gram-negative rods. The patient had already started empiric antibiotic therapy with meropenem and vancomycin with good response as he is not receiving IV vasopressors. The patient now has acute kidney injury with creatinine clearance of 18 mL/min. He is receiving only IV therapy because of ileus and decreased gastrointestinal absorption. What is the next step to consider?

a. Switch meropenem to cefepime and discontinue vancomycin.
b. Start liposomal amphotericin B and continue vancomycin and cefepime.
c. Discontinue meropenem and vancomycin and continue prophylaxis.
d. Switch voriconazole to isavuconazole and continue meropenem.

Answer: d. The patient's blood culture has gram-negative rods and vancomycin can be discontinued; however, switching meropenem to cefepime should not be done until the final organism and susceptibilities are known; that is why answer a is incorrect. There is no need to start AmBisome as there are no signs of a breakthrough fungal infection, so answer b is not correct. Answer c is clearly incorrect. The patient has decreased creatinine clearance and IV voriconazole is contraindicated as it has a sulfobutylether-β-cyclodextrin component that will accumulate given declining renal function, whereas IV isavuconazole does not have this formulation and does not need dose adjustment per renal function.

3. A 72-year-old male with a history of congestive heart failure, hypertension, and diabetes mellitus presents during the month of December with a 3-day history of cough, fever, and body aches. On examination, the patient's oral temperature is 100.9°F (38.2°C), blood pressure is 95/43 mm Hg, and his pulse rate is 103 beats/min with a pulse oximetry reading of 83% on room air. The patient's respiratory status worsened in the emergency department (ED), requiring him to be intubated. Chest x-ray showed bilateral diffuse ground glass opacities. What is the next step in his management?

a. Start empirical antibiotic therapy and send blood samples for cultures and bronchoalveolar lavage for gram stain and cultures.
b. Start empirical antibiotic therapy and send blood samples for cultures, bronchoalveolar lavage for gram stain and cultures, and conduct influenza rapid antigen test.
c. Start empirical antibiotic therapy and send blood samples for cultures, start oseltamivir, obtain an influenza reverse transcription polymerase chain reaction (RT-PCR) test, and send bronchoalveolar lavage specimen for gram stain and cultures.
d. Start empirical antibiotic therapy, give one dose of peramivir, and send blood samples for cultures, bronchoalveolar lavage specimen for gram stain and cultures, and obtain influenza RT-PCR test.

Answer: c. The patient has a high risk of influenza pneumonia. Although the onset of his symptoms has passed the 48 hours of the recommended time to start oseltamivir, the patient is critically ill and neuraminidase inhibitors can be effective up to 5 days of symptom onset. Answers a, b, and d are incorrect because the patient should start empirical influenza therapy. Also, when there is a high clinical suspicion of influenza infection, therapy should not be delayed until the results of influenza tests are available.

4. A 24-year-old Caucasian female presented to the emergency department with altered mental status. Her boyfriend is with her and states the patient does not have any prior medical history. They recently returned from a vacation trip to Miami, Florida. He does not recall having any sick contacts or that she had any febrile illness during or before the trip. He recalls that her symptoms started with a headache and fever a day ago, and she took two ibuprofen pills. The emergency physician ordered a computed tomographic scan of the head without contrast, which did not suggest any pathologic process. In the ED the patient was febrile, and because of depressed mental status she was intubated and was given one dose of IV vancomycin (2 g) and one dose of ceftriaxone (2 g). Otherwise, the rest of her vital signs were normal. She underwent lumbar puncture with a normal opening pressure. Cerebral spinal fluid (CSF) showed pleocytosis (lymphocytes predominant) and elevated protein. The patient started IV acyclovir 10 mg/kg every 8 hours for suspected herpetic encephalitis. On day 2 of admission the

results of her CSF herpes simplex 1 polymerase chain reaction (HSV-1 PCR) came back positive, and magnetic resonance imaging of the brain showed left temporal encephalitis. On day 3, she developed an 20% increase in her serum creatinine. What is the underlying pathophysiology behind her acute kidney injury (AKI)?

a. Acute tubular necrosis induced by iodinated contrast
b. Acyclovir crystalline precipitation in the renal tubules
c. Vancomycin-induced nephrotoxicity
d. Acute interstitial nephritis secondary to use of nonsteroidal antiinflammatory drugs

Answer: b. The patient's creatinine has changed, which is explained by the use of acyclovir, which tends to precipitate in the renal tubules. The process is usually mild and can be avoided or reversed with IV hydration. However sometimes it may require the discontinuation of medication and the use of hemodialysis. The patient did receive vancomycin but it was only a one-time dose and is not considered the cause of her AKI, so answer c is incorrect. Although the patient received ibuprofen before coming to the hospital, it is not thought to be the cause of her AKI in this occasion as it was a low dose and as such answer d is incorrect. Answer a is incorrect because the patient did not receive iodinated contrast.

5. A 37-year-old Hispanic male has acute myeloblastic leukemia who is receiving Cytarabine and Idarubicin with prolonged neutropenia. He was admitted to the ICU for febrile illness and was found to have invasive sinusitis secondary to mucormycosis. He began a regimen of 5 mg/kg IV AmBisome and underwent debridement of the lesion. The patient was given IV fluid hydration to avoid renal injury induced by AmBisome. What is the likely mechanism behind the risk of developing cardiac arrhythmia?

a. AmBisome affects L-type Ca^{++} cardiac channels.
b. Amphotericin releases inflammatory mediators from monocytes and macrophages.
c. Electrolyte disturbance (magnesium/potassium) occurs through tubular membrane wasting.
d. Human herpesvirus 6 (HHV-6) induces myocarditis.

Answer: c. The use of amphotericin B is associated with frequent renal tubular injury that results in low magnesium and potassium levels through renal tubular leaking of electrolytes. Thus close monitoring of serum electrolytes is necessary, and some experts recommend to preemptive supplementation of the patient with magnesium and potassium to avoid such a complication. Both answers a and b are incorrect. Isavuconazole is the drug that affects L-type Ca^{++} cardiac channels, and although amphotericin B causes the release of inflammatory mediators from monocytes and macrophages, it is not known to cause cardiac arrhythmia. Answer d is incorrect in this scenario. However, in rare cases HHV-6 can cause myocarditis in severely immunocompromised patients (e.g., after allogeneic hematopoietic stem cell transplantation).

- Adaptive Immunity
- Altered Inflammatory Response: Neutropenia

General Approach to Management of Patients With Altered Immune and Inflammatory Responses

Management of Specific Patient Populations
- Cancer Patients With Neutropenia
- Solid Organ Transplant Recipients
- Patients With HIV/AIDS

Immunosuppressed patients present special management issues because (1) opportunistic infections can present subtly but then progress rapidly; (2) opportunistic infections often require special diagnostic tests that would not usually be ordered for immunologically normal patients; (3) therapy often requires the use of unfamiliar antimicrobial agents plus the manipulation of immunosuppressive regimens; and (4) drug interactions between immunosuppressive agents and antimicrobial agent can compromise the efficacy and/or safety of therapies, and the complexity of these interactions can be compounded by the polypharmacy that patients in intensive care units (ICUs) are often receiving for their other acute and chronic diseases.

This chapter emphasizes the important ways in which immunosuppressed patients differ from immunologically normal individuals in terms of infectious complications. The noninfectious complications of immunosuppression are reviewed in Chapter 80.

Definition

Patients who are at increased risk for infectious complications because of a deficiency in any of their host defense mechanisms (e.g., immunologic, inflammatory, physical, or chemical) are referred to as *compromised* hosts. Almost all patients in the ICU are compromised because of one or more of these deficiencies—for example, almost all have catheters and many have wounds and/or are receiving drugs that alter their inflammatory or immunologic responses.

Patients are termed *immunocompromised* or *immunosuppressed* if their defect, whether acquired congenitally or postpartum, specifically involves immune response. Patients who have defects in inflammatory response, such as neutrophil number or function, are also considered immunosuppressed in most reviews.

Overview of Immune and Inflammatory Responses

Innate Immunity

All humans exist in an environment with billions of microorganisms that would threaten host survival if the host did not have highly effective mechanisms for protecting the host from pathogenic organisms. The innate immune system is the first-line barrier that quickly responds to microbial invasion. The innate immune system is an inherited system, inherited from parent to child, and directed against microbial molecules that are unique to microorganisms. Knowledge is rapidly expanding about specific defects in the components of innate immunity, such as defects in Toll-like receptors, mannose binding lectin, and complement. These innate responses do not change substantially during life due to prior experience with specific organisms. The innate immune system recognizes microorganisms through pattern recognition receptors (PRRs). PRRs are receptors specific for molecular components of microorganisms. Such responses can occur within minutes rather than hours or days. Innate immunity is vital to the initial encounter of the host to a microorganism. The critical effector component of the innate immune system consists of "professional" phagocytes (neutrophils, monocytes, macrophages).[1–3]

- The innate immune system is responsible for recognizing microbial invasion and modulating the inflammatory response. Components of the innate immune response include the following:
  - Physical barriers
    - For example, tight junctions in the skin, epithelial, and mucous membrane surfaces
  - Inflammation-related serum proteins
    - For example, complement and C-reactive protein

- Antimicrobial peptides
  - For example, defensins and cathelicidins on the surfaces of cells and within white cell granules
- Cell receptors that sense microorganisms and signal a defensive response
  - For example, Toll-like receptors.
- Phagocytes (neutrophils, monocytes, macrophages)

Adaptive Immunity

T cells regulate the activities of B cells and T cells, as well as other cells. T cells provide help for antibody production by B cells. T cells are the effectors of antigen-specific cell-mediated immunity. Cell-mediated immunity is the cornerstone for elimination of cells infected with intracellular pathogens and for causing graft rejection and some allergic responses.[4–8]

T-cell responses are divided into T helper 1 (TH1) and TH2 responses. TH1 responses promote production of opsonizing antibodies and induction of cellular cytotoxicity and macrophage activation. TH1 responses are central to the defense against pathogens that replicate intracellularly, such as mycobacteria, *Toxoplasma, Histoplasma, Cryptococcus,* and *Nocardia.* TH2 responses promote production of immunoglobulin E (IgE) and immunoglobulin G4 (IgG4).

Defects in each arm of the immune system are associated with characteristic infections. Knowledge of the defect produced by the underlying disease, or by medical interventions including chemotherapy, allows the clinician to develop logical preventive and empiric therapeutic management plans.[4–8]

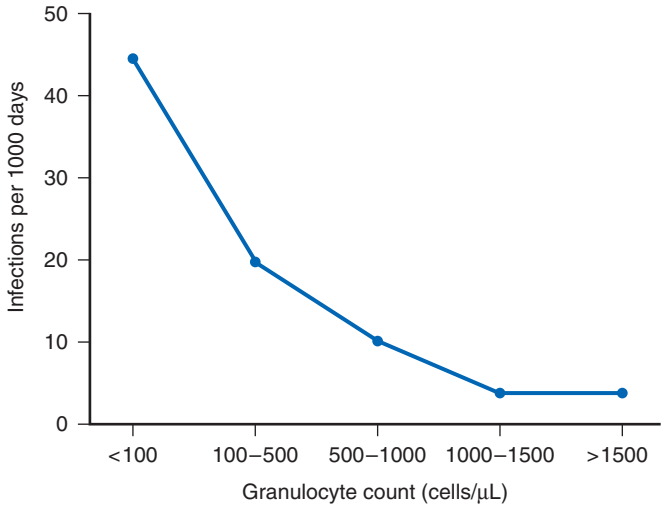
Altered Inflammatory Response: Neutropenia

Neutropenia is a well-recognized risk factor for invasive infections caused by bacteria and fungi.[9–12] The coexistence of mucosal ulcerations caused by cytotoxic therapy and neutropenia produces especially high caused by such infections.[13,14]

Patients who are neutropenic develop well-described syndromes and complications that have better outcomes if specific, evidence-based principles are followed. However, almost all neutropenic patients have mixed immunodeficiencies—that is, they have neutropenia for a variable period of time but they also have elements of cellular and/or humoral immune deficiencies owing to their underlying disease or therapies for their primary disease. These mixed immunodeficiencies make predictions of causative organisms and recommendations for optimal management more complex given the many variables involved in underlying disease, immunosuppressive regimen, and patient comorbidities.

Neutrophil counts below 1000 cells/μL—that is, an absolute neutrophil count (ANC) less than 1000/μL (the total absolute number of polymorphonuclear neutrophils plus bands) increase susceptibility to infection in a linear fashion (i.e., the lower the neutrophil count, the greater the degree of susceptibility) (Fig. 50.1).[9]

As shown in Fig. 50.1, a patient with a neutrophil count of 100 cells/μL is much more vulnerable to infection than a patient with 500 or 1000 cells/μL, and a patient with zero neutrophils is at much higher risk for fulminant infection than a patient with 50 or 100 cells/μL. The trajectory of the neutrophil count is also important: a patient with a neutrophil count of 1500 cells/μL whose neutrophil counts are dropping precipitously should best be treated like a patient with absolute neutropenia. Similarly, a patient with 500 neutrophils/μL whose counts are rising quickly



• **Fig. 50.1** Incidence of infection at declining granulocyte counts in patients with acute leukemia during induction therapy. (From Bodey GP, Buckley M, Sathe YS, et al. Quantitative relationships between circulating leukocytes and infection in patients with acute leukemia. *Ann Intern Med.* 1966;64:328–340.)

is not nearly as vulnerable to a poor outcome as a patient with a count of 500 neutrophils/μL that is stable. The risk of life-threatening infection related to neutropenia increases as the duration of neutropenia increases. The highest-risk patients are generally defined as those with ANCs less than 500 cells/μL for longer than 7 days.[15,16]

Typical pathogens that cause bacteremias in this population include gastrointestinal flora such as *Escherichia coli, Klebsiella pneumoniae, Enterobacter* spp., *Pseudomonas aeruginosa,* and *Candida* spp., as well as skin flora such as *Staphylococcus aureus.* In an earlier era, the majority of bacteremias in neutropenic patients were due to aerobic gram-negative bacilli. More recently, the majority of such infections are due to gram-positive cocci, in large part because of the frequent use of prophylactic regimens that include a quinolone (to prevent gram-negative bacillary infections) and trimethoprim-sulfamethoxazole (for *Pneumocystis jirovecii* pneumonia and toxoplasmosis, but which also inhibit many gram-negative bacilli as well as many non–group D streptococci).[10,11,17]

General Approach to Management of Patients With Altered Immune and Inflammatory Responses

With regard to infectious complications, effective management of immunosuppressed patients requires an understanding of several basic tenets of care, some of which are extensions of principles relevant to most patients who are in ICUs because of severe underlying diseases or acute infectious challenges.

1. Life-threatening complications often present with subtle symptoms and signs that can easily be overlooked.

   Because immunocompromised patients may lack inflammatory and immunologic mediators (e.g., because of high-dose steroids, neutropenia, or antilymphocyte antibodies), the clinical manifestations of infections are often less prominent and

less impressive than in immunocompetent patients with similar complications. Thus clinicians must recognize that even subtle changes in cognition or alertness, respiratory rate or heart rate, soft tissue tenderness or warmth, catheter site appearance, chest radiograph, or abdominal pain may warrant an aggressive diagnostic evaluation and early institution of broad-spectrum empiric therapy that is appropriate to the specific host involved.

2. Fever is not invariably present when patients have serious or life-threatening infections.

   An elevated temperature is often used as a proxy for likely infection. A temperature greater than 38.1°C twice consecutively or 38.3°C once often triggers "pan cultures" of blood, urine, and sputum, plus a chest radiograph. It should be clear to clinicians, however, that changes such as tachycardia, tachypnea, altered mental status, abdominal pain, and soft tissue tenderness may represent life-threatening, rapidly progressive infections even in the absence of an elevated temperature. Such manifestations require clinical experience and judgment to determine when aggressive diagnostic and empiric therapeutic interventions are warranted. Intensivists must also be cognizant of the potential unreliability in the methods that some health care facilities use to measure temperature, an important issue because a difference of a tenth of a degree can determine whether a fever workup is initiated and whether empiric therapy is started. Temperature elevations may be intermittent, and thus ICUs that record temperature every 1 to 2 hours or continuously are more likely to identify fevers than ICUs that measure temperature less frequently. Temperatures are measured with a wide array of temporal artery, forehead, oral, rectal, or axillary approaches, not all of which have good interdevice concordance.

   Even if temperatures are measured accurately, ICU patients have mechanical reasons (e.g., renal replacement therapy and open wounds) and pharmacologic reasons (e.g., high-dose corticosteroids) to have their fevers masked. Thus fever is only one of many parameters that should lead to a thorough evaluation for infection.

3. Immunosuppressed patients are predisposed to rapid progression of infectious complications.

   Although all ICU patients demand prompt attention and vigorous diagnostic and therapeutic management, many types of immunosuppression can be associated with especially precipitous clinical deterioration despite their innocuous presentation. Thus infected patients who are neutropenic, who are receiving high-dose corticosteroids, or who are receiving monoclonal antibodies that deplete key immunologic factors are especially likely to have a fulminant course and require expeditious diagnostic and therapeutic interventions.

4. Diagnostic evaluation needs to be prompt and definitive.

   As indicated earlier, patients with life-threatening infection may present with subtle symptoms and signs that progress rapidly to become life-threatening. These early manifestations merit aggressive attempts to define the anatomy of the lesion and the causative microbial pathogen(s). Because the spectrum of potential pathogens in such patients usually includes a wide array of viruses, fungi, protozoa, and bacteria, clinicians must be certain that appropriate specimens are obtained and the appropriate microbiologic and histologic tests are ordered to identify causative organism. Expensive or invasive tests such as magnetic resonance imaging (MRI) or invasive diagnostic techniques such as bronchoalveolar lavage (BAL) or tissue biopsies should be performed with less hesitancy than in immunologically normal patients.

   Patients often have enhanced risk factors for complications of invasive procedures, such as thrombocytopenia, coagulation factor deficiencies, hypoxemia, or renal failure. Part of the art of medicine is knowing when to be aggressive with diagnostic procedures and when to rely on empiric therapeutic approaches. However, the benefit of definitive diagnosis often outweighs these risks when the procedures are performed by experienced operators. It is also important to recognize that timing is important; delay in scheduling diagnostic procedures may result in the patient progressing and becoming too hypoxic for bronchoscopy, too unstable for computed tomography scan or MRI, or too coagulopathic for a lumbar puncture or needle aspirate of a fluid collection.

5. Prior colonization and exposures are important clues to the likely causative organisms.

   For any patient in any health care setting, a history of exposure to influenza, tuberculosis, or methicillin-resistant *S. aureus* (MRSA) would be of obvious importance in determining the likely cause of a patient's syndrome. For immunosuppressed patients, it is important to know if they have latent infections such as herpes zoster or *Toxoplasma gondii* as measured by antibodies or if they have been colonized with organisms of interest.

   Monitoring patients to determine the activity of viral, fungal and parasitic infections requires special expertise. Many transplant programs use quantitative serum polymerase chain reaction (PCR) measurements to monitor cytomegalovirus (CMV) and often Epstein-Barr virus (EBV) or BK virus as well as *Toxoplasma.* They monitor fungal pathogens with periodic serum galactomannan and β-D-glucan assays. Such information will help focus empiric therapy while the definitive cause is identified, although considerable expertise is needed to understand the sensitivity and specificity of these assays. Many oncology, transplant, and human immunodeficiency virus (HIV) programs maintain databases with such serial information that may be vital to access through the relevant consultant to optimize initial and definitive management.

6. PCR detection of an organism may identify microbes that are truly present but are not causing the patient's infectious syndrome.

   Any microbiologic test requires knowledge of the performance characteristics of the test for proper interpretation. Blood cultures are well known to occasionally reveal organisms that are contaminants rather than causative pathogens. All organisms that grow from sputum or BAL are not necessarily related to the cause of pulmonary or systemic dysfunction. However, the sensitivity of PCR tests provides a particular challenge in immunosuppressed patients who may shed organisms or nucleic acid for extended periods of time. The detection by PCR of CMV or EBV in the peripheral blood, for instance, does not necessarily indicate that a patient would benefit from treatment of the CMV or EBV. Moreover, some organisms can be detected by PCR in immunosuppressed patients for many weeks or months after an acute illness. Thus finding norovirus in the stool or influenza or RSV in a respiratory sample may represent small quantities of live organisms or residual nucleic acid acquired weeks or months earlier that

may be unrelated to the cause of the acute syndrome. They may also not reflect the patient's likelihood of transmitting the organism through another person's contact with respiratory secretions or other biologic samples.

7. Not all infections are related to the underlying disease or immunosuppression.

   Immunosuppressed patients may be admitted to the ICU with an infection related to their immunosuppression. However, they may also develop infections that occur in normal hosts, such as influenza, pneumococcal pneumonia, diverticulitis, catheter-related infection, aspiration pneumonia, or ventilator-associated pneumonia. While focusing on infections that could be related to underlying immunosuppressive disorder, the clinician should not overlook the possibility that the process is due to a more common process such as community-acquired influenza, urinary sepsis related to nephrolithiasis, aspiration pneumonia related to drugs or alcohol, or MRSA bacteremia owing to illicit drug use.

8. Empiric therapy should be started promptly.

   Time to appropriate antibiotics is an important correlate of successful outcome in any patient outcome, but time is especially important in these patients, whose conditions are prone to deteriorate rapidly. Thus the clinician must be especially vigilant that the full array of appropriate antimicrobial drugs is received by the patient and that there are no delaying factors related to pharmacy preparation, team communication, vascular access, or other factors. When multiple drugs must be given rapidly (i.e., when the differential diagnosis is broad), attention might be focused on drugs that can be given by rapid infusion such as daptomycin and meropenem.

9. Empiric therapy should be broad spectrum.

   For life-threatening infections in any patient population, it is an axiom of both critical care and infectious disease that the initial antimicrobial regimen should cover all likely pathogens, and that the regimen can be narrowed or targeted as additional information about the illness emerges. For immunosuppressed patients with a broad range of potential opportunistic, community-acquired, and hospital-acquired pathogens, such empiric regimens may include three to six antibacterial, antifungal, and antiviral agents. Although antibiotic stewardship is an important aspect of responsible resource and patient management, the first 24 to 72 hours of therapy for a life-threatening process is not the proper place to limit the number of drugs if each was chosen for a plausible reason.

10. Immunosuppressed patients receive multiple courses of prophylactic and therapeutic antimicrobial therapy, and thus are at high risk for acquiring drug-resistant pathogens. Immunosuppressed patients are likely to be colonized by MRSA, vancomycin-resistant enterococci (VRE), carbapenem-resistant Enterobacteriaceae, or azole-resistant *Candida* spp. Such prior inpatient and outpatient antibiotic exposure needs to be considered when choosing empiric antimicrobial regimens.

11. Antibiotic therapy should be narrowed when the causative organism is known. For targeted therapy (when the causative organism is known) monotherapy is usually adequate.

   Once the causative organism(s) and their antimicrobial susceptibilities are known, empiric regimens can be narrowed to focus on the identified organism. In some situations a positive blood culture result likely represents only part of the infectious process—for example, when there is *E. coli* bacteremia associated with a perforated bowel and bowel abscess. In such cases broad-spectrum drugs, including one active against the isolated organism, is appropriate. However, there are situations such as primary *Staphylococcus* bacteremia or meningococcemia or bacteremic pneumococcal pneumonia when it is likely that there is only one causative organism. For a patient with a life-threatening infection in such a case, should the clinician choose monotherapy or use multiple drugs with activity against the causative pathogen? There has been considerable discussion as to whether combination therapy produces superior outcomes for targeted therapy, including in current versions of the "Management of Adults With Hospital-Acquired and Ventilator-Associated Pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society" (http://www.idsociety.org/Guidelines/Patient_Care/IDSA_Practice_Guidelines/Infections_by_Organ_System/Lower/Upper_Respiratory/Hospital-Acquired_Pneumonia_(HAP)/) and the Surviving Sepsis Campaign Guideline on Management of Sepsis (http://www.survivingsepsis.org/Guidelines/Pages/default.aspx).

   In most cases when the targeted organism is susceptible to an antibacterial or antifungal or antiviral drug with known clinical efficacy, there is no reason to use more than one drug. There are some exceptions, such as pneumococcal pneumonia or sepsis, in which case a macrolide appears to add efficacy to a β-lactam drug; streptococcal bacterial endocarditis, for which a β-lactam plus an aminoglycoside may be optimal; cryptococcal meningitis, for which amphotericin B plus flucytosine is optimal; or tuberculosis, which requires four-drug therapy initially. In most other situations, including staphylococcal bacteremia, monotherapy is appropriate and prudent. Other situations in which combination therapy is likely to be indicated are cases in which the causative organism is nonsusceptible or resistant to all active drugs, or when the only drugs with activity have questionable clinical efficacy (e.g., colistin or tigecycline). In such situations, combination therapy is reasonable given the lack of better alternatives.

12. Foreign bodies and infectious foci should be assessed promptly for removal or drainage.

   Removal of infected foreign bodies and drainage of sequestered foci are tenets of critical care medicine. Such interventions are especially important for improving outcome in patients who have compromised inflammatory or immunologic defenses. This is most often an issue for intravascular catheters. Some immunosuppressed patients have permanent indwelling lines that are difficult to remove. Some have limited access that makes finding new, feasible sites for access time-consuming and potentially hazardous. In unstable patients or patients with persistent infection, such foreign bodies need to be considered for removal, although considerable clinical judgment rather than formulaic guidelines are needed to determine the optimal timing of such removal or site change.

13. Pharmacokinetics and pharmacodynamics require special attention.

   ICU patients characteristically require attentive monitoring to ensure the adequacy and safety of drug therapy. Immunocompromised patients often have multiple prior and concurrent insults to their renal and hepatic function. They often receive multiple drugs that can produce drug-drug interactions. Thus their pharmacokinetics can be especially difficult to predict.

Ideally peak and trough concentrations should be monitored for all antimicrobial agents to ensure optimal pharmacodynamics. However, few ICUs have access to antibiotic levels other than vancomycin, aminoglycosides, and voriconazole, especially in real time, such that adjustments could be made to account for current physiologic changes.

Many current immunosuppressive agents such as cyclosporine, tacrolimus, and sirolimus can have clinically important interactions with certain antibiotics, and thus close attention needs to be maintained to ensure that antimicrobial therapy is optimized and immunosuppression is properly managed.

14. Noninfectious syndromes specific to the immunosuppressive disorder can masquerade as infections.

Clinicians dealing with specific populations must be familiar with the noninfectious syndromes that occur, such as graft-versus-host disease, immune reconstitution syndrome, bronchiolitis obliterans, chemotherapy-induced cardiomyopathy, and veno-occlusive disease of the liver. Failure to recognize these entities exposes them to the toxicities and expense of unnecessary antimicrobial therapy and prevents institution of the appropriate therapy for the noninfectious syndrome.

Management of Specific Patient Populations

Cancer Patients With Neutropenia

Prevention of Infection and Preemptive Therapy

A distinction should be made between prevention of infection and preemptive therapy to reduce the impact of infections on patient survival.

- Prevention of infection includes interventions that prevent the host from acquiring a particular pathogen. Environmental control, including contact, respiratory, and airborne isolation, is well known and effective as a strategy to prevent infections. Other examples of effective preventive strategies include oral and skin hygiene, immunizations, oral antimicrobials, and colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF]).
- Preemptive therapy is defined as the initiation of an intervention when a pathogen is detected but before clinically apparent disease occurs. For example, after stem cell transplantation, CMV viremia is usually monitored on a scheduled basis. If the serum PCR becomes positive above a certain threshold, natural history studies demonstrate that pneumonitis, colitis, or systemic disease is likely to occur, and thus therapy is started preemptively before any clinical manifestations of disease occur. This strategy is especially advantageous when the optimally active antimicrobial is toxic or expensive (i.e., this strategy allows withholding the drug until replication of the organism becomes evident).

Infection prevention for neutropenic patients starts with the same general approaches used for all ICU patients: hand hygiene, oral hygiene, and antiseptic body washes for the patient. Established isolation precautions to prevent transmission of pathogens from other patients to the immunosuppressed person are also especially important.[17] Most programs also provide patients a "neutropenic diet" consisting exclusively of cooked foods to avoid pathogens associated with raw fruits and vegetables.[18] Avoidance of plants and flowers is also likely useful. For high-risk patients, such as allogeneic stem cell transplant recipients in the early posttransplant period, protective isolation is highly encouraged with high-efficiency particulate air filters, positive air differential between patient room and surroundings, at least 12 air exchanges per hour, and continuous pressure monitoring.[10,11]

For high-risk patients most programs use oral prophylactic regimens that target gram-negative bacilli including *P. aeruginosa.*[10,11] Levofloxacin is commonly used because it has activity against many gram-negative bacilli and has activity against oral flora such as viridans streptococci that are recognized to break through other prophylactic regimens. The benefits of such prophylaxis are debated given that there are adverse effects, including altering the host's microbial flora, predisposing to *Clostridium difficile* infection, and the drug-specific toxicities unique to individual drugs such as QT prolongations associated with quinolones and the enhanced susceptibility to *C. difficile* enterocolitis. Antibacterial prophylactic drugs are usually started in high-risk patients when cytotoxic therapy is initiated and stopped when the ANC has been above 500 cells/μL for 1 to 2 days. The use of prophylactic drugs has led to a shift in pathogens causing disease in neutropenic patients from gram-negative bacilli to gram-positive organisms.[19–25]

Reactivation of herpes simplex virus (HSV-1 and HSV-2) and varicella-zoster virus (VZV) occurs especially in patients with acute leukemia and those undergoing human stem cell transplants. HSV and VZV infections can be prevented with antiviral prophylaxis. Patients receiving hematopoietic stem cell transplants and certain other immunosuppressed persons who are seropositive for HSV or VZV should receive antiviral prophylaxis with famciclovir or valacyclovir.[26,27]

Antifungal prophylaxis against invasive fungal organisms with fluconazole, voriconazole, or posaconazole is often used for high-risk patients. The targets include fungemia caused by *Candida* spp. and invasive disease, especially pulmonary infections, caused by molds such as *Aspergillus* or *Rhizopus* spp.[28–33]

Prophylaxis against *Pneumocystis* pneumonia (PCP) is appropriate in selected patients who have T-cell immuodeficiencies in addition to neutropenia. Neutropenia alone is not a risk factor for PCP. Trimethoprim-sulfamethoxazole is always the drug of choice in terms of efficacy. However, given this drug's potential to cause bone marrow suppression, some programs prefer atovaquone or aerosol pentamidine.

For antibacterial, antifungal, and antiviral prophylaxis, the antimicrobial pressure on selecting resistant organisms is leading to a shift in the causes of disease to newly recognized pathogens or previously recognized by now drug-resistant pathogens that "break through" prophylaxis.[20,22,23,34,35] This reinforces the concept that when patients develop new syndromes while using antimicrobial prophylaxis, empiric regimens must take into consideration pathogens that are likely to evade the prophylactic regimen.

Although neutropenia itself is not a risk factor for PCP, the concurrent compromise of cell-mediated mechanisms by the underlying disease or chemotherapy often warrants the use of *Pneumocystis* prophylaxis. Trimethoprim-sulfamethoxazole is the prophylaxis of choice if the patient can tolerate sulfa drugs and if bone marrow suppression is not a contraindication. In such circumstances aerosolized pentamidine or oral atovaquone can be used. Unlike bacteria, viruses, and other fungi, there is no evidence to date that *Pneumocystis* develops clinically important resistance to prophylactic drugs.

Colony-stimulating factors (CSFs, also referred to as myeloid growth factors or hematopoietic growth factors), including granulocyte and granulocyte-macrophage colony-stimulating factors (G-CSF and GM-CSF), are recommended by some guidelines for afebrile neutropenic patients in whom the anticipated risk of fever and neutropenia is 20% or higher.[17,36–38]

When patients are in the ICU and develop acute syndromes, the choice of antimicrobial therapies clearly must take into consideration the prophylactic drugs that patients have been receiving. Thus for patients who have been receiving levofloxacin, trimethoprim-sulfamethoxazole, acyclovir, and voriconazole for prophylaxis, the selection of an empiric antimicrobial regimen should focus on drugs active against pathogens that would likely break through such prophylaxis.

Diagnostic Approach to Febrile Syndromes in Patients With Neutropenia

All neutropenic patients who develop a new fever should at a minimum have blood samples drawn for two blood cultures, with one obtained peripherally and one obtained through the lumen of the indwelling catheter that has either been in place the longest or is most suspicious for being infected. Other sites should be cultured as clinically indicated. The more time points that are sampled, and the higher the blood volume collected for culture, the more likely the blood culture result is to be positive. Drawing sample for two separate blood cultures at the onset of a new fever is a reasonable approach. Additional samples should be drawn for blood cultures if the fever persists, new clinical manifestations occur, or if the patient's condition worsens, although there is no specific algorithm other than "clinical judgment" that can be supplied to direct exactly how often such blood cultures should be obtained.

In the era of readily available imaging and laboratory testing, physical examination is often neglected as a method to assess the severity of the patient's illness and determine the cause of the infectious disorder. Physical examination is useful to identify sites that merit more focused investigation. With impaired inflammatory response, findings on examination may be subtle and require special attention to subtle changes in symptoms or signs.

Diagnostic microbiology is shifting rapidly from a system based on in vitro cultures, biochemical identification, and in vivo susceptibility testing to molecular approaches that can identify organisms and their susceptibility directly in human specimens or from isolates on a laboratory plate or tissue culture.[39–41] For immunosuppressed patients, such molecular techniques can permit recognition of causative organisms that might have been missed by conventional techniques, but may also pose difficult challenges for interpretation. Immunosuppressed patients may have detectable levels of normally latent viruses such as CMV, adenovirus, BK virus, and EBV. Finding such pathogens by PCR in the serum, for instance, does not necessarily indicate that the circulating virus is the cause of the febrile process or needs to be treated. Molecular diagnostics may also identify small quantities of pathogens that would be dismissed as irrelevant in immunocompetent patients, such as *P. jirovecii* or an *Aspergillus* species in a BAL. However, in a neutropenic patient such organisms might be the cause of life-threatening pathology and thus are rarely ignored—that is, their presence results in the initiation of therapy.

Quantitative PCR may provide some clues as to the relevance of the pathogen, but interpretation of such quantification is very complex and nonstandardized and depends both on the quantity of pathogen present and the quality and size/volume of the specimen collected. In addition, some pathogens in neutropenic patients persist for many weeks or months after the acute event has resolved; finding norovirus in the stool or RSV in BAL may represent colonization or shedding from an illness months ago rather than the cause of a new or emerging process. Thus the sensitivity of molecular techniques adds considerable opportunity for detection of true causative organisms but also complexity for determining whether the identified organism is causing disease, is transmissible, or merits treatment.[17,42–44]

Biomarker monitoring is standard for most programs treating immunosuppressed, neutropenic patients. Weekly serologic molecular (e.g., PCR) testing for CMV—and in some programs EBV, BK virus, adenovirus, and *Toxoplasma*, and periodic monitoring for hepatitis B virus (HBV) or hepatitis C virus (HCV) in certain patients—can provide useful information about the likelihood of impending or developing infectious syndromes.[45,46] Similarly, monitoring for fungal infections either weekly, or when clinically indicated, via β-D-glucan and/or galactomannan can provide useful information about fungal infections, although the sensitivity and specificity of such tests need to be well understood.

To supplement biomarker monitoring, patients who are already febrile with poorly defined sources may benefit from serial computed tomography or magnetic spectroscopy for chest, abdomen, pelvis, or central nervous system (CNS) imaging to identify pathology not apparent on routine imaging, ultrasound screening, or physical examination, thus providing the diagnostic team information on what further tests to pursue. In patients with radiographic abnormalities of the lungs (focal or diffuse), early BAL or biopsy may permit early institution of therapy and thus improve long-term prognosis.

Treatment of Infections in Patients With Neutropenia

Cytotoxic chemotherapy puts patients at risk for infection by suppressing myelopoiesis and by compromising the integrity of the gastrointestinal mucosa. Thus much of the invasive bacterial and *Candida* disease that occurs is a result of translocation or penetration of gastrointestinal flora across gastrointestinal mucosal surfaces, surfaces that may be eroded by cytotoxic therapy or graft versus host disease.

In the 1960s and 1970s, aerobic gram-negative bacilli such as *E. coli, K. pneumoniae,* and *P. aeruginosa* predominated as pathogens in neutropenic patients. In the 1990s the spectrum of causative pathogens in neutropenic patients shifted to gram-positive cocci including viridans and β-hemolytic streptococci, staphylococci (including oxacillin-resistant *S. aureus* [MRSA] and methicillin-sensitive *S. aureus*), and enterococci (including VRE).[20,22,23,34,35] *Candida* species became more frequent as pathogens, especially as patients have been receiving broad-spectrum antibacterial agents and have long-term venous access devices in place. The causative *Candida* species are also shifting from *Candida albicans* to other species owing to the effectiveness of azole prophylaxis. More recently, as prophylactic antimicrobial regimens have become broader and as immunosuppressive regimens have become more potent, invasive molds, reactivated viruses, and multidrug resistant bacteria have become more prominent, thereby complicating the empiric regimens that need to be instituted to ensure optimal patient outcomes when acute infectious syndromes develop.

Empiric therapy should be initiated because of fever (temperature of 38.3°C once or 38.1°C twice) alone in an asymptomatic patient, or the development of a clinical syndrome compatible with infection regardless of temperature. As indicated earlier, even subtle changes in clinical status should trigger diagnostic and therapeutic responses in these patients who are highly vulnerable to rapid progression of infectious processes. As with sepsis in general, fever plus neutropenia or a new syndrome comparable with infection in a neutropenic patient should trigger prompt broad-spectrum clinical antimicrobial therapy.

The management of febrile, neutropenic fever is summarized in guidelines that are widely used to direct care in North America.[10,11]

Algorithms for managing such patients are shown in Figs. 50.2 through 50.4.

The initial empiric regimens needs to be broad, as with any patient admitted to the ICU with a likely infectious syndrome. There are many reasonable options that can be selected based on host factors, local epidemiology, drug toxicities, and cost.

Some programs continue to treat neutropenic patients with septic presentations with monotherapy for bacterial processes using drugs such as a carbapenem, piperacillin-tazobactam, or cefepime. Ceftazidime is also used, but this cephalosporin has poor activity against many streptococci and thus is falling out of favor with some programs. Given the fact that such patients often have considerable exposure to prior antimicrobials, indwelling lines, gastrointestinal mucosal ulcerations, and are neutropenic, at many institutions the empiric regimen typically is composed of several drugs, including a drug active against MRSA, a drug active against anaerobes, and a drug active against gram-negative bacilli. Because gram-negative bacilli have so much antibiotic resistance in this era, more than one drug class may have to be used in some epidemiologic settings to provide activity against the pathogens commonly seen in a particular hospital's patient population.[22,34,35,47–60]

Coverage of MRSA with vancomycin or daptomycin empirically is controversial because of concern about overuse of these drugs leading to contributions to resistance, changing flora, and antibiotic toxicities. But in the ICU it can be difficult to avoid using multidrug regimens empirically, especially for patients who have been receiving fluoroquinolone prophylaxis and patients with indwelling vascular access devices. Linezolid is often avoided because of its potential to cause thrombocytopenia and neutropenia, especially after several days in patients with compromised marrow function.

Although combinations that are bactericidal and/or synergistic are often advocated, it is not easy to predict which regimens will in fact be synergistic or bactericidal for a given pathogen, nor is there good evidence that for this indication such considerations are clinically relevant.

Antifungal therapy is often reasonable to add to the empiric regimen. *Candida* is a common cause of bloodstream infections and can cause septic shock (molds rarely cause this syndrome and yeasts other than *Candida* spp. are uncommon in this population), and thus the inclusion of an echinocandin is prudent given the lack of toxicity of this class of antifungal drugs and the lack of drug interactions associated with these drugs.[55,57–60] Coverage for mold infections should also be considered for febrile events. Molds are rare as causes of septic shock, but they are common causes of life-threatening focal infections such as those in the lungs or CNS. Voriconazole or posaconazole is often used for mold plus yeast activity. Fluconazole is active against most *Candida* spp. but has

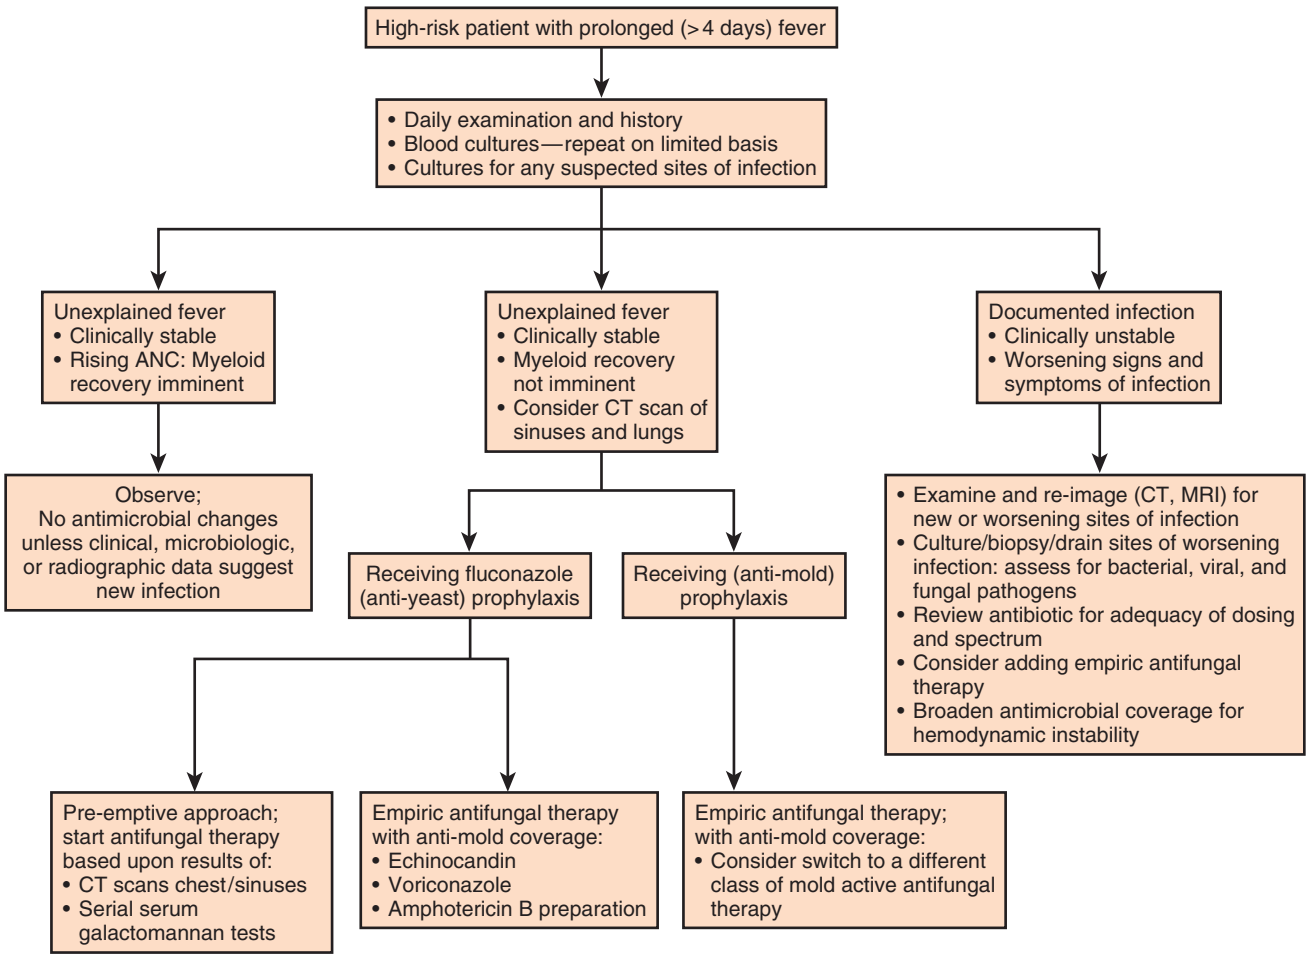
no activity against molds, and it has less activity against non-*albicans Candida* spp. than the more recently approved azoles such as voriconazole and posaconazole and isavuconzole.

The initial empiric regimen can be modified when the site of the infection is identified and when causative organisms are found in the bloodstream or other appropriate culture and when the patient becomes more stable clinically. Vancomycin (or linezolid or daptomycin) is usually stopped if no MRSA or VRE is found 48 to 72 hours after initial cultures from blood and other relevant sites are obtained and the suspicion for such vancomycin-resistant pathogens is low.

If patients respond to the empiric or modified regimens by becoming afebrile and no pathogen or likely site of infection is identified, antibiotics can be stopped after 10 to 14 days if neutropenia fails to resolve, or 5 to 7 days if neutropenia resolves.

If patients do not respond to the empiric regimen, continued investigation for sources should continue, with modifications of the empiric regimen as dictated by the clinical situation. Samples for blood cultures should be drawn periodically if patients remain febrile, with the frequency determined by the duration of fever, evolution of clinical manifestations, and severity of the syndrome.[9,48–50,52–61]

A common challenge in febrile, neutropenic patients is management of indwelling intravascular lines.[61,62] In general, these lines may be left in place initially if examination of the site reveals no indication of infection and the patient is hemodynamically stable after initial fluid resuscitation. Samples for blood cultures should be drawn through the catheter as well as peripherally. Although some experts advocate drawing samples for culture through each port of each catheter, obtaining this many samples is often not feasible because of time, cost, and the volume of blood. If a patient is hemodynamically unstable and does not respond promptly to fluid administration, it is prudent to remove the line in case an infected catheter is the source of the sepsis. Failure to remove the foreign body in this situation probably increases the likelihood of an unfavorable outcome (i.e., embolic phenomena, persistent infection, or recurrent infection). Should results of blood cultures become positive and should the suspicion be high that the catheter is the source, antibacterial therapy without catheter removal may be successful in some settings (e.g., if the pathogen is a bacterium



• **Fig. 50.4** High-risk patient with fever after 4 days of empiric antibiotics. *ANC,* Absolute neutrophil count; *CT,* computed tomography; *MRI,* magnetic resonance imaging. (From Freifeld AG, Bow EJ, Sepkowitz KA, et al. that is relatively sensitive to antibacterial therapy), thus avoiding the need to remove the catheter.[61] Situations suggesting that catheter removal is necessary include hemodynamic instability despite aggressive fluid resuscitation, tunnel infection, or infections resulting from yeast or relatively antibiotic-resistant bacteria such as *P. aeruginosa*.

Colony-stimulating factors are useful for accelerating bone marrow recovery. However, once febrile complications have developed, such growth factors have not been shown to change outcome but are plausible to give.

Granulocyte transfusions are also not routinely indicated. There have been no studies in neutropenic patients that have convincingly shown that granulocyte transfusions improve outcome. Moreover, obtaining sufficient numbers of granulocytes to maintain circulating levels greater than 500 cells/μL requires considerable logistical support that most centers do not have.[63–69]

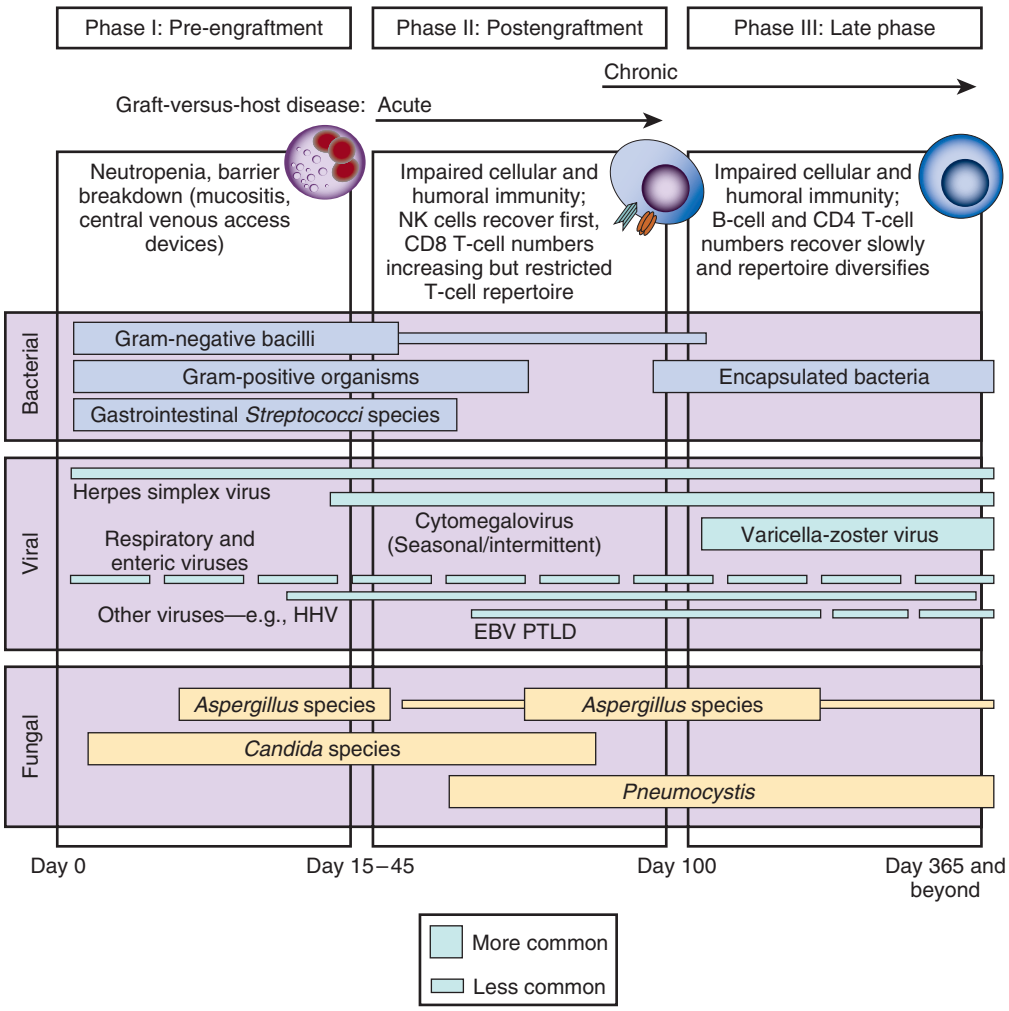
Solid Organ Transplant Recipients

Patients with solid organ transplants present with infectious complications specific to the organ transplanted and the immunosuppressive regimen used. Although solid organ transplant recipients may sometimes become neutropenic, their predominant immunosuppression is due to compromise of their cell-mediated and humoral immune systems by drugs such as the calcineurin inhibitors and corticosteroids. Thus their spectrum of likely causative organism in terms of opportunistic infections is different from the organisms that commonly cause disease in neutropenic patients.[70,71] Figs. 50.5 and 50.6 summarize the typical course of immunologic changes and infectious complications after a solid organ transplant.

In addition to opportunistic infections, each transplanted organ presents risks for infection related to (1) the surgical procedure, (2) anatomic and mechanical barriers that take time to return to normal, and (3) infections present in the donor organ at the time of transplantation.[72–74] Serial imaging of these transplanted organs is especially important to identify anatomic and infectious problems early when they can more readily be corrected or treated.

As with cancer patients who have received cytotoxic chemotherapy or immunotherapy, organ transplant recipients have inflammatory responses that are impaired by the regimens used to prevent graft rejection. Thus serious and life-threatening infections can present subtly with little signs of inflammation and modest or absent fever.

Reactivation of infections that were latent in the recipient or the donor is a common cause of infection in all solid organ



• **Fig. 50.5** Phases of opportunistic infections among allogeneic HCT recipients. *EBV,* Epstein-Barr virus; *HCT,* hematopoietic cell transplantation; *HHV,* human herpesvirus; *NK,* natural killer; *PTLD,* posttransplant lymphoproliferative disease. transplant programs. Thus depending on the immunosuppressive regimen and program focus, serial monitoring of often performed for CMV and some combination of, EBV, HSV, VZV, adenovirus, BK virus, *Toxoplasma*, HCV, and HBV.[71,73]

In addition to reactivated opportunistic infection, community-acquired infection, and infections related to the surgical procedure, donor-derived infections are an important consideration.[72,73] The donated organ may have been infected, despite predonation screening, with a bacterial or fungal process, a latent virus, or an unexpected community-acquired organisms such as *Babesia,* HIV, HBV, HCV, *Plasmodium, Trypanosoma chagas*, *Mycobacterium tuberculosis*, or *Legionella.* Organs can also be contaminated with skin flora or waterborne organisms during the procurement and transplantation process.

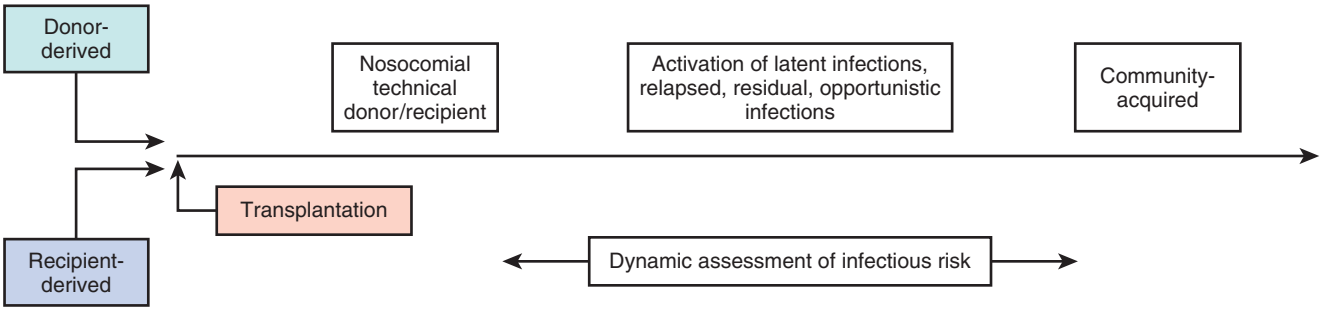
Organ biopsies are often very useful to distinguish graft rejection from infection and to identify the cause of infection if a microbial process is indeed present. Considerable experience and expertise are required to make prudent decisions about when to obtain a biopsy, how often to obtain a biopsy, and what technique should be used to secure a tissue sample adequate for the likely processes being sought.

Monitoring of drug levels for immunosuppressive agents is important to ensure appropriate activity of these drugs and to minimize their respective toxicities. Given the multiple drugs that organ transplant recipients receive, such levels can be difficult to predict. Trying to match the level of immunosuppression to graft viability and infection management is a balancing act that requires experience and judgment rather than a fixed algorithm.

An important concept for approaching infections after solid organ transplant is to focus on the time since transplantation, as well as the level of immunosuppression. Any timeline is a generalization that must be modified according to the organ involved and the specific immunosuppressive regimen used. However, Fig. 50.5 provides a conceptual overview of how such timelines can be useful.[71–73,75–80]

Patients With HIV/AIDS

Opportunistic infections continue to occur in three groups of HIV-infected patients: (1) those who are unaware of their HIV status until they develop an opportunistic infection or tumor such as *Pneumocystis* pneumonia, *Toxoplasma* encephalitis, or Kaposi



Common infections in solid organ transplantation recipients

Antimicrobial-resistant species: • MRSA • VRE • *Candida* species (non-*albicans*) Aspiration Line infection Wound infection Anastamotic leaks/ischemia *Clostridium difficile* colitis Donor-derived (uncommon): HSV, LCMV, rabies, West Nile Recipient-derived (colonization): *Aspergillus, Pseudomonas*	With PCP and antiviral (CMV, HBV) prophylaxis: • BK polyomavirus nephropathy • *Clostridium difficile* colitis • Hepatitis C virus • Adenovirus, influenza • *Cryptococcus neoformans* • *Mycobacterium tuberculosis* Anastamotic complications Without prophylaxis add: Pneumocystis Herpes viruses (HSZ, VZV, CMV, EBV) Hepatitis B virus *Listeria*, *Nocardia*, *Toxoplasma*, *Stronglyoides*, *Leishmania*, *Trypanosoma cruzi*	Community-acquired pneumonia, urinary tract infection: *Aspergillus*, atypical molds, *Mucor* species, *Nocardia*, *Rhodococcus* species Late viral: • CMV (colitis/retinitis) • Hepatitis (HBV, HCV) • HSV encephalitis • Community-acquired (SARS, West Nile) • JC polyomarvirus (PML), skin cancer, lymphoma (PTLD)

sarcoma; (2) those who are unable to receive appropriate therapy because social or financial impediments; and (3) those who develop opportunistic infections despite antiretroviral therapy (ART) and opportunistic infection prophylaxis.[81–95]

Spectrum of Clinical Manifestations

Patients with HIV infection develop clinical disease as a result of five basic processes: (1) opportunistic infections and tumors enabled by HIV-induced immunosuppression; (2) the direct effect of HIV on specific organs (e.g., cardiomyopathy, enteropathy, dementia); (3) immunologically mediated processes (e.g., glomerulonephritis, thrombocytopenia); (4) accelerated cardiovascular or renal or cerebrovascular disease as the result of HIV-related inflammation; and (5) processes unrelated to HIV/AIDS.

Management of Antiretroviral Drugs

For any HIV-infected patient in the ICU, clinicians must be cognizant of the need for careful management of antiretroviral drugs.[92] If patients present with a life-threatening opportunistic infection but are not receiving antiretroviral drugs at the time of ICU admission, it would seem plausible to start the drugs and enhance immune response to augment the effect of the specific antimicrobial regimen. However, this is almost never desirable and should be considered only in conjunction with an experienced HIV/AIDS provider.

Administering antiretroviral drugs and having predictable pharmacokinetics in the ICU is difficult because almost all antiretroviral agents are available only in oral form, and thus absorption is unpredictable. Some antiretroviral agents have considerable drug interactions, making pharmacokinetics of the antiretroviral and the interacting drug similarly unpredictable. If antiretroviral drug levels are higher than targeted, drug toxicities are more likely to occur. More ominously, if targeted levels are too low, HIV can develop drug resistance within days, losing that class of drug as a possible part of the anti-HIV armamentarium in that patient for the patient's lifetime.

The desirability of starting ART in the setting of acute opportunistic infections has been studied. The benefit of starting antiretroviral agents depends on the opportunistic infection being studied and the $CD4^+$ T-lymphocyte count at the time that therapy is being considered. There is no survival advantage in starting drugs within the first 2 weeks of therapy for most opportunistic pathogens (e.g., PCP, *Toxoplasma* encephalitis, CMV retinitis, *Mycobacterium avium* complex [MAC] bacteremia). However, for pathogens such as JC virus or *Cryptosporidium* for which there is no specific therapy, there may be no alternative except to start ART and hope that the drugs are absorbed and that the opportunistic infection responds. Moreover, when ART is started at the onset of therapy for an opportunistic infection, the suppression of HIV viremia may lead to rapidly enhanced immune function.

Immune reactivation of inflammatory syndromes can occur, manifesting as mild, moderate, or severe immune response to the replicating or dead organisms, causing organ dysfunction that can be life-threatening. Such rapidly enhanced immune and inflammatory responses can lead to severe physiologic deterioration, especially for fungal and mycobacterial processes such as cryptococcal meningitis, *Mycobacterium tuberculosis* meningitis or pericarditis or disseminated disease, or PCP. Thus starting ART for a patient in the ICU with a serious or life-threatening process requires considerable clinical experience and judgment, especially because there are no validated guidelines to help the clinician make appropriate therapeutic decisions.

If patients enter the ICU already receiving ART, an expert in HIV management should be consulted about the benefits of continuing the drugs rather than interrupting them. There is ample evidence that even brief interruption of antiretroviral drugs can have deleterious effects in terms of long-term loss of CD4 cells and in terms of the occurrence of opportunistic infections.[96,97] Stopping antiretroviral drugs may be the least harmful option. However, given the different half-lives of various antiretroviral agents, such discontinuation should be done in consultation with an HIV-experienced clinician.

Clinicians should refer to the Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents and the Guidelines for Antiretroviral Therapy in Adults and Adolescents for more detailed discussion on when to initiate ART in the setting of a specific opportunistic infection (https://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/0).

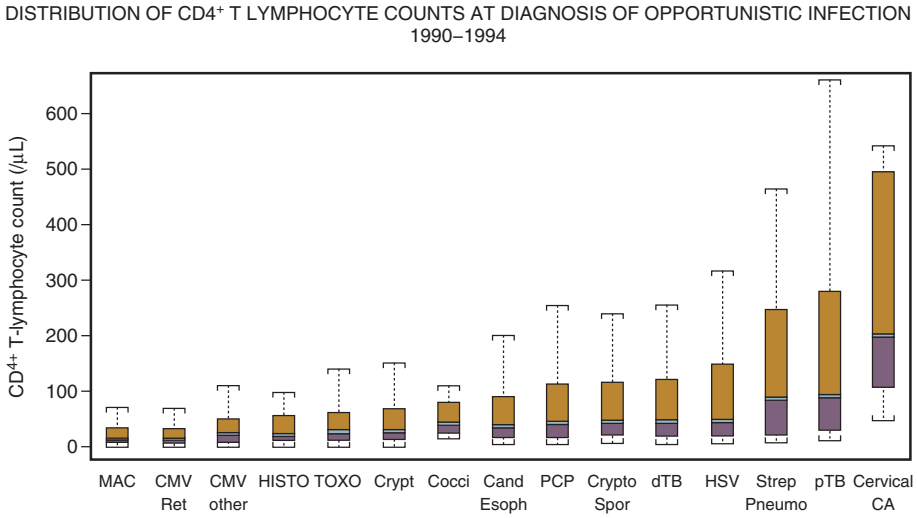
Diagnosis of Opportunistic Infections

The $CD4^+$ T-lymphocyte cell number continues to be a useful marker for predicting the occurrence of opportunistic infections in patients with HIV infection.[98] Fig. 50.7 demonstrates the typical relationship of $CD4^+$ T-lymphocyte counts to the occurrence of opportunistic infections. Knowledge of this relationship permits the focusing of diagnostic, therapeutic, and prophylactic management. This relationship is unique for HIV/AIDS. For other situations such as transplant recipients or patients receiving antiinflammatory or immunomodulating monoclonal antibodies, $CD4^+$ T-cell counts have some utility but are much less sensitive and specific for predicting the occurrence of disease.

For instance, if a patient with HIV infection and a $CD4^+$ T-lymphocyte count of 700 cells/μL presents with diffuse pulmonary infiltrates, the diagnostic evaluation and empiric antimicrobial regimen should focus on common, nonopportunistic pathogens such as *Mycoplasma, Legionella,* and *Chlamydia* organisms, as well as common community-acquired viruses such as influenza plus opportunistic infections that occur at high $CD4^+$ T-lymphocyte counts, such as *M. tuberculosis* or *Streptococcus pneumoniae*. In contrast, if the same patient had a $CD4^+$ T-lymphocyte count less than 50 cells/μL, the evaluation and empiric regimen would focus on pneumocystosis, pneumococcal pneumonia, and tuberculosis, although the previously mentioned processes that occur at high $CD4^+$ T-lymphocyte counts can also occur at lower $CD4^+$ T-lymphocyte counts.

Keeping in mind that $CD4^+$ T-lymphocyte counts are useful predictors of susceptibility to infection is important, but they are not perfect. Occasionally, patients will develop opportunistic infections at "uncharacteristically" high $CD4^+$ T-lymphocyte counts. For instance, 5% to 10% of cases of pneumocystosis occur at $CD4^+$ T-lymphocyte counts greater than 200 cells/μL.[99] Clinical parameters can provide additional clues; for example, oral *candidiasis*, a previous opportunistic infection, a prior episode of pneumonia, or high viral load are independent risk factors for the occurrence of *P. jiroveci* pneumonia, and logically for other infections as well.

Like other immunosuppressed individuals, patients with HIV infection and low $CD4^+$ T-lymphocyte counts require a prompt attempt to define the specific cause of their clinical syndrome. A patient's condition can deteriorate quickly and the range of causative organisms is broad.



• **Fig. 50.7** $CD4^+$ cell count range for common manifestations of acquired immunodeficiency syndrome. *Cand Esoph, Candida* esophagitis; *cervical CA,* cervical cancer; *CMV Other,* other cytomegalovirus diseases; *CMV Ret,* cytomegalovirus retinitis; *Cocci,* coccidioidomycosis; *Crypt,* cryptococcosis; *Crypto Spor,* cryptosporidiosis; *dTB,* disseminated tuberculosis; *HISTO*, histoplasmosis; *HSV,* herpes simplex virus; *MAC, Mycobacterium avium* complex; *PCP, Pneumocystis jirovecii* pneumonia; *pTB,* pulmonary tuberculosis; *Strep Pneumo, Streptococcus* pneumonia; *TOXO,* toxoplasmosis.

Clinical Syndromes

Pneumonia

P. jirovecii is the classic opportunistic infection that causes pneumonia in persons with HIV/AIDS. However, effective management of pulmonary dysfunction in patients with HIV/AIDS requires an organized approach to infectious and noninfectious processes.

Like any patient population, patients presenting with hypoxemia, ventilatory failure, or pulmonary infiltrates could have a wide array of infectious and noninfectious processes. Patients with HIV/AIDS have accelerated cardiovascular disease, increased procoagulants, and increased incidence of chronic obstructive pulmonary disease and pulmonary hypertension. Thus there are multiple noninfectious considerations that occur with increased frequency in HIV-infected persons in the differential diagnosis.

Persons with HIV/AIDS, even those with low $CD4^+$ T-cell counts, are not immune from community-acquired pathogens that are frequently seen in immunologically normal patients. Patients with HIV infection can develop severe pulmonary dysfunction because of common community-acquired pathogens such as *Legionella, Mycoplasma*, and *Chlamydia;* adenovirus; influenza; or respiratory syncytial virus, as well as other opportunistic viruses and fungi. Thus the diagnostic evaluation needs to be comprehensive, emphasizing direct smears of sputum or BAL.

It is important to recognize that the clinical presentations produced by many causative agents can be similar to PCP. For instance, histoplasmosis, tuberculosis, and nonspecific interstitial pneumonitis can present identically to PCP.[99–102] Thus although empiric diagnosis and empiric therapy may be reasonable as initial approaches to some patients with HIV infection and mild pneumonitis, such an approach is usually not appropriate for HIV-infected patients in an ICU.

Evaluation of induced sputum is the first step in the diagnostic approach to PCP if patients can tolerate nebulization of hypertonic saline solution and vigorous coughing to produce a sputum sample. Sensitivity of PCP diagnosis by induced sputum examination can be as high as 80% to 95% at many hospitals (at some institutions the yield is considerably lower).[103] Specificity should be 100% in an experienced laboratory, especially when immunofluorescent antibody staining is used. Other pathogens, including mycobacteria, fungi, and routine bacteria, can be identified in sputum as well. For intubated patients, respiratory secretions obtained by deep intratracheal suctioning are also likely to be useful, although they have not been as carefully studied as induced sputum. Should the diagnosis not be established by evaluation of sputum or intratracheal secretions, bronchoscopy should be performed. BAL should diagnose almost 100% of cases of PCP, even if patients have already received 7 to 10 days of empiric therapy at the time of the diagnostic procedure.[99] A diagnosis of PCP is established by visualizing one or more clusters of organisms. Some laboratories are now using PCR to diagnose PCP, but this test is not standardized and is likely to be highly sensitive but not highly specific for identifying *Pneumocystis* as the cause of the pulmonary dysfunction.[104–107]

Thus a negative PCR result of a BAL sample is a highly reliable test to rule of PCP as a diagnosis. A positive PCR result leaves some uncertainty as to whether *Pneumocystis* is the cause of the pulmonary dysfunction, or an airway colonizer that is unrelated to the current pathologic process.

Diagnostic criteria for other opportunistic infections are reviewed in Chapters 12 and 42. CMV merits special mention. CMV frequently is reactivated in patients with HIV infection and low $CD4^+$ T cells and can be found in the blood and secretions of such patients who have no end organ disease owing to CMV. CMV pneumonia almost never occurs in patients with HIV infection, as opposed to patients with solid organ or stem cell transplants. CMV should be considered the cause of pulmonary dysfunction only if other causative processes have been ruled out and there is convincing histologic or cytologic evidence. Culture of sputum or BAL for CMV does not provide useful information; in particular, patients with $CD4^+$ T-lymphocyte counts below 100 cells/μL will predictably have CMV present in their secretion independent of whether or not pulmonary disease is present.[108] A diagnosis of CMV pneumonia in this patient population is suggested by cytologic testing (especially if many cells with CMV inclusion bodies are seen) and confirmed by the presence of multiple inclusion bodies in lung tissue obtained by transbronchial or open lung biopsy.

Similarly, MAC and HSV can often be found in respiratory secretions of patients with HIV/AIDS with low $CD4^+$ T-cell counts by culture or by nucleic acid amplification tests, but these organisms almost never cause pneumonia in patients with HIV infection. In other patient populations they can clearly cause pneumonia, but the dearth of CMV, MAC, and HSV pneumonia in this patient population emphasizes the point that it is important to know from published literature what the clinical likelihood is for different microbial processes.

Fungal pneumonias other than PCP are generally diagnosed by direct microscopy or culture of respiratory secretions (sputum lavage or BAL). *Candida* organisms almost never cause pneumonia in patients with HIV infection. The frequency of *Cryptococcus, Histoplasma, Blastomyces,* and *Coccidioides* as causes of pneumonia depends on the geographic exposure of the patient. Among these mycoses, antigen detection techniques can be useful for finding *Cryptococcus* and *Histoplasma* organisms in blood or, for *Histoplasma,* in urine. In the Midwestern United States, pulmonary histoplasmosis can cause diffuse pneumonia as commonly as PCP in HIV-infected persons with low $CD4^+$ T-cell counts and can present with identical clinical and radiologic findings.

Therapy for opportunistic infections is summarized in web-based sites that are regularly updated (https://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/0).

While awaiting a specific diagnosis, it is reasonable to initiate empiric therapy in patients ill enough to merit admission to an ICU. For patients with a $CD4^+$ T-lymphocyte count greater than 250 to 300 cells/μL and serious acute pulmonary processes, levofloxacin or moxifloxacin plus ceftriaxone or, as an alternative, azithromycin plus ampicillin-sulbactam or vancomycin plus levofloxacin, would be reasonable choices. For patients with $CD4^+$ T-lymphocyte counts below 200 to 250 cells/μL, levofloxacin or moxifloxacin plus either trimethoprim-sulfamethoxazole or intravenous pentamidine would be appropriate regimens.

If PCP is documented, trimethoprim-sulfamethoxazole is always the drug of choice in patients who can tolerate it. Regardless of which specific anti-*Pneumocystis* regimen is used, corticosteroid therapy is indicated for any patient who presents with an oxygen pressure (P_{O_2}) below 70 mm Hg or an alveolar-arterial gradient higher than 30 mm Hg.[109–111] This may be counterintuitive, but there are ample controlled studies to support this approach. Patients with an initial P_{O_2} lower than 70 mm Hg are the subgroup with substantial mortality risk for whom corticosteroids have been shown to provide a survival benefit. Corticosteroids also provide more rapid resolution of pulmonary manifestations in patients who

present with better pulmonary function, but survival in this population is so high that clinical trials have not been able to show survival benefit and thus corticosteroids are not conventionally recommended for patients who present with a room air P_{O_2} greater than 70 mm Hg. Some experts are concerned that corticosteroid use will be associated with reactivation of latent infections such as CMV or MAC or tuberculosis. However, reactivation of life-threatening infections has not been associated with this corticosteroid regimen.

How should a patient with AIDS-associated PCP be managed if there is no improvement, or if there is deterioration, after 5 to 10 days of therapy? The median time to improvement in clinical variables is 4 to 8 days; therefore changes in therapy are probably not warranted before 5 to 10 days. At that point the accuracy of the diagnosis should be reassessed. Consideration should be given to repeat bronchoscopy with BAL or, perhaps, transbronchial or video-assisted transthoracic biopsy to determine if CMV, fungi, mycobacteria, or a nosocomial bacterial process is present.

Noninfectious processes such as congestive heart failure or tumor (e.g., Kaposi sarcoma or lymphoma) must also be considered for HIV-infected patients with focal or diffuse pulmonary processes. If pneumocystosis is the only causative process that can be identified and patients are not responding to anti PCP therapy after 4 to 8 days, corticosteroids should be added to the regimen if they have not been already added. Whether switching from one anti-*Pneumocystis* agent to another or adding a second agent is helpful has not been determined by clinical trials. Some human pneumocystosis isolates carry resistance mutations to sulfonamides, but such testing is available only in a few research centers, and the clinical significance of these mutations is unknown. Most experts add parenteral pentamidine to trimethoprim-sulfamethoxazole. Parenteral clindamycin-primaquine could be used as salvage regimens as well. Patients whose conditions have not improved after 14 to 21 days of therapy with specific chemotherapy plus corticosteroids have an exceedingly poor prognosis.

Central Nervous System Dysfunction

Meningitis

In HIV-infected patients with $CD4^+$ counts greater than 200 cells/μL, the causes of meningitis do not differ markedly from those in the normal population; *S. pneumonia, Neisseria meningitides,* and group B streptococci are the most common causes. For patients with $CD4^+$ counts lower than 100 cells/μL, *Cryptococcus neoformans* and *S. pneumoniae* are especially common.[112–114]

A diagnosis of cryptococcal meningitis is typically established by lumbar puncture. Essentially 100% of patients with HIV-related cryptococcal meningitis should have a positive cerebrospinal fluid (CSF) cryptococcal antigen and CSF culture. Most patients will have an elevated CSF protein, low glucose, and elevated mononuclear cell count. Almost all will also have a positive serum cryptococcal antigen.

The therapy of choice for cryptococcal meningitis in the United States is liposomal amphotericin B for at least 2 weeks, plus oral flucytosine. Fluconazole should not be used for initial therapy, although it can be used after the initial 2 weeks if patients have a good clinical response.[115,116]

Some patients with cryptococcal meningitis have symptomatic elevations of CSF pressure. Such patients should have therapeutic lumbar punctures to remove enough CSF to reduce the pressure to 20 to 25 cm H_2O.[117–119]

Multiple lumbar punctures may be needed. If after multiple lumbar punctures the patient still has symptomatic elevation of CSF pressure greater than 20 to 25 cm H_2O, the insertion of a ventricular shunt should be considered, although there are no specific guidelines regarding when to place such a shunt. Corticosteroids should not generally be used to treat elevated intracranial pressure in this situation.[112,120–122]

Focal Central Nervous System Lesions

Patients with HIV infection and $CD4^+$ T-cell counts less than 100 cells/μL may present with focal motor lesions, altered mental status, or seizures. Although the differential diagnosis is extensive, the major considerations are toxoplasmosis and lymphoma.[123,124]

CNS toxoplasmosis may present as one or multiple lesions that represent reactivation of latent disease. Lesions are characteristically enhancing in a ringlike pattern and typically occur in the basal ganglia, but many different radiologic presentations have been documented.

All patients with CNS toxoplasmosis are IgG seropositive for toxoplasmosis using sensitive assays. However, some laboratories use less sensitive assays and thus some patients may appear to be seronegative. If lumbar puncture can be performed, a CSF PCR for toxoplasmosis is positive in about 50% of cases, although there is no standardization of these *Toxoplasma* PCRs, making results variable from laboratory to laboratory.[125,126]

The standard practice for HIV-infected patients with $CD4^+$ T-lymphocyte counts less than 200 cells/μL is to undergo an empiric trial of oral sulfadiazine plus pyrimethamine plus leucovorin. Most patients who have toxoplasmosis will show clinical and radiologic improvement within 2 weeks. If such improvement has not been documented, and the diagnosis is in doubt, a needle biopsy of the intracranial lesion should be considered.[127–129]

CNS lymphoma can present identically to CNS lymphoma. A negative serum IgG for toxoplasmosis and a negative CSF toxoplasma PCR should suggest lymphoma.[130] Most patients with CNS lymphoma will have a positive CSF PCR for EBV, although this test is neither 100% sensitive nor 100% specific for lymphoma. Patients who are CSF EBV PCR negative or in whom the diagnosis is uncertain may require a brain biopsy to document the lymphoma.

Therapy for lymphoma should be determined in consultation with experienced oncologists.

Focal White Matter Lesions

In patients with HIV, JC virus encephalitis (also known as progressive multifocal encephalopathy) causes focal white matter lesions that are associated with progressive motor, sensory, and neurocognitive dysfunction.[131,132] A small fraction of patients can present with rapidly progressive cognitive decline. The computed tomography scan or MRI images of JC virus encephalitis are characteristic of this disease. Diagnosis is usually confirmed by CSF PCR for JC virus.[133]

There is no specific therapy. Patients' conditions may stabilize or improve if ART results in immune reconstitution.[112,131]

Diarrhea

Patients with HIV infection and $CD4^+$ T-cell counts below 100 cells/μL can develop severe diarrhea caused by a wide range of opportunistic pathogens, including CMV, cryptosporidiosis, or enteric bacteria such as *Salmonella*, *Shigella*, or *Campylobacter*. Diarrhea in HIV-infected patients can be so severe that patients can have life-threatening malabsorption, electrolyte abnormalities, and bowel perforations. Patients need a thorough stool evaluation for common pathogens such as *C. difficile*, which is the most

common cause of diarrhea in this patient population, even though it is not an opportunistic pathogen. If results of stool cultures are negative, testing samples for ova and parasites might be indicated if there is a history compatible with exposure.

For patients with negative evaluation of multiple stool samples, a sigmoidoscopy or colonoscopy with biopsy is indicated to assess the presence of CMV. CMV colitis occurs exclusively in patients with $CD4^+$ T-lymphocyte counts lower than 100 cells/μL. CMV colitis is best diagnosed by biopsy; there is no reliable correlation with serum CMV PCR or with stool culture or PCR for CMV. The therapy of choice for CMV colitis is intravenous ganciclovir. Intravenous foscarnet is also effective but is more toxic. Oral valganciclovir is not indicated for patients with severe diarrhea but can be used as maintenance therapy once the CMV colitis is controlled. The most effective remedy for CMV colitis is immune reconstitution with ART. As soon as absorption seems likely, ART should be initiated.

Hypotension

Patients with HIV infection develop hypotension resulting from the same types of disorders as with non–HIV-infected individuals—sepsis from a primary infection or a wound or device (especially an intravascular access device), fluid depletion from vomiting or diarrhea, and hemorrhage from a gastrointestinal lesion are examples of common causes. The evaluation of hypotension in a patient with HIV infection must take into account factors particular to this patient population. HIV-infected patients are susceptible to opportunistic infections; they undergo many procedures that can be associated with infectious complications; and they receive an array of drugs, some of which have cardiovascular effects. Thus evaluating hypotension in this patient population requires a comprehensive and thorough approach. Adrenal function always deserves special attention because several viral processes, fungal and mycobacterial diseases, HIV, and drugs can suppress the adrenal axis and either cause hypotension or exacerbate it.

Prevention of Opportunistic Infection

Intensivists usually focus on the management of acute processes, but if attention is not provided to opportunistic infection prevention, patients hospitalized for one process may develop a second life-threatening process given the high incidence of opportunistic infections. Current recommendations are maintained by guidelines maintained by governmental agencies and professional societies (Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents available at https://aidsinfo.nih.gov/guidelines/html/4/adult-and-adolescent-oi-prevention-and-treatment-guidelines/0).

Patients with HIV infection typically receive several antimicrobial agents to reduce the likelihood they will acquire opportunistic infections. *Primary prophylaxis* is the term used to indicate strategies that reduce the likelihood of an initial episode of a disease process. *Secondary prophylaxis* is the term that was used to indicate strategies that prevent reinfections and recurrences; *chronic maintenance* is the term used for strategies to prevent relapses. More recently, such prophylaxis is referred to as *chronic suppression* if the goal is to prevent a relapse, and secondary prophylaxis if the goal is to prevent reinfection.

All patients with HIV infection and $CD4^+$ T-lymphocyte counts below 200 cells/μL typically receive anti-*Pneumocystis* prophylaxis. Trimethoprim-sulfamethoxazole is the regimen of choice. Patients who take this drug have very few breakthroughs of PCP and receive considerable protection against toxoplasmosis and certain routine bacterial infections. Alternative regimens include daily dapsone or daily aerosol pentamidine. Prophylaxis against MAC is recommended for patients with $CD4^+$ T-lymphocyte counts below 100 cells/μL; clarithromycin and azithromycin are currently the drugs of choice.[112] This recommendation may change soon in the United States because, in contrast to the 1980s and 1990s. *M. avium* is not seen in the United States frequently as the cause of acute disease in patients with HIV/AIDS.

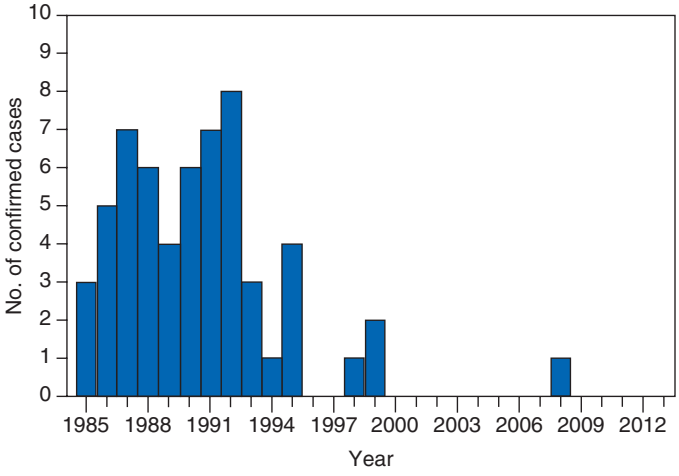
Fluconazole and acyclovir prophylaxis to reduce the frequency of fungal and viral processes, respectively, are not recommended in the United States. Isoniazid prophylaxis is important for any patient with a tuberculin skin test that shows more than 5 mm of induration or a history of substantial recent exposure.

HIV Transmission in the Intensive Care Unit

Transmission of HIV is an issue that requires attention in the ICU.[134–136] No evidence exists that HIV-infected health care professionals can infect patients, regardless of what procedure they perform, with the exception of two unusual and unexplained events. Intensivists should realize that although there are no federal policies defining how HIV-infected practitioners should be credentialed and monitored, many hospitals have relevant policies and procedures. Some are modeled after guidelines from the Society for Healthcare Epidemiology.[135,137]

Patients with HIV pose a risk to health care professionals, although there have been no documented cases of transmission since 2009 in the United States and only one since 2000 (Fig. 50.8).[138]

Whatever risk there is can be substantially reduced by staff education, by strict monitoring for compliance with universal precautions, and by having proper equipment. Guaranteeing that such strategies are in place is the responsibility of ICU leadership, who are committed to ensuring the safety of the workforce not only from HIV infection but also for other pathogens that can be transmitted by needle sticks such as HCV and HBV. Almost all HIV transmission has occurred in an occupational setting as a result of injuries involving sharp instruments (e.g., needles, scalpels). The risk of such injuries is based on older literature before the era



• **Fig. 50.8** Number of confirmed cases (N = 58) of occupationally acquired human immunodeficiency virus infection among health care workers reported to the Centers for Disease Control and Prevention in the United States, 1985–2013. (From Joyce MP, Kuhar D, Brooks JT. Occupationally acquired HIV Infection Among Health Care Workers—United States, 1985–2013. *MMWR Morb Mortal Wkly Rep.* 2015;63:1245–1246.

of antiretroviral prophylaxis, about 1 case of HIV transmission per 250 injuries, but the likelihood of transmission in an individual accident depends on the amount of the source patient's viremia at the time of the accident (late-stage patients generally have more circulating virus than do early-stage patients) and the nature of the accident. Most authorities recommend immediate prophylaxis if a significant injury occurs involving an HIV-infected patient. It is clear that initiating therapy within a period of hours rather than days is best. Many authorities now advocate an antiretroviral regimen for any situation when the patient and health care provider determine that therapy is appropriate and continuation of that therapy for 4 to 6 weeks.[139–142]

Key Points

- Knowledge of an immunosuppressed patient's specific defects in immunologic and inflammatory response helps predict which opportunistic pathogens are most likely to occur.
- ICUs are increasingly successful in enabling immunosuppressed patients to survive acute crises, especially if the defect in immunologic or inflammatory function is reversible.
- For neutropenic patients, gram-positive cocci have become more frequent than gram-negative bacilli as causes of bacteremia.
- Resistance to antimicrobial agents is becoming a major problem including not only bacteria (e.g., carbapenemase-producing Enterobacteriaceae, MRSA, VRE, and penicillin-resistant pneumococci) but also fungi (e.g., fluconazole-resistant *Candida* organisms) and viruses (e.g., acyclovir-resistant herpes simplex and ganciclovir-resistant CMV).
- In neutropenic patients, broad-spectrum empiric therapy should be considered when treating any febrile process; the choice of drugs is influenced by host factors including the specific immunologic defect. Local epidemiology and the patient's prior colonization and antibiotic exposures are also important factors.
- Organ transplant recipients develop a different spectrum of infections than patients with cancer-related neutropenia.
- The infections in organ transplant recipient are related to their immunosuppressive regimen and the organ that is transplanted. Their occurrence follows a predictable time course.
- Infections in organ transplant recipients may be derived from the donor or the recipient as well as from environmental and person-to-person exposures.
- The $CD4^+$ T-lymphocyte count and the HIV viral load are sensitive and specific predictors of the likelihood that an HIV-infected person will develop specific opportunistic infections.
- Adjunctive corticosteroid therapy is indicated for respiratory failure related to PCP.

Review Questions

1. For patients with prolonged neutropenia owing to stem cell transplant preparative chemotherapy, who are at risk for both yeast and mold infections, which of the following is the preferred prophylaxis for fungal infection?
   a. Fluconazole
   b. Posaconazole
   c. Caspofungin
   d. Micafungin
   e. Liposomal amphotericin B
   Answer: b. In stem cell transplant recipients with prolonged neutropenia immediately before transplantation (e.g., aplastic anemia) and for those who are anticipated to have slow engraftment (>28 days) or whose engraftment fail, prophylaxis with a drug with both anti-mold and anti-*Candida* activity is preferred in contrast to a narrower anti-*Candida* agent such as fluconazole. Thus posaconazole or voriconazole is the preferred agent in this question.
2. Which of the following antimicrobial agents is most likely to be bone marrow suppressive?
   a. Daptomycin
   b. Linezolid
   c. Piperacillin-tazobactam
   d. Metronidazole
   e. Colistin
   Answer: b. Linezolid causes thrombocytopenia, which in patients with normal pretreatment typically occurs after 10 to 14 days. Leukopenia and anemia then follow. Cytopenias may develop earlier in patients with compromised bone marrows (e.g., those recovering from antineoplastic chemotherapy or a stem cell transplant). Linezolid is thus avoided in most populations with compromised marrow function when possible.
3. Which of the following is the most likely cause of diffuse interstitial infiltrates in a patient 2 weeks after lung transplant?
   a. BK virus
   b. Adenovirus
   c. Cytomegalovirus (CMV)
   d. JC virus
   e. Toxoplasma
   Answer: c. CMV is a well-recognized cause of diffuse interstitial pulmonary infiltrates in patients who have received solid organ or hematopoietic stem cell transplants. Adenovirus can also cause similar infiltrates but does so much less commonly than CMV. Adenovirus and BK virus more typically cause hemorrhagic cystitis. JC virus is the cause of JC encephalitis, previously referred to as progressive multifocal leukoencephalopathy. Toxoplasmosis can present as pulmonary infiltrates that mimic *Pneumocystis* pneumonia but is not common, especially in North America where the seroprevalence of toxoplasma is much lower than in Western Europe or the developing world.
4. For a patient with human immunodeficiency virus (HIV) (CD4 count 700 cells/μL, viral load 500,000 copies/μL) who is not yet undergoing antiretroviral treatment, what is the most likely cause of diffuse interstitial infiltrates, fever, hypoxemia, and cough of 3 days' duration?
   a. *Pneumocystis jirovecii*
   b. CMV
   c. *Mycobacterium avium* complex (MAC)
   d. *Cryptosporidium*
   e. Influenza
   Answer: e. For a patient such as this one with a CD4 count of 700 cells/μL, the likelihood of an opportunistic infection is low, and thus influenza is the correct answer here. *Pneumocystis* almost never occurs at such high CD4 counts. MAC and *Cryptosporidium* cause disease in patients with CD4 counts below 100 cells/μL, but neither causes pulmonary disease in HIV-infected patients at any CD4 count with very rare exceptions.
5. Which of the following should be done to evaluate a health care worker who has just sustained a significant needle stick injury from a patient who absconded from the emergency department but who is known to be HIV-infected and not receiving therapy, but little else is known?
   a. *Toxoplasma* antibody test
   b. Hepatitis C virus antibody test
   c. CMV antibody test
   d. Human papillomavirus (HPV) antibody test
   e. Adenovirus antibody test
   Answer: b. Needle sticks are notorious for transmitting hepatitis B virus (HBV), HCV, and HIV. The likelihood of transmission depends on factors related to the source (viral load) and the recipient (for HBV and HCV, prior antibody titers). CMV could be transmitted by needle stick, but such transmissions are extremely rare. *Toxoplasma,* HPV, and adenovirus would not be expected to be transmitted by a needle stick.

Specific Infections With Critical Care Implications

HENRY S. FRAIMOW AND ANNETTE C. REBOLI

CHAPTER OUTLINE

Overwhelming Infections of the Central Nervous System
- Acute Bacterial Meningitis
- Encephalitis
- Brain Abscess
- Spinal Epidural Abscess

Fulminant Endovascular Infections
- Acute Infective Endocarditis
- Device-Related Endovascular Infections

Primary Bacteremias
- Meningococcemia and Meningococcal Sepsis
- Primary Pneumococcal Bacteremia

Toxin-Mediated Infections
- Staphylococcal Toxic Shock Syndrome
- Streptococcal Toxic Shock Syndrome
- Tetanus
- Botulism
- Diphtheria

Serious Skin and Soft Tissue Infections
- Necrotizing Fasciitis
- Clostridial Myonecrosis (Gas Gangrene)
- *Vibrio* Infections
- Community-Acquired MRSA

Serious Gastrointestinal and Intra-abdominal Infections
- Bacteremia Associated With Enteric Pathogens
- Peritonitis
- Intra-abdominal Abscess
- Biliary Tract Infections
- Pancreatic Infections
- *Clostridium difficile* Colitis

Life-Threatening Infections of the Head and Neck
- Ludwig's Angina, Lateral Pharyngeal Space Infections, and Peritonsillar Abscess
- Lemierre Syndrome
- Epiglottitis
- Mediastinitis

Serious Vector-Borne Infections
- Rocky Mountain Spotted Fever
- Ehrlichiosis and Anaplasmosis
- Babesiosis
- Malaria

Severe Viral Infections
- Viral Hemorrhagic Fevers
- Dengue
- Hantavirus Pulmonary Syndrome
- Influenza

Potential Agents of Bioterrorism
- Anthrax
- Smallpox
- Plague
- Tularemia

Serious infections and their complications are major indications for admission to critical care units worldwide. A wide variety of localized and systemic infections can result in critical illness, and review of all of these syndromes is beyond the scope of this chapter. The diseases discussed here include many of the more common infectious syndromes likely to be encountered by critical care specialists, as well as some less common infections of particular epidemiologic importance or those conditions in which critical care management is an essential component of management, including emerging infectious diseases with potential for spread beyond specific traditional geographic regions. The topics of community-acquired pneumonia, urinary tract infections, and other nosocomial infections are addressed specifically in other chapters.

Overwhelming Infections of the Central Nervous System

Most patients with serious central nervous system (CNS) infections require either admission to an intensive care unit (ICU) or the

participation of a critical care specialist in their management. Patients with CNS infections may already be critically ill at the time of presentation but even if they are less ill initially they also have the potential for rapid progression with development of fulminant complications. They also require prompt initiation of diagnostic and therapeutic interventions to optimize outcomes. Acute CNS infectious syndromes include bacterial meningitis, encephalitis, brain abscess, and spinal epidural abscess, although other primary and secondary infectious syndromes can present catastrophically, such as nonbacterial infectious meningitis, transverse myelitis, suppurative intracranial thrombophlebitis, and mycotic aneurysms. There are also other neurologic sequelae that may follow acute infections, such as Guillain-Barré syndrome. The presentations of various infectious syndromes may overlap, and they may also mimic the presentations of noninfectious CNS catastrophes such as stroke, hemorrhage, and autoimmune CNS vasculitis and encephalitis.

Acute Bacterial Meningitis

Epidemiology, Pathogenesis, Risk Factors, and Clinical Presentation

The annual incidence of community-acquired bacterial meningitis in developed countries has continued to decline over the past several decades.[1–3] Rates in the United States in 2006–2007 were less than 2 cases per 100,000 for all adult cohorts, and a population-based study from the Netherlands in 2013–2014 found rates of less than 1 case per 100,000.[2,3] In recent studies from the United States and the Netherlands, the predominant organisms in microbiologically confirmed cases of bacterial meningitis in adults were *Streptococcus pneumoniae* (>70%), *Neisseria meningitidis* (10%–15%), group B streptococcus (7%), and *Listeria monocytogenes* (4%).[1–3] No pathogen is identified in 10% to as many as 30% of cases of clinically diagnosed bacterial meningitis.[4,5] Both the overall decline in the incidence of community-acquired bacterial meningitis and recent changes in microbiologic etiology reflect the impact of current vaccination strategies.[6] *Haemophilus influenzae* meningitis has been nearly eliminated in both children and adults, and recent introduction of conjugated pediatric pneumococcal vaccines has resulted in decreased rates of invasive pneumococcal disease in both children and adults.[1,6] Conjugate meningococcal vaccines, including quadrivalent vaccines and serogroup B–specific vaccines, have also become available in the United States for adolescents and other high-risk populations with the potential to further decrease rates of invasive meningococcal disease.[7] Another important trend in bacterial meningitis is the increasing prevalence of health care–associated meningitis and ventriculitis.[1,8] The microbiology of nosocomial meningitis differs from that of community-acquired cases, with higher rates of infection caused by staphylococci and aerobic gram-negative organisms, including antimicrobial-resistant strains.[8]

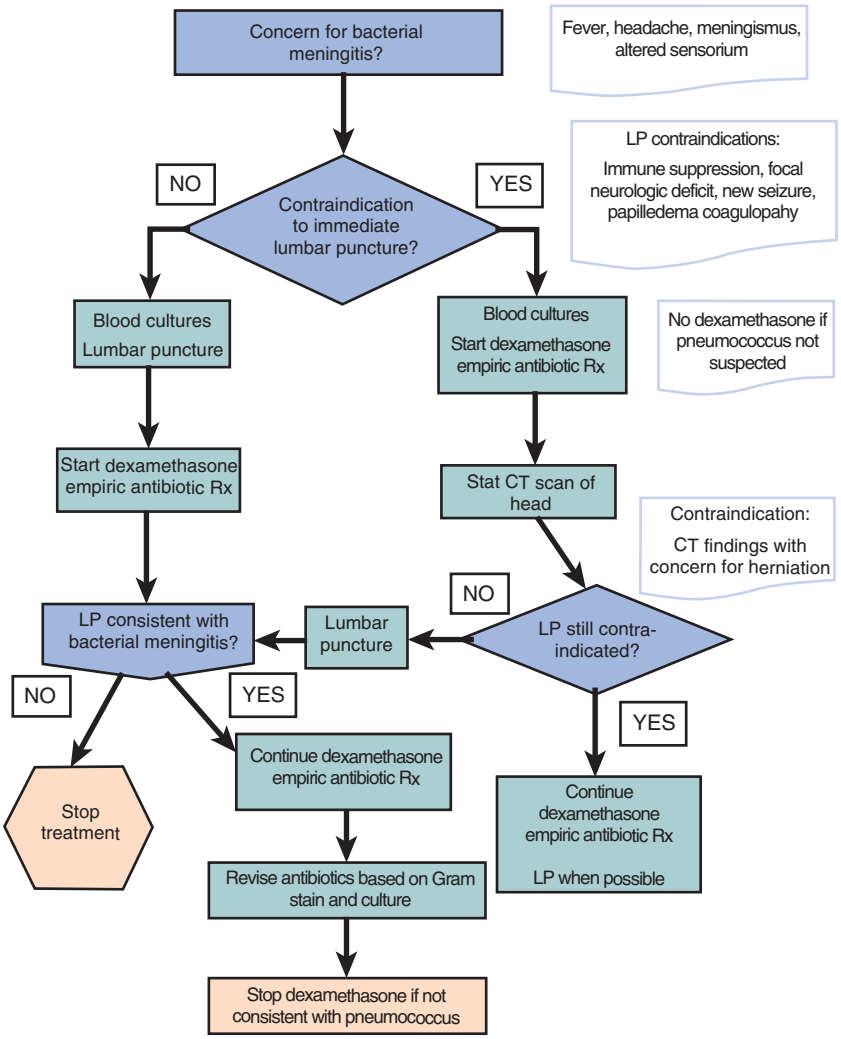
The predominant mode of acquisition of bacterial meningitis results from nasopharyngeal bacterial colonization with subsequent hematogenous spread and invasion of cerebrospinal fluid.[1,5] Less frequently, infection occurs via hematogenous dissemination from distant sites; from other localized intracranial focal infections such as sinusitis, mastoiditis, or otitis; or is secondary to trauma or neurosurgery. Once bacterial organisms have invaded cerebrospinal fluid (CSF), there are a wide variety of immunologic deficits that result in impaired clearance of encapsulated organisms. These include organism-specific deficits such as terminal complement deficiencies predisposing to meningococcal disease,[7] and more general deficits, such as immunoglobulin deficiencies, splenectomy, alcoholism, cirrhosis, diabetes mellitus, and human immunodeficiency virus (HIV).[1] Patients with defects leading to impaired cell-mediated immunity including advanced age and general debility, as well as hematologic malignancies, chemotherapy, and use of tumor necrosis factor (TNF)-β inhibitors, are predisposed to *Listeria* infection.[9]

The presenting symptoms of bacterial meningitis include fever, headache, stiff neck, and altered sensorium. In a large series of 1268 cases from the Netherlands, each of these symptoms individually was found in more than 70% of patients, although only 41% had all of the classic triad of headache, fever, and stiff neck.[3] Other important presenting symptoms in this cohort included nausea in 62%, focal neurologic deficits in one-third of patients, and Glasgow Coma Scale scores of less than 8 in 13% of cases.[3] Rash, especially a petechial or purpural rash, was seen in only 8% of these patients, less than rates of up to 25% reported in earlier series, most with rash had meningococcal meningitis.[3] Presenting symptoms alone without CSF findings and microbiologic data cannot adequately distinguish between bacterial meningitis and viral or other aseptic meningitis. However, certain features are more suggestive of bacterial rather than viral origin, including winter versus summer onset, rapid progression of disease, presentation in shock, and presence of another focal site of bacterial infection, such as sinusitis, otitis, or pneumonia. In addition to viruses, many other infections, including cryptococcal meningitis, tuberculous meningitis, rickettsial diseases, Lyme disease, and syphilis, are in the differential diagnoses of acute bacterial meningitis.

Diagnostic Strategies and Early Management of Suspected Bacterial Meningitis

The early management of suspected bacterial meningitis requires careful coordination and appropriate sequencing of the procedures necessary for appropriate diagnosis (lumbar puncture and imaging studies) and the interventions necessary for optimal treatment (antibiotics and dexamethasone). Rapid initiation of therapy leads to improved outcomes but may decrease specific microbiologic yield on CSF analysis.[1,5] Lumbar puncture, the key diagnostic study, can usually be performed safely without any imaging studies, but computed tomography (CT) scan may be required to minimize the risk of this procedure, leading to potential delays in institution of antimicrobial therapy.[5,10] One widely implemented standard algorithm for the initial management of bacterial meningitis is shown in Fig. 51.1.[5]

The primary tenet of this algorithm is that the initiation of treatment assumes highest priority, and that any delay in performing a lumbar puncture either because of the need for imaging before the procedure or because of other patient-specific contraindications should not delay antibiotic therapy. Brain herniation from elevated intracranial pressure (ICP) is a feared but rare complication of lumbar puncture when performed for diagnosis of suspected meningitis, but a recent study of a cohort of 301 patients with suspected bacterial meningitis demonstrated the relative safety of lumbar puncture without CT scanning in patients without specific clinical contraindications.[10] Proposed criteria for performing imaging before lumbar puncture include new-onset seizures, prior CNS disease, immunocompromised state, papilledema, focal neurologic deficits, or moderate to severe impairment of consciousness.[5] Although only approximately 45% of patients with bacterial meningitis have criteria for neuroimaging before lumbar puncture, it has become standard practice in many hospitals for all patients with suspected meningitis to undergo imaging first to look for evidence of brain shift.[1,5] Less stringent criteria for the need



• **Fig. 51.1** Algorithm for early management of suspected bacterial meningitis including when to suspect the diagnosis, when imaging prior to lumbar puncture is appropriate, and when to initiate and discontinue empiric antibiotics and adjuvant dexamethasone. *CT,* Computed tomography; *LP,* lumbar puncture; *Rx,* treatment. (Based on Tunkel AR, Hartman BJ, Kaplan SL, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis.* 2004;39:1267–1284; and additional information from Hasbun R, Abrahams J, Jekel J, et al. Computed tomography of the head before lumbar puncture in adults with suspected meningitis. *N Engl J Med*. 2001;345:1727–1733; Glimåker M, Johansson B, Grindborg Ö, et al. Adult bacterial meningitis: earlier treatment and improved outcome following guideline revision promoting prompt lumbar puncture. *Clin Infect Dis.* 2015;60:1162–1169; and Brouwer MC, McIntyre P, Prasad K, et al. Corticosteroids for acute bacterial meningitis. *Cochrane Database Syst Rev.* 2015;12(9):CD004405.)

for CT scan before lumbar puncture have decreased time to antibiotic administration and improved outcome in recent series.[11] Both noncontrast CT and magnetic resonance imaging (MRI) can be used for this purpose. Considerations for the optimal imaging modality may be different when studies are done to manage complications of meningitis or to better characterize space-occupying lesions. Other contraindications to performing lumbar puncture include coagulopathies and the presence of local disease such as stasis ulcers, burns, or cellulitis overlying the lumbar puncture site.

The diagnosis of bacterial meningitis is heavily reliant on CSF studies, including opening pressure, cell count, protein, glucose, Gram stain, and culture. Typically patients with bacterial meningitis have elevated opening pressures of 200 to 500 mm H_2O, including 40% with opening pressure greater than 400 mm in one recent cohort.[1,5] White blood cell (WBC) counts may range from 100 to 10,000 cells/mm^3, with most counts in the range of 1000 to 5000 cells/mm^3; very low CSF WBCs are associated with a worse prognosis. Usually a polymorphonuclear (PMN) cell predominance of 80% or greater exists, although up to 10% will have a lymphocytic predominance, particularly early on. CSF-to-serum glucose ratios are less than 0.4, and CSF protein levels are nearly always increased.[5,12] In studies comparing cohorts of patients with bacterial and viral meningitis, CSF glucose ratios of less than 0.31, total WBC of greater than 2000 cells/mm^3, and total PMN of greater than 1180 cells/mm^3 have been predictive of bacterial rather than viral etiology.[13] Gram stains are positive in 60% to 90% of cases of bacterial meningitis, and results on Gram stain are reported to be 97% specific as to etiology.[5] Yield of Gram stain is higher on specimens concentrated by Cytospin centrifuge (Thermo Fisher Scientific, Waltham, MA). Highest diagnostic yield from Gram staining is for *S. pneumoniae* meningitis; Gram stains in *Listeria* meningitis may reveal organisms in only one-third of cases because of the lower inoculum of bacteria in the CSF. In patients without prior antibiotic exposure, cultures are positive in up to 90% of cases. Initiation of antibiotic therapy before lumbar puncture will not significantly alter cell count, protein, glucose, and even Gram stain results but will decrease CSF culture yield by up to 20%.[5] Blood cultures should be performed in all patients with suspected bacterial meningitis and should be done before initiation of antibiotics, even if the lumbar puncture is delayed.

Additional CSF and blood tests have been used to confirm a diagnosis of bacterial meningitis or help distinguish bacterial from viral disease. An elevated CSF lactate of greater than 4.2 mmol/dL is reported to be a sensitive marker for bacterial meningitis, but specificity has been questioned.[12] Elevated serum C-reactive

protein levels are not specific for bacterial meningitis, but a low C-reactive protein level has good negative predictive value for bacterial meningitis in patients with abnormal CSF and negative CSF Gram stains.[5] Serum procalcitonin may also prove useful for diagnosis.[12]

Non–culture-based pathogen-specific tests are increasingly being used to diagnose bacterial and viral meningitis. Latex agglutination tests for bacterial antigens are widely available, but they have not been shown to contribute significantly to the management of most patients with suspected meningitis and false-positive test results are reported.[5] Nucleic acid amplification tests (NAATs) such as polymerase chain reaction (PCR) of CSF for bacterial DNA may be useful to confirm an etiologic diagnosis. Multiplex NAATs for concurrent testing for several bacterial and viral pathogens have recently become commercially available. NAAT studies have the potential advantages of rapid diagnosis and enhanced sensitivity, especially in the setting of previously administered antimicrobial therapy that can decrease yield of culture based methods.[12] The FilmArray Meningitis/Encephalitis Panel (BioFire Diagnostics, Salt Lake City, UT), recently available in the United States, is one example of a multiplex NAAT that can detect 14 different bacterial, viral, and fungal pathogens in a single CSF sample.[14] Additional CSF studies that may be useful for diagnosis of other specific meningeal infections include CSF cryptococcal antigen tests and Venereal Disease Research Laboratories (VDRL) slide test.

Initial antibiotic therapy for suspected bacterial meningitis is commonly initiated before culture and even Gram stain results are available. Initial empiric therapy must include agents active against the most likely pathogens based on the patient's age and underlying illnesses and modified for other specific risk factors, such as nosocomial acquisition (Table 51.1). Treatment regimens must reflect local rates of antimicrobial resistance, particularly rates of high-level resistance to penicillin and third-generation cephalosporins in *S. pneumoniae*. Standard regimens include vancomycin administered at doses targeted to achieve adequate CSF levels (serum troughs of 15 to 20 μg/mL) and a third-generation cephalosporin, either ceftriaxone or cefotaxime. In areas with increased rates of pneumococcal resistance to third-generation cephalosporins, rifampin may be added. When there is risk for *Listeria* infection based on age older than 50 years or on other specific risk factors such as alcoholism or altered immunity,

TABLE 51.1 Empiric Treatment of Suspected Bacterial Meningitis in Adults[a,1,2,5,8]

Host Factors to Consider	Age >50 years? Risk for *Listeria monocytogenes* and aerobic gram-negative rods		
	Immune suppression? Includes host defects (e.g., HIV, alcoholism, lymphoma) and treatment-related (e.g., posttransplant, corticosteroids)		
	Health care–associated? Includes trauma, postneurosurgical, shunt- or ventriculostomy-related		
	Life-threatening penicillin/β-lactam allergy? Aztreonam or fluoroquinolone alternatives for gram-negative rods; trimethoprim-sulfamethoxazole an alternative for *L. monocytogenes*		
Host	**Likely Pathogens**	**Empiric Therapy**	**Additional Considerations**
Age 15–50 years Without Immune Suppression	*Streptococcus pneumoniae, Neisseria meningitidis*, group B β-hemolytic streptococci	Vancomycin + third-generation cephalosporin[b]	Adjuvant dexamethasone Consider rifampin if high rates of cephalosporin-resistant *S. pneumoniae*
Age ≥50 years Without Immune Suppression	*S. pneumoniae, N. meningitidis,* group B β-hemolytic streptococci, *L. monocytogenes,* aerobic gram-negative rods	Vancomycin + ampicillin + third-generation cephalosporin[b]	Adjuvant dexamethasone Consider rifampin if high rates of cephalosporin-resistant *S. pneumoniae*
Immune Suppression	*S. pneumoniae, N. meningitidis,* group B β-hemolytic streptococci, *L. monocytogenes*, *Staphylococcus aureus*, aerobic gram-negative rods including *Pseudomonas aeruginosa*	Vancomycin + ampicillin + cefepime or meropenum[c]	Adjuvant dexamethasone Consider rifampin if high rates of cephalosporin-resistant *S. pneumoniae*
Health Care–Associated: Trauma, Postneurosurgical, or Shunt-Associated[c]	*S. aureus*, coagulase-negative staphylococci, aerobic gram-negative rods including *P. aeruginosa*	Vancomycin + ceftazidime or cefepime or meropenem[c]	Dexamethasone not indicated Consider rifampin for staphylococci Consider intrathecal therapy for shunt-/ventriculostomy-associated infection
Health Care–Associated: Basilar Skull Fracture	*S. pneumoniae*, *Haemophilus influenzae*, group A β-hemolytic streptococci	Vancomycin + third-generation cephalosporin[b]	Adjuvant dexamethasone Consider rifampin if high rates of cephalosporin-resistant *S. pneumoniae*

[a]Age older than 15 years.
[b]Third-generation cephalosporin: ceftriaxone 2 g q12h or cefotaxime 2 g q4–6h.
[c]Dosing of other agents (modified for renal insufficiency): vancomycin targeted to vancomycin trough levels of 15–20 μg/mL; ampicillin 2 g q4h; ceftazidime 2 g q8h; cefepime 2 g q8h; meropenem 2 g q8h.
HIV, Human immunodeficiency virus.

high-dose ampicillin is added to the regimen. For patients with health care–associated bacterial meningitis, cefotaxime or ceftriaxone should be replaced by a β-lactam such as cefepime, ceftazidime, or meropenem that has activity against *Pseudomonas aeruginosa*, with choice based on local susceptibility data.[8] Antibiotic therapy should then be modified based on culture and susceptibility results. Standard recommended treatment durations are 7 days for meningococcal disease and *H. influenzae*, 10 to 14 days for S. *pneumoniae*, and 21 or more days for *Listeria*.[1,5]

The benefit of adjuvant corticosteroids in decreasing mortality and neurologic sequelae in patients with bacterial meningitis continues to be debated.[15,16] In one large, randomized, placebo-controlled trial of 301 adults with suspected bacterial meningitis and cloudy CSF, adjuvant dexamethasone decreased mortality from 15% to 7% and decreased unfavorable outcomes from 25% to 15%.[15] Benefits of corticosteroids were most evident in those with pneumococcal infection and those with a moderately impaired level of consciousness. Additional prospective cohort studies and meta-analyses of available data confirm the benefits of corticosteroids for decreasing hearing loss and decreasing neurologic sequelae, although the evidence for mortality benefit in patients with confirmed or suspected pneumococcal meningitis is weaker. No benefit was demonstrated for meningococcal disease or for other organisms, nor was any benefit clearly demonstrated in prospective studies of adults with bacterial meningitis in developing countries.[12,16] The recommended steroid regimen is 10 mg of dexamethasone every 6 hours for 4 days and initiated before or concurrent with the first dose of antibiotics.[1,5] The benefit for steroids administered after antibiotic initiation is not defined.

Patients with suspected or confirmed meningococcal meningitis should be placed in isolation to prevent nosocomial transmission via respiratory droplets during the first 24 hours of therapy. Meningococcal prophylaxis is indicated for household and other close contacts of meningococcal cases including first responders. Conversely, patients with Gram stains and clinical presentations consistent with nonmeningococcal disease should also be quickly identified to eliminate unnecessary administration of meningococcal prophylaxis.

Complications of Bacterial Meningitis, Need for ICU Monitoring, and Outcome

Patients with bacterial meningitis often require ICU care either to manage complications evident on presentation or for monitoring for any complications that may subsequently develop during their course.[1] Some criteria for admission to an ICU (Table 51.2) include sepsis and septic shock, respiratory compromise or pulmonary infiltrates, high risk of brain herniation, moderately impaired and deteriorating level of consciousness, new or evolving neurologic deficits, and the presence of seizures.[1,17,18] Patients with generally good outcomes can be defined early in their course on the basis of age, Glasgow Coma Scale score, APACHE II (Acute Physiologic Assessment and Chronic Health Evaluation II) score, absence of focal neurologic abnormalities, and favorable laboratory features, but these stratification schemes still fail to identify some patients

TABLE 51.2 Major Complications of Bacterial Meningitis Requiring ICU Level of Care for Monitoring and Management[1,3,4,5,18]

Type of Complication	Etiologies, Prevalence	Management Strategies
Neurologic Complications		
Increasing intracranial pressure	Brain edema, 6%–10%	Strategies: osmotic diuresis, intracranial pressure monitoring, head of bed elevation, prophylactic lumbar drain Glycerol and hypothermia not beneficial and may result in higher mortality
Hydrocephalus	Communicating hydrocephalus, 3%–8% Obstructive hydrocephalus uncommon	Repeated lumbar puncture, lumbar drain, ventriculostomy
Focal neurologic deficits	Arterial infarct or vasculitis, 10%–15% Venous infarction, 3%–5% Hearing loss, 14%–30% Cranial nerve deficits, especially eighth nerve, 15%–30% Hemorrhage, <1% Brain abscess, subdural empyema <1%	Radiographic studies to look for focal intracranial complications Administer dexamethasone for suspected pneumococcal meningitis to decreases risk of hearing loss
Seizures	Multiple etiologies, 14%–33%	Continuous EEG monitoring, antiepileptic agents Prophylactic antiepileptic agents not routinely recommended
Agitation	Common	Careful sedation
Other Complications		
Hyponatremia	Up to 25%–30%	? Hypertonic saline solution Presence of hyponatremia did not affect outcome
Sepsis and cardiorespiratory failure	38%	Hemodynamic support, mechanical ventilation
Pneumonia	17%, most often with *Streptococcus pneumoniae*	Ventilatory support

EEG, Electroencephalographic.

with more complicated courses, and conversely, some patients with poor Glasgow Coma Scale scores may still have good outcomes.[2,3,17] Some authors recommend ICU admission for all cases of bacterial meningitis, as patients may benefit from early intensive monitoring for the presence of new neurologic signs or subtle seizures and for effective control of agitation.[1,17]

The major complications that occur during the course of bacterial meningitis have been reported in both older and more recent post–steroid era case series. Complications most notably include deteriorating level of consciousness, which may be due to development of meningoencephalitis (15%–30% of cases); seizures (14%–33%); brain edema (6%–10%); or hydrocephalus (3%–8%).[1,2,17] Increased ICP is associated with worse prognosis, but no single approach to treatment has been confirmed to be effective in all cases.[1,2,17] Elevation of the head of the bed, mannitol, hyperventilation, repeated lumbar punctures, prophylactic lumbar drainage, prophylactic ventriculostomy, and normal fluid and electrolyte homeostasis have all been proposed for management of increasing ICP. Patients with severely increased pressure with impending herniation may require ventriculostomy with continuous CSF pressure monitoring. Often multiple interventions may be necessary for targeted strategies where ICP is maintained at less than 20 mm Hg. Glycerol and induced hypothermia were also recently studied as potential interventions for management of ICP and for cerebral protective effects in bacterial meningitis, but trials were stopped because of worse outcomes in the intervention arms.[18] All patients with bacterial meningitis should be monitored for seizures, including nonfocal seizures that may only manifest as worsening level of consciousness, but routine use of prophylactic antiepileptic medication is not recommended.[5] Focal neurologic deficits early in the course of meningitis are most often caused by cerebrovascular complications or arteritis secondary to inflammation or less commonly to venous infarcts. The most common late neurologic complication is hearing loss, described in up to 20% of patients overall and in up to 34% of those with pneumococcal meningitis.[1,2] The incidence of hearing loss appears to be decreased in patients treated with dexamethasone.[1,12,15] Subdural empyema, brain abscess, and hemorrhage are all rare but potentially catastrophic complications of bacterial meningitis.

Repeat lumbar punctures are no longer routinely recommended in patients with bacterial meningitis who are improving.[5] Repeat lumbar puncture is indicated in those with worsening or suboptimal clinical response at 48 hours or in patients who develop recurrent fevers. Repeat CSF analysis may also be indicated for infections caused by more drug-resistant organisms such as cephalosporin-resistant *S. pneumoniae*, especially if treated with dexamethasone, as steroids may potentially decrease antibiotic penetration into CSF and delay sterilization. Repeat imaging by MRI or enhanced CT scan should be performed in patients with clinical deterioration or persistent decreased level of consciousness to assess for intracranial complications as described earlier. Overall mortality rates for bacterial meningitis without the use of steroids are reported to be approximately 20%, and an additional 14% have moderate or major neurologic sequelae.[1,17] The prognosis for meningococcal meningitis is better than for pneumococcal infection. Late neuropsychiatric cognitive effects are seen in up to 10% of cases of bacterial meningitis.

Encephalitis

The other major CNS infectious syndrome besides bacterial meningitis presenting with fever, headache, altered sensorium, and meningeal signs is acute encephalitis, which is most commonly of viral etiology. Although there is significant overlap between clinical presentations of patients with bacterial meningitis and viral encephalitis, the presentation of viral encephalitis is dominated by evidence of parenchymal brain dysfunction, including moderate to severely impaired sensorium, delirium, psychosis, focal neurologic findings, and seizures.[19,20] The presence of meningismus is more variable, but most patients have some evidence of meningeal enhancement on imaging and inflammatory cells in CSF.

A wide variety of viruses can cause encephalitis, but management strategies focus on the most common etiologies, especially those most likely to respond to specific interventions such as encephalitis caused by herpes simplex virus (HSV).[20–32] Other herpes group viruses with worldwide distribution capable of causing encephalitis include varicella-zoster virus, Epstein-Barr virus, and cytomegalovirus, especially in immunocompromised patients.[19,20,22] Influenza virus, mumps, measles, and enteroviruses are also important etiologies of acute viral encephalitis worldwide. Acute HIV infection may present as fulminant meningoencephalitis.[19,20] Acute presentations of progressive multifocal leukoencephalopathy caused by JC virus are also increasingly reported in patients with HIV infection and other immunocompromised patients.[23] In addition to viruses with worldwide distribution, there are many vector-borne encephalitis-causing viruses having more regional and seasonal distributions.[22] Important pathogens include Eastern, Western, and Venezuelan equine encephalitis; Japanese B encephalitis; St. Louis encephalitis; La Crosse encephalitis; and Nipah encephalitis. New cases of meningoencephalitis may be one of the first indications of spread of an emerging infectious disease into a new geographic area.[24] Recently West Nile encephalitis emerged as a major pathogen in the Western Hemisphere, first appearing in New York City in 1999 but with cases now distributed throughout the country.[25] Another recently emerging virus associated with encephalitis is Zika virus, a mosquito-borne *Flavivirus* that appeared in Brazil in 2015 and rapidly spread through the Western Hemisphere. Guillain-Barré syndrome is the most common serious neurologic manifestation and is seen in approximately 1 in 4000 infections in children and adults, but rare cases of encephalitis and encephalomyelitis have also been reported.[26]

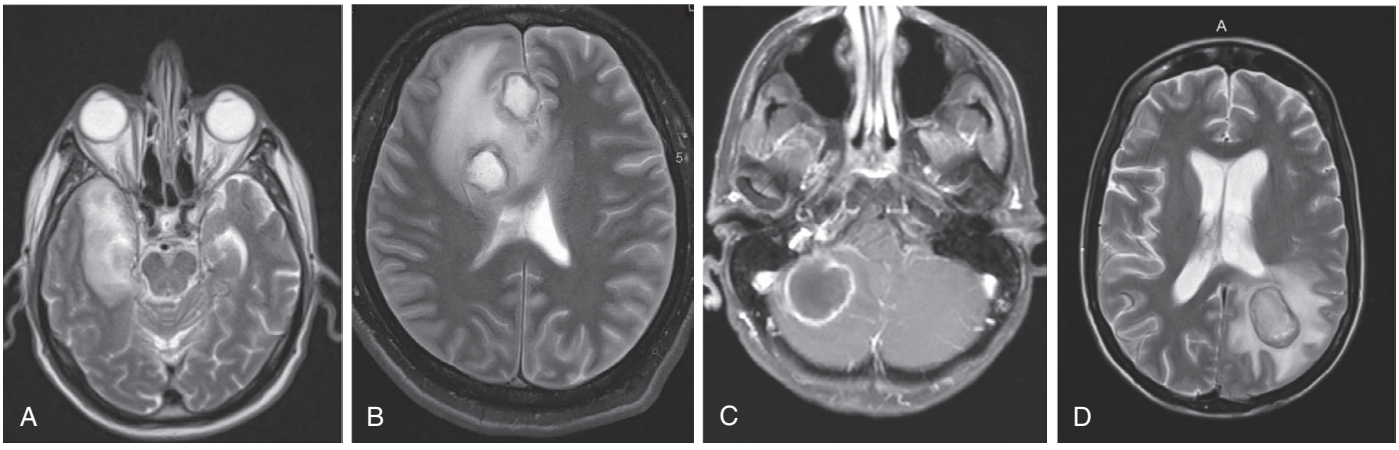
Rabies, although extremely rare in developed countries, also needs to be considered in the differential diagnosis of fulminant encephalitis, both for its epidemiologic implications and for the potential of survival now for patients with this previously universally fatal infection who have received aggressive ICU management.[27] In addition to viral infections, many atypical bacteria, fungi, and protozoal organisms can present as acute meningoencephalitis. Particularly important to consider early in the differential diagnosis are infections that may respond to specific antimicrobial treatment, including rickettsial diseases such as Rocky Mountain spotted fever, and meningoencephalitis from spirochetal infections including leptospirosis, neurosyphilis, and Lyme disease.[22,28,29] Important clues to these diseases include epidemiologic history and associated clinical features such as rash or icterus. Recently developed consensus case definitions and standardized approaches to diagnosis for infectious encephalitis should facilitate understanding of this heterogeneous syndrome, in which diagnoses are determined less than 50% of the time even after aggressive evaluation for infectious etiologies.[30]

Herpes simplex encephalitis is the most common sporadic cause of serious viral meningoencephalitis, causing 3% to 10% of cases of infectious encephalitis in adults with an estimated frequency of about 1000 to 2000 cases per year in the United States.[20,21,31]

Most cases beyond the neonatal period are caused by HSV type 1, usually as reactivation disease and not primary infection; HSV type 2 commonly causes aseptic meningitis but much less commonly presents as fulminant encephalitis.[21,31] Herpes encephalitis is an acute necrotizing process, typically causing hemorrhagic necrosis with particular predilection for the frontotemporal lobes and cingulated gyrus. Mortality rates are up to 70% in untreated cases, with 95% of survivors having serious neurologic sequelae.[21,22] Cases of herpes encephalitis beyond the neonatal period occur throughout life, but the highest case rates occur in those younger than 20 years or age or in adults older than age 50 (half of cases). Presentation may include a prodromal viral syndrome in 50% of cases, followed by a generally rapid onset of headache, confusion, and altered level of consciousness. Meningismus, focal neurologic findings, and seizures are also common.[20–32] Concurrent herpetic rashes are not generally seen in patients with HSV encephalitis. In one series of patients with encephalitis, focal CNS disease was much more likely than diffuse CNS disease to be caused by HSV.[32] The approach to cases of suspected herpes encephalitis, as well as other viral or unknown encephalitis, includes early initiation of antiviral therapy and concurrent rapid clinical evaluation that includes imaging, CSF studies, and electroencephalogram (EEG) to establish a diagnosis.[20–32] CT scans can remain normal up to 4 to 5 days into the course; thus MRI is considered the imaging modality of choice. MRI results are positive in more than 90% of cases, often showing changes of edema and necrosis in the medial temporal lobes, insular cortex, and cingulate gyrus as soon as 2 to 3 days into the illness (Fig. 51.2). EEGs are abnormal in nearly all cases, but early findings are nonspecific with characteristic periodic lateralizing epileptiform discharges often not seen until later in the course.[21] CSF findings include low- to moderate-grade lymphocytic pleocytosis in 85% and elevated protein in 80%; elevated red blood cell counts and mildly decreased glucose levels are common but not universal, and cell counts may be completely normal in 8% of cases.[21,31] In recent management guidelines, PCR of CSF for HSV DNA has replaced brain biopsy as the diagnostic method of choice for HSV encephalitis.[20–32] In two trials comparing PCR with brain biopsy, the sensitivity of PCR was 98% and specificity was 94% for diagnosing HSV encephalitis; the negative predictive value of PCR on CSF obtained more than 72 hours into the course of illness was close to 100% for excluding HSV.[22,33,34] PCR has also expanded understanding of the range of clinical presentations of HSV encephalitis including recognition of less severe cases.[34] Viral culture has low sensitivity for diagnosis in older children and adults, and CSF and serum antibody studies have little role in the diagnosis.[21,22] Treatment should be initiated on the basis of clinical suspicion pending PCR results using intravenous (IV) acyclovir at high doses of 10 mg/kg every 8 hours and continued for 14 to 21 days. Treatment is generally discontinued when negative PCR results are available or an alternative diagnosis is established. In patients with a low probability of HSV encephalitis who have normal imaging results, CSF pleocytosis of less than 5 cells, and normal mental status, a single negative PCR assay is adequate to exclude the diagnosis more than 99% of the time; in patients with higher clinical evidence for HSV encephalitis, repeating PCR testing of CSF before stopping antiviral therapy may be appropriate.[21] There are insufficient data to recommend oral valaciclovir as an alternative to parenteral therapy at this time.

West Nile Virus Encephalitis

Since first emerging in the Western Hemisphere in 1999, West Nile virus (WNV) has become a major infectious cause of invasive neurologic disease throughout the United States, with nearly 1500 cases from 43 states reported in 2015.[25] WNV is a mosquito-borne arbovirus affecting birds, mammals, and humans. Of human cases, 80% are asymptomatic and most of the remainder have West Nile fever, but 1% develop neuroinvasive disease manifesting as meningitis, encephalitis, and/or a polio-like flaccid paralysis syndrome.[35,36] The risk of encephalitis increases with age or with immunosuppression, particularly organ transplantation, and manifestations can range from mild disorientation to coma and death.[25,35] Parkinson-like tremors are also commonly reported. The flaccid



• **Fig. 51.2** Magnetic resonance imaging (MRI) of intracranial infections. A, MRI imaging showing herpes encephalitis appearing as a "mass-like" lesion in the right temporal lobe in a patient with subacute presentation of seizures and altered mental status. B, MRI imaging of two periventricular brain abscesses in the right frontal lobe with surrounding edema and mass effect and impinging on the ventricle. Ventricular rupture is a catastrophic complication of brain abscesses. C, MRI imaging showing characteristic ring enhancement after administration of gadolinium of a right cerebellar brain abscess that grew *Streptococcus intermedius* and microaerophilic streptococci. D, MRI imaging of an inflammatory mass lesion in the occipital lobe in an HIV-positive patient presenting with headache and seizures; cultures grew *Mycobacterium tuberculosis*.

paralysis syndrome, caused by viral infection of anterior horn cells, may have an abrupt onset and patients may require prolonged ventilatory support. The fatality rate is 9% for WNV neuroinvasive syndromes, and survivors may have prolonged or permanent deficits.[35,36] CSF findings of WNV are similar to those of other viral infections with lymphocytic pleocytosis predominating. Neuroimaging results may be normal, but some scans may demonstrate abnormal signal in the basal ganglia, thalamus, and other deep brain structures or abnormal signal in anterior horn cells of the spinal cord.[35,36] Diagnosis is confirmed by the finding of WNV-specific immunoglobulin (Ig) M antibodies in CSF and serum or by nucleic acid–based PCR of CSF, serum, or other fluids.[35] Treatment is primarily supportive; multiple interventions such as ribavirin, interferon alfa, and immunoglobulin have been studied, but there is limited evidence for benefits.

Brain Abscess

Brain abscesses are focal infections of brain parenchyma, occurring (1) from direct spread from local, contiguous infection (ear, sinuses, mastoid, bacterial meningitis); (2) from hematogenous spread of infecting organisms from distant sites; or (3) by direct inoculation from trauma or surgery.[37,38] The incidence in developed countries is reported as 0.4 to 0.9 cases per 100,000 per year, with a higher incidence in immunosuppressed populations.[37] Modern imaging modalities have improved the initial management and follow-up care of patients with brain abscess, but morbidity and mortality of this syndrome remains high. Presenting symptoms may be indistinguishable from those of other CNS infections. Headache is the most frequently reported symptom; fever is common but prevalence is less than seen in bacterial meningitis.[38,39] Focal neurologic findings reflect the location of the abscess. Seizures, reported in 25% in one series, and decreased level of consciousness are also common; systemic sepsis is less common.[37–39] Brain abscess symptoms may be much more subtle and nonspecific compared with bacterial meningitis or viral encephalitis, contributing to delay in diagnosis. Microbiology reflects the source of the original infection and most commonly includes streptococci, staphylococci, oral anaerobes, and enteric gram-negative organisms, but multiple other bacterial, fungal, tuberculous, and atypical organisms can also be found and many specimens are polymicrobial.[38–40] Molecular testing for bacterial DNA has been used to identify pathogens from culture-negative specimens.[40] In areas of high HIV prevalence, opportunistic brain infections, especially toxoplasmosis, and CNS lymphoma become more prevalent than bacterial pyogenic abscesses, and knowledge of HIV status is crucial to initial management of mass lesions.[41] CNS tuberculomas are also important considerations in patients in or from TB endemic areas, especially immunosuppressed patients or patients with HIV infection.[42]

The diagnosis of brain abscess is suggested by the clinical presentation and imaging findings by either CT or MRI showing enhancing parenchymal lesions, usually with surrounding inflammatory changes.[37,38] Radiographic appearance may be indistinguishable from a malignant lesion, although MRI with diffusion-weighted imaging in one study demonstrated 96% specificity for distinguishing brain abscess from primary or metastatic cancer. Management of suspected abscess includes either stereotactic aspiration or surgical drainage to both establish a microbiologic diagnosis and for primary treatment of the abscess. Blood and CSF cultures, if lumbar puncture can be safely performed, will provide positive microbiologic results in only up to 25% of patients. Smaller lesions (<1 cm) can be treated with antibiotics alone, but larger lesions will require either aspiration or open drainage.[37,38] Duration of treatment traditionally has been at least 6 to 8 weeks of parenteral therapy but now most often is determined by resolution of the abscess on serial imaging studies. Unlike bacterial brain abscesses, toxoplasmosis lesions in patients with AIDS are usually multiple and may respond to empiric toxoplasmosis therapy without need for further invasive diagnostic procedures.[41]

Spinal Epidural Abscess

Spinal epidural infections most commonly arise by contiguous spread of infection into the spinal canal as a complication of vertebral infections or, less commonly, as a complication of epidural procedures such as epidural injections or epidural catheterization.[43–46] Vertebral infections result from hematogenous infection of vertebral bodies or disk space or by direct introduction of organisms from surgery or trauma. In addition to affecting the vertebral bodies and/or intervertebral disk spaces, vertebral osteomyelitis may expand into surrounding paravertebral soft tissues and spinal canal and even rarely into the medullary spinal cord. Paravertebral and epidural infections can rapidly progress, resulting in severe neurologic symptoms from compression of nerve roots or the spinal cord, or by infarction of the spinal cord from inflammation and vasculitis of vertebral arteries.[43,44] Thus an aggressive diagnostic and therapeutic approach is necessary to prevent catastrophic consequences such as irreversible paraplegia and death.

The incidence of spinal epidural infection from large retrospective reviews is reported as approximately 0.2 to 2 cases per 10,000 hospital admissions, but the frequency of this diagnosis may be increasing, perhaps because of improvements in radiographic diagnosis.[45,46] Incidence in adults increases with age older than 30 years; important predisposing factors include diabetes, injection drug use, alcoholism, immunosuppression, underlying spinal disorders, trauma, invasive procedures, and extraspinal sites of infection that cause significant bacteremia.[43,45,46] Infections can occur at any level of the spinal cord, although most series report predominance of lumbar involvement. Approximately two-thirds of infections are caused by *Staphylococcus aureus*, with a variety of other gram-positive organisms (coagulase-negative staphylococci, viridans streptococci, β-hemolytic streptococci), as well as gram-negative organisms all reported in lesser numbers.[44–46] Granulomatous infections including tuberculosis and brucellosis remain major etiologies of vertebral and epidural infection in many areas of the world. Approximately 10% are culture-negative.[45]

Presenting symptoms are back pain in more than 95% of cases and fever in two-thirds of cases; unfortunately, these symptoms are extremely nonspecific.[44,45] Thirty percent of patients present with evidence of early neurologic deficits such as muscle weakness, incontinence, or sensory deficits, and up to one-third have evidence of paralysis on examination.[44–46] Associated laboratory features include leukocytosis in two-thirds of cases and elevated erythrocyte sedimentation rate in nearly all cases. The most sensitive imaging modality is MRI with gadolinium, with reported sensitivity of greater than 95%, but most infections were also visualized on CT and unenhanced MRI.[44,45] Owing to the lack of specificity of the presenting symptoms, especially back pain, the overall yield of MRI studies when performed to look for spinal epidural abscess is low, and algorithms using specific risk factors such as history of recent *S. aureus* bacteremia, recent spinal procedures or contiguous focus of infection, and elevated inflammatory markers have been proposed to facilitate more rapid diagnosis in the appropriate setting.[46,47] Until recently, standard therapy included emergent

drainage of the abscess and systemic antibiotic therapy. Over the past 2 decades there has been an emerging literature on more conservative medical management using percutaneous aspiration and antibiotics without open surgical drainage.[43–46] These reports have suggested that outcomes are similar or better (i.e., less neurologic sequelae) without open surgery.[44] Several recent reviews and meta-analyses have failed to show a clear difference between medical and surgical outcomes, but there was significant heterogeneity between studies and significant patient selection bias and in other studies failure rates for medical therapy exceeded 40%.[48] Indications for surgery include neurologic progression on treatment or lack of clinical response; thus those managed without surgery require careful monitoring.[44,45] Other proposed indications for surgical management include those with more severe neurologic deficits on initial presentation, older age, diabetes, methicillin-resistant *S. aureus* (MRSA) infections, and cervical infections.[44,45,48]

Fulminant Endovascular Infections

Infectious endocarditis and other endovascular infections are common causes of bacteremia and sepsis, and these patients are frequently admitted to critical care units for management of sepsis and other complications. Often the diagnosis of endovascular infection is unsuspected and initiation of appropriate treatment is delayed. Even relatively stable patients with bacterial endocarditis, especially left-sided endocarditis, require careful monitoring and management of potential major complications, including heart failure or other cardiac events, and for septic emboli, especially intracranial emboli. The role of early surgical intervention in improving outcome has become increasingly appreciated in the management of complicated bacterial endocarditis, especially *S. aureus* endocarditis.

Acute Infective Endocarditis

Several recent large case series and population-based studies have addressed changes in the epidemiology of bacterial endocarditis over the past 30 years.[49,50] In some population-based studies the annual incidence of endocarditis of 5 to 7 cases per 100,000 has not changed significantly over time, but other hospital-based databases suggest that rates of endocarditis have been increasing in the United States.[49,50] The International Collaboration on Endocarditis Prospective Cohort Study of 1779 cases from 39 medical centers in 16 countries has illustrated the recent changes in microbiology and clinical presentation of bacterial endocarditis.[51] In most recent cohorts, *S. aureus* rather than *S. viridans* streptococci were the predominant pathogens with an increasing proportion of cases considered as either nosocomially acquired or health care–associated.[51] *S. aureus* endocarditis is associated with significantly higher mortality, a higher rate of stroke, and other systemic embolization and a higher rate of sustained bacteremia than endocarditis caused by other organisms.[51,52] The increased antibiotic resistance in organisms causing endocarditis, notably the increasing prevalence of MRSA and antibiotic-resistant Enterococci, is reflected in recent guidelines for treatment of endocarditis from the American Heart Association (AHA) and the European Society of Cardiology (ESC).[52,53] Other important recent epidemiologic trends are the decreased importance of congenital valvular and rheumatic disease as predispositions, the increasing age of patients, and the increased role of hemodialysis and indwelling cardiac devices such as pacemakers and implantable defibrillators as risk factors.[49,50,54]

Infectious endocarditis must be considered in the differential diagnosis of a broad range of clinical syndromes. Fever is the single most common presenting symptom, often accompanied by other constitutional symptoms of anorexia, weight loss, and fatigue. Onset may be acute or subacute. Signs and symptoms may be caused by direct cardiac effects of infection, including new or changing heart murmur, worsening congestive heart failure and valvular dysfunction, and onset of heart block from myocardial abscesses.[52,53] The clinical presentation may also be dominated by systemic manifestations of emboli or immune complex disease, including such findings as skin lesions, splenomegaly, glomerulonephritis, cerebrovascular events, and other acute vascular embolic events. Patients with acute, fulminant endocarditis, particularly *S. aureus* endocarditis, may present with concurrent cardiogenic and septic shock.

The Modified Duke Criteria for Diagnosis of Infective Endocarditis are a prospectively evaluated set of criteria that are widely utilized for establishing a clinical diagnosis of infective endocarditis.[55,56] The modified Duke Criteria rely predominantly on blood culture results and echocardiographic findings as the major clinical criteria for diagnosis; additional minor clinical criteria (fever, underlying predisposition, embolic phenomena, immunologic phenomena) can also be used as supporting evidence for determining confirmed or suspected cases.[56] Patients with endocarditis have sustained bacteremia; in the absence of prior antibiotic therapy the yield of at least one positive blood culture after three sets are drawn is greater than 90%, and typically multiple cultures are positive. Two to three separate sets of blood cultures should always be obtained in suspected endocarditis before initiation of therapy. Blood culture–negative infectious endocarditis cases may be caused by prior antimicrobial therapy or fastidious or difficult-to-cultivate organisms.[52,53] Follow-up blood cultures are critical to document sterilization of blood on treatment and should be repeated frequently until negative. Echocardiography should be performed as soon as possible on all patients with suspected endocarditis.[52,53] Transthoracic echocardiography (TTE) is reported to have sensitivity of 60% to 75% compared with as high as 95% for transesophageal echocardiography (TEE) for the diagnosis of native valve infection. In both the AHA and ESC guidelines, TTE is recommended the initial testing mode of choice, but for patients with a high initial risk for endocarditis, moderate to high clinical suspicion of endocarditis despite negative TTE, or difficult TTE study, this should be quickly followed by TEE.[52,53] Other indications for TEE include evaluation for prosthetic valve endocarditis, and for many even with diagnostic TTE to better assess for complications such as perivalvular abscess that may affect management (Table 51.3).[52] In children and uncomplicated adult cases in which TTE is diagnostic, TEE may not be necessary. If initial studies are negative, TEE should be repeated in 5 to 7 days if clinical suspicion remains high.[52,53]

Embolic complications may occur at any time with an overall incidence of 20% to 50% in cases of infective endocarditis; risk decreases but still remains high for at least the first 2 weeks after initiation of antimicrobial therapy, especially with large vegetations.[50,54,57] Risks for embolization include specific organisms, especially *S. aureus*, Candida, HACEK organisms, and *Abiotrophia*, increased vegetation size (>10 mm) and mobility as determined by echocardiography; mitral versus aortic valve involvement; and anterior versus posterior location on the mitral valve.[52,53] More than half of clinically manifesting emboli involve the CNS, most commonly in the middle cerebral artery distribution.[52,58] In addition to emboli, other risks for mortality include congestive heart failure, abnormal mental status, comorbidities, higher APACHE score,

TABLE 51.3 Use of Echocardiogram in the Diagnosis of Infective Endocarditis

Pretest Risk Assessment	Explanation/Examples	Most Appropriate Initial Study[a]	When to Perform TEE	Additional Comments
Lower clinical suspicion	Includes patients without underlying predispositions, no blood culture results suggesting endocarditis, and no other clinical manifestations of endocarditis	TTE	TTE negative: stop if suspicion remains low TTE positive: Perform TEE if high-risk echocardiographic features (large/mobile vegetation, valve insufficiency, possible perivalvular abscess) or to assess for other cardiac complications	Perform TEE if clinical suspicion increases Perform TEE if complications occur during therapy
Higher (moderate to high) clinical suspicion	General: includes patients with predispositions (e.g., prosthetic valve, congenital valve disease, prior endocarditis), suspicious blood culture results, or suspicious clinical features (e.g., new valvular insufficiency, embolic phenomena)	TTE or TEE	If TTE inadequate If TTE negative and clinical suspicion persists If TTE positive, to better assess for cardiac complications	Consider repeat TEE if high clinical suspicion persists Perform TEE if complications occur during therapy Consider repeat TTE or TEE to assess clinical response (e.g., vegetation size)
	Staphylococcus aureus bacteremia	TTE	If TTE inadequate or if negative TTE but persistent clinical suspicion Consider if planning short-course (14-day) therapy for bacteremia If TTE positive, to assess for complications	Repeat TEE by 5–7 days for persistent bacteremia
	Concern for prosthetic valve Endocarditis	TTE or TEE	If TTE positive, to better assess for cardiac and perivalvular complications	Consider repeat TEE by 5–7 days if initial TEE negative and high clinical suspicion persists Repeat TEE to evaluate for complications during therapy
	Evaluation for infected cardiac device (AICD, pacemaker, other)	TTE or TEE	If TTE inadequate If TTE negative	Intraoperative TEE may be more sensitive; negative studies do not exclude infected lead
	Right-sided endocarditis	TTE	If TTE inadequate	TEE better for pulmonic valves

[a]The sensitivity of TTE is approximately 70%, and the sensitivity of TEE is approximately 96% for native valve endocarditis. The sensitivity of TTE is approximately 50%, and the sensitivity of TEE approximately 90% for prosthetic valve endocarditis. The specificity of echocardiography is only 90%.

and *S. aureus* infection.[52,59] Congestive heart failure has the highest association with mortality.[52,59] Medical therapy (versus surgical therapy) was also associated with higher 6-month mortality in one recent study.[59]

The decision to perform valvular surgery for patients with active endocarditis remains complex, and indications for surgery must be balanced against the patient's clinical status and predicted operative mortality. Indications for surgery include refractory congestive heart failure; persistent infection despite optimal antimicrobial therapy; fungal or other difficult-to-treat organisms; one or more emboli during the first weeks of antimicrobial therapy; and valvular complications of dehiscence, perforation, fistula, and large perivalvular abscesses (Table 51.4).[52,53] Vegetation size and location are also emerging as independent indications for surgery.[52] The ESC guidelines list refractory heart failure and cardiogenic shock as the strongest indication for emergent valve surgery. The risk of infecting a new prosthetic valve during surgery for active endocarditis is only 2% to 3%; thus active infection is not a contraindication to surgery when indicated for complications associated with high associated mortality.[52,53] Several studies have suggested decreased mortality of cohorts of patients who were managed with early surgical intervention, especially those with left-sided *S. aureus* endocarditis, but to date there has been only one small randomized trial of medical versus surgical therapy.[52,53] The optimal surgical procedure and the role of more conservative procedures such as vegetation resection remain controversial. For tricuspid valve endocarditis with large vegetations, uncontrolled infection, and ongoing septic pulmonary emboli, valve resection and valve repair are alternatives although valve replacement may eventually be required for severe right heart failure.[52,53]

Anticoagulation in patients with active endocarditis can present difficult management dilemmas and the level of evidence informing decisions is low. Initiation of anticoagulation in patients not already receiving it and without other indications is not recommended.[52,53]

TABLE 51.4 Indications and Relative Contraindications for Early Surgical Intervention for Acute Left-Sided Infective Endocarditis

Indication	AHA Guideline[52]	ESC Guideline[54]	Comments
INDICATIONS FOR SURGERY FOR NATIVE VALVE ENDOCARDITIS			
Heart failure	Indicated with valve dysfunction and symptoms or signs of heart failure (class I) Reasonable if severe regurgitation and vegetation size >10 mm (class IIb)	Emergent[a] for refractory pulmonary edema or cardiogenic shock (class I) Urgent[a] for heart failure or echocardiogram with poor hemodynamics (class I)	Most common indication for surgery in endocarditis
Heart block, annular or aortic abscesses	Indicated (class I)	Urgent for locally uncontrolled infection (abscess, false aneurysm, fistula, enlarging vegetation) (class I)	Intracardiac infection is not curable with medical therapy
Persistent infection with ongoing bacteremia ± fever	Indicated after >5–7 days (class I)	Urgent for persistent positive blood cultures (class IIa)	For patients receiving appropriate antibiotics, and other sources/ embolic foci are controlled
For prevention of emboli: recurrent emboli or persistent/enlarging vegetations	Reasonable with recurrent emboli and persistent/enlargin vegetations (class IIa) May be considered with vegetations >10 mm especially involving mitral left anterior leaflet and with other relative surgical indications (class IIb)	Urgent for persistent vegetations >10 mm after one or more emboli (class I) Urgent for vegetation >10 mm with stenosis or regurgitation (class IIa) Urgent for very large vegetations >30 mm (class IIa) Urgent for large vegetations >5 mm and no other indication (class IIb)	Criteria include both patients having recurrent emboli on appropriate antibiotic therapy and patients with echocardiogram features suggesting ongoing high risk for further emboli
Fungi or multidrug-resistant bacteria	Should be considered (class I)	Urgent/elective (class I)	Examples: vancomycin-resistant enterococci and multidrug-resistant gram-negative bacilli
ADDITIONAL INDICATIONS SPECIFIC TO PATIENTS WITH PROSTHETIC VALVE ENDOCARDITIS			
Heart failure from valve dehiscence, intracardiac fistula, or severe prosthetic valve dysfunction	Indicated (class I)	Emergent for severe acute regurgitation/ fistula, refractory edema (class I) Urgent for abscess/fistula (class I)	
Relapsing PVE	Reasonable (class IIa)	Not specifically addressed	
Staphylococcal or non-HACEK gram-negative	Not specifically addressed	Urgent/elective (class IIa)	
IMPACT OF ACUTE NEUROLOGIC EVENTS ON TIMING OF SURGERY			
Nonhemorrhagic silent embolus or transient ischemic attack	May be considered without delay (class IIb)	No delay if surgery indicated (class I)	Angiography for aneurysm should be considered if unexplained CNS symptoms
Acute stroke without hemorrhage on CT scan/MRI	May be considered without delay (class IIb) For major ischemic stroke, it is reasonable to delay surgery for 4 weeks (class IIa)	No delay if surgery indicated (class IIa)	Surgery is not appropriate for patients with severe neurologic damage or coma For patients with major CNS events, delay seems reasonable
Intracranial hemorrhage	Reasonable to delay surgery for 4 weeks (class IIa)	Surgery should be delayed for >1 month (class IIa)	

[a]Emergent indicates immediate/as soon as possible; urgent indicates during acute hospitalization.

CNS, Central nervous system; *CT,* computed tomography; *HACEK, Haempholus, Actinobaccilus, Cardiobacterium, Eikenella, Kingella*; *MRI*, magnetic resonance imaging; *PVE*, prosthetic valve endocarditis.

From Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications: a scientific statement for healthcare professionals from the American Heart Association. *Circulation.* 2015;132:1435–1486; and Habib G, Lancellotti P, Antunes MJ, et al. 2015 ESC guidelines for the management of infective endocarditis: the Task Force for the Management of Infective Endocarditis of the European Society of Cardiology (ESC). Endorsed by: European Association for Cardio-Thoracic Surgery (EACTS), the European Association of Nuclear Medicine (EANM). *Eur Heart J.* 2015;36:3075–3128.

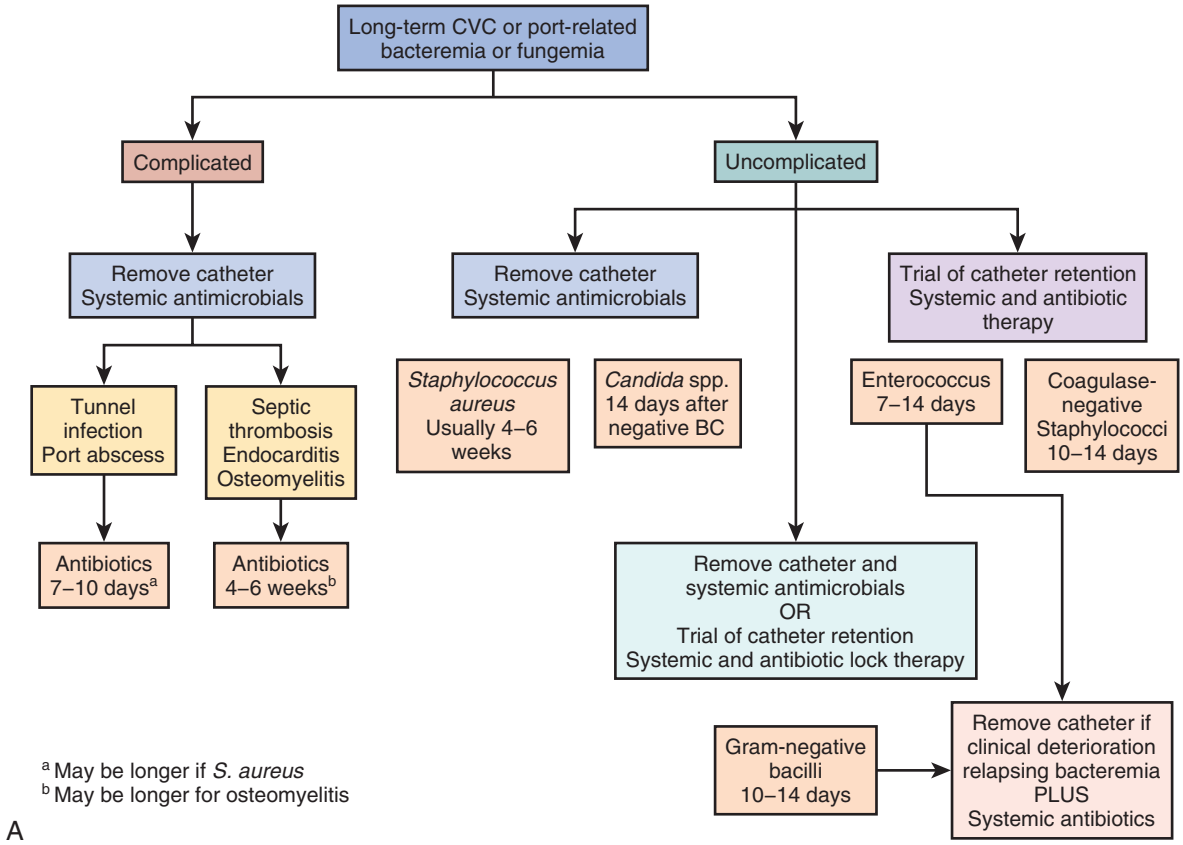
CNS embolic events in left-sided infective endocarditis are common and anticoagulation may increase the risk of hemorrhagic CNS events, and there is no proven benefit for aspirin therapy in humans, despite benefits in animal models.[52] In patients already receiving anticoagulation for mechanical valves or other specific indications, a change of warfarin to bridging therapy with heparin or low–molecular-weight heparins in the initial phase of therapy is a reasonable option, especially when surgical intervention is being considered. If possible, anticoagulation should be discontinued for 2 weeks after acute CNS embolic events.[52,53] Neurologic events, most commonly emboli but also mycotic aneurysms, are the second leading cause of mortality in acute endocarditis after heart failure. Decisions on timing of surgery and management of anticoagulation perioperatively and postoperatively in patients with CNS events are particularly challenging. An acute nonhemorrhagic CNS event is not a contraindication to urgent or emergent surgery, but surgery should be delayed for at least a month after a hemorrhagic event.[52,53]

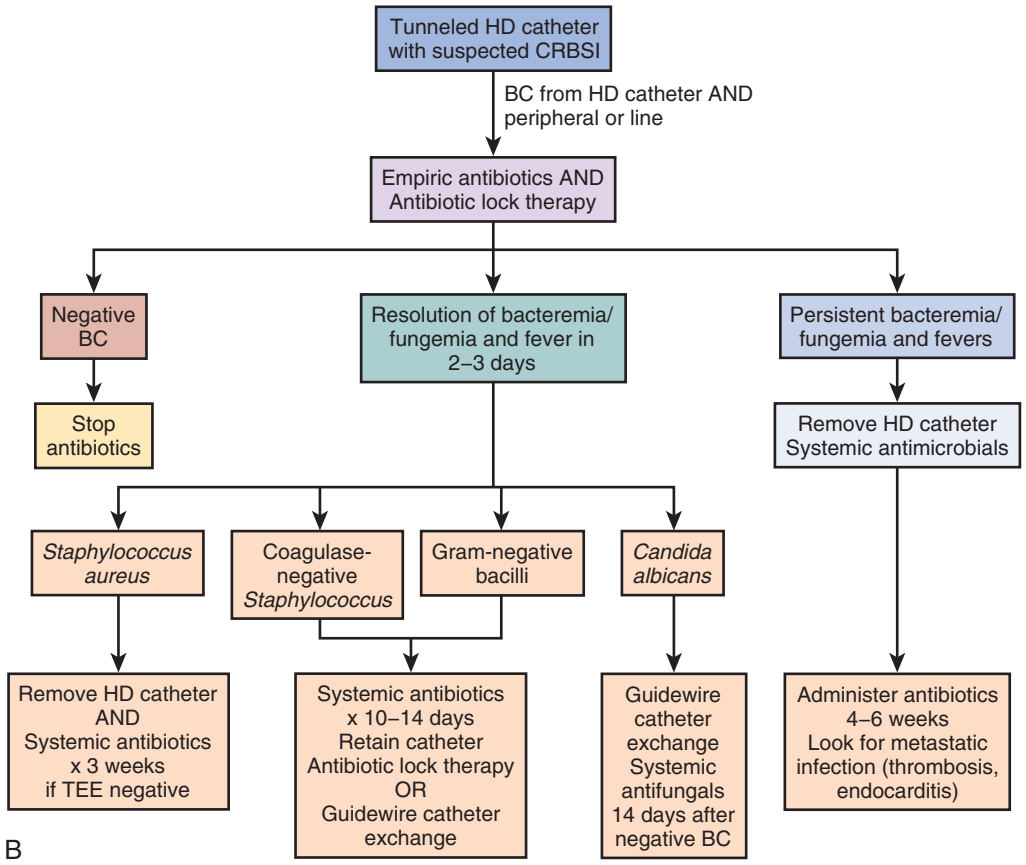
Optimal antibiotic therapy for patients with infective endocarditis is outlined in the AHA and ESC guidelines.[52,53] Individual treatment regimens, including choice of antibiotic, the need for combination antibiotic therapy, and treatment duration are based on the organism, susceptibility data, location of the infected valve, and whether the infection is complicated or uncomplicated. Left-sided *S. aureus* endocarditis is generally treated for 6 weeks with a parenteral β-lactam or vancomycin; addition of gentamicin during initial therapy is no longer recommended owing to a lack of benefit and increased nephrotoxicity.[60] Vancomycin is still recommended for methicillin-resistant staphylococcal infections, although daptomycin may be an alternative. Uncomplicated right-sided endocarditis in injection drug users may have a more benign course. There is evidence for use of 2-week courses of β-lactam therapy or daptomycin therapy for uncomplicated MSSA infections that quickly respond to treatment; short-course regimens are not recommended for MRSA infection or when vancomycin must be used for methicillin-sensitive *S. aureus* (MSSA).[52] Oral therapy with a fluoroquinolone plus rifampin for 4 weeks has also been used in patients with uncomplicated right-sided endocarditis caused by quinolone-susceptible strains.[52] Treatment of highly penicillin-susceptible viridans streptococcal endocarditis and *Streptococcus gallolyticius* (formerly *S. bovis*) endocarditis is 4 weeks of a β-lactam or vancomycin; gentamicin is added for disease caused by relatively penicillin-resistant strains. Selected patients with uncomplicated viridans streptococcal infections have been treated with 2 weeks of combination therapy. β-Lactam therapy for susceptible isolates is always preferred to vancomycin in nonallergic patients. *Enterococcus faecalis* endocarditis is usually treated for 4 to 6 weeks with synergistic combinations of antibiotics, owing to low inherent cidality of cell wall–inhibiting penicillins or vancomycin alone. Recent studies have demonstrated comparable effectiveness with decreased nephrotoxicity using 6 weeks of penicillin plus ceftriaxone compared to penicillin plus an aminoglycoside. Regimens for enterococcal infections, especially antibiotic-resistant *E. faecium*, need to be modified on the basis of specific resistance patterns. Prosthetic valve infections require longer treatment courses and use of combination therapy, and failure rates of medical therapy in treating prosthetic valve disease are high.[52]

Device-Related Endovascular Infections

Endovascular infections other than valvular infections have become increasingly common as causes of bacteremia and sepsis. This is due to the increased use of indwelling devices, including vascular catheters for chemotherapy and other long-term parenteral therapies, use of accesses for hemodialysis, and the expanding indications for implantable cardiac devices for patients with congestive heart failure and arrhythmias. Infection is the most common serious complication of peripherally inserted central venous catheters, tunneled catheters, and totally implanted intravascular devices.[61–63] Patients presenting with sepsis and focal findings related to the catheter, such as tunnel infection, port abscess, or cellulitis; those with associated venous thrombosis; or those with concurrent endocarditis or osteomyelitis require removal of the catheter.[61] Management decisions are more difficult in patients with sepsis or bacteremia without local signs of infection where catheter removal is not a trivial procedure. Determination of the catheter as the source of a bacteremia can sometimes be made with use of paired central and peripheral blood cultures. Positive central with negative peripheral blood cultures or central cultures that are positive significantly earlier than peripheral cultures may implicate the catheter as the source.[61] The majority of infected permanent catheters require removal; selected uncomplicated catheter infections in nonseptic patients whose blood has sterilized with antibiotic treatment can be treated with catheter retention and antibiotic therapy, especially infections caused by coagulase-negative staphylococci and other less virulent organisms.[61] Algorithms for the management of suspected and confirmed line infections in patients with long-term access devices are shown in Fig. 51.3. Antibiotic lock therapy, in which antibiotic solutions are used to fill the catheter lumen to maintain high antibiotic concentrations in the catheter and catheter hub, have yielded higher rates of catheter salvage than parenteral antibiotics alone.[61] Hemodialysis catheter infections pose particular management challenges because of the high prevalence of infection in these patients and the need to preserve dialysis access. Catheter salvage strategies and guidewire exchange strategies are used more frequently in hemodialysis catheter–associated infections and treatment durations may differ.[62]

Recent studies suggest that rates of implanted cardiac devices, including permanent pacemakers and automatic implantable cardioverter-defibrillator devices (AICDs), are increasing. AICDs are increasingly being implanted in older and more debilitated patients, likely contributing to the increasing prevalence of AICD infections.[53,62] Infection rates are much higher for revision procedures than for primary insertions and probably higher for AICDs compared with permanent pacemakers.[62] Device infections include both pocket infections and lead infections and both can occur concurrently; lead infections may be complicated by sepsis and septic shock, suppurative thrombophlebitis, and endocarditis. Lead infections almost always require explantation of the entire device and mortality is higher when removal of infected leads is delayed.[63,64] Diagnosis is typically made by blood cultures and TEE. TEE may show vegetations on the leads or associated endocarditis, but negative TEE does not exclude the diagnosis and incidental lead masses can be seen in up to 10% of TEE done for other reasons when there is no concern for infection. Intraoperative TEE may be helpful in some cases. The most common organisms are coagulase-negative staphylococci and *S. aureus* in 60% to 80% of cases.[62] Most infected leads can be removed percutaneously, especially because experience with laser extraction of AICD leads is increasing, although very large vegetations may be an indication for an open procedure. Devices should not be replaced until bacteremia has completely resolved.





• **Fig. 51.3** Algorithms for management of catheter-related bloodstream infection (CRSBI) in bacteremic patients with long-term central venous catheter *(CVC)* or ports (A) and for suspected CRSBI in patients with tunneled hemodialysis catheters (B) including indications for removal versus attempt at salvage of infected indwelling long-term catheters. *BC,* Blood culture; *HD,* hemodialysis; *TEE*, transesophageal echocardiography. (Data from Mermel LA, Allon M, Bouzon E, et al. Clinical practice guidelines for the diagnosis and management of intravascular catheter-related infection: 2009 update by the Infectious Diseases Society of America. *Clin Infect Dis.* 2009;49:1–45.)

Primary Bacteremias

In 10% to 30% of patients presenting from the community with bacteremia and sepsis, the primary source of the bacteremia remains unknown, even after careful clinical and radiographic evaluation.[64,65] This includes patients with infections manifesting as a primary bacteremia, as well as those with probable secondary bacteremia from an occult focus. Bacteremia of unknown etiology is associated with higher mortality.[64] Primary bacteremias are more common with certain microorganisms and with specific host predispositions. These syndromes, if unrecognized, have particularly high morbidity and mortality. Patients with impairment in immunoglobulin production or function and impaired or absent splenic function are predisposed to infections with encapsulated organisms such as S. *pneumoniae, N. meningitidis, H. influenzae*, and group B streptococcus.[66] Patients with advanced liver disease and cirrhosis are predisposed to these as well as a variety of other spontaneous bacteremias.[67] Patients with cell-mediated immune defects may present with other unusual bloodstream infections such as *Listeria* and *Salmonella* sepsis. Severe neutropenia greatly increases the risk of spontaneous bacteremia and sepsis from endogenous gastrointestinal flora, and the management of fever in neutropenic patients incorporates empiric initiation of broad-spectrum antibacterial therapy including activity against *Pseudomononas*.[68] Several important bacteremia syndromes are described in the following sections.

Meningococcemia and Meningococcal Sepsis

Invasive meningococcal disease can present as either bacterial meningitis or as the syndrome of meningococcemia with meningococcal sepsis without meningitis.[7] The proportion of primary meningococcemia cases depends in part on the serotypes present in the community. The annual incidence of meningococcal disease in the United States is approximately 0.3 cases per 100,000, with mortality of 10% to 15% and significant residual morbidity in up to 20%.[7] In addition to young children, adolescents and young adults 11 to 19 years of age are at increased risk for meningococcal disease, but risk persists throughout life and is increased in those with certain immune deficiencies such as terminal complement deficiency and cirrhosis.[7,69] Patients with meningococcemia present with fever, headache, malaise, vomiting, and myalgias.[69,70] Most patients will also present with rapid development of a characteristic nonblanching petechial or purpuric rash, but the rash can be maculopapular or absent. Early symptoms that may be important clues to the diagnosis are leg pains and cold hands and feet.[70] If untreated, disease may progress rapidly within 24 hours to fulminant purpura and hemorrhagic shock. Early recognition and rapid initiation of antibiotic therapy with a penicillin or third-generation cephalosporin can significantly improve outcomes. PCR of blood is useful for diagnosis, especially in patients who received antibiotics before hospitalization.[7,70] Several multivalent conjugated meningococcal vaccines as well as serogroup B–specific vaccines are both now available in the United States for routine vaccination of adolescents and other high-risk populations.[7,71]

Primary Pneumococcal Bacteremia

Pneumococcal bacteremia is most commonly a consequence of pneumococcal pneumonia, but 5% to 10% of episodes occur without an identified underlying focus.[72] Severe episodes may present with fulminant sepsis and purpura fulminans clinically indistinguishable from meningococcal sepsis. Important risk factors for pneumococcal sepsis include asplenia and hyposplenism, HIV infection, sickle cell disease, alcoholism, malignancy, and other immunocompromised states, although this syndrome can occur in otherwise healthy adults and children without predisposing risks.[66,72] *S. pneumoniae* causes 50% to 90% of cases of the fulminant sepsis syndrome that occurs in postsplenectomy or functionally asplenic patients.[67] Rates of invasive pneumococcal disease including bacteremia in adults in the United States have declined after introduction of conjugate pneumococcal vaccines.[73] Other causes of the postsplenectomy sepsis syndrome include *N. meningitidis*; *H. influenzae*; and, less commonly, *Capnocytophaga canimorsus, Escherichia coli, Salmonella*, and the vector-borne parasitic infections malaria and babesiosis. Immunization with pneumococcal, meningococcal, and *H. influenzae* vaccines is recommended for those at risk for postsplenectomy sepsis.[66]

Staphylococcus aureus Bacteremia

S. aureus bacteremia can occur from localized staphylococcal disease such as skin and soft tissue infection or pneumonia, endovascular infection, and endocarditis. It can also be of occult origin. Regardless of the initial source of bacteremia, there is significant risk for development of late complications, including endocarditis, bone and joint disease, or other metastatic foci, in up to one-third of cases.[74] Features associated with complicated *S. aureus* bacteremia include prolonged bacteremia, prolonged fever, and embolic lesions. MRSA bacteremias may have worse outcome than MSSA bacteremias.[75] Longer-course parenteral therapy (at least 4 weeks) is recommended for patients with complicated disease, whereas 2 weeks of treatment may be adequate for selected patients with uncomplicated bacteremia, although late complications and relapse of bacteremia may occur even with more prolonged courses of therapy.[74] TEE has been recommended to exclude endocarditis in patients with otherwise clinically uncomplicated *S. aureus* bacteremia when short-course therapy is being considered.[74,75]

Toxin-Mediated Infections

Staphylococcal Toxic Shock Syndrome

S. aureus produces multiple virulence factors that contribute to its success as a human pathogen. These virulence factors potentiate local adherence, tissue invasion, and avoidance of host defenses, all features that are important in the pathogenesis of localized skin and soft tissue infection, pneumonia, bacteremia, and metastatic infections. Staphylococci also produce a variety of exotoxins that are released into the systemic circulation and act at distant sites.[76] Some of these exotoxins are directly pathogenic to specific cells, such as exfoliative toxin B, which causes staphylococcal scalded skin syndrome. Other exotoxins function as potent superantigens, antigens that bypass the intermediate T-cell antigen processing steps by binding directly to Vβ domains on T-cell receptors. This causes direct activation of multiple T-cell classes resulting in unopposed release of large amounts of cytokines, including interleukin (IL)-2, IL-4, IL-6, interferon gamma, TNF-α, and IL-1β. The resulting "cytokine storm" can lead to shock, multiorgan failure, and death.

The most well-studied staphylococcal superantigens are the pyrogenic antigens toxic shock syndrome toxin (TSST)-1 and TSST-2 and enterotoxins B and C. TSST-1 and enterotoxin B are the primary exotoxins causing the staphylococcal toxic shock syndrome.[76] First described in 1979 as a unique syndrome primarily associated with menstruating women using super-absorbent brands

of tampons, staphylococcal toxic shock syndrome can potentially occur from any infection or colonization caused by an exotoxin-producing strain, including both MSSA and MRSA.[77,78] Disease is associated with conditions leading to exotoxin production in a host who lacks preexisting antibodies to TSST-1. The overall incidence of this syndrome, as well as the proportion of cases associated with menstruating women, has decreased since 1980 and is estimated at 0.5 to 1 case per 100,000 per year in the United States.[78] Toxic shock syndrome is characterized by the acute onset of fever, hypotension, myalgia, scarlatiniform or erythroderma-like rash, nausea, vomiting, diarrhea, and development of multiple-organ failure, including renal failure, elevated liver enzymes, and disseminated intravascular coagulopathy (DIC).[77–79] Typically the rash evolves and results in late desquamation of hands and feet. Specific criteria for the diagnosis of staphylococcal toxic shock syndrome have been recently updated (Box 51.1).[79] Treatment is primarily supportive, but antistaphylococcal agents are administered to treat the underlying staphylococcal colonization or infection; some evidence suggests that immunoglobulin may be beneficial by binding exotoxin and attenuating the cytokine response.

Streptococcal Toxic Shock Syndrome

Group A β-hemolytic streptococci are also capable of producing a toxic shock–like syndrome analogous to staphylococcal toxic shock syndrome.[76,80] Most often this is seen in the setting of severe bacteremic streptococcal soft tissue infection or with streptococcal necrotizing fasciitis. In one large survey of invasive streptococcal infections in Ontario, 13% of cases were complicated by toxic shock syndrome, and the mortality rate of these infections was 81%.[80] The pathogenesis of this syndrome has been attributed to streptococcal pyrotoxins functioning as superantigens. Binding of streptococcal M protein-fibrinogen complexes to polymorphonuclear (PMN) cells causing PMN activation and endothelial damage may also be important. Clinical criteria for the diagnosis of streptococcal toxic shock syndrome in the United States were recently updated (see Box 51.1).[81] In addition to antibiotics that decrease toxin production, such as clindamycin and linezolid, IV immunoglobulin has also been used for treatment of streptococcal toxic shock syndrome and recent studies suggest that both clindamycin and IV immunoglobulin contribute to increased survival.[82] Other streptococcal species have also been reported to produce a toxic shock–like illness including viridans streptococci, groups B, C, and G β-hemolytic streptococci, and *Streptococcus suis*.

Tetanus

Tetanus is a syndrome of increased muscle rigidity and convulsive spasms caused by a toxin produced by the environmental spore-forming anaerobic bacterium *Clostridium tetani*.[7] Since the introduction of routine immunization, tetanus has become increasingly rare, with the incidence of U.S. cases decreasing from 3.9 per million in 1947 to 0.10 cases per million in 2001–2008.[7] Clinical disease is caused by contamination of wounds, most commonly traumatic wounds, with bacterial spores. Spores then germinate and produce toxins including tetanospasmin, a highly potent neurotoxin that inhibits neurotransmitter release, resulting in blockage of inhibitor impulses and unopposed muscle contractions. Cases predominate in the summer or wet season, and the disease is now most common in older adults because of either missed primary immunization or waning effects of childhood immunization.[7] The most common syndrome is that of generalized tetanus

• BOX 51.1 CDC Criteria for Diagnosis of Nonstreptococcal (i.e., Staphylococcal) and Streptococcal Toxic Shock Syndromes

Toxic Shock Syndrome Other Than Streptococcal—2011 CDC Case Definitions

A. Clinical criteria for diagnosis
   1. Fever ≥102.0°F (≥38.9°C)
   2. Rash: diffuse macular erythroderma
   3. Desquamation 1–3 weeks after onset of rash
   4. Hypotension: systolic blood pressure ≤90 mm Hg for adults
   5. Multisystem involvement (3 or more of the following organ systems):
      Gastrointestinal: vomiting or diarrhea at onset of illness
      Muscular: severe myalgia or CPK levels at least twice the upper limit of normal
      Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
      Renal: BUN or creatinine at least twice upper limit of normal or ≥5 leukocytes per high-power field in absence of urinary tract infection
      Hepatic: total bilirubin, AST or ALT at least twice the upper limit of normal
      Hematologic: platelets <100,000/mm^3
      CNS: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

B. Laboratory criteria for diagnosis
   Negative results on the following tests if obtained:
      Blood, throat, or CSF fluid cultures (blood cultures may be positive for *Staphylococcus aureus*)
      Negative serologies for Rocky Mountain spotted fever, leptospirosis, or measles
   Probable case:
      Meets the laboratory criteria and 4 of the 5 clinical criteria above are present
   Confirmed case:
      Meets the laboratory criteria and all 5 of the clinical criteria above including desquamation are present, unless the patient dies before desquamation occurs

Streptococcal Toxic Shock Syndrome—2010 CDC Case Definitions

C. Clinical Criteria for Diagnosis
   1. Hypotension (systolic BP ≤90 mm Hg for adults)
   2. Multiorgan involvement characterized by two or more of the following:
      Renal impairment
      Coagulopathy
      Liver involvement
      Acute respiratory distress syndrome
      A generalized erythematous macular rash that may desquamate
      Soft tissue necrosis including necrotizing fasciitis or myositis, or gangrene

D. Laboratory Criteria for Diagnosis
   1. Isolation of Group A *Streptococcus*
   Probable Case:
      A case that meets the clinical case definition in the absence of another identified etiology for the illness and with isolation of group A *Streptococcus* from a nonsterile site.
   Confirmed case:
      A case that meets the clinical case definition with isolation of group A *Streptococcus* from a normally sterile site

ALT, *Alanine aminotransferase;* AST, *aspartate aminotransferase;* BP, *blood pressure;* BUN, *blood urea nitrogen;* CDC, *Centers for Disease Control and Prevention;* CFS, *cerebrospinal fluid;* CNS, *central nervous system;* CPK, *creatine phosphokinase.*

Accessed August 9, 2017.

with descending symptoms of trismus (lockjaw), difficulty swallowing, muscle rigidity, and spasms.[7] Symptoms may persist for several weeks, and complete recovery may take months. Complications include laryngospasm, fractures, hypertension, nosocomial infections, and death. Treatment is primarily supportive, although metronidazole or penicillin may be given to treat potentially infected or colonized wounds.[83] Patients require admission to an ICU for control of rigidity and spasms with benzodiazepines or neuromuscular blocking agents and for ventilator support. Human tetanus immunoglobulin may be administered, but this only binds free toxin, so there may be little benefit by the time of clinical presentation. Routine childhood and adult immunization with tetanus toxoid remains the primary strategy for preventing this rare but often fatal condition. Guidelines for use of immunoglobulin and vaccination in management of potentially infected wounds have been published.[7]

Botulism

Clostridium botulinum is an anaerobic spore-forming bacteria that produces botulinum toxin, a family of closely related but immunologically distinct polypeptide toxins that are among the most potent neurologically acting poisons known.[84] Other, less common clostridial species can also produce botulinum toxin. Botulinum toxin binds irreversibly to synaptic complexes, affecting ganglionic synapses, presympathetic synapses, and neuromuscular junctions. Clinical syndromes include those caused by ingestion of preformed toxin such as food botulism and those resulting from acquisition of the organism and production of toxin in vivo such as infant botulism in very young children and wound botulism from contaminated wounds, most commonly seen in injection drug users. Patients present initially with cranial nerve dysfunction and evolve to descending paralysis without sensory or cognitive effects. Diagnosis is made on clinical grounds; testing of food products or human samples in the United States is performed by the Centers for Disease Control and Prevention (CDC). Treatment is primarily supportive, but heptavalent equine antitoxin active against neurotoxin serotypes A, B, C, D, E, F, or G is available through the CDC; human antitoxin is preferred for infant botulism.[84] Antitoxin is effective in binding free toxin only if given in the first 72 hours. Because of its potency, environmental stability, and potential for aerosolization, botulinum toxin is considered a potential agent of bioterrorism.[84]

Diphtheria

Diphtheria is caused by toxigenic strains of the bacterial species *Corynebacterium diphtheriae*. This disease has become extremely rare in the United States secondary to universal vaccination with diphtheria toxoid vaccine, with an average of one confirmed case per year.[7] Patients with respiratory diphtheria present with sore throat; low-grade fever; occasional neck swelling; and the characteristic grayish adherent membrane covering the tonsils, throat, or nose.[7] Complications include myocarditis, polyneuritis, and airway obstruction, with mortality rates of 5% to 10%. Outbreaks of diphtheria continue to occur in many parts of the world.

Serious Skin and Soft Tissue Infections

Severe skin and soft tissue infections are common. They are characterized by rapidly progressive inflammation and necrosis of skin, subcutaneous fat, and fascia. Occasionally, muscle is also involved. Several terms have been used to describe these infections: *necrotizing fasciitis; synergistic necrotizing cellulitis; progressive bacterial synergistic gangrene; anaerobic cellulitis*; and, when muscle is involved with clostridial infection, *clostridial myonecrosis (gas gangrene)*.[85] Differentiating among these entities is difficult and somewhat artificial. A variety of features of some of the most important necrotizing skin and soft tissue infections are shown in Table 51.5.

TABLE 51.5 Differentiating Features of Necrotizing Skin and Soft Tissue Infections

Feature	Progressive Bacterial Synergistic Gangrene	Nonclostridial Anaerobic Cellulitis	Clostridial Myonecrosis (Gas Gangrene)	Necrotizing Fasciitis Type 1	Necrotizing Fasciitis Type 2
Risk factors	Surgery, ileostomy, colostomy, chronic ulceration	Diabetes mellitus	Trauma, surgery	Diabetes mellitus, surgery, perineal infection	Trauma, surgery, none
Microbiology	Microaerophilic streptococci plus *Staphylococcus aureus*	Non–spore-forming anaerobes ± coliforms, streptococci, *S. aureus*	*Clostridium* spp.	Polymicrobial (Enterobacteriaceae plus anaerobes)	Group A streptococci
Course	Slow	Slow or rapid	Very rapid	Rapid	Very rapid
Pain	++++	++/+++	++++	+++/++++	++++
Gas formation	–	++++	++	++	–
Appearance	Central necrotic ulcer, erythematous periphery	Erythematous skin necrosis	Bullae, necrosis	Bullae, skin	Bullae, necrotic skin and tissue
Drainage	Purulent if present	Purulent	Serosanguineous	"Dishwater," seropurulent	Serous if present
Depth of involvement	Skin, soft tissue	Skin, soft tissue	Muscle	Fascia	Fascia
Systemic toxicity	±	+++/++++	++++	+++/++++	++++

–, Absent; ±, occasionally present; +, minimal; ++, mild; +++, moderate; ++++, marked or severe.

Microbiologically, these infections may be caused by a single pathogen such as group A β-hemolytic streptococcus; however, they are more frequently polymicrobial in nature. Risk factors for these infections include diabetes, old age, peripheral vascular disease, malignancy, alcoholism, renal failure, and immunosuppressive therapy. Infection may follow traumatic injuries that become contaminated by soil. The primary traumatic event may be relatively minor. Initial signs and symptoms may be similar to a severe cellulitis. Immune status, exposure history, and travel history should be assessed.[86] Early findings include fever, tachycardia, moderate to severe pain, and swelling and induration of the skin.[86] Late findings include severe pain or even anesthesia, skin necrosis, hemorrhagic bullae, crepitus, drainage, and signs of systemic inflammatory response syndrome or severe sepsis including multiorgan failure.[86] Laboratory tests usually demonstrate leukocytosis and metabolic acidosis. Plain radiographs may reveal gas in the soft tissues. CT or MRI is useful in delineating the extent of disease or the presence of soft tissue gas. Diagnostic evaluation should also include blood cultures, Gram staining of tissue exudates, and aerobic and anaerobic cultures obtained at surgery or from a needle aspiration. Incision and exploration or biopsy can even be done at the bedside to obtain material for Gram stain, culture, and histologic evaluation.

Skin and soft tissue infections are defined as severe if a patient meets any of the following criteria: (1) ICU patient with an acute change in sequential organ failure assessment score greater than or equal to 2 points owing to infection; (2) non-ICU patient meeting two of three sequential organ failure assessment criteria (altered mental status, systolic blood pressure ≤100 mm Hg, or respiratory rate greater than 22 breaths/min). Once a necrotizing soft tissue infection has been identified, prompt therapy is important. Early aggressive surgical debridement is essential for source control. Serial debridement every 24 to 48 hours may be necessary until there is no longer any necrosis and the patient's condition is stable.[86–88] Because most cases of necrotizing skin infection are polymicrobial, empiric antibiotic coverage should be sufficiently broad spectrum to cover gram-positive cocci (specifically MRSA), gram-negative bacilli, and anaerobes.[89] A reasonable empirical regimen might consist of a β-lactam/β-lactamase inhibitor, a carbapenem, or a third- or fourth-generation cephalosporin combined with an agent effective against MRSA, such as vancomycin or a semisynthetic lipoglycopeptide such as dalbavancin or oritavancin.[86–88] Antibiotic therapy can subsequently be adjusted on the basis of results of cultures and sensitivities.[88] In cases of group A β-hemolytic streptococcal infection, penicillin plus clindamycin is the therapy of choice. Clindamycin is effective in stopping toxin production. Linezolid also has similar activity. The use of IV immunoglobulins for treatment of necrotizing skin and soft tissue infections has been based on the binding of endotoxins produced by streptococci and staphylococci, but use remains controversial as discussed in several recent guidelines.[87] Intravenous IG (IVIG) may be a useful adjuvant therapy for streptococcal or staphylococcal toxic shock when associated with skin and soft tissue infections.[80,87]

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon, severe infection that causes necrosis of the subcutaneous tissue and fascia with sparing of the underlying muscle. Two predominant types, based on microbiology, are described. In type I, at least one anaerobic species is isolated along with one or more facultative anaerobes and members of the Enterobacteriaceae.[90,91] This form of necrotizing fasciitis most commonly affects the extremities but may involve the abdominal wall, postoperative wounds, perianal area, and groin. It occurs after trauma or a variety of surgical procedures, perirectal abscess, decubitus ulcer, or perforation of the intestines. Patients at increased risk include those with diabetes mellitus, alcoholism, and injection drug use. The involved area is initially erythematous and painful, but over several days skin changes include color changes, formation of bullae, and cutaneous gangrene. The involved area becomes anesthetic secondary to thrombosis of small blood vessels and destruction of superficial nerves. Anesthesia may develop before the appearance of skin necrosis and is an important clue to the presence of necrotizing fasciitis rather than simple cellulitis.[86] Subcutaneous gas is often present, and systemic toxicity is common.[91] When the lesion is probed at the bedside or in the operating room, there is no resistance along tissue planes. In type II (also known as hemolytic streptococcal gangrene), group A streptococci are generally isolated alone or in combination with *S. aureus*.[92] These strains usually produce pyrogenic exotoxin A. Periodically, group C or group G streptococci are causative organisms. Infection usually develops at a site of trauma but may occur in the absence of an obvious portal of entry.[91] The involved area is extremely painful, erythematous, and edematous. Infection spreads widely in deep fascial planes with relative sparing of the overlying skin and therefore may not be recognized. This form of necrotizing fasciitis is present in approximately 50% of cases of streptococcal toxic shock syndrome.[92] Over several days, the skin becomes dusky and bullae develop. Bullae then rupture and evolve into an area covered by necrotic eschar, often resembling a third-degree burn. Streptococci can usually be cultured from fluid of the early bullae and frequently from blood. Complications include metastatic abscess formation, and the mortality rate from this infection is high. Treatment requires surgical source control with immediate surgical debridement and empiric broad-spectrum antibiotics.[90]

Fournier gangrene is a form of necrotizing fasciitis that involves the male perineum, usually the scrotum, but can involve the penis, the perineum, or the abdominal wall. It is caused by anaerobic streptococci along with other bacteria such as *E. coli*; *S. aureus*; β-hemolytic streptococci; *Proteus* spp.; a variety of anaerobes; and, on occasion, *Pseudomonas* spp.[93] The first symptoms are commonly scrotal swelling and pain followed by progressive necrosis of scrotal skin and subcutaneous tissues.[93] The patient may appear toxic. Initially the patient may be erroneously diagnosed with an acute abdomen unless the genitalia are examined. Gangrene of the perineum and sometimes the penis may develop. Urgent and aggressive surgery is necessary along with broad-spectrum antibiotics.

Clostridial Myonecrosis (Gas Gangrene)

Gas gangrene is a life-threatening infection of skeletal muscle most frequently caused by *Clostridium* spp.. It should be suspected when the Gram stain of drainage reveals gram-positive bacilli in a patient who is critically ill. Penicillin G is the drug of choice with or without clindamycin. Aggressive surgical exploration and debridement is the mainstay of therapy. The role of hyperbaric oxygen therapy in the treatment of clostridial myonecrosis or in the treatment of necrotizing fasciitis remains controversial. If used, it must be as an adjunct to surgery.[94]

Vibrio Infections

Various *Vibrio* species including *Vibrio vulnificus* have caused mild to severe cellulitis in patients who sustained lacerations or puncture

wounds when in contact with saltwater in the southeastern United States and the Gulf of Mexico. Recent advances in genetic analysis have led to the reclassification of some *Vibrio* spp. into other genera, including *Grimontia* and *Photobacterium*.[95] Septicemia with secondary necrotizing soft tissue infection may occur after ingestion of raw or undercooked shellfish in immunocompromised hosts, especially those with cirrhosis.[95] An increased incidence of *Vibrio* infections has been described as a result of flooding after natural disasters. Identification of *Vibrio* organisms in the clinical laboratory using conventional methods may be difficult. Newer molecular technologies such as multilocus sequence analysis, 16S ribosomal DNA gene sequencing, and matrix-assisted laser desorption/ionization time of flight mass spectrometry, are promising for the identification of these organisms.[95] Doxycycline, third-generation cephalosporins, and fluoroquinolones are effective therapies, along with aggressive surgical debridement of necrotic tissue.

Community-Acquired MRSA

Approximately 2 decades ago, the emergence of MRSA infections in patients without health care–associated risk factors led to the term *community-acquired MRSA* (CA-MRSA). The recent movement of CA-MRSA strains into nosocomial settings now limits the utility of using clinical risk factors alone to designate community- or health care–associated status.[96] Many of these strains carry the staphylococcal cassette chromosome mec type IV element and the gene encoding Panton-Valentine leukocidin, a toxin that promotes tissue destruction.[96] Although most CA-MRSA infections are mild skin and soft tissue infections, severe, life-threatening cases of necrotizing fasciitis, myonecrosis, necrotizing pneumonia, and sepsis have occurred.[96] Historically, CA-MRSA strains were broadly susceptible to several non–β-lactam antibiotics. For patients with invasive infections caused by CA-MRSA, vancomycin, linezolid, daptomycin, and newer semisynthetic lipoglycopeptides such as dalbavancin are appropriate therapeutic options. Newer cephalosporins such as ceftaroline and ceftobiprole are also active.[97] Rates of resistance among CA-MRSA strains to clindamycin, fluoroquinolones, tetracyclines, and trimethoprim/sulfamethoxazole vary with geographic location.[96]

Serious Gastrointestinal and Intra-abdominal Infections

Bacteremia Associated With Enteric Pathogens

In common with pathogens that cause inflammatory diarrhea, the gram-negative organisms that cause enteric fever syndrome are invasive.[98] Of the enteric pathogens, *Salmonella* spp. are most likely to cause bacteremia and serious infection. Enteric fever is usually caused by *Salmonella enterica* serotype typhi and rarely by *Salmonella paratyphi, Salmonella choleraesuis, Yersinia enterocolitica*, *Brucella* spp., or *Campylobacter fetus*.[99] Features of classic typhoidal fever caused by *S. enterica* include sustained fever, bacteremia, headache, and abdominal pain. Physical findings include "rose spots," which are 2- to 4-mm discrete, irregular, blanching pink macules that are often seen on the anterior chest; hepatosplenomegaly; and relative bradycardia. Multiorgan system dysfunction can occur as a consequence of metastatic infection or immune complex deposition.[97] Intestinal bleeding or perforation may occur as a result of hyperplasia of the lymphoid tissue in the terminal ileum. Diarrhea is seen in less than 50% of cases and only early in the illness. Constipation is a frequent later complaint. The following specimens should be sent for culture: stool, blood, or bone marrow. Serologic findings may provide supportive evidence or may be useful in epidemiologic evaluation.

Therapeutic options include third-generation cephalosporins, fluoroquinolones, and trimethoprim-sulfamethoxazole. Antimicrobial resistance has been reported. Treatment for uncomplicated cases is 12 to 14 days; 30 days of therapy may be necessary for metastatic foci. Metastatic foci are relatively common in the setting of bacteremia. Infection may involve the gallbladder, spleen, bone, joints, and the meninges. There is a propensity to infect preexisting intravascular lesions such as atherosclerotic plaques and aneurysms. Sickle cell anemia and the presence of an orthopedic prosthesis are risk factors for osteomyelitis.[97] Meningitis tends to occur in young children.[97]

Peritonitis

Peritonitis is a localized or general inflammation of the peritoneal cavity that is generally caused by bacteria or fungi but may be caused by a variety of noninfectious agents such as gastric contents, talc, or bile salts. Infective peritonitis has been classified as primary, secondary, or tertiary. Peritonitis is primary when it is not related directly to other intra-abdominal processes.[100] This classification includes spontaneous bacterial peritonitis (SBP), which occurs in patients with underlying ascites from cirrhosis or nephrotic syndrome, and tuberculous peritonitis. Secondary peritonitis most often arises from an enteric source or pelvic focus and includes peritonitis following an acute perforation of the gastrointestinal tract, intestinal necrosis, postoperative peritonitis that may be secondary to an anastomotic leak, and posttraumatic peritonitis following blunt or penetrating abdominal trauma. Intestinal ischemia and frank necrotic bowel may be caused by a variety of processes, including malignancies, vascular insufficiency, volvulus, or intussusception.[100] Rupture of an abscess in the pancreas, liver, or spleen or, rarely, rupture of a distended gallbladder can also cause peritonitis. Localized lower abdominal peritonitis can also result from gynecologic infections such as salpingitis and endometritis. Tertiary peritonitis is described as occurring when clinical and systemic signs of peritonitis persist or recur after treatment for secondary peritonitis. A distinct form of device-associated peritonitis is seen in patients undergoing peritoneal dialysis.

Bacterial peritonitis is typically caused by flora of the large intestine including aerobes, with *E. coli* being the most frequent, and anaerobes, of which *Bacteroides fragilis* is the predominant isolate.[101] Common symptoms include localized or generalized abdominal pain, nausea, and vomiting. Treatment with corticosteroids may mask typical signs and symptoms, delaying the diagnosis. Signs may include abdominal rigidity, distention, fever, and an overall toxic appearance. A rigid abdomen may be seen in the early stages of an acute peritonitis, although it may be absent in a peritonitis that progresses more slowly, such as that caused by tuberculosis, or when sterile bile, pancreatic fluid, or urine leaks into the peritoneal cavity. As intraperitoneal fluid accumulates, abdominal distention and an ileus occur. The WBC count is usually elevated. Bacteremia may occur, and the sepsis syndrome may develop as peritonitis evolves. Aspiration of peritoneal fluid is an essential part of the evaluation for peritonitis. Laparoscopy or laparotomy may be necessary. Studies performed on peritoneal fluid should include a cell count with differential blood cell count, amylase, Gram stain and aerobic and anaerobic cultures, acid-fast smear and culture, and fungal smear and culture.

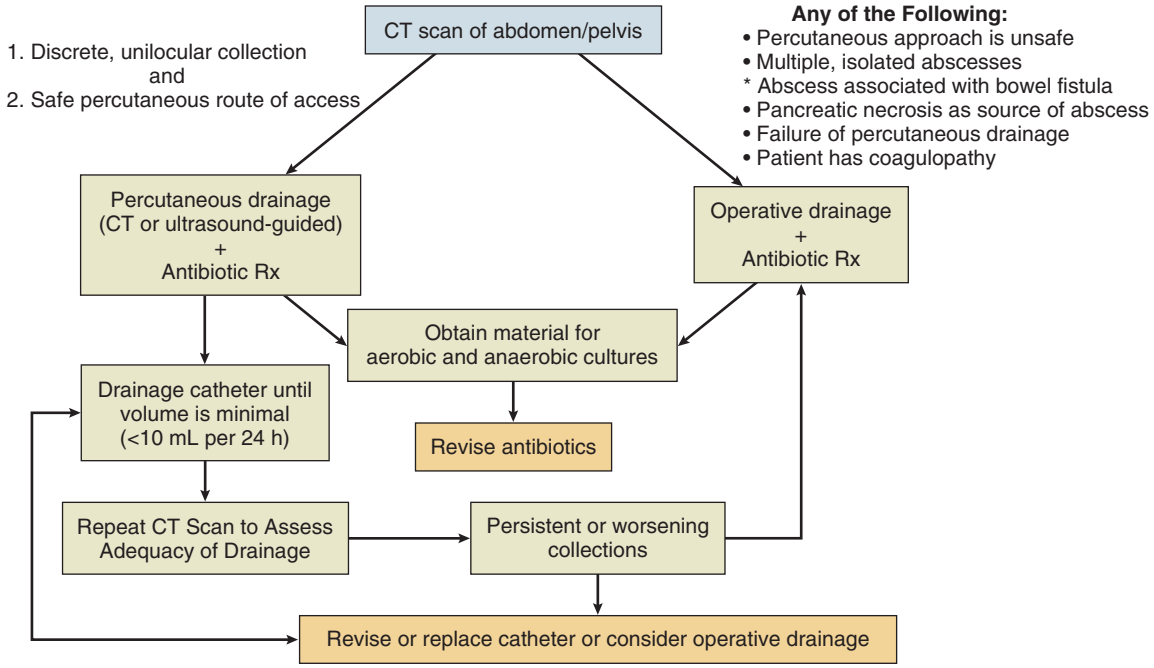
Adequate management of severely ill patients with secondary peritonitis requires source control of infection, antimicrobial therapy, and supportive therapy of organ dysfunction.[102] The primary cause of secondary peritonitis should be sought and eliminated if possible. Liver function tests and a serum amylase level may define a source in the liver, gallbladder, or pancreas. A plain film of the abdomen or a chest radiograph may reveal free air under the diaphragm in the case of a ruptured viscus. A CT scan of the abdomen may reveal an underlying intra-abdominal abscess or other focal process. Antibiotic therapy to cover gram-negative bacillary organisms and anaerobes should be initiated. Risk factors for resistant organisms such as recent hospitalization, comorbidities, previous antibiotic therapy, and colonization should be considered. Options for empiric therapy include combinations such as a third- or fourth-generation cephalosporin or a fluoroquinolone with metronidazole or monotherapy with a β-lactam/β-lactamase inhibitor combination, a carbapenem, or a glycylcycline such as tigecycline.[102–107] Empirical therapy should always include coverage for Enterobacteriaceae and *Bacteroides* spp. The need for empirical coverage of *Enterococcus* spp. is debatable. Empirical enterococcal coverage is warranted in nosocomial secondary peritonitis, in patients with septic shock who have received prior cephalosporin therapy, in immunocompromised patients, in patients with prosthetic heart valves or prosthetic intravascular devices, and in septic patients with recurrent intra-abdominal infections.[102] The optimal duration of therapy is not well defined, although nonbacteremic patients are generally treated for 7 to 10 days.[101] Regimens as short as 2 days of treatment may be adequate in uncomplicated situations with adequate surgical source control and in those with penetrating trauma. Bacteremic patients are generally treated for a total of 14 days using a combination of IV therapy followed by de-escalation to oral therapy.

SBP is caused by the translocation of enteric organisms to regional lymph nodes, which produce bacteremia and ultimately seeding of ascitic fluid.[108] Periodically a urinary tract infection may be the initial source of bacteremia. SBP occurs most commonly in adults with cirrhosis, nephrotic syndrome, or systemic lupus erythematosus.[108,109] Coliforms are the most common pathogens in adults, accounting for 70% of infections, with *E. coli* the most common isolate followed by *Klebsiella* spp. Gram-positive cocci may be seen in up to 20% of cases and anaerobes in less than 5%. Generally SBP is monomicrobial in contrast to the polymicrobial nature of most other forms of peritonitis. Findings of SBP may be subtle, so a high index of suspicion is necessary. Ascites is almost always present.[108] Fever and abdominal pain are seen in the majority of patients. New onset or worsening of hepatic encephalopathy may be seen. Some patients may have abdominal tenderness or rebound tenderness, but these findings are less frequent than in other forms of peritonitis. The most useful diagnostic test is paracentesis.[108–110] Ascitic fluid testing should include cell count with differential, Gram stain, culture, and total protein and albumin to determine the serum–ascites albumin gradient.[110] SBP is defined by an ascitic segmented neutrophil count of at least 250 cells/mm^3 with or without a positive fluid culture and no obvious intra-abdominal source of infection.[109,110] Despite the low sensitivity (≈33%), Gram staining of ascitic fluid should be performed. Patients with other infections of the abdomen, such as tuberculous peritonitis, secondary bacterial peritonitis caused by perforation, or peritonitis caused by noninfectious processes including pancreatitis or malignancy, also may show elevated neutrophil counts. The presence of a single organism generally supports the diagnosis of SBP, although there is a variant of SBP caused by traumatic entry into the bowel during paracentesis that may be polymicrobial, and conversely, gram-negative bacillary organisms may occur as sole pathogens in secondary peritonitis. If mixed gram-positive and gram-negative bacteria are seen, an intestinal perforation is the more likely source.[110] Peritoneal fluid should be cultured aerobically and anaerobically. Blood cultures should also be performed and are positive in up to 75% of patients with SBP.[109] Other than for symptom relief, a repeat paracentesis is necessary only when the patient fails to have a clinical response or when an unusual organism is isolated. Third-generation cephalosporins are the agents of choice for SBP. A fluoroquinolone, such as levofloxacin, is a reasonable alternative. A β-lactam/β-lactamase inhibitor combination such as piperacillin-tazobactam should be considered for patients with health care–associated SBP or for those whose conditions fail to improve. Selective albumin supplementation is an important part of management. It has been shown to prevent renal impairment and is associated with lower mortality. Norfloxacin, ciprofloxacin, and trimethoprim-sulfamethoxazole have been studied for primary and secondary prophylaxis and are effective.[110] Treatment is usually continued for a total of 7 to 10 days, although some studies have shown that a 5-day course of IV therapy may be adequate.[109–112] Mortality is high, ranging from 10% to 46% for this syndrome, and after an initial episode of SBP, the probability of recurrence within 1 year is 70%.[110,111]

Intra-abdominal Abscess

Considering the presence of a potential intra-abdominal abscess in febrile patients without any obvious cause of fever is important, especially if there is a predisposing condition such as diverticulitis, inflammatory bowel disease, or a history of recent abdominal surgery or abdominal trauma. Intra-abdominal abscess formation may complicate either primary or secondary peritonitis. The processes that typically predispose to intra-abdominal abscess formation are the same as those that cause secondary peritonitis and include perforation, complicated acute cholecystitis, suppurative cholangitis, acute appendicitis, diverticulitis, intestinal malignancy, surgical procedures, blunt or penetrating trauma, or intestinal ischemia from a mesenteric vascular occlusion, an intestinal obstruction, or a volvulus. Most commonly, abscesses are postoperative complications of trauma or of gastrointestinal or biliary surgery.[113] Abscesses can be found anywhere within the abdomen including the retroperitoneal space. Generally their location is in proximity with the original site of contamination, but they may develop at distant sites.[114] One example of distal infection is subphrenic abscess, which may be a consequence of a perforated appendix. Symptoms of intra-abdominal abscess may include fever, chills, anorexia, weight loss, and abdominal pain. Unexplained fever may be the only sign of an occult intra-abdominal abscess. An abdominal CT scan is the imaging modality of choice for diagnosis of abdominal abscess. Drainage is essential to establish the diagnosis, obtain microbiology to target antimicrobial therapy, and achieve therapeutic success. This may be accomplished by the insertion of percutaneous catheters, or by laparoscopic or operative drainage.[113,114] Large abscesses cannot be eradicated by antibiotic therapy alone. Criteria for considering percutaneous drainage include the presence of a well-defined fluid collection and a safe percutaneous route of access.[115] Drains should remain in place until drainage volume is minimal, usually less than 10 mL in a 24-hour period.

A repeat CT scan should be performed to demonstrate complete collapse of the abscess cavity.[113] Indications for operative surgical drainage rather than percutaneous drainage include the following situations: (1) when percutaneous drainage cannot be performed



• **Fig. 51.4** Approach to management of intra-abdominal abscesses including indications for consideration of percutaneous versus operative drainage. *CT,* Computed tomography; *Rx,* treatment.

safely; (2) when percutaneous drainage fails; (3) when there are multiple interloop abscesses; (4) when there is a coagulopathy; or (5) when there is infected pancreatic necrosis. Antibiotic therapy is indicated to treat inflammation in the surrounding tissue and to prevent metastatic infection and sepsis from bacteremia. Antibiotic coverage should be directed at abdominal flora, including aerobic and anaerobic organisms, even if anaerobes are not isolated.[103,112,113] The mortality rate with undrained pancreatic, hepatic, or retroperitoneal abscesses is reported to be 45% to 100%.[114] An approach to the management of intra-abdominal abscesses is outlined in Fig. 51.4.

Biliary Tract Infections

Infections of the biliary tract, including the gallbladder and the common bile duct, are usually associated with obstruction to the flow of bile. The biliary tract of healthy individuals is sterile. In acute cholecystitis, infection of the gallbladder is most commonly caused by microorganisms that are generally part of the normal intestinal flora.[116] Most biliary infections are polymicrobial, and anaerobes are more frequently isolated in the elderly and in those with common bile duct manipulation or prior biliary procedures. The source of bacteria is presumed to be the duodenum.[116] Many antibiotics achieve good levels in the bile in the absence of obstruction; however, when obstruction of the hepatic ducts or the common bile duct is present, the levels of such antibiotics are often subtherapeutic. Antibiotic therapy is adjunctive to decompression/drainage, which can be accomplished surgically, percutaneously, or endoscopically via endoscopic retrograde cholangiopancreatography. Antibiotics prevent the development of bacteremia, progression of infection, and development of liver abscesses. Cultures of blood and bile should be obtained. Empiric antibiotic therapy should generally be directed at gram-negative bacteria. In patients who are critically ill, the elderly, and those with prior common bile duct and complex biliary procedures, antianaerobic and antienterococcal therapy should also be instituted.

Acute acalculous cholecystitis is an acute inflammation of the gallbladder that occurs in the absence of gallstones. Individuals at risk include debilitated, hospitalized patients such as those who have had major surgical procedures, prolonged intensive care stays, hyperalimentation, or predisposing conditions that result in bile stasis, cholecystoparesis, or gallbladder ischemia.[116] The symptoms and findings are similar to those of calculous cholecystitis and include fever, right upper quadrant abdominal pain, nausea, vomiting, leukocytosis, and elevated liver function tests with an obstructive pattern. Diagnostic imaging modalities include ultrasonography, CT scanning, and hepatoiminodiacetic acid scanning. If an open or laparoscopic cholecystectomy cannot be accomplished because of the patient's underlying condition, then urgent percutaneous cholecystostomy should be performed. In addition, broad-spectrum antibiotics should be instituted.

Acute cholangitis is a serious infection with high morbidity and mortality rates. The most common cause of acute cholangitis is obstruction and subsequent infection associated with stones in the common bile duct, which have usually migrated from the gallbladder. Other causes of biliary tract infection include malignant obstruction of the bile duct secondary to pancreatic cancer, cholangiocarcinoma, cancer of the papilla of Vater, or portahepatic metastases. Periodically biliary strictures, pancreatitis, and infection with the intestinal nematode *Ascaris lumbricoides* can cause obstruction. Bacteria enter the bile duct from the gastrointestinal tract through the bloodstream or lymphatics.[117] The most common presenting symptoms are fever, abdominal pain, and jaundice, also known as *Charcot's triad*. Septic shock may occur if treatment is delayed. Blood cultures should be obtained, and ultrasound or CT scanning should be performed. Broad-spectrum antibiotics should be initiated, and biliary decompression accomplished either endoscopically with an endoscopic sphincterotomy, via a

percutaneous transhepatic biliary drainage procedure, or by surgical decompression. Endoscopic or percutaneous procedures may be the initial treatment of choice in patients who are seriously ill and at high risk for complications. Once biliary drainage has been accomplished, antibiotic therapy can be shortened to 2 to 3 days in mild cases and 5 to 7 days for moderate or severe cholangitis. Elective surgery, which generally includes cholecystectomy and bile duct exploration, can be deferred to a later date when the patient's condition has stabilized.

Pancreatic Infections

Although acute pancreatitis is usually a sterile inflammatory process, infectious complications may occur. In addition, a variety of viral infections (rubella; coxsackievirus type B; mumps; Epstein-Barr virus; cytomegalovirus; and hepatitis A, B, and C); *Mycoplasma pneumoniae*; and parasites such as *A. lumbricoides* have been implicated as causes of pancreatitis.[118] Some patients may develop sterile or infected pancreatic or peripancreatic necrosis, infected pancreatic pseudocysts, or abscess formation as complications of acute pancreatitis.[118] Sterile necrosis of either the parenchyma or the duct system usually occurs very early in the clinical course of severe pancreatitis. Risk for infection increases as necrosis becomes more extensive. Of patients with acute pancreatitis, only approximately 5% develop pancreatic infections; however, the highest mortality rate from pancreatitis occurs in these patients.[118] The incidence of infection increases over the first few weeks and peaks during the third and fourth weeks. Patients with extensive necrosis, those who are very ill, and those with early infection have the highest mortality rates.[118] CT scan with high-dose contrast is the most useful modality for predicting who is at risk for the development of infection. Between 40% and 70% of those with more than 30% necrosis seen on CT scan will ultimately become infected.[118] If gas bubbles are seen in the region of the pancreas, it should be presumed that infection is present. Clinically, it is extremely difficult to determine whether patients with necrotizing pancreatitis have superimposed infection because sterile pancreatic necrosis may cause leukocytosis and fever even in the absence of infection, and approximately 50% of infected patients may not show early clinical signs of infection. CT-guided fine-needle aspiration of necrotic pancreatic tissue for Gram stain and aerobic and anaerobic culture is a useful procedure to determine the presence of infection.[118] The microbiologic picture resembles that of the intestinal flora. *E. coli* is most frequently isolated, followed by *Klebsiella pneumoniae, Enterococcus* spp., *Pseudomonas* spp., and *S. aureus*.[100] Fifteen percent of organisms isolated are intestinal anaerobes. Fungal infection of necrotic pancreatic tissue is being reported with increased frequency. *Candida albicans* is the predominant fungal pathogen.[119] Treatment of pancreatic infection usually involves débridement of infected tissue or drainage of infected pseudocysts or abscesses combined with antimicrobial therapy based on cultures of the infected site. Surgical management often requires multiple staged procedures. Antibiotics that penetrate into pancreatic tissue include the carbapenems, especially imipenem, fluoroquinolones, piperacillin, advanced generation cephalosporins, and metronidazole.[101]

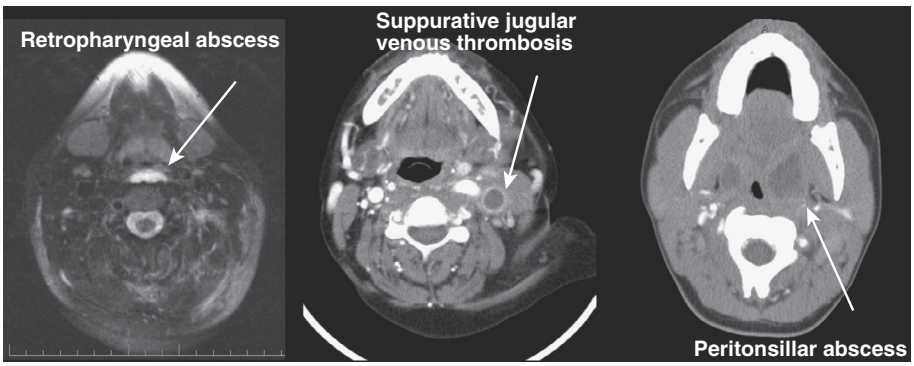
Clostridium difficile Colitis

Clostridium difficile colitis is the most common and costly health care–associated infection in the United States.[120] Manifestations of *C. difficile* infection may range from asymptomatic carriage to a fulminant, relapsing, or life-threatening colitis.[120] Antibiotics or chemotherapeutic agents have been associated with alteration of normal bowel flora and growth of *C. difficile*.[121] Diarrhea may develop while a patient is receiving antibiotics or several weeks after completion of a course of antibiotics. *C. difficile* forms spores that are resistant to heat, common disinfectants, and alcohol-based hand sanitizers, contributing to transmission in health care facilities but also in the community.[121] Only strains that produce toxins are capable of causing diarrhea or colitis.[121] Common symptoms include fever, which may be either low grade or high; crampy abdominal pain; and diarrhea, which is watery, profuse, and foul-smelling. Approximately 50% of patients have leukocytes in smears of the stool. Leukocytosis is common. The diagnosis is established by positive stool testing for *C. difficile* toxin or the presence of pseudomembranes on colonoscopy or pathology in a patient with diarrhea or radiologic evidence of ileus or toxic megacolon.[122] Complications of severe disease include electrolyte derangements, dehydration, toxic megacolon, and colonic perforation. Some patients may have little or no diarrhea but present with toxic megacolon, colonic perforation, peritonitis, or even septic shock without other localizing symptoms. An epidemic strain of *C. difficile,* NAP1/B1/027, produces an additional toxin and causes outbreaks of illness characterized by increased severity, poorer response to antibiotic therapy, and frequent relapse.[122] Treatment of *C. difficile* infection involves discontinuation of the causative antibiotic whenever possible. Oral metronidazole remains the first-line treatment for mild to moderate disease; empiric therapy with oral metronidazole should be started while testing for *C. difficile* toxin is being performed. If patients do not have a favorable response within 5 to 7 days, they should be switched to oral vancomycin. Oral vancomycin should be administered to those with severe infection or unresponsiveness to or intolerance of metronidazole. A combination of oral vancomycin and IV metronidazole should be administered to patients with severe/complicated disease. For patients who are unable to tolerate oral medication, IV metronidazole, vancomycin retention enemas, or vancomycin instillation through a colonic catheter should be administered. Fidaxomicin is more active against NAP1/B1/027 strains than vancomycin. First recurrence may be treated with metronidazole, vancomycin, or fidaxomicin but subsequent recurrences should be treated with fidaxomicin or vancomycin. The use of fecal microbial transplantation in recurrent or severe disease such as toxic megacolon has yielded favorable results with high success rates.[122] Surgery is indicated for complications such as severe toxic megacolon and colonic perforation. A variety of surgical procedures, including diverting ileostomy, cecostomy, colostomy, and subtotal colectomy, have been performed to manage toxic megacolon. Subtotal colectomy is considered the procedure of choice for the management of fulminant toxic megacolon.

Life-Threatening Infections of the Head and Neck

Ludwig's Angina, Lateral Pharyngeal Space Infections, and Peritonsillar Abscess

Infections arising from the flora of the mouth and posterior pharynx can involve the fascial planes of the neck and have the potential to progress rapidly and cause serious life-threatening illness.[123,124] In general, these infections are polymicrobial and the microbiology reflects the normal flora of the mouth. These infections spread



• **Fig. 51.5** Magnetic resonance imaging and computed tomography images showing a variety of life-threatening head and neck infections including retropharyngeal abscess (A), suppurative jugular venous thrombosis (B), and peritonsillar abscess (C). (Images provided by Dr. Joshua Brody, Department of Radiology, the Cooper Health System, Camden, NJ.)

rapidly through contiguous fascial spaces and it is essential that they be diagnosed and treated expeditiously to prevent serious sequelae such as airway obstruction, hematogenous infection, and mediastinitis. Potentially life-threatening infections of the head and neck may involve three cervical spaces. Fascial planes both separate and connect these areas. The spaces and infectious manifestations are as follows, and representative images are shown in Fig. 51.5:

1. The submandibular space may be affected by infection involving the flora of the mouth and tongue. A bilateral cellulitis of the soft tissue, known as *Ludwig's angina*, is the most important common infection in the submandibular space. Manifestations of this infection include swelling and upward displacement of the tongue and submandibular swelling. An odontogenic focus is the origin of infection in up to 90% of cases.[125,126] Other causes include oral malignancies and facial trauma. Complications include airway obstruction and mediastinitis.
2. The lateral pharyngeal space consists of an anterior and a posterior compartment divided by the styloid process. The anterior compartment is composed of musculature, and the posterior compartment has nerves and blood vessels. Infection in the anterior compartment causes soft tissue swelling that results in unilateral trismus caused by irritation of the internal pterygoid muscle, induration and swelling along the angle of the jaw, bulging of the palatine tonsil into the posterior pharynx, and systemic toxicity. Patients may present with unilateral neck or jaw pain along with ear pain and dysphagia. Pain may worsen when the head is turned because of compression of infected tissue. Dental infection, upper respiratory tract infection, pharyngitis, and otitis media with mastoiditis may all cause lateral pharyngeal space infection.[126,127] The carotid sheath is within the posterior compartment and contains the internal carotid artery, the internal jugular vein, the vagus nerve, cranial nerves IX through XII, and lymph nodes. When infection occurs in this space, patients most commonly present with signs of sepsis without localizing signs at the neck. Generally signs and symptoms are related to complications from involvement of the neurovascular structures. The most common complication is suppurative jugular venous thrombosis. Bacteremia and septic emboli may be seen. The carotid artery may also rupture. The carotid sheath is dense and not easily penetrated; thus generally arterial erosion is usually a complication of infections of longer duration (1–3 weeks). Intermittent bleeding from the mouth or nose may precede rupture.[126] Cranial nerve palsies or Horner syndrome may occur.
3. The retropharyngeal space contains an area that extends from the base of the skull to the diaphragm and hence is a portal for neck infections to extend into the chest. Infections of the retropharyngeal space or prevertebral space may spread as a result of extension through this area. Retropharyngeal space abscesses are relatively uncommon and are most often seen in young children. These abscesses usually result from odontogenic infection, penetrating trauma, or peritonsillar abscess.[126] Peritonsillar abscess, also known as "quinsy," is an unusual complication of acute tonsillitis seen predominantly in adolescents and young adults. Patients usually present with fever, pharyngitis, odynophagia, dysphagia, trismus, drooling, and a muffled voice that has been described as "hot potato" in quality. On examination there is usually swelling of the anterior tonsillar pillars and soft palate. The most common symptoms of retropharyngeal space infection in adults are fever, dysphagia, pharyngeal pain, dyspnea, noisy breathing, and stiff neck. A lateral radiograph of the neck may reveal prevertebral soft tissue swelling. Any deep neck infection has the potential to spread to the mediastinum via the retropharyngeal space.

Other potential complications of infection of the oral cavity are aspiration pneumonia and lung abscess. Because most of these infections originate from an odontogenic focus, the microbiology reflects polymicrobial oral flora and generally includes *Bacteroides* spp., aerobic streptococci, microaerophilic streptococci, peptostreptococci, fusobacteria, *Veillonella* spp., and *Actinomyces* spp. On occasion, enteric gram-negative bacilli, *P. aeruginosa,* or *S. aureus* may play a role.[127]

Deep neck infections are medical and surgical emergencies. Complications include hematogenous dissemination with sepsis syndrome, airway obstruction, necrotizing pneumonia or empyema, osteomyelitis of the mandible or maxilla, mediastinitis, or intracranial extension and cavernous sinus thrombosis. A contrast CT scan or MRI of the neck is important to help define the anatomy including the vascular structures and to indicate the potential need for drainage. Consultation should be obtained from an otolaryngologist. When patients have dyspnea, stridor, or an inability to handle secretions, an artificial airway should be established. Airway obstruction is most likely to occur in infections of the submandibular

space. Surgically obtained specimens should be cultured aerobically and anaerobically. For patients with peritonsillar abscess, high-dose IV penicillin is the therapy of choice. Other treatment options include clindamycin or ampicillin-sulbactam. Patients with peritonsillar abscess should undergo incision and drainage to prevent spontaneous rupture, aspiration pneumonia, airway obstruction, or dissection of infection into the lateral retropharyngeal space. Surgical drainage is especially important for infections involving the retropharyngeal and lateral pharyngeal space. Approximately half of cases of Ludwig's angina in the submandibular space can be cured without surgical intervention.[126]

Lemierre Syndrome

Lemierre syndrome (postanginal sepsis) is a fulminant infectious syndrome caused by acute oropharyngeal infection that is complicated by secondary septic thrombophlebitis of the internal jugular vein. It is usually seen in healthy adolescents or young adults. Most cases arise from the pharynx and peritonsillar tissues with spread through the lateral pharyngeal space leading to internal jugular thrombophlebitis and metastatic complications.[125] *Fusobacterium* spp. are most commonly implicated. Other pathogens, including MRSA, have been isolated.[125] Complications include septicemia, pneumonia, empyema, meningitis, brain abscess, and vocal cord paralysis. This infection may complicate a routine case of infectious mononucleosis.[128] The diagnostic workup should include blood cultures, a CT scan of the neck with contrast, and a chest radiograph or CT of the lungs to look for septic pulmonary emboli. Other organs or large joints may be affected with metastatic infection.[125] Therapy usually consists of surgical drainage of the focus and broad-spectrum IV antibiotic therapy with a β-lactam/β-lactamase inhibitor or a carbapenem or moxifloxacin plus clindamycin or metronidazole. Empirical treatment for MRSA should be considered until culture results are available. Fever may persist for up to 2 weeks despite appropriate antibiotics. Because this is an endovascular infection antibiotics should be given for an extended period of up to 6 weeks. When the patient is afebrile and neck pain has resolved, therapy can be de-escalated to an oral regimen. Use of anticoagulation is controversial and is usually warranted in cases with retrograde cavernous sinus thrombosis.[125]

Epiglottitis

Acute infectious epiglottitis is an inflammatory process of the epiglottis, supraglottis (in adults), and surrounding soft tissues.[125,129] Since the near disappearance of invasive *H. influenzae* infections in children following universal immunization, acute epiglottitis has become primarily a disease of adults, with an annual incidence of 1 case per 100,000 and peak incidence from ages 40 to 50 years. Adult patients present with severe pharyngitis; pain on swallowing; fever; and, less commonly, shortness of breath, hoarseness, drooling, and muffled voice. Findings on examination include marked anterior neck tenderness, lymphadenopathy, and respiratory distress.[129,130] The standard of diagnosis for suspected epiglottitis in adults is visualization of the epiglottis with flexible laryngoscopy.[125] Plain radiographs have lower sensitivity and specificity. CT may be used when flexible laryngoscopy is not an option. Treatment includes maintenance of an airway; depending on severity and rapidity of onset of symptoms, this may include emergent tracheostomy, elective intubation, or only close observation in an ICU for the mildest cases.[129] Antibiotics active against β-lactamase–producing *H. influenzae* and β-hemolytic streptococci should be administered. The role of corticosteroids is unclear.[125] Disease may be more aggressive in patients with HIV infection or other immunocompromised individuals.

Mediastinitis

Acute mediastinitis is an infection of mediastinal structures that can develop from direct extension of pharyngeal and neck infections (descending necrotizing mediastinitis), from esophageal trauma or rupture, or as a complication of cardiothoracic surgical procedures.[131,132] Descending necrotizing mediastinitis and mediastinitis from esophageal procedures have both become uncommon, and most cases are seen as complications of cardiothoracic surgery procedures or from trauma.[131] Symptoms of mediastinitis may initially be mild, but as disease progresses, patients develop chest pain; dysphagia; and respiratory distress, as well as fever, tachycardia, crepitus, and localized swelling. Sepsis is common. Patients with postcardiothoracic mediastinitis will generally have evidence of local or deep sternal wound infection. Leukocytosis is typical. Plain films may show mediastinal widening; mediastinal air-fluid levels; and subcutaneous, mediastinal, or pericardial air. CT is more sensitive than plain radiographs for diagnosis; contrast esophagography with water-soluble contrast is the optimal study for esophageal perforation.[131]

Treatment of infection related to descending neck infection or esophageal perforation requires broad-spectrum antibiotics directed at oropharyngeal flora, including streptococci, oral anaerobes, and gram-negative bacilli in addition to surgical intervention.[131,132] Mediastinitis after cardiothoracic surgery is most commonly caused by staphylococci, but a large variety of other gram-positive and gram-negative organisms have been implicated. Treatment requires surgical drainage and débridement along with antibiotic therapy.[131]

Serious Vector-Borne Infections

Rocky Mountain Spotted Fever

Tick-borne rickettsial diseases can cause severe illness and death in otherwise healthy individuals. Although the various rickettsial diseases may have distinct epidemiologic and etiologic differences, they are clinically similar.[133] Rocky Mountain spotted fever (RMSF) is caused by *Rickettsia rickettsii*, which is a gram-negative, obligate, intracellular bacterium. Infection is transmitted to humans by a variety of ticks but most frequently by the dog tick, *Dermacentor variabilis*. The incidence is greatest in the southeastern and south central United States. The vast majority of cases occur from April to September but can occur at any time of the year.[134] Reported risks for infection include living in wooded areas and exposure to dogs. *R. rickettsii* infects endothelial cells, resulting in vasculitis, which leads to the characteristic rash and involvement of the lungs, brain, and other organs.[133,135–138] After an incubation period of up to 2 weeks, patients frequently present with fever, rash, and headache.[138] Thirty percent to 40% of patients do not recall a tick bite.[133] Other symptoms include chills; myalgias; nausea; vomiting; abdominal pain that may be severe enough to mimic an acute abdomen; diarrhea; headache; photophobia; mental status changes; conjunctival injection; and, periodically, cough or arrhythmias secondary to myocarditis. The rash is classically an erythematous macular rash that appears initially on the ankles/soles and wrists/palms and spreads centripetally to the arms, legs, trunk, neck, and face.[135–137] The lesions evolve to become petechial. The rash typically appears after 2 to 6 days of illness. Although rash is the hallmark

of this illness, up to 20% of patients are "spotless" or have an atypical rash at presentation.[139] The most characteristic laboratory abnormality is thrombocytopenia. The WBC count is usually normal but more than two-thirds of patients have increased band forms. The creatine phosphokinase level may be elevated, as may transaminases and bilirubin.[133] The chest radiograph may reveal infiltrates consistent with pneumonitis or acute respiratory distress syndrome (ARDS). RMSF is frequently a severe illness. Serious complications, in addition to ARDS, include renal failure, DIC, hemophagocytic syndrome, meningoencephalitis, and gangrene.[133]

Rickettsial infections may be difficult to diagnose. The best way to establish the diagnosis of RMSF in patients with a rash is by obtaining a skin biopsy for immunohistochemical or direct immunofluorescent staining. This test has a sensitivity of 70% and specificity of 100%.[138] PCR can also be performed on tissue specimens.[133] However, both immunohistochemical staining and RMFS PCR may not be readily available in many institutions. Serologic testing by indirect immunofluorescence or enzyme-linked immunosorbent assay may also be performed. Empiric treatment with doxycycline should be instituted for suspected RMSF before laboratory confirmation of a diagnosis.[139] Distinguishing RMSF from meningococcemia is especially important. Gastrointestinal symptoms, a pulse-temperature disparity, periorbital edema, edema of the extremities, conjunctival injection, hepatosplenomegaly, and elevated serum transaminase levels are more likely in RMSF. If there is any doubt as to which infection is present, treatment for both should be instituted empirically.

Ehrlichiosis and Anaplasmosis

Illnesses that cause fever and rash are listed in Box 51.2. Other serious rickettsial diseases include ehrlichioses and anaplasmosis, caused by *Ehrlichia chaffeensis* (human monocytic ehrlichiosis), *E. ewingii* (infects granulocytes), and *Anaplasma phagocytophilum* (human granulocytic anaplasmosis), respectively.[134,138–140] They have a similar presentation, but rash is much less commonly seen than in RMSF. These infections are transmitted by ticks and are distributed across the United States and Europe. All are intracellular pathogens that infect leukocytes. Common laboratory abnormalities include leukopenia, relative lymphopenia, presence of atypical lymphocytes, eosinopenia, thrombocytopenia, and elevated transaminase levels.[140] Anemia and renal involvement are rare. PCR of serum is now the rapid diagnostic test of choice. Blood smear microscopy might reveal the presence of morulae in infected leukocytes, which is highly suggestive of anaplasmosis or, less commonly, ehrlichiosis.[140] Serologic results from paired sera can also be diagnostic. Complications include ARDS, bleeding, rhabdomyolysis, and myocarditis. Doxycycline is the treatment of choice.[138,139]

• BOX 51.2 Differential Diagnosis of Fever With Maculopapular or Petechial Rash

Rocky Mountain spotted fever
Meningococcal disease
Enteroviral infection (echovirus and coxsackievirus)
Human herpesvirus 6 infection (roseola)
Human parvovirus B19 infection (fifth disease)
Epstein-Barr virus infection
Disseminated gonococcal infection
Murine typhus
Ehrlichiosis
Group A streptococcal pharyngitis
Mycoplasma pneumoniae Infection
Leptospirosis
Secondary syphilis
Kawasaki disease
Thrombotic thrombocytopenic purpura
Drug reactions
Immune complex–mediated illness
Toxic shock syndrome
Erythema multiforme
Stevens-Johnson syndrome

Babesiosis

Babesiosis is an infection caused by intraerythrocytic protozoan parasites of the genus *Babesia*. Three species have been reported to cause human disease, of which the most common is *Babesia microti*.[140] *Babesia* spp. in the United States are transmitted by the same tick that causes Lyme disease and patients may present with coinfection. Infection can also be transmitted through transfusions and during pregnancy. Symptoms and signs are similar to malaria and include fever, chills, sweats, headache, myalgia, and arthralgia. Hemolytic anemia, thrombocytopenia, and elevated transaminase levels are the most notable laboratory findings. The elderly and those who are immunocompromised, including asplenic patients, are at higher risk for complicated disease. Severe infection may present as congestive heart failure, renal failure, acute respiratory failure, and/or DIC. The diagnosis can be established by demonstration of the classic tetrad of merozoite forms known as the "Maltese cross sign" on Giemsa-stained thin blood films, by PCR, or by serology. Azithromycin and atovaquone are recommended for uncomplicated babesiosis; clindamycin and quinine are recommended for severe disease. Red blood cell exchange transfusion is indicated for severe hemolysis, greater than 10% parasitemia, and/or hepatic, respiratory, or renal failure.[138]

Malaria

Malaria is a protozoan infection transmitted by female anopheline mosquitoes. The severity of malaria infection depends on a variety of factors, including host immunity and age and the species of malaria. Of the four main human pathogens, *Plasmodium falciparum* causes the most serious infection. Chloroquine-resistant *P. falciparum* has spread through many parts of the world. The incubation period of *P. falciparum* is approximately 12 days. It parasitizes all ages of red blood cells and causes the highest degree of parasitemia of any of the species.[141] *P. falciparum* has worldwide distribution and causes a severe illness frequently termed *blackwater fever*. Common symptoms and signs include fever, chills, headache, myalgia, arthralgia, and hepatosplenomegaly. Other symptoms include jaundice, vomiting, diarrhea, and nonproductive cough.[141] Severe malaria is a multisystem illness with a mortality rate of up to 25% in the nonimmune, untreated patient.[141] Defining criteria for severe malaria include (1) severe normocytic anemia, (2) renal failure, (3) pulmonary edema, (4) hypoglycemia, (5) shock, (6) DIC, (7) metabolic acidosis, and (8) cerebral involvement with coma or generalized seizures. Other signs or symptoms frequently present in severe disease include altered mental status, prostration, jaundice, and high-grade fever.[141] Additional laboratory features include thrombocytopenia, elevated transaminase levels, hyperbilirubinemia, evidence of coagulopathy, elevated blood urea nitrogen and

creatinine levels, and macroscopic hemoglobinuria. Levels of parasitemia are often high. Patients may develop pulmonary edema, or pulmonary edema may occur after successful treatment of parasitemia. ARDS or secondary infection with bacterial pneumonia may also occur.

The differential diagnosis is broad and includes bacterial sepsis, meningitis, rickettsial infections, pneumonia, viral hemorrhagic fever, leptospirosis, severe influenza, meningococcemia, typhoid fever, and viral hepatitis. The diagnostic test of choice has been the thick/thin peripheral Giemsa-stained blood smear, which confirms the diagnosis. Rapid diagnostic tests are excellent in patients with symptomatic malaria who have relatively high parasite densities.[142] Patients from an endemic area may occasionally present with another serious illness that may be erroneously attributed to malaria because of incidental parasitemia. Treatment for severe malaria regardless of species consists of IV quinidine-gluconate combined with IV doxycycline or IV clindamycin.[143] When using quinidine, continuous cardiac monitoring should be performed. IV or intramuscular artesunate is available as an investigational new drug through the CDC for those with severe malaria who are unable to obtain IV quinidine or who are intolerant to it, have a contraindication, or in whom therapy has failed. IV therapy should be continued for at least 24 hours and until the parasite density is less than 1% and oral therapy can be tolerated.[143] If artesunate is not available, artemether can be given. Steroids are not recommended for cerebral malaria. In addition, broad-spectrum antibiotics for bacterial sepsis and pneumonia should be given if there is concern for secondary bacterial infection.

Severe Viral Infections

Viral Hemorrhagic Fevers

Viral hemorrhagic fevers are caused by several different families of viruses. Symptoms generally include fever, myalgia, bleeding/hemorrhage, shock, coma, seizures, and possibly renal failure. The diagnosis is established by viral isolation or serologically. Treatment involves supportive care.

The recent West African Ebola epidemic was the largest documented outbreak. There is usually an abrupt onset of symptoms 8 to 10 days after exposure. The symptoms are nonspecific and include fever, chills, myalgias, and malaise. Patients may develop a diffuse erythematous macular papular rash involving the face, neck, trunk, and arms. Gastrointestinal symptoms include nausea, vomiting, abdominal pain, and severe watery diarrhea that was the hallmark of advanced disease in this epidemic.[144] Shortness of breath, chest pain, headache, and confusion may also occur. The conjunctiva are frequently injected. Cerebral edema has been reported and seizures may occur. Bleeding may not always occur but may manifest as ecchymosis, petechiae, and mucosal hemorrhage. The diagnosis is most commonly established by enzyme-linked immunosorbent assay or viral culture. There is no effective antiviral treatment. Administration of convalescent serum from patients who have recovered is approved for use in infected patients.[144] ZMapp is an investigational monoclonal antibody treatment that has also been used.[144] Investigational drugs and vaccines are under development.

Dengue

Dengue is the most frequent arthropod-borne viral infection worldwide.[144] Generally dengue has a geographic endemicity and is seen predominantly in Africa, South America, and Asia. Dengue is transmitted by mosquitoes and has no other reservoir except humans. It is now endemic in at least 112 countries worldwide, including many parts of the Caribbean, Mexico, Puerto Rico, and Central America, and has recently reemerged in the United States in the Florida Keys and along the Mexican border.[145] In many areas the mosquito vector is *Aedes aegypti*. This mosquito species has adapted to man-made conditions, and therefore urban transmission is frequent. The virus has four major serotypes, each with a number of genotypes.[145] Dengue is generally divided into four clinical syndromes: a mild influenza-like illness; classic dengue (characterized by fever, retro-orbital headache, severe bone pain and myalgia, maculopapular rash, and nausea and vomiting); dengue hemorrhagic fever (DHF); and dengue shock syndrome (DSS).[145] DHF or DSS may manifest after a few days of typical dengue symptoms, and classically symptoms start as the temperature normalizes.[145] Those with DHF have bleeding, petechiae, ascites, pleural effusion, and sometimes encephalopathy. Laboratory features include hemoconcentration, leukopenia, elevated transaminase levels, and thrombocytopenia.[145] DHF and DSS are severe forms of dengue.[145] The differential diagnosis includes many of the infectious entities also in the differential diagnosis of malaria. Noninfectious illnesses in the differential diagnosis include hemolytic uremic syndrome and thrombotic thrombocytopenic purpura. Diagnosis can be established serologically or by detection of ribonucleic acid by quantitative reverse transcription PCR.[145] Treatment is supportive.[145]

Hantavirus Pulmonary Syndrome

Acute infections caused by species of hantavirus are transmitted to humans from rodents and are characterized by nephritis and hemorrhage or by a syndrome of acute noncardiogenic pulmonary edema.[146] Four hantaviruses are associated with hantavirus pulmonary syndrome. This syndrome was first recognized in the southwestern United States and is caused by Sin Nombre virus. Rodents, especially deer mice, are the host. Transmission to humans occurs by inhalation of aerosols of rodent urine or feces. Initial symptoms of hantavirus pulmonary syndrome resemble those of influenza and consist of fever, myalgia, headache, and gastrointestinal symptoms. Two to 15 days later, acute noncardiogenic pulmonary edema and shock develop.[146] Laboratory findings at this stage include leukocytosis, hemoconcentration, and thrombocytopenia. Chest radiographic findings include increased vascular markings consistent with pulmonary edema, bilateral infiltrates, and pleural effusions.[146] Treatment is supportive and consists of ventilator support and treatment of shock. This syndrome has a high mortality rate of 50% to 70%, but those who survive improve rapidly after 5 to 7 days and often have complete recovery within 2 to 3 weeks.

Influenza

Influenza results from infection with influenza A or B virus. Infection occurs in yearly epidemics, typically during the winter in temperate climates, with occasional worldwide epidemics referred to as *pandemics*, which occur when there is antigenic shift (a major antigenic change resulting in a new subtype of influenza A).[147] These viruses are spread from person to person primarily through coughing and sneezing.[147] Onset of symptoms is abrupt and occurs after an incubation period of a day or two.[147] Symptoms include fever, chills, headache, myalgia, sore throat, and malaise.[147]

Respiratory symptoms, especially a dry cough, are usually present. As systemic signs and symptoms decrease, respiratory complaints become more prominent. Of these, cough is the most frequent and may persist 1 to 2 weeks after fever resolves. Leukocytosis is common early in the illness, and mild leukopenia may be observed later. Most cases are not associated with any significant complications, but when complications do occur, pulmonary complications are the most frequent. Two types of pulmonary complications are recognized: primary influenza viral pneumonia and secondary bacterial pneumonia.[147,148] Primary influenza viral pneumonia occurs mainly in individuals with cardiovascular disease or in pregnant women. Rapid progression of fever, cough, dyspnea, and hypoxemia usually occurs. Chest radiographs reveal bilateral findings consistent with pulmonary edema. Patients may develop ARDS. Culture of the sputum fails to reveal significant bacteria, whereas molecular diagnostic tests and viral cultures will demonstrate influenza virus. Severe influenza viral pneumonia requires intensive monitoring and support. The mortality rate is high.

Secondary bacterial pneumonia is more common than primary viral pneumonia. It occurs most often in the elderly or those with preexisting pulmonary disease. Following a classic influenza syndrome and a period of improvement of a few days, there is recrudescence of fever and cough accompanied by sputum production and consolidation on chest radiograph. Gram stain and culture of sputum most often demonstrate *S. pneumoniae*, *H. influenzae*, or *S. aureus*. Other rare complications of influenza include Reye syndrome, which is an often fatal CNS and hepatic complication; myositis; transverse myelitis; myocarditis; and pericarditis.[147] Influenza virus is readily isolated from nasal or throat specimens, sputum, or tracheal secretions in the first 2 or 3 days of illness. Inhaled and IV zanamivir, oral oseltamivir, and IV peramivir are active against influenza A and B viruses and are effective in treating acute influenza if started early in the illness.[147] Secondary bacterial pneumonia should be treated with antibiotics. Respiratory syncytial virus is emerging as an important cause of serious illness in the elderly and high-risk adults with clinical manifestations, length of hospital stay, use of ICU, and mortality rates similar to influenza.[149]

Potential Agents of Bioterrorism

Potential agents of bioterrorism include rare infections that may occur sporadically in specific epidemiologic settings, such as anthrax, as well as diseases considered eradicated, such as smallpox. Features of these illnesses are their potential to cause illness and death, the potential for large-scale dissemination, their ability to cause public disruption, and the requirement for specific public health interventions in the setting of an outbreak. Illness is generally severe, and infected patients are likely to require admission to critical care units. Recognition of these syndromes by clinicians is crucial to triggering the appropriate medical, public health, and governmental response.

Anthrax

Bacillus anthracis, the causative agent of anthrax, is an aerobic, gram-positive, sporulating bacillus. When human infection occurs, spores germinate in blood and tissue. Human infection can be of four types: (1) cutaneous, (2) inhalational, (3) gastrointestinal, and (4) injectional.[150] The cutaneous form is the most common and characteristically appears as a painless papule that evolves to a vesicular stage and then to a depressed black eschar surrounded by a ring of vesicles. Untreated, it carries a mortality rate of less than 1%.[150]

The inhalational form is the form most likely to be encountered in the critical care setting. After an incubation period of generally 1 to 7 days but potentially up to 60 days, patients present with fever, malaise, dry cough, and an influenza-like illness. Progression to severe respiratory distress and septic shock occurs. The hallmark of this infection is a hemorrhagic mediastinitis.[150] The mortality rate has been as high as 85%. In virtually all cases, chest radiographs are abnormal and show either a widened mediastinum or pleural effusions. CT scan is particularly sensitive in detecting mediastinal changes.[150] Blood culture results are positive in 70% of cases. Clinical suspicion should be raised by the sudden appearance of multiple cases of severe influenza-like illness with a fulminant course and high mortality rates. The diagnosis is generally established by culturing the organism from blood, CSF, pleural fluid, or vesicular fluid; by PCR; or by biopsy. Therapy for systemic infections is initially empiric and consists of the combination of an oral fluoroquinolone, linezolid, and meropenem if meningitis is suspected and a fluoroquinolone plus clindamycin or linezolid if meningitis has been ruled out.[150] Steroids should be initiated for meningitis.[150]

Smallpox

Smallpox is caused by the variola virus. This serious infection is highly contagious and fatal in about 30% of cases. Two major clinical forms exist; the most common is variola major. This is a severe form that produces extensive rash and high fever. After an incubation period of 12 to 14 days, patients develop high fever, malaise, headache, myalgias, and vomiting. The rash appears initially as small intraoral spots and within 24 hours develops on the face, then spreads to the legs, feet, arms, and hands.[150] The rash appears as papules, which are filled with a thick, opaque fluid and have a depressed center. They evolve into pustules, which are raised, round, and firm to the touch. The differential diagnosis includes varicella. Treatment is supportive. The antiviral agent cidofovir may have activity.[150] Smallpox is contagious; therefore airborne precautions should be used.

Plague

The causative agent of plague is *Yersinia pestis*, an aerobic gram-negative bacillus. The three clinical forms are (1) bubonic, (2) pneumonic, and (3) septicemic.[150] Pneumonic plague is transmitted person to person through inhalation of contaminated aerosols and is highly contagious. After an incubation period of 2 to 3 days, patients develop fever, chills, headache, hemoptysis, dyspnea, stridor, cyanosis, respiratory failure, circulatory collapse, and bleeding.[150] Diagnosis is based on clinical suspicion and confirmed by culture. Treatment is with streptomycin, gentamicin, or doxycycline.[150]

Tularemia

Tularemia is caused by *Francisella tularensis*, which is a gram-negative coccobacillus. Types of infection include ulceroglandular, typhoidal, and pneumonic. If there were to be an intentional release of this agent, infection would likely occur via the aerosol route.[150] Symptoms include cough, substernal pain, abdominal pain, prostration, fever, chills, and headache. Diagnosis is established by culture onto special media, by serologic testing, or by PCR. Treatment is with streptomycin or gentamicin.

Key Points

- Of patients with bacterial meningitis, 95% have at least two of the following symptoms: fever, headache, stiff neck, and altered sensorium.
- Morbidity and mortality rates of bacterial meningitis are decreased with prompt administration of antibiotics.
- When dexamethasone is administered as adjunctive therapy for bacterial meningitis, it should be given before or concurrent with initial antibiotic doses.
- The standard for diagnosis of herpes encephalitis is PCR of CSF, and treatment for suspected herpes encephalitis should be continued until PCR results are back.
- *S. aureus* has become the most common cause of bacterial endocarditis, and *S. aureus* endocarditis is associated with a high risk of complications and high mortality rates.
- Major indications for surgery in acute endocarditis include congestive heart failure, persistent bacteremia and sepsis, ongoing emboli with appropriate antibiotic therapy, and local valvular complications such as dehiscence and perivalvular abscess.
- Staphylococcal and streptococcal toxic shock syndromes are mediated by systemic effects of bacterial exotoxins that trigger massive release of cytokines.
- Necrotizing fasciitis, although uncommon, is a severe infection that causes necrosis of subcutaneous tissue and fascia and requires prompt identification and therapy to minimize morbidity and mortality rates.
- CA-MRSA can cause life-threatening illness, including necrotizing skin infections, pneumonia, and sepsis.
- Empiric antibiotic therapy for bacterial peritonitis should be directed at gram-negative bacillary organisms and anaerobes.
- The presence of an intra-abdominal abscess should be entertained in febrile patients without any obvious cause of fever or in the seriously ill patient who is receiving corticosteroid therapy.
- An epidemic strain of *C. difficile* has enhanced toxin production and causes increased severity of illness, poorer response to therapy, and frequent relapse.
- Serious infections of the head and neck are polymicrobial and most frequently have an odontogenic source.
- Serious complications of influenza include primary influenza viral pneumonia, bacterial pneumonia, Reye syndrome, and myocarditis/pericarditis.

Review Questions

1. Which of the following is correct about the use of adjuvant dexamethasone for treatment of bacterial meningitis?
   - **a.** Adjuvant dexamethasone reduces mortality in *Listeria* meningitis.
   - **b.** Corticosteroids should be administered within 12 hours of starting antibiotic therapy.
   - **c** Dexamethasone has been shown to be of benefit for treatment of health care–associated bacterial meningitis.
   - **d.** Dexamethasone has been shown to decrease hearing loss and other neurologic sequelae in patients with pneumococcal meningitis.

   Answer: d. The strongest evidence for benefit of dexamethasone in bacterial meningitis has been decreased rates of hearing loss and other neurologic sequelae in confirmed pneumococcal meningitis; the mortality benefit in pneumococcal disease has not been as clearly demonstrated. The benefit of steroids has not been shown in adults for meningitis owing to any other organism and is not recommended for treatment of postneurosurgical or ventriculostomy–associated meningitis as these are rarely due to pneumococcus. Steroids should be administered before or concurrent with the first doses of antibiotics; there are no studies demonstrating benefit if given after antibiotic therapy is started.
2. Which of the following is correct about the diagnosis of suspected bacterial meningitis?
   - **a.** Noncontrast head computed tomography (CT) scan should be done before a lumbar puncture because of the risk of herniation.
   - **b.** A cerebral spinal fluid (CSF) white blood cell (WBC) count of less than 100 cells/mm^3 with a lymphocytic predominance excludes a diagnosis of bacterial meningitis.
   - **c.** Gram staining of spun CSF is positive in 60% to 90% of cases of bacterial meningitis
   - **d.** Initiation of antibiotic therapy for suspected meningitis before lumbar puncture does not significantly decrease the yield of CSF cultures.

   Answer: c. The Gram stain of CSF is a very useful diagnostic study in management of bacterial meningitis and is reported to be positive in 60% to 90% of confirmed cases of bacterial meningitis; the yield on Gram stain is highest for pneumococcal disease. Lumbar puncture without prior CT scan has been demonstrated to be safe in many patients with bacterial meningitis without specific features suggesting a higher risk of focal mass lesions with higher risk of herniation such as new-onset seizures or new focal findings. Although CSF WBC counts of greater than 100 cells/mm^3 are typically found in most patients with bacterial meningitis, a CSF WBC count of less than 100 cells/mm^3 does not exclude the diagnosis and a very low CSF WBC count can be seen with overwhelming infections. CSF profiles in meningitis typically show neutrophilic predominance, but early during infection the profiles may demonstrate a lymphocytic predominance. Administration of antibacterial therapy before lumbar puncture has been reported to decrease the likelihood of a positive CSF culture by as much as 20%.
3. Which of the following is correct regarding viral encephalitis?
   - **a.** Herpes simplex virus type 2 causes about 10% of cases of infectious encephalitis in the United States.
   - **b.** Rabies encephalitis is a uniformly fatal infection.
   - **c.** West Nile virus meningoencephalitis can present with flaccid paralysis or with parkinsonian-like tremors.
   - **d.** A specific etiology will eventually be found in over 75% of patients presenting with infectious encephalitis.

   Answer: c. The manifestations of West Nile neuroinvasive disease include aseptic meningitis, meningoencephalitis, and polio-like flaccid paralysis syndromes. Parkinsonian-like tremors can be a prominent feature of West Nile meningoencephalitis. The incidence of neuroinvasive disease increases with age. Even after extensive diagnostic studies, the etiology remains undiagnosed in more than half of patients presenting with presumed infectious encephalitis. Herpes simplex type 1 infection is the cause of up to 10% of diagnosed cases of infectious encephalitis. Herpes simplex type 2 is associated with aseptic meningitis but much less commonly is a cause of encephalitis. Rabies encephalitis was previously considered uniformly fatal but there have been several recent documented cases of survival after aggressive intensive care protocols.
4. Which of the following is an indication for urgent valve replacement in patients with bacterial endocarditis?
   - **a.** Infection caused *Enterococcus faecalis*
   - **b.** Recurrent septic pulmonary emboli while receiving treatment
   - **c.** Refractory congestive heart failure and valvular insufficiency
   - **d.** Septic embolus to the middle cerebral artery with hemorrhage shown on CT scan

   Answer: c. The most common indication for urgent valve replacement in infectious endocarditis is refractory congestive heart failure and valvular insufficiency. Although early surgery may be indicated for fungi and multidrug-resistant bacterial organisms, patients with more typical endocarditis pathogens such as staphylococci, streptococci, and *Enterococcus faecalis* would generally need to either be failing therapy or have other specific indications to consider urgent surgical therapy. Unlike systemic emboli in left-sided endocarditis, even recurrent pulmonary emboli are not a definitive indication for surgery for right-sided disease. Hemorrhagic embolic brain lesions would be a contraindication to immediate surgical intervention; in such cases surgery is usually deferred for at least 4 weeks.
5. Which of the following statements is correct regarding the role of echocardiography in the diagnosis and management of infective endocarditis?
   - **a.** Echocardiographic findings are a key component of the modified Duke Criteria for diagnosis of infective endocarditis.
   - **b.** Transesophageal echocardiography (TEE) is preferred to transthoracic echocardiography (TTE) as the initial study for diagnosis of infective endocarditis
   - **c.** The sensitivity of TEE is equivalent to TTE for diagnosis of prosthetic valve endocarditis.
   - **d.** A negative TEE study in a patient with a high suspicion for the diagnosis of infective endocarditis does not need to be repeated.

   Answer: a. The diagnosis of endocarditis relies very heavily on echocardiographic findings and is one of the two major criteria in the modified Duke Criteria, in addition to blood culture results. Both the American Heart Association and European Cardiology Society guidelines recommend TTE as the initial screening test for diagnosis of infective endocarditis, but the sensitivity of TEE is higher in most circumstances; when suspicion remains moderate to high and TTE is either negative

or not definitive, TEE should be pursued. The sensitivity of TEE is 90% for prosthetic valve infective endocarditis, which is much higher than the 50% to 70% sensitivity reported for TTE. In patients for whom there is persistent high suspicion for infective endocarditis even after a negative TEE study, a repeat TEE study in 5 to 7 days is reasonable.

6. Which of the following is correct regarding staphylococcal and streptococcal toxic shock syndromes?

a. Antibiotic therapy is a key component of the management of staphylococcal toxic shock syndrome due to super-absorbent tampons.

b. Therapy for toxic shock syndrome caused by severe group A streptococcal infections may include antibiotics that decrease bacterial toxin production such as clindamycin.

c. The incidence of staphylococcal toxic shock syndrome has not changed in the United States in the past 3 decades.

d. The rash of staphylococcal toxic shock syndrome is most commonly petechial or purpuric.

Answer: b. Antibiotics such as clindamycin and linezolid shut down production of bacterial exotoxins in streptococci and are recommended for treatment of severe group A streptococcal skin and soft tissue infections and for suspected group A toxin-mediated syndromes. The role of antibiotic therapy for staphylococcal toxic shock syndrome is less clear than for streptococcal toxic shock syndromes as toxin is often produced by colonizing and not infecting organisms such as in tampon-associated toxic shock syndrome. The incidence of tampon-associated toxic shock syndrome, which was most associated with highly absorbent brands of tampons, has declined markedly since the first descriptions of this syndrome in the 1980s. Rash is a prominent component of the clinical manifestations of staphylococcal toxic shock syndromes and is most commonly a scarlatiniform or erythroderma-like rash that progresses to desquamation.

Acute Kidney Injury

THOMAS L. SALAZER AND IRAM AQEEL

CHAPTER OUTLINE

Definition
- Epidemiology

Pathogenesis
- Prerenal Acute Kidney Injury
- Postrenal Acute Kidney Injury
- Intrinsic Acute Kidney Injury

Clinical Manifestations
- Retention of Filtration Markers and Formulas as an Assessment of Glomerular Filtration Rate

Diagnostic Approach
- General Aspects
- Urinalysis and Urine Indices
- Radiologic Imaging
- Other Laboratory Testing
- Renal Biopsy

Prevention
- Maintenance of Renal Perfusion
- Avoidance of Nephrotoxicity
- Prevention of Contrast Nephrotoxicity

Management of Established Acute Kidney Injury
- General Aspects
- Management of Volume Status
- Preventing, Monitoring, and Treating Complications
- Medication Dosing Considerations
- Nutritional Considerations
- Renal Replacement Therapy

Prognosis and Outcomes

Definition

Acute kidney injury (AKI) is the sudden loss of kidney function resulting in the inept excretion and accumulation of metabolic waste products such as urea and nitrogenous waste products with associated dysregulation of water and electrolytes. AKI is not a specific disease entity but rather represents a spectrum of renal dysfunction that can occur as a result of hemodynamic factors such as decreased renal perfusion from dehydration, partial or complete urinary tract obstruction, or parenchymal renal injury. The term *acute kidney injury* has largely replaced prior terminology of acute renal failure. This new terminology reflects an attempt to broaden recognition that even smaller decreases in renal function that do not result in overt organ failure may still represent significant clinical changes that are associated with increased morbidity and mortality.

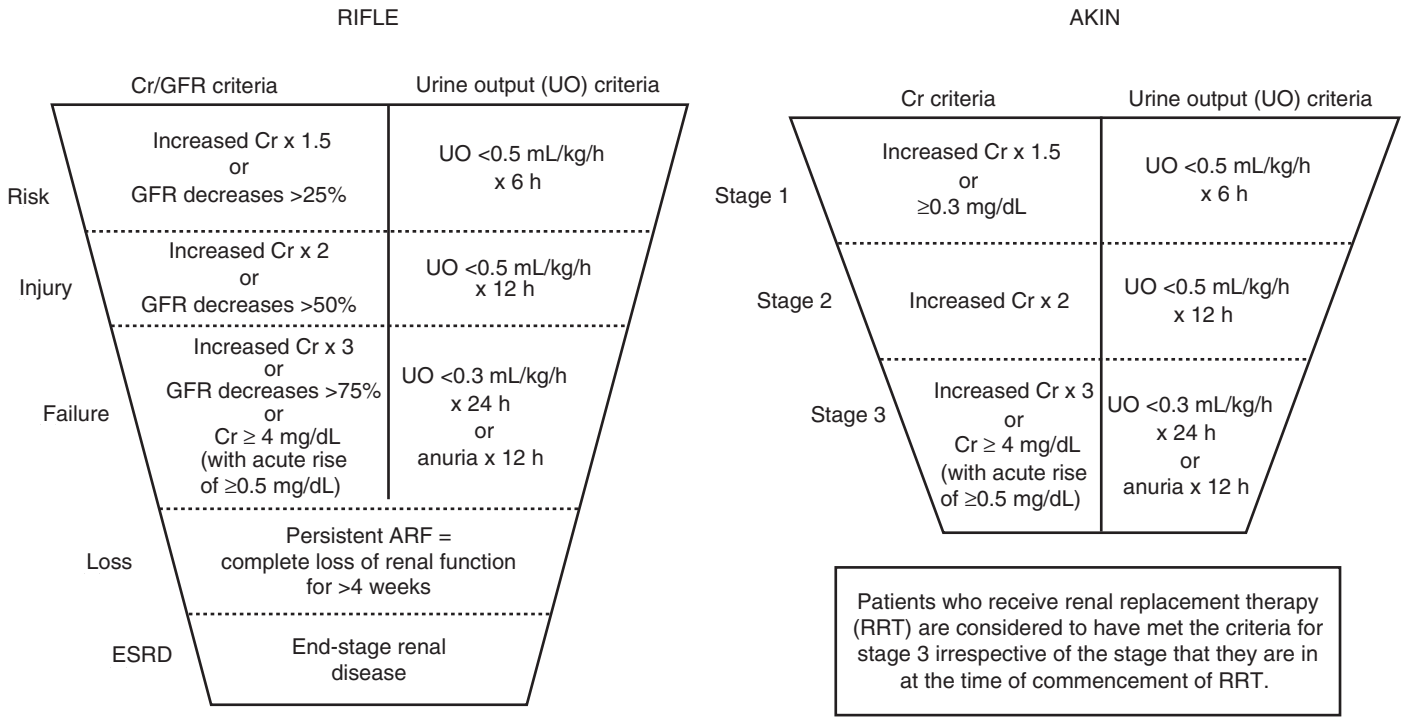
The loss of kidney function has traditionally been defined by the accumulation of metabolic waste products, most notably blood urea nitrogen (BUN) and creatinine. However, creatinine, the classical biomarker for the assessment of glomerular filtration rate (GFR), has several limitations. Creatinine is only a reliable marker of GFR if the patient is in a steady state. Until recently, there has been a lack of consensus on the quantitative definition of AKI. This lack of uniformity has formerly confounded interpretations of clinical studies for diagnosing, classifying, and assessing outcomes of AKI.

Since 2004, three consensus definitions have been developed to improve uniformity in the diagnosis of AKI in critically ill patients. In 2004, the Acute Dialysis Quality Initiative (ADQI) work group developed a consensus definition best known by the acronym RIFLE (Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease).[1]

The classification was based on three diagnostic indices: changes in serum creatinine from baseline, GFR, and urine output. There were three graded levels of kidney dysfunction (risk, injury, and failure) based on the degree of creatinine elevation or the change in GFR or urine output and there were two outcome measures (loss and end-stage renal disease). It was subsequently reported that the RIFLE criteria correlated with prognosis with a stepwise increase in the relative risk of death in patients who met the RIFLE criteria for various stages of AKI.[2] However, several notable limitations with the RIFLE criteria were noted. The change in serum creatinine concentration did not correlate with the percent decrease in GFR cited by the RIFLE criteria classification.[3] Additionally, the relative risk for mortality by RIFLE stage based on the change in serum creatinine did not correlate well with the mortality risk by RIFLE stage based on the decline in urine output criteria.

In 2007, in an effort to further define uniform standards for diagnosing and classifying AKI, the Acute Kidney Injury Network (AKIN) diagnostic criteria were developed. They served as a modified version of the RIFLE criteria. They provided both diagnostic criteria and a staging system for AKI. The diagnostic criteria used were both creatinine and urine output. However, as noted in Fig. 52.1, there were several notable differences between the RIFLE and AKIN criteria.[4]

The AKIN criteria added an absolute rise in creatinine of 0.3 mg/dL or more to the AKIN diagnostic criteria in stage 1. The serum creatinine changes had to occur within 48 hours as opposed to the RIFLE criteria with which changes in creatinine could occur up to 7 days, and the loss and end-stage renal disease (ESRD) were removed from the AKIN criteria as they were considered



• **Fig. 52.1** The RIFLE (Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease) and AKIN (Acute Kidney Injury Network) criteria. *ARF,* Acute renal failure; *Cr,* creatinine; *ESRD,* end-stage renal disease; *GFR,* glomerular filtration rate. (From Cruz DN, Ricci Z, Ronco C. Clinical review: RIFLE and AKIN—time for reappraisal. *Crit Care.* 2009;13:211.)

outcomes, not stages. Furthermore, because transient oliguria may be an appropriate physiologic response to intravascular volume depletion without any notable change in renal function,[5] the diagnostic changes for urine volume could only be applied after volume status was optimized. Urinary tract obstruction also needed to be excluded in the AKIN criteria if oliguria was used as the only diagnostic criterion. Despite these modifications to the initial RIFLE criteria, the AKIN criteria failed to materially change the classification of AKI or help predict hospital mortality.

In 2012, the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines proposed a modified version of the RIFLE and AKIN criteria.[6] They included a revision to the AKI definition but retained the AKIN staging criteria. In the KDIGO definition for AKI, the time frame for an absolute increase in the serum creatinine of 0.3 mg/dL or higher was maintained at 48 hours, similar to the AKIN definition, while the time frame for a 50% or higher increase in serum creatinine of 7 days was maintained from the RIFLE criteria. The KDIGO criteria did not use changes in GFR for staging; only serum creatinine and urine output were used. The KDIGO criteria also did not stipulate that adequate fluid resuscitation should have been undertaken and urinary tract obstruction be excluded before applying the criteria. Similar to the RIFLE and AKIN criteria, KDIGO criteria suggested that patients be classified to the highest stage of achieved renal dysfunction.

Overall, there is a general consensus among experts that a standardized definition for AKI has epidemiologic benefits as well as clinical benefits for both preventative and therapeutic research.[7] However, as with both the RIFLE and AKIN criteria, the potential clinical usefulness at the bedside with this latest definition and classification of AKI by KDIGO has been questioned.[8–10]

For example, using creatinine as a biomarker for determining AKI has clear limitations; it can result in both false-positive and false-negative diagnosis. Serum creatinine changes may not reflect an actual GFR in the non-steady state. It has been shown that the true GFR after an acute renal ischemic insult will drop rapidly but the serum creatinine peak rise could take many hours to several days before a steady state is reached.[11] Additionally, it has recently been demonstrated that inherent laboratory and biologic variabilities of serum creatinine in the same patient can result in a false-positive rate of AKI diagnosis in up to 30.5% of patients with baseline creatinine values greater than 1.5 mg/dL.[12] Conversely, a biopsy study found that 35% of cases had acute diffuse parenchymal pathology despite not meeting the KDIGO criteria for AKI secondary to a slow rise in serum creatinine.[13] This latter study suggests that using creatinine alone as a marker for parenchymal renal injury could underestimate patients with significant glomerular pathology. Similarly, the use of urine output criteria for a diagnosis of AKI has not been shown to independently predict mortality.[14] There has been an overall concern that despite the increased awareness of AKI using the modified KDIGO definition, this may result in a marked increase in nephrology referrals and as such, it has been recommended that appropriate discretion be used to guide the clinical relevance of an AKI diagnosis.[15]

Despite these potential limitations in using the KDIGO classification of AKI, its use has been endorsed by the National Kidney Foundation and has generally replaced the prior RIFLE and AKIN criteria in diagnosing AKI; its use in clinical practice is now considered the consensus standard. The clinical utility of an early AKI diagnosis is to optimize hemodynamics, promptly treat the underlying cause, and avoid potential nephrotoxins. In the future, more sensitive and specific biomarkers of AKI will likely be

• BOX 52.1 Factors Contributing to the Variability in Incidence of Acute Kidney Injury

Development before hospitalization
Specific definition used for describing acute kidney injury
Location of admission (general medical/surgical ward vs. intensive care unit)
Diagnosis and clinical characteristics (after coronary artery bypass grafting vs. acute ischemic stroke vs. intracranial hemorrhage)

• BOX 52.2 Causes of Intravascular Volume Depletion Associated With Prerenal Azotemia

Decreased in water intake
Gastrointestinal hemorrhage
Diarrhea
Vomiting
Diuretics
Polyuric states (e.g., diabetes insipidus)

developed that would certainly change, alter, or create a new paradigm to current consensus definitions, which hopefully would improve patient outcomes and cost-effectiveness in the delivery of care in patients who develop AKI.

Epidemiology

AKI is a growing concern for health care worldwide and establishing an accurate reported incidence of AKI is important for health care policy, quality initiatives, and the design of clinical trials to enhance clinical decision making. The reported incidence of AKI has been variable and dependent on several factors (Box 52.1).

Despite the limitations of much published data as being retrospective and single-center studies, several large epidemiologic studies have reported an overall increased incidence of AKI over the past several decades in the United States.[16–18] Using data from the Healthcare Cost and Utilization Project's (HCUP) National Inpatient Sample (NIS) representing more than 18 million hospitalizations from 1049 U.S. hospitals, there has been an annual increase of reported AKI of 14% per year from 2001 to 2011, which correlates to a near fivefold increase in AKI during this time frame.[17] In a study conducted by the Centers for Disease Control and Prevention using data from the National Hospital Discharge Survey in the United States, AKI among hospital patients increased from 18 per 100,000 population in 1980 to 365 per 100,000 population in 2005.[15] Data from Kaiser Permanente of northern California reported a rise in incidence for the cohort of AKI not requiring renal replacement therapy (RRT) from 323 to 522 cases per 100,000 person-years between 1996 and 2003.[16]

For hospitalized patients, estimates of the incidence of AKI range from 5% to 7% for the overall hospital population, and 10% to 35% for ICU patients; 4% to 6% of the latter cohort require RRT.[19–21] The variety of ICU settings has also had variable recorded rates of AKI. In a retrospective observational study of more than 600,000 patients admitted to 191 Veterans Health Administration hospitals, the overall frequency of AKI ranged from 9% to 30% with variable rates depending on the primary ICU site of care: 12% for neurosurgical ICU admissions, 20% to 25% for orthopedic and abdominal surgery–related ICU admissions, and 32% in patients undergoing cardiovascular surgery.[22] As expected, the earliest stages of AKI (stages 1 and 2) have a higher reported incidence across these various ICU settings than more advanced stages (stage 3).[23] Varying rates of AKI incidence were similarly reported by Khatri and colleagues in the ICU setting in a single-center sample of more than 500 patients with either acute ischemic stroke or acute intracranial hemorrhage; the incidence of AKI was 14% and 21%, respectively.[24] AKI and dialysis requiring AKI after cardiac surgery has been associated with increased mortality.[25] The reported AKI incidence in this cohort has been reported to be variable at 5% to 10%[26,27]; a recent meta-analysis including more than 242,000 patients after cardiopulmonary bypass surgery reported an AKI incidence of 18.2%.[28] High incidence rates of AKI have been reported after gastric bypass surgery,[29] burns,[30] and trauma[31] and in recipients of living allogeneic bone marrow transplants in whom AKI incidence has been reported between 20% and 73%.[32]

In an attempt to review the worldwide incidence of AKI, a meta-analysis by Susantitaphong and colleagues reviewed 312 studies that included more than 49 million cases of patients primarily in the hospital setting. For the 154 studies that included 3.5 million cases of AKI using the KDIGO definition, 1 in 5 adults and 1 in 3 children worldwide developed an AKI episode during a hospital episode of care.[33] The AKI-EPI study, a cross-sectional study specifically evaluating the worldwide incidence of AKI in the ICU that included 1802 ICU patients, reported an AKI frequency of greater than 50%.[34]

Sepsis and major abdominal surgery are the two most common predisposing risk factors for AKI[35] in critically ill patients; additional contributing factors include baseline chronic renal failure (CRF), cardiogenic shock, liver failure, and medication-associated toxicity. The metabolic syndrome and obesity are also risk factors for AKI.[36] Both preoperative and postoperative proteinuria have been reported as risk factors for patients with AKI undergoing cardiac surgery.[37,38]

Pathogenesis

AKI has traditionally been categorized into either prerenal, postrenal, or intrinsic causes with multiple etiologies in each category. The two most common causes of AKI in the hospital setting are prerenal azotemia and acute tubular necrosis (ATN), accounting for up to 30% to 75% of cases.[39] Although this classification is helpful in forming a differential for AKI, oftentimes multiple causes with differing pathophysiologic features for AKI occur in the same patient.

Prerenal Acute Kidney Injury

Prerenal azotemia results from a decrease in effective blood volume, resulting in a decrease in glomerular perfusion and GFR. There are several mechanistic etiologies, including intravascular volume depletion (hypovolemia), decreased cardiac output, intrarenal hemodynamic changes, obstruction of the renal arteries, and an increased renal venous pressure. Prerenal azotemia from intravascular volume depletion remains the most common etiology for AKI in the hospital setting and typically remains the most easily treatable and reversible (Box 52.2).

Typically, with early treatment of prerenal azotemia, parenchymal renal injury does not occur. However, with delayed treatment, kidney injury with resultant ATN can occur primarily through ischemic effects on the renal tubules in the corticomedullary

junction, which have the least blood flow and the highest oxygen demand.

Autoregulatory processes often occur that attempt to mitigate potential end-organ renal injury from prerenal azotemia. For example, in patients in whom systemic hypoperfusion and a drop in mean arterial pressure develop, both arterial and cardiac baroreceptors are activated, which increases sympathetic neural tone and release of both renin and antidiuretic hormone. These physiologic responses result in arteriolar and venular constriction with a subsequent increase in systemic blood pressure and cardiac output. The release of renin activates the renin-angiotensin-aldosterone system. Renin release helps cleave angiotensinogen to angiotensin I. Angiotensin-converting enzyme cleaves angiotensin I to angiotensin II; the latter stimulates both afferent and efferent arteriolar vasoconstriction. The afferent vasoconstrictor effects are opposed by the vasodilatory prostaglandins. The net effect is to maintain the tone of the afferent arteriole while constricting the efferent arteriole to maintain intraglomerular pressure and glomerular ultrafiltration. When these physiologic regulatory processes are insufficient or overwhelmed, GFR decreases and AKI ensues.

Although the majority of causes of prerenal AKI are secondary to decreased renal perfusion, altered intrarenal hemodynamics from certain vasoactive medications may decrease renal blood flow without decreasing effective circulating intravascular volume. Calcineurin inhibitors, such as cyclosporine and tacrolimus, may cause renal vasoconstriction and subsequent AKI that is often exacerbated in hypovolemic states. Nonsteroidal antiinflammatory drugs (NSAIDs) decrease vasodilatory prostaglandin production through their inhibitory effects of cyclooxygenase. These vasodilatory prostaglandins often help maintain renal blood flow and GFR by afferent arteriolar vasodilatory properties. Use of NSAIDs in patients with baseline prerenal azotemia, congestive heart failure (CHF), or with underlying chronic kidney disease (CKD) are at increased risk for AKI. Medications with specific inhibitory effects on the renin-angiotensin-aldosterone system may also induce an AKI. Typically, intrarenal formation and actions of angiotensin II help to maintain GFR through vasoconstrictive effects on the efferent arteriole. This compensatory autoregulatory mechanism is especially helpful when renal perfusion is decreased. Renin inhibitors, angiotensin-converting enzyme inhibitors (ACEs), and angiotensin receptor blockers (ARBs) may induce an AKI either through their direct inhibition of angiotensin II production or its action. The risk of AKI increases with underlying prerenal azotemia, CKD, renal artery stenosis, or CHF.

Prerenal AKI can also result from an increase in renal venous pressure. This is typically seen in patients with abdominal compartment syndrome (ACS); the latter typically occurs in trauma patients with an incidence ranging from 1% to 14%[40–42] with an overall 4.2% ACS incidence of all medical and ICU patients.[43] Intra-abdominal pressure (IAP) is the steady-state pressure within the abdominal cavity. For most critically ill patients, an IAP between 5 and 7 mm Hg is considered normal,[44] although patients with high body mass index and pregnancy may have higher IAP of up to 10 to 15 mm Hg without any untoward effects.[45] Typically, intraabdominal hypertension is defined as a sustained IAP of 12 mm Hg or higher and ACS is defined by a persistent elevation in IAP of 20 mm Hg or higher with associated end-organ dysfunction.[45,46] The primary renal mechanism of ACS is renal vein compression resulting in an increase in resistance that impedes renal venous drainage.[47,48] Similar to other prerenal states, spot urine sodium and chloride levels are decreased, whereas plasma renin activity, aldosterone, and antidiuretic hormone levels are increased.[49] With progressively higher IAPs, there is a further decrease in urine volume.[50] The progressive renal effects, if left untreated, are a decrease in renal perfusion followed by oliguria, anuria, and AKI. There is general consensus that surgical decompression is indicated for ACS.[51]

Postrenal Acute Kidney Injury

Urinary tract obstruction refers to an interference of normal urine flow anywhere along the genitourinary system from the renal pelvis extending to the urethral meatus. The classification is often based on the location of the obstruction—either intrinsic (occurring within the urinary tract and encompassing both intramural and intraluminal etiologies) or extrinsic (obstruction from external compression)—as well as whether the etiology is an upper tract (above the level of the bladder) or lower tract obstruction. There are no large published epidemiologic data on the incidence of obstructive uropathy in the ICU. Differing demographics often affect the likely potential etiologies for obstructive uropathy. In older men, prostate enlargement is the most common cause. Adenocarcinoma of the prostate is second only to carcinoma of the cervix as the leading cause of extrinsic compression secondary to tumors. In women, pregnancy is the most common cause of extrinsic compression with ureteral dilatation typically observed in the third trimester, more commonly involving the right ureter and with typical spontaneous resolution after delivery. The second most common cause of urinary obstruction in women is carcinoma of the cervix, with urinary obstruction seen in up to 30% of cases.[52] Other etiologies of extrinsic compression in women include prolapsed uterus, pelvic inflammatory disease, and endometriosis.

Obstructive uropathy may also be seen with neurogenic bladder dysfunction (from diabetes mellitus or spinal cord injury), vascular syndromes (from abdominal aortic aneurysms or rarely vasculitis), or certain medications with anticholinergic effects. Retroperitoneal fibrosis (RPF) may lead to an obstructive uropathy. It is characterized by inflammatory and fibrous tissue that encases the ureters and other intraabdominal organs. RPF is typically classified as idiopathic versus secondary, with idiopathic RPF accounting for up to 70% of cases.[53] Idiopathic RPF is an immune-mediated disease that more recently has been associated with a fibro-inflammatory process called immunoglobulin (Ig) G4-mediated disease (IgG4-RD). Secondary forms of RPF are numerous with multiple associations, including radiation therapy for testicular carcinoma, medications, malignancies, and retroperitoneal hemorrhage.

Urinary tract obstruction is typically reversible when diagnosed early. If left untreated, it can lead to urinary tract infection (UTI), urosepsis, and ESRD in patients with prolonged bilateral obstructive uropathy or unilateral obstruction in a solitary functioning kidney. The primary pathologic lesion in the medulla and papilla is ischemic atrophy associated with flattening and atrophy of the tubular epithelium and interstitial fibrosis.

The clinical presentation of patients with obstructive uropathy is quite variable and is often dependent on the site, acuity, etiology, and degree of obstruction. Hyperkalemic renal tubular acidosis may be suggestive of an obstructive uropathy[54] but typically laboratory studies such as urinalysis and degree of creatinine elevation are nondiagnostic. Radiographically, a renal ultrasound (US) is the initial preferred test for screening for most patients with suspected obstructive uropathy, unless an obstructing stone is considered likely; then a noncontrast computed tomography (CT) should be the initial diagnostic study. Magnetic resonance imaging (MRI) is an alternative, but gadolinium should be avoided with advanced

renal insufficiency given the potential for nephrogenic systemic fibrosis. Unilateral obstruction from calculi typically presents with acute flank pain; however, pain is typically absent with external compression from tumors secondary to a slowly progressive course. Urine volume is often variable as well. Complete bilateral obstruction causes anuria, whereas partial bilateral obstruction often does not result in a change in urine volume secondary to the tubular injury causing impaired concentrating ability and sodium reabsorption. Complete unilateral obstruction in the setting of a normal contralateral kidney often does not alter urine volume.

Treatment of obstructive uropathy is dependent on the etiology. For bladder outlet obstruction, placement of a bladder catheter typically relieves the obstruction. In patients with ureteral or other upper tract disease, placement of ureteral stents or percutaneous nephrostomy tubes may be indicated. Recovery of renal function is typically dependent on the duration of the obstructive uropathy.

Intrinsic Acute Kidney Injury

The causes of intrinsic AKI are typically categorized by the primary area of renal pathology: tubulointerstitial, glomerular, vascular, and tubular obstruction. At times, the associated clinical manifestations such as polyuria in patients with lithium-induced nephrogenic diabetes insipidus correlate with the expected area of tubulointerstitial renal involvement. However, there is often an overlap between pathologic categories. For example, patients with lupus nephritis and glomerular involvement have a worse prognosis if there is significant tubulointerstitial disease on renal biopsy.[55,56] Additionally, secondary focal segmental glomerulosclerosis mediated by structural-functional adaptations to glomerular hyperfiltration can be seen in a variety of disease entities including reflux nephropathy.

Acute Tubular Necrosis

The most common cause of intrinsic AKI in the ICU is ATN, accounting for up to 90% of cases.[57,58] There are three major causes of ATN: renal ischemia, sepsis, and nephrotoxins. All causes of severe prerenal azotemia, especially when associated with hypotension, can also lead to ATN. Sepsis-induced ATN is typically secondary to decreased renal perfusion in the setting of hypotension. There are many nephrotoxins that can also cause ATN, including antimicrobials, chemotherapeutic agents, and radiocontrast media. ATN frequently occurs with many underlying comorbidities. The history, physical examination, and certain laboratory findings may provide diagnostic clues to ATN, but a definitive diagnosis can only be made by renal biopsy. Most often, a renal biopsy is not performed when the clinical diagnosis is most consistent with ATN because establishing a pathologic diagnosis concordant with the clinical diagnosis would not alter treatment. The pathophysiology of ischemic ATN involves a complex process of renal hemodynamics, tubular and endothelial cell injury, and inflammatory processes.[59] The histologic changes of ATN include denuding of the epithelium, focal areas of proximal tubular dilatation, and occlusion of the tubular lumen by casts and cellular debris.[60] Clinically, the decrease in GFR in patients with ATN is not always correlative with a decreased urine output. Patients are typically nonoliguric, although anuria may occur. Although it has been shown in several prospective multicenter observational studies that positive fluid balance is an independent risk factor for increased mortality in ATN,[61–63] a nonoliguric ATN has not been routinely associated with a uniformly better outcome.[64] As such, the use of diuretics in patients with ischemic ATN should be used only to treat volume overload and their use for the sole oliguric state is not recommended.[6,65,66]

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is a common cause of AKI in the ICU manifested by an inflammatory interstitial infiltrate and tubulitis in the kidney causing renal insufficiency. The glomeruli and blood vessels are typically spared. Various etiologies have been identified with drug-induced causes accounting for up to 71.1% of cases; of these cases antibiotics account for up to one-third of cases.[67] AIN may be idiopathic, but infections (such as leptospirosis and *Legionella*), autoimmune disorders (such as sarcoidosis, Sjögren syndrome), and tubulointerstitial nephritis uveitis syndrome are additional potential etiologies. The classic clinical triad of sterile pyuria, rash, and peripheral eosinophilia[68] may not be seen with certain causative agents such as proton pump inhibitors (PPIs) and NSAIDs.[69,70] A renal biopsy remains the only way to make a definitive diagnosis of AIN. The pathogenesis of drug-induced AIN is a type B idiosyncratic non–IgE-mediated immune reaction.[71] The classic histologic finding on renal biopsy includes a tubulitis, interstitial inflammation, and edema. The interstitial infiltrate is often composed of mononuclear cells, predominantly $CD4^+$ T lymphocytes, macrophages, monocytes, plasma cells, and eosinophils.[72] A less common histologic drug-induced interstitial nephritis caused by certain anticonvulsants, antibiotics, and diuretics is a granulomatous interstitial nephritis manifested by the presence of hypersensitivity granulomas composed of multinucleated giant cells and reactive epithelioid histiocytes.[73] It is imperative to consider AIN in the differential for any unexplained AKI in the ICU as once the acute interstitial inflammation occurs, it can progress to a fibrogenic process marked by tubular atrophy and interstitial fibrosis.[74,75] Because the chronic injury to the tubulointerstitial compartment has been shown to be a major determinant in the development of CKD,[76] an early diagnosis for drug-induced AIN with appropriate treatment is warranted. The primary intervention and treatment for drug-induced AIN is identification and removal of the offending agent. Although corticosteroids are most often used to treat drug-induced AIN even after the offending agent has been stopped, there are no prospective randomized controlled trials to support its use. Despite several retrospective studies showing discordant results with both select benefit[68,77–81] as well as no clear benefit,[82,83] it has been suggested that corticosteroids are a reasonable treatment option for patients whose renal function does not rapidly improve within 3 to 5 days after stopping the offending agent.[84]

Acute Glomerulonephritis

Acute glomerulonephritis (GN) is an unusual cause of AKI in the ICU. However, if undiagnosed, the potential morbidity and mortality is markedly increased because a delay in diagnosis often leads to irreversible renal injury. Because sepsis is a common cause of AKI in the hospital setting, one needs to consider a postinfectious GN in the differential diagnosis of any unexplained AKI. Postinfectious GN used to be referred to as a poststreptococcal GN. With the general improvement in treating streptococcal infections, the incidence of poststreptococcal GN has been decreasing. In contrast, with the rise of antibiotic-resistant *Staphylococcus* strains such as methicillin-resistant *Staphylococcus aureus,* the incidence of *S. aureus*–related acute GN has increased.[85] Clinically, patients with *S. aureus*–related GN typically present with a concurrent infection as opposed to poststreptococcal GN, in which the infection has typically resolved by the time the GN is diagnosed.[86] The site of

infection for *Staphylococcus* GN is typically not an upper respiratory tract infection, and these patients typically present with signs of an acute GN, including hypertension, edema, proteinuria, and an active urine sediment demonstrating microscopic hematuria and red blood cell casts. Many other forms of GN may occur in hospitalized patients with complications requiring ICU care. IgA nephropathy is the most common GN in the world[87,88] and commonly presents with a synpharyngitic microscopic or gross hematuria after an upper respiratory tract infection. There are no reliable blood or urine tests to make a diagnosis of IgA nephropathy and a renal biopsy is required for definitive diagnosis. The pathognomonic finding on renal biopsy is prominent deposits of IgA in the mesangium.[89] AKI often occurs during episodes of gross hematuria and has been attributed to both ATN[90,91] and tubular obstruction from red blood cell casts.[92] Patients with a higher baseline creatinine, heavier proteinuria, and underlying hypertension have a higher risk to progress to ESRD.[93] Rapidly progressive GN (RPGN) is a clinical syndrome often used to describe a rapid deterioration in renal function over days to weeks with an associated renal biopsy finding of crescents.[94] Crescents develop in response to glomerular capillary wall injury.[95] There are typically three broad mechanisms of glomerular injury leading to crescent formation; an anti–glomerular basement membrane antibody (anti-GBM Ab)-mediated disease, a pauci-immune process, or an immune complex–mediated disease. Patients with renal biopsies demonstrating less crescents involving the glomeuruli have been shown to have a better prognosis.[96] Anti-GBM Ab disease is a disorder involving circulating antibodies directed against an antigen in the glomerular basement membrane leading to an RPGN. When associated with pulmonary hemorrhage, it is often termed Goodpasture syndrome, and when the anti-GBM Ab, pulmonary hemorrhage, and renal failure are all present, the entity is typically referred to as Goodpasture disease. Patients with Goodpasture disease typically present with AKI, alveolar hemorrhage in approximately 50% of cases,[97] and a nephritic urine sediment. Approximately 30% to 40% of patients have an associated antineutrophil cytoplasmic antibody (ANCA),[98,99] which is typically anti–myeloperoxidase-specific (MPO-ANCA).[97] As with most causes of RPGN, Goodpasture disease has a better outcome with earlier diagnosis[100] and treatment involves a combination of plasmapheresis, prednisone, and cyclophosphamide.[101] Pauci-immune RPGN refers to a necrotizing GN in which immune deposits in the glomeruli are absent on renal biopsy. ANCA-positive serology is noted in 96% of patients,[102] and they clinically develop a systemic symptom complex of either microscopic polyangiitis or granulomatosis with polyangiitis, formerly called Wegener granulomatosis. The clinical presentation for both of these disorders has significant overlap but generally involves older adults with constitutional symptoms of fatigue, weight loss and anorexia,[103,104] sinusitis and nasal crusting,[103,105] cough and dyspnea,[106] and active GN, including hematuria, red blood cell casts, subnephrotic proteinuria, and renal insufficiency.[107] RPGN disorders with immune complex generation include IgA nephropathy, postinfectious GN, and systemic disorders such as systemic lupus erythematosus (SLE).

Acute Vascular Syndromes

Acute renal vascular disorders causing AKI can affect both the arterial and venous circulation. With increased diagnostic and therapeutic interventional vascular procedures used in daily hospital practice, atheroembolic renal disease (AERD), also known as cholesterol crystal emboli, is a diagnostic consideration in any patient with unexplained AKI who has undergone recent vascular interventions. AERD generally occurs when portions of a cholesterol plaque break off and embolize into distal renal arteries or glomerular arterioles, causing partial or total occlusion with resulting ischemic atrophy rather than acute total renal infarction. Although AERD can occur spontaneously, most cases are iatrogenic.[108] The most common procedure causing AERD has been coronary angiography occurring in up to 1.4% of cases[109]; renal angiography has reported an even higher incidence rate up to 2%.[110] The classic triad is a precipitating vascular procedure, a subacute or AKI, and skin manifestations such as livedo reticularis, blue toe syndrome, or digital gangrene.[111] The typical clinical renal manifestations are a gradual worsening of renal function[112] associated with an inactive urine sediment. Eosinophiluria,[113] peripheral eosinophilia,[114] and hypocomplementemia[115] in the acute phase may also be seen. A definitive diagnosis can only be made by renal biopsy. The diagnostic renal pathologic lesion is cholesterol clefts. There is no definitive treatment for AERD. Anticoagulation with warfarin has been suggested to potentially worsen the clinical course. As opposed to AERD, clot embolism tends to embolize to larger arteries, which is more likely to lead to renal infarction. The primary causes of renal infarction are patients with atrial fibrillation,[116] renal artery dissection,[117] and hypercoagulable states.[116] Less common etiologies include fibromuscular dysplasia and cocaine use.[118] In one series, 30.1% of cases were classified as idiopathic.[116] Patients often report flank and abdominal pain.[119] Laboratory abnormalities may include an elevated serum lactate dehydrogenase level, microscopic hematuria, and mild leukocytosis.[120] Diagnosis is often made by CT with contrast. Treatment options are variable based on etiology and may include anticoagulation, thrombolytic agents, and open surgery.

Intratubular Obstruction

Intratubular obstruction is a cause of AKI in certain clinical syndromes. It may reflect a mechanism of renal injury rather than an actual clinical syndrome. For example, the two heme pigment–containing proteins myoglobin and hemoglobin may be released from muscles or hemolyzed red blood cells (RBCs), causing myoglobinuria or hemoglobinuria, respectively. Both of these pigments are filtered in the glomerulus and subsequently degraded in the urinary space releasing heme pigment. One of the main mechanisms of tubular injury is a tubular obstruction.[121] Patients with rhabdomyolysis often develop red to brown urine and have associated pigmented granular casts and a urinalysis positive for dipstick heme despite an unremarkable urine microscopy with markedly elevated blood creatine phosphokinase levels.[122] Patients with hemolysis and AKI have the same urinary findings in addition to having a low haptoglobin.[123] Patients with ATN from rhabdomyolysis or hemolysis both typically have a fractional excretion of sodium of less than 1%, possibly reflecting vasoconstriction.[124]

Intratubular obstruction can also be a cause of AKI in tumor lysis syndrome, an oncologic emergency typically occurring after initiation of cytotoxic agents. The tumor lysis results in overwhelming release of cellular contents, such as nucleic acids, potassium, and phosphorus, into the circulation. Nucleic acids are metabolized to uric acid, resulting in hyperuricemia. Renal injury is primarily due to urate crystals and calcium phosphate deposition in renal tubules.[125]

Marrow infusion toxicity has been implicated in the pathogenesis of AKI among patients undergoing hematopoietic stem cell transplantation.[126] The pathogenesis is believed to be harvested stem cells exposed to cryoprecipitants such as dimethyl sulfoxide during the hematopoietic stem cell transplantation procedure, resulting in precipitation of heme proteins in the renal distal tubule

causing obstruction.[127] In ethylene glycol intoxication, the renal failure is primarily due to glycolate tubular injury but tubular obstruction from calcium oxalate crystals is often contributory.[128] A similar pathogenesis of calcium oxalate tubular obstruction can be seen with primary hyperoxaluria, rare inborn errors of glyoxylate metabolism,[129] or secondary forms of hyperoxaluria such as patients undergoing gastric bypass procedures.[130] Acute phosphate toxicity has been described in patients using bowel purgatives that contain oral sodium phosphate or sodium phosphate–containing enemas. In response to this recently described entity, certain commercial forms of oral sodium phosphate are no longer sold. The most likely mechanism of renal injury is from severe hyperphosphatemia resulting in calcium phosphate deposition in the tubular lumen[131,132] and causing luminal obstruction.[132] Crystal-induced nephropathy can be caused by several drugs and toxins, resulting in an intratubular precipitation of crystals causing tubular obstruction. Patients are usually asymptomatic. The urinalysis is variable including microscopic hematuria, mild proteinuria, and crystalluria. Although a clinical diagnosis is often made with the temporal relationship of an offending agent with subsequent AKI, definitive diagnosis requires a renal biopsy. Agents reported to cause AKI via crystalluria include acyclovir,[133] protease inhibitors including indinavir[134] and atazanavir,[135] sulfonamide antibiotics,[136] methotrexate,[137] ciprofloxacin,[138,139] amoxicillin,[140] and orlistat.[141,142] Treatment for crystalluric AKI is generally intravenous fluid (IVF) and, in certain cases, bicarbonate-rich IVF. Paraproteinemias often cause renal failure through intratubular obstruction. Light-chain cast nephropathy, formerly termed myeloma kidney, can result in an AKI or CKD by intratubular cast deposition and obstruction.[143] Intratubular amyloid cast nephropathy is a rare mechanism of renal injury.[144]

Clinical Manifestations

The manifestations of AKI vary among patients. Many patients are asymptomatic despite laboratory abnormalities demonstrating significant renal injury. At some point in the continuum of progressive renal failure that does not improve, patients may become symptomatic. Clinical manifestations may include edema, hypertension, and oliguria. Laboratory abnormalities often include elevated BUN and creatinine levels, and an abnormal urinalysis, including hematuria and proteinuria with potential additional metabolic derangements, including an elevated anion gap, metabolic acidosis, hyperkalemia, hyperphosphatemia, hypocalcemia, and hyperuricemia. The clinical diagnosis of AKI is often made when oliguria occurs or when the patient develops or presents with an elevated BUN or creatinine level above baseline. However, the GFR rate may significantly decline before this rise in BUN or creatinine occurs and this often delays the therapeutic interventions to alleviate and treat the cause of AKI.

Retention of Filtration Markers and Formulas as an Assessment of Glomerular Filtration Rate

The GFR varies depending on age, sex, and body size and is equal to the sum of filtration rates of all functioning nephrons and is generally 130 mL/min per 1.73 m^2 and 120 mL/min per 1.73 m^2 for men and women, respectively.[145] Estimation of the GFR is often used clinically to address the degree of renal insufficiency, assess worsening renal function, and to clinically map out the planned therapeutic intervention. However, GFR serves to depict the degree of renal insufficiency and does not define etiology, which ultimately guides treatment recommendations. Even when the GFR is defined accurately, it has limitations in regard to predicting stable disease. For example, compensatory hypertrophy typically occurs in patients with a nephrectomy and thus there is not a direct linear relationship between loss of renal mass and loss of GFR.

GFR cannot be measured directly and as such, it is often estimated by using an ideal filtration marker. Inulin has been used as the gold standard but it is expensive and cumbersome to use and as such, not clinically adopted.[146] Nuclear radiographic agents such as iothalamate and iohexol are sparingly used given their limitations.[147] The most common methods to assess GFR use creatinine as the filtration marker and include creatinine clearance, as well as the following estimating equations: the Cockcroft-Gault equation, the Modification of Diet in Renal Disease (MDRD) equation, and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation. Because the individual variability of creatinine production can be calculated based on both demographic and clinical variables, such as gender, race, weight, and age, the use of creatinine in these estimating equations was deemed reasonable. Creatinine clearance is determined by measuring 24-hour urine creatinine excretion; shorter collections provide less accurate results. The major limitations of creatinine clearance are inaccurate collections and secretion of urinary creatinine, leading to overestimation of GFR. The estimating equations also have limitations and are not accurate when used in AKI. The Cockcroft-Gault equation is not adjusted for body surface area and was developed before standardized creatinine assays and thus can overestimate creatinine clearance by up to 40%. Normalization for body surface area increases the accuracy of this equation in patients, especially with renal insufficiency.[148] However, most pharmacokinetic studies for drug dosing in renal disease have used this formula for guidelines.[149] The MDRD equation in estimating GFR is more accurate in patients with CKD[150] and less accurate in patients with a normal GFR.[151] Conversely, the CKD-EPI equation is more accurate in assessing GFR in patient populations with normal or near-normal GFR.[152]

Creatinine

Creatinine is derived primarily from metabolism of creatine in skeletal muscle in addition to dietary meat intake. Creatinine is generally released at a constant rate from skeletal muscle; it is not metabolized by the kidney and there is no tubular reabsorption. Urinary creatinine primarily is derived from its filtration at the glomerulus, but 10% to 40% is derived from a tubular secretion in the proximal tubule in patients with renal insufficiency.[153] As such, because a decrease in GFR is accompanied by an increase in tubular excretion of creatinine, an initial reduction in GFR may not be correlated to an equally reciprocal rise in creatinine. Creatinine can be used to estimate GFR only when renal function is stable. In the steady state, a rise in serum creatinine reflects a decrease in GFR. However, in AKI there can be a significant decrease in GFR before creatinine has time for accumulation. This has potential therapeutic implications. Limitations in using creatinine in assessing GFR include variations in creatinine secretion and production, extrarenal creatinine excretion, and serum measurement of creatinine.

Creatinine production varies among people over time and with different muscle mass. Patients with a higher muscle mass produce more creatinine and patients with a decreased muscle mass secondary to small body frames or those with amputations may have lower creatinine values. Creatinine production may also be reduced in sepsis.[154] Certain disease states such as rhabdomyolysis may have

exaggerated increases in creatinine above the expected range. Creatinine secretion can increase in the proximal tubule with an initial decrease in GFR, possibly blunting a rise in the serum creatinine. However, the proximal tubular secretion is saturated above a creatinine of 1.5 to 2.0 mg/dL and subsequently any rise in creatinine reflects a decrease in GFR.[153] Creatinine secretion may also be inhibited by competition with certain medications such as trimethoprim and cimetidine, leading to a pseudohypercreatininemia (a rise in serum creatinine without any decrease in renal function). Extrarenal excretion of creatinine by intestinal bacterial creatininase activity may result in a lower than expected creatinine value but is often difficult to quantify clinically.[147] Differences in both methods and equipment in creatinine measurement can also account for variable creatinine values.[155] Attempts by the National Kidney Disease Education Program to standardize the assay have limited this variation. Additionally, a dilutional blunting of a creatinine rise may occur with aggressive fluid resuscitation.[156] Given the many potential variables affecting the serum creatinine value and its use in the estimating equations of assessing GFR, these equations are not considered reliable for estimating GFR in critically ill patients with AKI.

Urea

Urea is the chief end product of nitrogen metabolism. Blood urea concentration, measured in blood as BUN, is dependent on the balance between hepatic production and renal excretion of urea. BUN, similar to serum creatinine, varies inversely with GFR. BUN production is not constant and can vary quite significantly based on protein intake, gastrointestinal hemorrhage, protein loading with parenteral nutrition, and hypercatabolic states, such as trauma, sepsis, and glucocorticoid administration. Normally, filtered urea is passively absorbed in the proximal tubule. In prerenal states such as dehydration, CHF, and cardiomyopathy, there is an associated decreased renal perfusion that often results in BUN rising out of proportion to the level of serum creatinine. Secondary to this variability in both production and excretion, it is considered less valuable than creatinine in assessing GFR. However, the one clinical scenario in which measuring urea clearance for assessing renal function has shown potential benefit is in patients with advanced renal failure. In this subset, urea clearance significantly underestimates GFR and creatinine clearance overestimates GFR. The 2005 European best practice guidelines recommended averaging the creatinine and urea clearance to achieve the best results in assessing GFR in patients with advanced renal impairment.[157]

Cystatin C

Given the limitations of both creatinine and BUN in accurately assessing GFR, there is continued interest in finding a more reliable endogenous laboratory marker for GFR assessment. The best studied is cystatin C, which is a low–molecular-weight protein produced by all nucleated cells, is filtered at the glomerulus, and is not reabsorbed. It has a shorter half-life than creatinine; initially studies showed it as a more sensitive marker for assessment of GFR in ICU patients.[158] However, its limitations as an endogenous substance to adequately reflect GFR have recently been elucidated. Cystatin C is metabolized in renal tubules, increases with age,[159] gender, height, and weight,[160] thyroid disease,[161] diabetes mellitus,[162] and body size. Similar to creatinine, there have also been quite variable cystatin C values despite using the same instruments and reagents in the same laboratory.[163] Similar to the creatinine assay standardization, certified reference materials for cystatin C assays were created. It was also proposed that cystatin C–based equations would be more accurate than creatinine-based equations in assessing GFR in certain populations, such as the elderly, renal transplant recipients, and patients with cirrhosis, but results have been variable.[164] There have been several published reports, however, demonstrating that combining the serum creatinine and cystatin C into a single equation may better estimate GFR than equations that use creatinine or cystatin C singularly,[165] especially in patients with CKD.[166] Despite these potential benefits, few have routinely adopted the measurement of cystatin C in clinical practice.

Markers of Tubular Injury and Novel Biomarkers

Given the limitations of creatinine, BUN, and cystatin C in detecting an early change in GFR, there has been continued interest in the development of early biomarkers of renal tubular injury. An ideal biomarker should have several properties, including universal ease of measurement, earlier detectability than the rise in serum creatinine to allow an earlier diagnosis of AKI, adequate specificity to distinguish functional prerenal azotemia from a tubular injury or CKD, identification of the location of renal injury, allowing prediction of renal and patient outcomes and potentially offering pharmacologic response to therapy.[167] Several biomarkers have been reported to be early predictors of AKI, including neutrophil gelatinase-associated lipocalin (NGAL),[168–170] kidney injury molecule-1,[171] *N*-acetyl-β-D-glucosaminidase,[172] retinol-binding protein,[173] micro–ribonucleic acid molecules,[174] cytokine interleukin 18,[175] as well as others. NGAL serum and urinary levels have been shown to have better sensitivity than serum creatinine in patients with ischemic AKI.[176] Urinary NGAL has been shown to be a predictive biomarker for delayed graft function after kidney transplantation[177] as well as a predictor of AKI in patients with septic shock.[178] In adult patients undergoing cardiac surgery, urinary kidney injury molecule-1 could predict the development of AKI better than NGAL.[179] Several of these biomarkers have been shown to have improved utility to current measures in earlier diagnosis of AKI. However, studies have reported variable results in the predictability of AKI with many of these biomarkers.[180] As such, despite certain biomarkers showing superior and earlier detection of AKI in specific patient cohorts, further validation of these benefits with large multicenter prospective studies is needed before any single biomarker replaces the current laboratory studies that are currently universally used.

Oligoanuria

Oligoanuria is one of the three clinical parameters used by KDIGO in defining AKI.[6] Oliguria is generally defined as urine output less than 400 mL/day and anuria as less than 50 mL/day. In patients who become oligoanuric, the creatinine and BUN will rise to help diagnose and define AKI. However, many patients in whom AKI develops in the ICU are nonoliguric. The absence of oligoanuria does not define a less critical attention to AKI. There are many severe forms of intrinsic AKI that are nonoliguric and without appropriate diagnostic and therapeutic responses, AKI will worsen. However, in patients who are anuric, this often is a sign of a severe form of renal injury that requires immediate diagnostic and potentially therapeutic intervention. Unilateral obstruction in a solitary functioning kidney, bilateral ureteral obstruction, cortical necrosis from profound ischemic ATN or in pregnancy-related AKI,[181,182] pigment nephropathy, acute renal vascular events, or active proliferative GN can all initially manifest with anuria. In a prospective cohort study in a single tertiary care hospital over a 2-year period, septic and postoperative AKI were the primary causes

of anuric AKI.[183] Oligoanuria does not necessarily narrow the differential in regard to the etiology but it does signify a nephrologic emergency requiring immediate evaluation.

Detection of Clinical Complications of AKI

At times, patients may seek medical attention secondary to complications of AKI in which oligoanuria or an elevated BUN and creatinine level are not the initial diagnostic abnormality prompting evaluation. Patients with nephrotic syndrome may present with new-onset edema or anasarca. Uremic encephalopathy may be a presenting sign but is less common with the advent of routine diagnostic laboratory screening for renal insufficiency. A pericardial friction rub may develop in patients with advanced renal failure.[184] At times, electrolyte abnormalities, such as hyperkalemia, hyponatremia, metabolic acidosis, hyperuricemia, and hyperphosphatemia, may be the presenting laboratory abnormality signifying an AKI.

Diagnostic Approach

General Aspects

The initial step in evaluating and assessing the cause of AKI in the ICU is to follow a diagnostic algorithm. As the treatment of AKI is dependent on the etiology, it is incumbent upon the provider to use all appropriate and available diagnostic testing to narrow the differential. A history and physical examination often assist in the differential diagnosis by outlying potential etiologies. A patient with prerenal azotemia in whom AKI develops after an intravenous contrast study is more likely to have contrast nephrotoxicity if additional history does not suggest other potential etiologies. Patients with severe hypotension and previous recent normal renal function who require multiple pressors often have ischemic ATN as a leading diagnosis in the latter ICU setting. AKI that develops after the patient receives potentially nephrotoxic medications may provide a diagnostic clue. Obtaining a urinalysis with microscopy at the time of the AKI will potentially help narrow the differential diagnosis. Oftentimes, the urine microscopy provides diagnostic clues. A bland urinalysis lacking cellular components such as RBCs, white blood cells, or RBC casts makes an active proliferative GN less likely. Radiographic imaging may also be helpful. A bladder scan is now often used to screen for a bladder outlet obstruction, especially in the current hospital environment to limit catheter-associated UTIs. A renal US with or without Doppler of the renal vasculature, a CT scan of the renal collecting system, and an MRI of the urinary tract all have potential utility in providing diagnostic aid in certain clinical scenarios. In some patients, a renal biopsy is necessary for a definitive diagnosis. In the ICU, this often becomes relevant when patients develop AKI from presumed ischemic ATN after a prolonged hypotensive episode. Although not often clinically required, a renal biopsy often provides the only method for establishing a definitive cause of the AKI. Some patients in the ICU have a prolonged AKI after a clinical scenario of associated oligoanuria with ATN as the clinical diagnosis. Many of these patients receive multiple medications and antimicrobials, which raises the possibility of an associated alternative diagnosis such as an AIN. The only way to make the latter diagnosis is by renal biopsy. Certainly, if an AIN were the cause of AKI in the ICU, either removing the offending agent versus administering steroids would be warranted at times. It is not uncommon for critically ill patients to have related coagulopathies, often making renal biopsy not feasible. An empiric course of steroids is sometimes used in the latter scenario.

Patient History and Physical Examination

The initial step in evaluating a patient with AKI in the ICU is to review the patient's pertinent medical history and perform a physical examination to help narrow the differential (Table 52.1). Reviewing the clinical scenario prompting their ICU presentation may identify potential etiologies. For example, NSAID use or other potentially nephrotoxic medication administration before the development of AKI may provide diagnostic clues in the correct clinical context. A history of benign prostatic hypertrophy or prostate cancer in men or a gynecologic malignancy in women with known retroperitoneal lymphadenopathy should raise the suspicion for an obstructive uropathy. A history of nephrolithiasis, especially in the setting of a superimposed unilaterally functioning kidney, with either renal colic or gross hematuria, should alert the provider to screen for obstructive uropathy. Recent administration of chemotherapeutic agents in a patient with a high tumor burden should suggest the possibility of either tumor lysis syndrome or a tubular or glomerular toxicity. Identifying events even before admission may prove diagnostic. A history of diarrhea, vomiting, decreased fluid intake, severe cardiomyopathy, heart failure, or cirrhosis may certainly suggest some component of prerenal azotemia. Associated other primary organ involvement in the disease state such as pulmonary infiltrates may suggest a pulmonary-renal syndrome. Jaundice suggests liver disease with a broad differential, including hepatorenal syndrome or a potential secondary GN from known primary liver disease. Constitutional symptoms such as poor appetite, fever, and weight loss may suggest the development of a systemic disorder such as a primary GN. Administering antimicrobials when patients have a superimposed rash and fevers may alert the physician to the possibility of an AIN. Obtaining a history of over-the-counter medication use such as a PPI may suggest an AIN, or the ingestion by the patient of excess amounts of the herb star fruit (carambola) would suggest the possibility of a calcium oxalate kidney stone in a patient who had acute sepsis from nephrolithiasis in the latter setting. Reviewing the medical record should also focus on indices such as frequent weights, accurate intake and outputs, blood pressure, and heart rate measurements that would help assess the volume status of the patient. An extensive review of all medications is required with the knowledge of their potential nephrologic side effects. As previously outlined, urine output may help in the differential as anuria does signify a likely severe nephrologic emergency requiring immediate evaluation.

The physical examination should initially focus on the volume status of the patient, in particular, the intravascular volume. Even with evidence of total body water excess on examination, the intravascular volume often dictates therapeutic interventions. If the intravascular volume is decreased, expansion with IVFs fluids or colloid is often the initial approach. To help evaluate intravascular volume, assessing orthostatic changes in heart rate and blood pressure from a supine to standing position and evaluating skin turgor and mucous membranes may all offer additional physical examination clues to accurately identify the patient's fluid balance. A consensus statement defining orthostatic hypotension was published in 2011.[185] Diagnosing orthostatic hypotension requires rest in the supine position for 5 minutes, subsequent standing for 2 to 5 minutes, and observing one or both of the following: a drop in systolic blood pressure of at least 20 mm Hg or a drop in the diastolic blood pressure of at least 10 mm Hg. Although the presence of orthostatic hypotension suggests an intravascular volume depletion, it is not specific.

TABLE 52.1 Steps for Diagnosing Acute Kidney Injury in the Intensive Care Unit

1. History
   1. Identify any chronic renal failure component
   2. Review for nephrotoxic agents (e.g., contrast, antibiotics, NSAIDs, chemotherapy)
   3. Identify risk factors for obstruction:
      a. Nephrolithiasis
      b. Prostate cancer
      c. Retroperitoneal lymphadenopathy
      d. Gynecologic malignancy
   4. Identify surgical history (e.g., nephrectomy)
   5. Presence of constitutional symptoms suggestive of prerenal etiology (e.g., vomiting, diarrhea, decreased oral intake, cardiomyopathy, cirrhosis)

2. Physical examination
   1. Assess volume status
      a. Measure blood pressure, heart rate
      b. Check for othostatic hypotension
      c. Assess skin turgor, mucous membranes
      d. Assess for edema suggestive of total body water excess, possible nephrotic syndrome, cardiomyopathy
   2. Lung examination
      a. Crackles may reflect congestive heart failure
   3. Abdominal examination
      a. Ascites may indicate liver disease or hepatorenal syndrome
   4. Skin assessment
      a. Rash may be suggestive of AIN
      b. Purpura may reflect cutaneous vasculitis
   5. Ophthalmologic examination
      a. Papilledema may be associated with hypertensive emergency/crisis
   6. Cardiac examination
      a. Valvular murmurs may be indicative of renal perfusion abnormalities
   7. Extremity examination
      a. Livedo reticularis reflective of atheroembolic renal disease

3. Laboratory Findings

Laboratory	Potential Causes
Urine	
Gross Assessment	
Turbid urine	UTI
Gross hematuria	Urologic cause, glomerulonephritis, rhabdomyolysis
Brown urine	Rhabdomyolysis
White urine	Chyluria
Dipstick	
Heme	Urologic causes, glomerulonephritis, rhabdomyolysis
Protein	Primary glomerulonephritis, paraproteinemia, diabetes hypertension
Urine Microscopy	
RBC	Glomerulonephritis, urologic cause
RBC casts	Glomerulonephritis
Acanthocytes	Glomerulonephritis
WBC	Infection, AIN, CIN, TB, malignancy
WBC casts	Infection
Urine eosinophils	AIN, AERD
Other cellular casts	
Broad	CRF
Fatty	Nephrotic syndrome
Granular	ATN
Urine Electrolytes	
Decreased spot sodium	Prerenal azotemia
Fe_{Na}, percent	Prerenal azotemia (<1%) vs. ATN (>2%)
Decreased spot urine chloride	Prerenal azotemia with metabolic alkalosis
Increased spot urine potassium	Hyperaldosteronism/secondary hypertension
Blood	
Hypercalcemia	Multiple myeloma, paraproteinemia, sarcoidosis, humoral hypercalcemia of malignancy
CPK	Rhabdomyolysis
Hyperphosphatemia	Phosphate nephropathy, tumor lysis syndrome, AKI, CKD
Hyperuricemia	Uric acid nephropathy, tumor lysis syndrome
Prolonged PTT	Lupus anticoagulant, SLE
Peripheral eosinophilia	AIN
Thrombocytopenia, elevated LDH, bilirubin	Hemolytic uremic syndrome, TTP
Serologies: ANA, dsDNA, C3, C4, ANCA, anti-GBM antibody, cryoglobulin, hepatitis, HIV, ENA	Vasculitic syndromes

4. Radiographic Testing

Radiographic Tests	Significance of Findings/Diagnostic Screen
Renal ultrasound	Enlarged kidneys may suggest obstruction, infiltrative disorders, renal vein thrombosis, HIV, diabetes mellitus Small kidneys suggest CRF
CT scan	Nephrolithiasis, obstruction and malignancy
MRI	Obstruction and renal infarcts
MRA	Renal artery stenosis
MRV	Renal vein thrombosis
Renal angiography	Polyarteritis nodosa
Nuclear scan	Renal infarcts

AERD, Atheroembolic renal disease; *AIN,* acute interstitial nephritis; *AKI,* acute kidney injury; *ANCA,* antineutrophil cytoplasmic antibody; *ATN,* acute tubular necrosis; *CIN,* chronic interstitial nephritis; *CKD,* chronic kidney disease; *CKR,* chronic kidney disease; *CPK,* creatine phosphokinase; *CRF,* chronic renal failure; *CT,* computed tomography; *dsDNA,* double-stranded DNA; *ENA,* extractable nuclear antigen; *FENa,* fractional excretion of sodium; *GBM,* glomerular basement membrane; *HIV,* human immunodeficiency virus; *LDH,* lactate dehydrogenase; *MRA,* magnetic resonance angiography; *MRI,* magnetic resonance imaging; *MRV,* magnetic resonance venography; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PTT,* partial thromboplastin time; *RBC,* red blood cell; *SLE,* systemic lupus erythematosus; *TB,* tuberculosis; *TTP,* thrombotic thrombocytopenic purpura; *UTI,* urinary tract infection; *WBC,* white blood cell.

Common alternative causes of orthostatic hypotension include aging,[186] medications,[187] cardiovascular etiologies such as aortic stenosis,[187] and neurally mediated etiologies.[188] A cardiopulmonary examination may certainly help in establishing a diagnosis of heart failure. Evaluation for the presence of jugulovenous distention, pulmonary basilar rales, and presacral and lower extremity edema may all be suggestive of the presence of CHF. In certain cohorts such as the morbidly obese, critically ill, or cirrhotic patients, these clinical findings may be difficult to define. Therefore additional radiographic tests such as a chest radiograph and laboratory studies such as an elevated brain natriuretic peptide may be ordered to aid in the clinical assessment. Central venous catheters are oftentimes in place, allowing for monitoring of the central venous pressure assessment, which can help determine a patient's volume status. Unfortunately, the central venous pressure measurement does not predict whether an IVF challenge will increase stroke volume and cardiac index.[189] Pulmonary artery catheter use has fallen out of favor over the past several years owing to the lack of improvement in mortality benefit or the ICU length of stay with lack of cost benefit.[190] The pulmonary artery catheter still remains a potential diagnostic tool in assessing the different types of shock (hypovolemic, distributive, cardiogenic, obstructive), which may be difficult to discern on clinical assessment alone.[191]

Assessment for ascites, jaundice, or scleral icterus in the setting of an AKI may suggest the presence of underlying liver disease. Palpation of abdominal masses or bladder distention may signify an obstructive uropathy or bladder outlet obstruction, respectively. A rectal and pelvic examination may also provide clues of an obstructive uropathy. A retinal examination may demonstrate the presence of papillary edema, which is nondiagnostic but may be indicative of an untreated hypertensive emergency from a primary proliferative GN, renovascular-induced uncontrolled hypertension, or even an illicit drug ingestion such as cocaine. The presence of Hollenhorst plaques would suggest an atheroembolic event. Presbycusis could signify aminoglycoside toxicity or Alport syndrome in the correct clinical context. Skin manifestations such as a rash may be suggestive of an AIN, livedo reticularis suggestive of atheroembolic renal disease, or palpable purpura possibly reflecting a cutaneous vasculitis, such as Henoch-Schönlein purpura or the presence of a microangiopathic process typical for a hemolytic uremic syndrome or a thrombotic thrombocytopenic purpura.

Urinalysis and Urine Indices

The first application of urine microscopy to clinical practice is generally attributed to a French nephrologist, Pierre Rayer, in the early 1800s.[192] Since that time, the evolution of evaluating urine in providing diagnostic clues to assist in narrowing the differential diagnosis or specifically defining the etiology of the renal failure has continued to evolve. The three primary components of a complete urinalysis include gross assessment, dipstick analysis, and urine microscopy. Various findings on urinalysis may suggest specific categories of renal disease and in certain circumstances be pathognomonic, but these findings need to be interpreted in the appropriate context of the history, physical examination, and other laboratory data. The gross assessment of a turbid and cloudy urine with associated dysuria is often indicative of a UTI or pyelonephritis. The color of urine may also provide diagnostic clues. Gross hematuria could be secondary to bleeding anywhere in the urinary system, including the urethra, bladder, ureters, or the kidneys. Certain etiologies of GN such as IgA nephropathy can often present with gross hematuria in up to 45% of cases.[87] Hematuria can also result when only the supernatant of a centrifuged urine is red, such as in myoglobinuria in the setting of rhabdomyolysis or hemoglobinuria, which can occur with hemolysis. Milky white urine may be a manifestation of chyluria,[193] whereas purple urine may suggest a catheter-related UTI.[194] Orange urine may be seen with use of certain medications such as pyridium, and green urine may be seen with propofol use.[195] The urine dipstick typically provides analysis for heme, nitrite, leukocyte esterase, albumin, hydrogen ions, specific gravity, and glucose. A urine dipstick result largely positive for heme with no significant RBCs on urine microscopy often suggests rhadomyolysis. A dipstick result positive for nitrite or leukocyte esterase is often indicative of a UTI. Dipstick albuminuria is suggestive of a potential glomerular injury, although non-albumin proteins such as immunoglobulin light chains seen in multiple myeloma are often not positive on urine dipstick. A 24-hour urine collection for protein is the initial step in quantifying the degree of dipstick albuminuria because nephrotic range proteinuria would suggest a differential for AKI different than in patients who have minimal proteinuria. Overall, albuminuria has been associated with worse cardiovascular morbidity and mortality.[196–198] The urine hydrogen ion concentration, measured as urine pH, is typically used in evaluating different forms of renal tubular acidosis. Glyosuria is typically seen in the setting of uncontrolled diabetes mellitus, but it may be a manifestation of a proximal renal tubular injury seen with Fanconi syndrome.[199]

The third component of a urinalysis evaluation is performing a urine microscopy that primarily evaluates for cells, casts, and crystals, all of which can often help to identify certain causes of AKI, and at times, specific microscopic findings are essentially pathognomonic for the disease state causing the AKI. The presence of RBCs on urine microscopy raises concern for a GN but the latter needs to be differentiated from urologic causes. Distinguishing between glomerular and non-glomerular bleeding is the key initial step in identifying the source of hematuria. To help differentiate between glomerular versus urologic causes of hematuria, the presence of dysmorphic RBCs known as glomerular RBCs on urine microscopy often suggests a glomerular etiology.[200] In a subset of glomerular RBCs known as acanthocytes there are characteristic membrane protrusions with increased specificity for GN.[201] The presence of RBC casts on urine microscopy is often a nephrologic emergency requiring a renal biopsy for definitive diagnosis. Although RBC casts have been primarily identified with an active proliferative GN, they have been described in up to nearly 30% of cases of AIN.[202] White blood cells identified on urine microscopy are often associated with bacteriuria but when an infection is not present, the differential is broad and should include an AIN, a chronic tubulointerstitial nephritis, nephrolithiasis, tuberculosis, and malignancy.[203] Urine eosinophils are best identified using Hansel stain.[204] Eosinophiluria has been traditionally ordered in the workup for AKI in hospitalized patients as a potential diagnostic aid for defining an AIN. However, eosinophiluria can be seen in many disorders, including atheroembolic renal disease, cystitis, pyelonephritis, transplant rejection, and in patients with ileal conduits.[113,205–207] In a recent study, the sensitivity and specificity for urine eosinophils in the setting of renal biopsy-proven AIN was quite low—30% and 68%, respectively. As such, its diagnostic accuracy and clinical use needs to be revisited and interpreted with caution.[208] Casts are generally divided into two categories: cellular and noncellular. Urine casts are cylindrical structures that are formed in the tubular lumen and are composed primarily of Tamm-Horsfall mucoprotein. Cellular casts have cellular components within a

matrix and are diagnostic of an intrarenal origin. RBC casts are generally consistent with a glomerular etiology, white blood cell casts suggest an interstitial inflammation, and broad casts are generally seen in CRF. The presence of fatty casts, oval fat bodies, or free fat on urine microscopy suggests nephrotic syndrome. Noncellular casts include hyaline, waxy, broad, granular, and renal tubular. Hyaline casts are usually not indicative of renal pathology. Granular casts are a typical microscopic finding in ischemic ATN, which is the leading cause of AKI in hospitalized patients.[209] Despite general adoption and concordance between automated and manual microscopy in identifying certain cellular components in the urinalysis such as white blood cells and RBCs, manual microscopy is often required in AKI to evaluate for the presence of cellular casts.[210] In addition, those providers most familiar with microscopy interpretation such as nephrologists are best at defining cellular components on the urinalysis.[211] An observation of crystals on urine microscopy may identify or suggest a certain stone composition that may lead to screening for an obstructive uropathy.

Urine electrolytes may also be helpful in narrowing the differential for AKI, such as in differentiating between prerenal azotemia and ATN. In patients with ATN, renal tubular cells are damaged and this affects the proximal tubular reabsorption of sodium. In prerenal azotemia, the physiologic response of the proximal renal tubule remains intact and urine sodium reabsorption is typically increased. Thus in prerenal states the urine sodium is expectedly low, but with ATN the spot urine sodium is often elevated. The fractional excretion of sodium (FE_{Na}) is more accurate than the spot urine sodium alone in differentiating prerenal azotemia from ATN because FE_{Na} directly measures sodium handling. The FE_{Na} measures the percent of filtered sodium excreted in the urine and is calculated by

$$\text{FENa}\ (\%) = \frac{U_{Na} \times S_{Cr}}{S_{Na} \times U_{Cr}} \times 100,$$

where U_{Na} is the spot urine sodium concentration, U_{Cr} is the spot urine creatinine concentration, S_{Na} is the serum or plasma sodium concentration, and S_{Cr} is the serum or plasma creatinine concentration. Several studies have identified a benefit of the FENa in differentiating prerenal azotemia from ATN[212–214] with other reported studies demonstrating less clinical utility.[215] Overall, a FENa less than 1% is generally expected in prerenal states, a value greater than 2% is typically seen with ATN, and a value between 1% and 2% can be seen with either disorder. However, these urinary indices have several limitations. The FE_{Na} may be greater than 1% despite prerenal azotemia in patients with active diuretic tubular effects, in patients with CKD who have a delayed response to maximizing urine sodium reabsorption, or in patients with metabolic alkalosis with resultant bicarbonaturia. Conversely, the FE_{Na} may be less than 1% in several settings other than prerenal azotemia, including radiocontrast media,[216] myoglobinuric or hemoglobinuric ATN,[217] certain forms of ATN,[214,218] AKI from AIN,[219] and even with the absence of kidney disease such as cirrhosis.[220] Given the potential limitations of FE_{Na} in certain clinical situations, the fractional excretion of urea (FE_{Urea}) has been proposed as an alternative assessment of tubular function and to add clinical utility in assessing for prerenal azotemia. A FE_{Urea} of 50% to 65% or less than 35% has been proposed in differentiating ATN from prerenal azotemia, respectively. The FE_{Urea} is calculated by

$$FE_{Urea}\ (\%) = \frac{U_{Urea} \times S_{Cr}}{S_{Urea} \times U_{Cr}} \times 100,$$

where U_{Urea} is the spot urine urea concentration, U_{Cr} is the spot urine creatinine concentration, SUrea is the serum or plasma urea concentration, and the S_{Cr} is the serum or plasma creatinine concentration. The FE_{Urea} has been shown to be potentially useful in differentiating prerenal azotemia, especially in patients receiving diuretics,[221,222] although discordant results have been noted.[223] The fractional excretion of other urine molecules such as uric acid[224,225] and lithium[225] have also had limited study but this measure is not clinically used.

In the subset of patients with metabolic alkalosis caused by vomiting or nasogastric tube suctioning, the assessment of intravascular volume is better assessed by obtaining a spot urine chloride (UCl) rather than a spot UNa, including in the ICU setting.[226] In patients with metabolic alkalosis, bicarbonaturia develops with a subsequent rise in UNa, which may result in a normal or even high spot UNa finding despite an intravascular volume depletion. Thus the spot UCl in the latter cohort of patients is always appropriately low and typically less than 20 mEq/L and is a better marker for intravascular volume depletion. Similar to other spot urine electrolytes, a spot UCl may be affected by other clinical scenarios. An elevated spot UCl level may be present despite intravascular volume depletion in settings such as persistent diuretic effect. Patients with metabolic alkalosis from laxative abuse or cystic fibrosis with excess sweating[227] may have a low UCl. Patients with metabolic alkalosis, hypovolemia, and a spot UCl level that is not low and often high can be seen in disorders such as excess licorice ingestion, primary hyperaldosteronism, and Liddle syndrome.

Urine potassium excretion may also be helpful in identifying certain causes of hypertension that may present with hypertensive urgency or emergency and even renal insufficiency. Patients with hypokalemia not caused by urinary losses are expected to have an appropriate decrease in urinary potassium excretion to less than 30 mEq/day,[228] a spot urine potassium of less than 15 mEq/L,[229] and a spot urine potassium-to-creatinine ratio of less than 13 mEq/g.[230] Because spot urine potassium concentration is affected by urine volume, a spot urine potassium-to-creatinine ratio is preferred to a spot urine potassium value alone, especially if a 24-hour urine collection is not available or cannot be performed. In patients with both hypokalemia and hypertension with inappropriately elevated urinary potassium excretion, secondary causes of hypertension such as primary aldosteronism and renovascular disease should be considered.

Radiologic Imaging

Several radiographic studies are often utilized in the workup of AKI (see Table 52.1). A renal US is typically the first radiographic test ordered when AKI is unexplained and obstructive uropathy is considered.[231] A renal US with false-negative results for obstructive uropathy may be seen with early obstruction, RPF, or with malignancy, and thus a CT scan of the urinary system without contrast is sometimes required to rule out obstructive uropathy. Nonobstructive findings may occasionally be useful in defining causes of AKI. An enlarged kidney on renal US may be indicative of a renal vein thrombosis,[232] especially in the clinical setting of flank pain and severe nephrotic syndrome. The average size of kidneys on renal US is 10 to 11 cm in length.[233] At times, patients present with renal insufficiency with no prior laboratory studies for many years. Renal US findings suggestive of CKD include shrunken kidneys less than 10 cm in length and an increased renal echogenicity often indicative of fibrous tissue associated with CKD.

Patients with ATN may also present with increased echogenicity on renal US.[234] Therefore a renal US cannot be used to distinguish AKI from CKD. Enlarged kidneys on US can occur with acute renal vein thrombosis, obstructive uropathy, malignancy and infiltrative disorders, human immunodeficiency virus, and diabetic nephropathy. Intravenous radiocontrast administration may worsen or delay renal recovery in AKI and should be avoided whenever possible. MRI is sometimes useful in screening for an obstructive uropathy or diagnosing renal infarction.[235] Magnetic resonance angiography has been extensively used to screen for renal artery stenosis[236,237] and magnetic resonance venography for renal vein thrombosis.[238] However, using gadolinium-containing contrast agents should be avoided if possible in AKI and in patients with CRF with a GFR of 30 mL/min or less given the concern for the development of nephrogenic systemic fibrosis.[239] Nephrogenic systemic fibrosis has been associated with all five of the most common gadolinium agents used in the United States and the Food and Drug Administration has issued updated boxed warnings with their administration.[240] Renal arteriography is sometimes necessary to diagnose polyarteritis nodosa.[241] Nuclear renal scans may also be useful in diagnosing renal infarction.[242]

Other Laboratory Testing

Certain specific laboratory results are nearly diagnostic for certain causes of AKI such as a positive anti-GBM Ab in Goodpasture syndrome. However, most often a final diagnosis is achieved by using and reviewing many associated laboratory findings that may help narrow the differential and result in a diagnosis; at times, a renal biopsy is required for definitive diagnosis. For example, AKI with associated anemia, hypercalcemia, a normal anion gap metabolic acidosis, an elevated total serum protein, and rouleaux formation on peripheral smear all suggest multiple myeloma. AKI with microangiopathic hemolytic anemia, an elevated lactate dehydrogenase and bilirubin level, a negative Coomb test result, and thrombocytopenia suggest a thrombotic thrombocytopenic purpura or a hemolytic uremic syndrome. A markedly elevated creatine phosphokinase with AKI suggests rhabdomyolysis. Bicytopenia or pancytopenia with an elevated sedimentation rate and a prolonged prothrombin time suggests the presence of a lupus anticoagulant with possible associated SLE. Peripheral eosinophilia with AKI suggests the possibility of an AIN. Hypercalcemia and AKI would warrant a workup for a paraproteinemia, malignancy, sarcoidosis, or tuberculosis in the appropriate clinical setting. Marked hyperphosphatemia and AKI suggest acute phosphate nephropathy. Hyperphosphatemia, hyperuricemia, and severe hyperkalemia raise the possibility of a tumor lysis syndrome. Severe hyperuricemia alone with AKI suggests an acute uric acid nephropathy. Overall, additional specific laboratory testing is often required to narrow the differential for AKI. Certain specific serologic tests ordered to screen for vasculitides include antinuclear antibody, anti–double-stranded DNA, extractable nuclear antigen, complements including C3 and C4 levels, ANCAs including antimyeloperoxidase, anti-proteinase 3, anti-GBM antibody, hepatitis B and C antibodies, cryoglobulins and cryocrit, human immunodeficiency virus, antiphospholipid, and anticardiolipin antibodies.

Renal Biopsy

The most common causes of acute renal injury such as prerenal azotemia and ATN do not require a renal biopsy. Renal biopsy is indicated for any cause of renal failure that is indeterminate and where tissue diagnosis may alter treatment.[243] Renal biopsy is sometimes considered for critically ill patients who develop unexplained AKI and have been exposed to multiple offending nephrotoxic agents with either incomplete or no renal recovery. Cortical necrosis may develop in some patients with prolonged and profound ischemic ATN requiring multiple pressor agents in the setting of severe hypotension. This is an essentially irreversible form of AKI that is likely a continuum of ATN, and although rare, is often diagnosed on renal biopsy. The presence of a nephritic syndrome with dipstick hematuria and proteinuria and a urine microscopy demonstrating RBCs, RBC casts, and acanthocytes all suggest an active proliferative GN that often requires a renal biopsy for definitive diagnosis. Considerations of performing a renal biopsy in the critically ill patient is often confounded by comorbid conditions (such as infections, coagulopathy, respiratory failure requiring ventilator support) and certain medications (such as antiplatelet agents and other anticoagulants). Absolute contraindications to renal biopsy initially included uncontrolled severe hypertension, uncooperative patients, a bleeding diathesis, and a solitary kidney.[244] More recently, it has been suggested that with better techniques and procedures, a percutaneous renal biopsy can be performed in patients with a solitary kidney.[245] Renal biopsy has also been shown to be safe in ventilated ICU patients.[246] The primary risk of renal biopsy is bleeding[247–249] into the collecting system resulting in hematuria, underneath the renal capsule essentially causing a renal tamponade, or into the perinephric space. Most clinically significant bleeding occurs within the first 24 hours and thus most patients are observed for one day after a renal biopsy.[250]

Prevention

The prevention of AKI in the ICU setting should be aimed at changing or altering those modifiable risk factors that have been shown to increase the risk of AKI. These modifiable risk factors include appropriate dosing of medications, avoidance of potentially nephrotoxic agents, optimizing volume status to maintain renal perfusion, and avoiding hypotension. Certain preventative measures for AKI are also disease, agent, and medication specific.

Maintenance of Renal Perfusion

Prerenal azotemia and ATN account for the majority of causes of AKI in the hospital and ICU setting. ATN is often multifactorial with several confounding factors often potentially contributing, including ischemia, sepsis, and nephrotoxic agents. The first step in preventing ATN is to identify patients with comorbidities that increase the risk of ATN; these include patients with CKD, diabetes mellitus, obesity, malignancy, and coronary artery disease.[251–253] Patients in the hospital setting at risk for ATN should also be identified, including patients requiring intravenous contrast studies, patients with sepsis, or patients at high risk for developing hypotension, including those with hemorrhagic and cardiogenic shock and severe dehydration.

For all patients at increased risk for ATN, optimizing volume status and hemodynamic status to improve or maintain renal perfusion is a prudent first step in AKI prevention. Perioperative optimization of hemodynamic status in surgical patients undergoing both elective and emergent surgical procedures has been shown to decrease the risk of AKI.[254] Most published data exist for preventative strategies with IVF administration that is specific for the clinical scenario

of the patient. Intravascular volume expansion has been shown to decrease the risk of AKI for radiocontrast-induced nephrotoxicity,[255,256] myoglobinuric and hemoglobinuric AKI,[257–259] cisplatinum,[260] aminoglycoside,[261,262] amphotericin nephrotoxicity,[263,264] and the tumor lysis syndrome.[265] Given the complex nature of AKI development in the setting of sepsis, the role of volume administration in its prevention in this cohort is more challenging. Proposed mechanisms of renal injury in patients with sepsis have included renal ischemia owing to hypoperfusion and hypoxemia,[266] but newer evidence suggests other multiple contributing factors, including renal macrocirculatory and microcirculatory disturbances, surge of inflammatory markers and oxidative stress, coagulation cascade activation, and bioenergetic adaptive response with controlled tubule cell-cycle arrest.[267] Patients with sepsis have now been shown to have normal or even elevated renal blood flow, which has been shown to be associated with a redistribution of blood flow from the cortical to medullary regions. Septic shock with resulting hypotension is secondary to a combination of factors, including diffuse vasodilatation, a redistribution of intravascular fluid, and myocardial depression.[268,269] Despite these complex and interrelated systemic factors in the setting of sepsis, such as an increased cardiac output in the setting of hypotension and a depressed myocardium, the use of IVFs and goal-directed therapy have been advocated in the setting of sepsis with some reduction in AKI incidence.[270] The optimal volume of resuscitation is unknown; however, in a prior study, the mean volume of resuscitation was 5 L within the first 6 hours[271] with more recent studies using 2 to 3 L within the first 6 hours.[272,273] Careful monitoring of these patients is crucial. Although IVF boluses are intended to prevent hypotension and maintain renal perfusion, patients with sepsis are at increased risk for developing CHF and noncardiogenic pulmonary edema (ARDS). Excess amounts of fluid given to patients with sepsis have been shown to prolong ventilator dependency.[274]

The choice of fluids for intravascular volume expansion in patients with hypovolemic shock and septic shock include crystalloid solutions (such as saline solution and buffered solutions such as Ringer lactate and bicarbonate-buffered 0.45% saline solution), colloid-containing solutions (such as albumin), and blood products (including packed RBCs or their substitutes).

For hypovolemic shock not caused by bleeding, crystalloid solutions, particularly saline solution, are preferred to colloid-containing solutions because no mortality benefit has been attributed to colloids over crystalloid solutions[275–277]; additionally, colloids are much more expensive. The use of synthetic colloids has been thought to provide a better intravascular volume expansion than colloid solutions; however, hyperoncotic starch solutions should be avoided as they have an associated increased risk of AKI, need for RRT, and even death.[278–281] Similar to intravascular volume depletion, in the setting of sepsis, crystalloids are preferred to colloids because no definitive mortality benefit has been observed with albumin versus crystalloids[282,283] and synthetic colloids should similarly be avoided.

Multiple pharmacologic agents have been studied in an attempt to decrease the risk of AKI and maintain renal perfusion. Dopamine has been shown to be ineffective in preventing AKI[284–286] and in some cases has demonstrated deleterious renal effects.[287] The use of fenoldopam, a dopamine receptor-1 agonist, has also had discordant results with both positive protective effects[288,289] and results demonstrating no benefit.[290] Natriuretic peptides such as atrial natriuretic peptide (ANP) have been studied but similar discordant results have limited its use.[291] Diuretics have also not demonstrated any preventive AKI effects.[292,293] Overall, as such none of these pharmacologic agents has shown reproducible beneficial protective AKI effects and therefore cannot be advocated.[6]

Avoidance of Nephrotoxicity

A major function of the kidney is the concentration and excretion of potentially toxic medications, many of which are used to treat critical illness in hospitalized ICU patients. The kidney is a frequent site of drug toxicity because medications can damage cells within all compartments of the kidney, including the renal tubules, the interstitium, or most commonly, a combined tubulointerstitial injury. Medication-induced glomerular injury is less common. Drug-induced nephrotoxicity has been reported to cause between 8% and 60% of in-hospital AKI.[294] Common nephrotoxins include NSAIDs, aminoglycosides, radiocontrast agents, antibiotics, ACE inhibitors and ARBs, PPIs, chemotherapeutic agents, lithium, interferon, acyclovir, colistin, methotrexate, and nucleoside inhibitors.

The prevention of nephrotoxicity from certain medications requires several approaches, including early recognition of their potential nephrotoxicity, because stopping the offending agent often leads to renal recovery. As in the case for certain causes of AIN, the use of steroids has shown some potential benefit in renal recovery. Additional considerations in preventing medication-induced nephrotoxicity include avoiding combined nephrotoxic agents that may have additive nephrotoxicity, identifying high-risk cohorts, using nephrotoxic agents for the shortest interval possible, using alternative nonnephrotoxic medications when available, monitoring renal function closely, and following measurable blood levels when appropriate.

NSAIDs including selective cyclooxygenase inhibitors (COX-2) can cause renal insufficiency via several mechanisms in up to 5% of patients,[295,296] with the most common being a hemodynamically mediated etiology. Risk factors for NSAID-induced AKI include CKD, volume depletion, heart failure, hypertension, older age, and concomitant use of certain medications including ACEs, ARBs, and diuretics.[297–299] The mechanism of the hemodynamically mediated AKI is inhibition of cyclooxygenase enzymes with subsequent decrease in prostaglandin-mediated afferent vasodilatation, which can lead to reversible renal ischemia.[300] The combination use of NSAIDs with other potential nephrotoxic medications or agents such as radiocontrast media should be avoided given the increased risk of nephrotoxicity.[301,302]

Prevention of NSAID nephrotoxicity should be aimed at avoiding their use in high-risk patients. Other potential manifestations of NSAID-induced renal effects include interstitial nephritis, minimal change disease, membranous nephropathy, papillary necrosis, and electrolyte abnormalities such as hyperkalemia and hyponatremia. NSAID-induced AIN typically occurs after a more prolonged course of treatment than in β-lactam–induced AIN.[303]

PPIs have been used for the treatment of acid reflux disorders for many years. Several studies have demonstrated their role in causing AIN.[304–307] Typically patients with PPI-induced AIN lack the triad of symptoms typically associated more with antibiotic-induced AIN. More recently, PPI use has been associated with an increased risk of incident CKD, progression of CKD, and ESRD.[308,309] Whether the mechanism of increased incident CKD is related to an increased AIN incidence or other mechanism is unknown.

Aminoglycosides have been commonly used in the treatment of multiple infections in the hospitalized patient and rates as high as 24% in vascular surgery patients have been described.[310] The

proximal renal tubule is the typical site of injury. Renal insufficiency typically occurs 5 to 7 days after treatment with creatinine typically returning to baseline approximately 21 days later after allowing for regeneration of healthy proximal renal tubular cells. Risk factors for aminoglycoside toxicity include prolonged use, elevated plasma drug levels, increased age, associated concomitant comorbid conditions (such as leukemia and diabetes mellitus), decreased intravascular volume, endotoxins and sepsis, concomitant use of certain medications (such as furosemide [Lasix], ACE inhibitors, and vancomycin), as well as the type of aminoglycoside.[311–318]

Preventive strategies to minimize aminoglycoside nephrotoxicity include selecting the least nephrotoxic agent, a once-daily dosing regimen, and avoiding their use either in a prerenal state or with other potentially nephrotoxic medications. Gentamicin has been reported as the most nephrotoxic aminoglycoside[311] with tobramycin less nephrotoxic than gentamicin.[319,320] Once-daily dosing of aminoglycosides versus standard dosing has shown comparable bacteriologic cure rates with lower rates of AKI.[321,322] ACE inhibitors and ARBs are extensively used because their use has shown benefits in multiple clinical cohorts, including the slowing of kidney disease progression in patients with diabetic nephropathy,[323] as well as improved mortality in patients with cardiomyopathy[324] and acute myocardial infarction.[325] ACE inhibitors can also cause an acute decrease in GFR in patients with CKD, bilateral renal artery stenosis, and hypertensive nephrosclerosis.[326,327] Typically many patients using an ACE inhibitor already have a reduction of their intrarenal perfusion pressure. GFR is partially maintained via an angiotensin II–induced increase in resistance of the efferent arteriole, which helps maintain intraglomerular pressure and GFR. Blocking this physiologic response with ACE inhibitors by relaxing the efferent arteriole results in a lower intraglomerular pressure and a subsequent reduction in GFR. ACE inhibitor use in intravascular volume–depleted states such as vomiting and diarrhea may cause AKI and should be avoided.[328] The rise in creatinine can be acute but generally occurs 3 to 5 days after initiation of an ACE or ARB. The most common electrolyte abnormality associated with ACE inhibitors is hyperkalemia.[329]

Many other medications occasionally used in the ICU may cause nephrotoxicity. Colistin has been reported to cause AKI in up to 43% of patients.[330–333] Intravenous vitamin C, secondary to possible antioxidative effects, has been shown to have potential renoprotective effects for colistin-induced AKI[334] but study results have been discordant.[335] As previously described, most medications cause nephrotoxicity through a tubulointerstitial process but glomerular injury can occur. Various exogenous interferons are associated with minimal change disease and focal segmental glomerulosclerosis.[336] Oral bisphosphonates are considered nonnephrotoxic, whereas intravenous bisphosphonates are potentially nephrotoxic; pamidronate is associated with nephrotic syndrome and a collapsing form of focal segmental glomerulosclerosis[337,338] and zoledronic acid is associated with a tubular toxicity.[339] A thrombotic microangiopathy (TMA) is associated with certain antiangiogenesis medications such as vascular endothelial growth factor inhibitors[340] and certain chemotherapeutic agents such as gemcitabine[341,342] and mitomycin C.[341,343] There is no clear evidence for prevention of TMA in the above settings and treatment primarily consists of stopping the offending agent if TMA develops.

Prevention of Contrast Nephrotoxicity

The use of iodinated contrast studies is often unavoidable in the care of critically ill patients. As early as the 1960s, intravenous contrast was described as causing AKI[344] with multiple subsequent studies linking contrast media with AKI.[345–349] The incidence of contrast-induced AKI (CI-AKI) in critically ill patients has been reported to be 2% to 18% with multiple factors contributing to this wide variation, including the variable study population and the definition of AKI.[350] The simple daily variation of serum creatinine values in critically ill patients who have not even received intravenous contrast has been reported to also complicate the interpretation of CI-AKI in the critically ill population,[351] for which small rises in creatinine are often used to define AKI. Typically the creatinine rises within 24 to 48 hours after the contrast is administered. The pathophysiology of contrast nephrotoxicity is not completely understood but primarily involves a tubular injury inducing ATN. The proposed mechanisms of ATN include renal vasoconstriction and direct cytotoxic effects.[352–355] Risk factors for CI-AKI include CKD, diabetes mellitus, increasing age, type of ionic contrast agent used, CHF, hypovolemia, and multiple myeloma.* The risk of CI-AKI in patients who do not have these associated risk factors is low.[347] Because the clinicians caring for patients are responsible for the timing of the patient receiving iodinated contrast, preventive strategies to minimize AKI risk should be pursued as there is no specific treatment once CI-AKI develops. Certainly, using alternative diagnostic modalities with avoidance of iodinated contrast in the higher-risk populations should be considered whenever possible. Although not widely used, carbon dioxide has been given in angiographic procedures as an alternative diagnostic interventional radiographic agent.[358] However, if intravenous contrast is required, other preventive strategies are required. Lower doses of iodinated contrast should be used wherever possible as the risk of AKI is less with lower administered doses.[359,360] The type of iodinated contrast also affects risk of CI-AKI as the nonionic low osmolal or iso-osmolal agents have a lower risk of AKI than the first-generation hyperosmolal ionic contrast agents.[347,361] The primary therapeutic intervention in preventing CI-AKI is administering periprocedure isotonic IVF when it is not clinically prohibitive, such as in patients who have CHF. The type of IVF used to prevent CI-AKI has been shown to be important as isotonic saline solution has been shown to be superior to one-half isotonic saline solution.[256] Because alkalinization may protect against free radical injury, using isotonic bicarbonate has been compared with isotonic saline solution but results have been conflicting.[362–365] Thus as there are no clear superiority benefits of isotonic bicarbonate solutions over isotonic saline solution, periprocedure isotonic saline solution for 6 to 12 hours both before and after the procedure is generally used as a preventive strategy in the hospitalized patient when clinically appropriate.

In addition to IVF serving to prevent CI-AKI, multiple additional agents, either administered alone or in combination with other pharmacologic agents, have been studied but most have not demonstrated a clear benefit with some agents actually demonstrating increased risks of nephrotoxicity. The use of diuretics and mannitol with IVF[366,367] has not shown benefits in preventing CI-AKI and has shown potential harm; thus it has been recommended to consider holding oral diuretics before any contrast periprocedure study.[365] Forced diuresis with matched saline solution infusion has shown some renoprotective effect[368,369] but further studies are needed before wider adaptation given concerns regarding arrhythmia risk and volume administration. Oral hydration compared with IVF in preventing CI-AKI has demonstrated discordant results.[370,371]

*See references 345, 346, 348, 352, 356, 357.

Dopamine infusion and ANP use have been reported as having an increased risk of CI-AKI.[372] The use of ascorbic acid has also had variable results in preventing CI-AKI.[371,373] N-acetylcysteine (NAC), a thiol compound with both antioxidant and vasodilatory properties, is available in both oral and intravenous formulations, and its favorable side effect profile and relative low cost have prompted its study for potential prophylactic benefits in preventing CI-AKI. Multiple studies, however, have shown discordant results[374–377] and thus even practice guidelines have had variable recommendations with KDIGO suggesting using NAC and IVF in high-risk patients,[6] whereas the American College of Cardiology and American Heart Association guidelines do not recommend its use.[378]

The potential of removing the iodinated contrast from the circulation to limit CI-AKI after contrast has been administered has prompted several studies evaluating the potential benefit of hemofiltration and hemodialysis (HD). A meta-analysis from 2012 consisting of 11 published studies concluded that periprocedural RRT did not decrease the incidence of CI-AKI, with HD potentially increasing CI-AKI risk.[379]

Management of Established Acute Kidney Injury

General Aspects

Once AKI develops, the specific management is generally tailored to the etiology of the AKI, carefully monitoring volume status, and managing the clinical manifestations associated with AKI, including electrolyte and organ-specific complications. Patients with prerenal azotemia should have intravascular deficits replaced. Those with cardiorenal syndrome (CRS) should have cardiac function optimized. The early descriptions and definitions of CRS focused more on a unidirectional etiology in that CRS was defined as a condition in which therapy to relieve CHF was affected by a decrease in the GFR. More recent definitions have focused on the bidirectional interactions between the heart and the kidney. Five types of CRS were initially proposed by Ronco and colleagues.[380] Type 1 was acute heart failure causing AKI, whereas type 2 was chronic heart failure causing renal insufficiency. Types 3 and 4 bring attention to the primary role of kidney disease potentially worsening heart failure, and type 5 CRS describes systemic disorders worsening both cardiac and renal function.[380] Defining renal failure as secondary to heart failure can be clinically difficult because there are no specific diagnostic tests, but typically patients lack proteinuria and have an inactive sediment unless the patient has underlying CKD. In 2012, the 11th Consensus Conference of ADQI group developed a work group to better review the pathogenesis of type 1 CRS. Potential mechanisms of CRS type 1 in causing AKI included low cardiac output, activation of vasoactive substances resulting in decreased renal perfusion, increased IAP, and activation of the sympathetic nervous system and the renin-angiotensin-aldosterone system.[381] Further studies are necessary, however, to better define the pathophysiology of these different types to improve evaluation of the treatment of patients clinically within these different categories of the CRS.

Patients with an obstructive uropathy should have all reasonable attempts undertaken to relieve the obstruction. Patients with an AIN should have the offending agent stopped and, although not conclusive, initiating steroids has shown some benefit. Typically an acute GN is treated dependent on the specific syndrome but generally involves immunosuppressive agents including steroids. Rhabdomyolysis is often treated with IVF. The ACS is often treated surgically by decompression. The best treatment for the hepatorenal syndrome is to treat the underlying etiology of the liver failure. For critically ill patients, norepinephrine, vasopressin, and albumin have shown effectiveness.[382–385] Overall, many AKI complications are not unique to the specific cause of renal failure and thus treatment of AKI is always initially driven by the specific cause.

Management of Volume Status

After optimizing volume status, the use of diuretics to treat AKI should be based on the volume status of the patient. Oliguria is typically defined as urine volume less than 400 mL/day and anuria as urine volume less than 50 mL/day. Some data suggest that critically ill patients with nonoliguric AKI have better outcomes with overall lower morbidity and mortality and lower incidence of dialysis than patients with nonoliguric ATN[386–388]; however, some studies have shown discordant results with increased in-hospital mortality in patients with nonoliguric ATN that could possibly be secondary to delayed initiation of dialysis secondary to diuretic use.[64] Overall, there is a lack of evidence supporting the use of diuretics in attempting to convert an oliguric AKI to a nonoliguric AKI. Thus use of diuretics in this clinical scenario should be dependent on the volume status of the patient; if the patient does not have intravascular volume expansion or total body water excess, diuretics should be avoided.[6,65] However, there are data to suggest that patients with positive fluid balance after AKI have higher mortality.[61–63,385] Thus in the latter cohort of patients, a trial of diuretics as short-term treatment for volume control would seem appropriate.

Prophylactic use of other medications with renal vasodilatory properties to prevent ATN or treat AKI, such as fenoldopam, dopamine, and atrial natriuretic peptide, has been studied with overall lack of evidence supporting their general use. Fenoldopam, a dopamine receptor-1 agonist, has shown discordant results.[288–290,389–392] In a recent large multicenter randomized, placebo-controlled parallel-group study of fenoldopam use in early AKI after cardiac surgery, fenoldopam showed no effect on the need for RRT or mortality at 30 days.[392] In a recent meta-analysis of fenoldopam use in the perioperative setting of patients undergoing cardiothoracic surgery, partial nephrectomy, or liver transplantation, fenoldopam use was associated with a reduction in postoperative AKI but, similar to many previous studies, its use had no impact on RRT or hospital mortality.[393]

Dopamine has natriuretic effects on the proximal tubule as well as vasodilatory properties on both the afferent and efferent arterioles.[394–396] As such, low dose dopamine has been extensively studied as a prophylactic agent in ATN. However, many studies have shown that it is ineffective in preventing ATN.[284–287,397] ANP, a natriuretic peptide, has both diuretic and natriuretic effects. It inhibits tubular sodium reabsorption and causes vasodilatation of afferent arterioles. Some small studies regarding ANP use in preventing AKI have shown some potential benefit,[398–400] but its use has not been clinically endorsed.[6]

Preventing, Monitoring, and Treating Complications

Complications of AKI include the development of several electrolyte abnormalities, such as hyperkalemia, hyponatremia, hyperphosphatemia, hypocalcemia, metabolic acidosis, hyperuricemia,

hypercalcemia, and hypermagnesemia. At times, certain preventive approaches can prevent these complications such as a low-potassium diet to help prevent hyperkalemia. In certain clinical scenarios, hypercalcemia may occur. AKI is also associated with an increased risk of infections and hematologic disturbances including bleeding and anemia. There are several organ-specific associations, including neurologic disturbances, respiratory failure, cardiac dysfunction, and gastrointestinal complications. (A detailed discussion of these complications can be found in the online supplement at www.expertconsult.com.)

Hyperkalemia

The incidence of hyperkalemia has increased among hospitalized patients[401] and is a potentially serious complication of AKI that has been associated with increased all-cause and in-hospital mortality.[402,403] Among patients with AKI, hyperkalemia is considered the most serious electrolyte abnormality given its potential for increased cardiac arrhythmias. Potassium is primarily an intracellular cation with a cellular concentration of 140 mEq/L compared to 4 to 5 mEq/L in the extracellular space. This difference in concentration is maintained by the sodium-potassium-adenosine triphosphatase (Na-K-ATPase) pump and is the main determinant of the resting membrane potential. Hyperkalemia reduces the resting membrane potential and electrocardiographic (ECG) changes can occur. Although a specific serum potassium level does not correlate with precise ECG manifestations, the typical progression of ECG changes with progressive hyperkalemia include peaked T waves, atrial asystole, prolongation of both the PR and QRS intervals with eventual sine wave, ventricular fibrillation, and asystole. Although muscle weakness and paralysis can occur with severe hyperkalemia, most patients are initially asymptomatic. The treatment of hyperkalemia often includes treatment of the precipitating risk factors, preventing life-threatening cardiac arrhythmias by administering calcium-based salts, shifting of potassium from the extracellular to the intracellular space, and enhancing potassium elimination by inducing a kaliuresis or using cation exchange resins.[404] Patients with oliguric or anuric AKI and associated hyperkalemia often require a more emergent treatment approach. Unless patients have a readily reversible cause of AKI producing hyperkalemia (such as bladder outlet obstruction where placement of an indwelling catheter can relieve the obstruction and improve solute clearance relatively rapidly), treatment options may be limited and the patient may require HD. HD removes potassium more rapidly versus peritoneal dialysis (PD) and thus HD is preferred to PD in treating patients with severe hyperkalemia.[405]

The first assessment in the treatment of hyperkalemia is to address whether effective removal of potassium from the body can be achieved. Options include attempted kaliuresis with IVFs in the setting of prerenal azotemia with expectant recovery of solute clearance and improved urine output with intravascular volume replacement. Loop diuretics may be helpful in inducing kaliuresis in hypervolemic patients or in euvolemic patients with mild hyperkalemia receiving IVF, but they are not recommended as a sole treatment of severe hyperkalemia with advanced renal failure. Gastrointestinal losses of potassium by administration of cationic exchange resins are available but should be avoided in postoperative patients and those with suspected bowel obstruction given the higher risk for intestinal necrosis. Two widely used cation exchange resins are patiromer and sodium polystyrene sulfonate. The active moiety of patiromer is a nonabsorbed polymer that binds potassium in exchange for calcium predominantly in the distal colon.[406] Sodium polystyrene sulfonate may also lower the serum potassium and may be given orally or as a retention enema. Removal of potassium from the body may not always be feasible, and especially with hyperkalemic-induced ECG changes, medications to shift serum potassium intracellularly are often used. Insulin administration can help lower the serum potassium by enhancing the activity of Na-K-ATPase pump in skeletal muscle, which helps drive potassium intracellularly.[407] Glucose is often administered simultaneously to prevent hypoglycemia. The serum glucose should be monitored closely after insulin administration to check for potential development of hypoglycemia. Sodium bicarbonate can also lower serum potassium by raising the serum pH, which results in hydrogen ion release from cells and compensatory movement of potassium intracellularly to maintain electroneutrality. The overall clinical benefit of the effect of sodium bicarbonate in lowering serum potassium has been variable and often is the least effective of the available potential treatment interventions.[408] Albuterol, a β_2-adrenergic agonist, can also be used to help drive potassium intracellularly by also activating the Na-K-ATPase pump in skeletal muscle. Its effect can be additive with insulin and glucose in lowering serum potassium.[409] Use of intravenous calcium to antagonize and stabilize cardiac membrane excitability in patients with severe hyperkalemia will have effects that typically last only up to 60 minutes. One of the major concerns of intravenous calcium use is that many of these AKI patients have associated hyperphosphatemia and intravenous calcium may cause precipitation of calcium and phosphate in cardiac, vascular, and soft tissues. After initial treatment of moderate to severe hyperkalemia, guidelines suggest that a repeat serum potassium level be checked 1 to 2 hours later.[410]

Hyponatremia

Hyponatremia is commonly seen with AKI and becomes more prevalent as AKI worsens. The etiology is usually secondary to an inability to excrete free water. As renal failure worsens, the lowest urine osmolality that can be achieved often rises to 200 to 250 mOsm/kg despite a decrease in antidiuretic hormone, whereas in patients with normal renal function, the urine osmolality can be lowered to 50 mOsm/kg. This defect in free water excretion can lead to accumulation of free water with resultant hyponatremia. Typically patients with hyponatremia have a proportional reduction in the serum osmolality, but this may not occur with advanced renal failure because the rise in BUN can counteract the fall in serum osmolality induced by the hyponatremia. Patients are often asymptomatic but mental status changes and seizures can occur if the hyponatremia becomes severe. Treatment includes water restriction, avoidance of medications that can worsen hyponatremia, and occasionally dialysis is indicated.

Calcium, Phosphorus, and Magnesium Disorders

Hyperphosphatemia is a known complication of AKI and is often associated with hypocalcemia. The kidney has a major influence on phosphate balance, and thus hyperphosphatemia in AKI results from a decreased urinary phosphorus excretion. In normally functioning kidneys, only 5% to 20% of filtered phosphorus is excreted in the urine because most of the filtered phosphorus is absorbed in either the proximal tubule (60%–70%) or distal tubule (10%–20%).[411] With a decrease in GFR that accompanies AKI, there is both a decrease in filtration and excretion of phosphorus. Phosphorus homeostasis can be maintained by the phosphaturic response of increased secretion of both parathyroid hormone (PTH) and phosphatonins such as fibroblast growth factor 23. In the setting of hyperphosphatemia, this adaptive decrease in proximal tubular phosphate reabsorption can be generally maintained until

the GFR falls below 25 to 40 mL/min. Once phosphate tubular reabsorption is maximally suppressed and the increased urinary excretion can no longer keep pace with phosphate intake, the serum phosphate level will rise. As the serum phosphorus level increases, the calcium level often decreases. Mild elevations in serum phosphorus can usually be treated by preventive measures such as limiting phosphate intake[412] or by using phosphate binders with meals to prevent dietary absorption of ingested phosphate.[413] Phosphate binders are generally divided into calcium-containing binders such as calcium carbonate and calcium acetate and noncalcium-containing binders such as sevelamer, lanthanum carbonate, sucroferric oxyhydroxide, and aluminum hydroxide. The optimal choice of phosphate binder remains controversial; however, aluminum-containing phosphate binders should be avoided for any prolonged use to avoid aluminum toxicity. In severe hyperphosphatemia, standard HD is usually ineffective in removing lowering serum phosphorus, but prolonged nocturnal HD does provide much better phosphate control and often obviates the need for phosphate binders.[414–416]

Hypocalcemia in AKI is often multifactorial in etiology. Hyperphosphatemia often leads to chelation with calcium, leading to hypocalcemia and the potential for calcium-phosphate salt deposition in soft tissues. Another contributory factor to hypocalcemia in AKI is the skeletal resistance of bone to PTH. This skeletal resistance to PTH may result from the inability of the kidney in AKI to convert the inactive form of 25-(OH)-vitamin D to the active 1,25-$(OH)_2$-vitamin D. Low levels of this active form of vitamin D are typically seen with AKI. Typically patients with hypocalcemia in AKI are asymptomatic, although with more severe hypocalcemia, symptoms such as carpopedal spasm, tetany, and seizures may occur. Treatment is generally aimed at lowering the serum phosphorus level, which often results in improved serum calcium levels. Treatment with intravenous calcium is usually reserved for the rare occurrence of symptomatic hypocalcemia.

When hypercalcemia occurs in the setting of AKI, the pathophysiology may be multifactorial and includes primary hyperparathyroidism secondary to PTH–mediated osteoclast activation, multiple myeloma via osteoclast activating factors, humoral hypercalcemia of malignancy via PTH-related protein effects, and in the recovery phase of rhabdomyolysis secondary to release of calcium into the circulation from prior deposition of calcium into injured muscle.

Hypermagnesemia may be seen in AKI. Even small amounts of ingested daily magnesium can result in hypermagnesemia with AKI. Medications with any magnesium content should generally be avoided in patients with renal failure. Treatment options for mild hypermagnesemia include IVF and diuretics when clinically feasible, but in more severe hypermagnesemia, intravenous calcium[417] and HD may become necessary.

Hyperuricemia

Many epidemiologic studies and meta-analysis have linked hyperuricemia as a risk factor for AKI development in several settings, including hospitalized patients, those undergoing coronary artery bypass grafting, contrast studies, or cisplatin therapy.[418–423] The kidneys account for approximately two-thirds of uric acid excretion with gut elimination accounting for the other one-third under normal physiologic circumstances. In the kidney, approximately 90% to 95% of the filtered urate is absorbed in the proximal tubule. Uric acid may cause AKI through several mechanisms, including direct tubular toxicity from crystal-induced injury or indirectly through potential vasoconstriction, oxidative stress, and inflammatory changes.[418] In AKI, the GFR is usually quite low with small amounts of uric acid filtered and thus intratubular precipitation of uric acid does not occur. Uric acid nephrolithiasis and acute gouty flares are not typically seen with AKI. Hyperuricemia, however, is common with AKI but is mostly asymptomatic and the level is often less than 12 mg/dL. However, in those patients who are prerenal secondary to intravascular vole depletion or are receiving loop and thiazide diuretics when proximal reabsorption of sodium and urate are increased, higher serum uric acid levels may be seen. One disorder in which uric acid is nephrotoxic is in acute uric acid nephropathy (UAN). UAN typically develops in patients treated for leukemia, lymphoma, or bulky tumors with radiation or chemotherapy that results in a marked overproduction and excess excretion of uric acid. Patients generally have associated oligoanuria and marked hyperuricemia. The serum uric acid level is usually greater than 15 mg/dL. The urinalysis in patients with UAN often demonstrates uric acid crystals but the latter are nondiagnostic. Another potential clue for the diagnosis of UAN is an elevated spot urine uric acid/creatinine ratio that is typically greater than 1 with UAN, whereas it is less than 0.6 to 0.75 with other forms of AKI.[424,425] Although treatment of asymptomatic AKI-induced hyperuricemia is usually not initiated, in patients with UAN a combination of preventative and therapeutic modalities, including aggressive IVF, recombinant urate oxidase, and xanthine oxidase inhibitors, is often used.

Metabolic Acidosis

The kidney plays a major role in acid-base regulation. The relatively fixed daily nonvolatile acid production rate is approximately 50 to 100 mEq of hydrogen ions (H^+)/day. Elimination of this acid load and maintenance of acid-base homeostasis is maintained by the urinary excretion of hydrogen ions, both as titratable acidity and as ammonium. Metabolic acidosis begins to develop in AKI when either a combination of the damaged kidney to generate new bicarbonate or an inability of the kidney to further increase ammonium excretion results in the accumulation of plasma organic acids and other unmeasured ions. This typically occurs when the GFR decreases below 40 to 50 mL/min. Much of the acid secreted by the kidney is the product of daily metabolism and as such, the metabolic acidosis in AKI is typically mild and usually does not require treatment with alkali. The decline in plasma bicarbonate concentration is usually 0.5 to 1.0 mmol/L per day.[426] However, many patients with AKI have contributing factors that result in worsening acidosis, such as hypotension, sepsis, and multiorgan failure, or even superimposed toxic ingestions that can often lead to generation of lactic acid and ketoacids and a more severe metabolic acidosis. The latter acidemia that develops is typically a high anion gap metabolic acidosis. As there are no official guidelines or general consensus to suggest the optimal timing of administering alkali therapy or initiating dialysis in patients with severe metabolic acidosis and AKI, the treatment strategies are based on the individual clinical situations.

Hematologic Complications: Anemia and Bleeding

Anemia is frequently associated with AKI in critically ill patients[427] and has been associated with worse outcomes in ICU patients.[428] Some degree of anemia often occurs with AKI, and the etiology is often multifactorial; causes include reduced RBC production secondary to erythropoietin deficiency, frequent phlebotomy, bone marrow suppression from certain medications, systemic disorders affecting both the kidney and the hematopoietic system (such as hemolytic uremic syndrome and SLE), gastrointestinal bleeding,

and blood loss from dialyzers. The anemia in AKI is typically mild, slowly developed, well tolerated, and asymptomatic; treatment using erythropoietin has not been associated with a decrease in transfusion requirements or enhanced renal recovery.[427] A restrictive strategy of blood transfusions using a threshold of 7 g/dL in hemodynamically stable ICU patients without ischemic heart disease had similar 30-day mortality rates compared to liberal transfusion, and in certain subgroups such as those younger than 55 years of age and with Acute Physiology and Chronic Health Evaluation (APACHE) II scores less than 20, the mortality rates were actually lower in the restrictive strategy cohorts.[429] The overall relationship between anemia and AKI and the effect of anemia on long-term mortality in critically ill patients is unresolved. In a recent retrospective analysis of 2145 ICU patients with anemia and AKI with long-term follow-up of 10 years, a hemoglobin level less than 10.5 g/dL was associated with both an increased 10-year mortality and AKI risk.[430]

Similarly, in a study of 3472 patients undergoing transcatheter aortic valve implantation for severe aortic stenosis, both preprocedural and postprocedural anemia were significantly associated with AKI and 1-year mortality.[431]

Bleeding

Overt bleeding in the setting of AKI and uremia can be manifested by gastrointestinal bleeding, active bleeding after procedures such as percutaneous renal biopsies, spontaneous bleeding directly into the skin or joints, oropharyngeal bleeding, or bleeding in the respiratory system.[432] The mechanism by which AKI and uremia affect bleeding risk is multifactorial and includes platelet dysfunction, uremic toxins, anemia, and nitric oxide. Impaired platelet function secondary to impaired platelet aggregation and adhesiveness is considered the major cause of uremic bleeding.[433] Mixing studies have shown that uremic toxins can cause platelet dysfunction. Correction of anemia has also demonstrated improved platelet dysfunction.[434] Nitric oxide has been shown to be an inhibitor of platelet aggregation, and nitric oxide synthesis has been shown to be increased in uremic patients.[435] In addition to these specific AKI-induced potential contributory factors that may result in clinical bleeding, other comorbid conditions such as liver disease, thrombocytopenia associated with sepsis, disseminated intravascular coagulation, or disorders such as thrombotic thrombocytopenic purpura may all additionally contribute to the increased risk of bleeding in AKI. Certain medications such as aspirin have been shown to have a cyclooxygenase-independent prolongation of the bleeding time that is greater than that seen in normal subjects taking aspirin.[436] Generally, patients with AKI without active bleeding do not require specific treatment. With uremia, the platelet count, prothrombin time, and partial thromboplastin time are generally normal. The bleeding time, however, is generally prolonged in uremia.[437] Some patients with AKI may develop a bleeding diathesis secondary to abnormalities of primary hemostasis which require treatment. Several therapeutic options to improve and possibly correct the bleeding time in AKI are available. Desmopressin, an analog of antidiuretic hormone, has been shown to shorten the bleeding time in uremia.[438] Desmopressin can be administered intravenously or intranasally and the bleeding time begins to correct within 1 hour of administration. Its effects are short-lived and last only 4 to 8 hours and tachyphylaxis is common. Cryoprecipitate can also be used to shorten bleeding time in uremia[439] and its effects on shortening bleeding time begin in 1 hour and last 4 to 24 hours. Although the specific mechanism of action of these agents in reducing bleeding time is unknown, it is thought that cryoprecipitate results in direct infusion of multimeric forms of factor VIII. Von Willebrand factor aggregates and desmopressin induces the release of large factor VIII; von Willebrand factor multimers from endothelial cells which enhance the binding of platelets to endothelial surfaces.[440,441] Conjugated estrogens have been shown to control bleeding in uremic patients with normalization of the bleeding time.[442] Intravenous administration of estrogens has been studied with its effects noted within 1 day of administration and lasting up to 1 week or longer after the last administered dose.[443] Short courses of estrogens have safely been used in men. The specific mechanism of action is unknown but is possibly related to decreased generation of nitric oxide.[444] Lastly, both PD and HD have been shown to shorten the bleeding time in uremic patients.

Infectious Complications

Although large epidemiologic surveys have clearly described increased mortality associated with AKI, there are few data available on the proximate cause of death among patients with AKI. Infectious complications, however, remain a leading cause of death in patients who develop AKI in the ICU. In a cohort study of 3930 hospitalized patients prospectively identified as having AKI via AKIN criteria, the in-hospital mortality rate was 21.9% and data on the primary cause of death were available for 93.4% of the deceased patients. Death from sepsis was listed as the primary cause of death in 41.1% of patients, whereas AKI was listed as the primary cause of death in only 3.1% of patients.[445]

In a study of CI-AKI, the frequency of sepsis after AKI was 45%.[446] Common sources of infection include intravenous vascular access, including dialysis and triple-lumen catheters; indwelling urinary catheters; operative sites; and skin and respiratory infections. Many ICU patients with AKI are treated with antibiotics for these superimposed infections and are therefore at risk for development of infection with *Clostridium difficile*, the causative agent for antibiotic-associated colitis. Patients with AKI in the ICU may not mount the typical expected response of fever and leukocytosis in the setting of infection compared to those patients with normal renal function[447] and thus careful clinical vigilance is required to monitor for infection. To reduce the risk of infection, all preventive and clinical interventions should be considered to prevent, diagnose, and treat infections early. A careful physical examination with particular attention to central line exit sites should be performed routinely. In addition, central venous and arterial lines and indwelling urinary catheters should be removed as soon as possible. Tailored antibiotic usage with assistance from the antibiotic stewardship program should be used whenever possible to optimize the antibiotic regimen and prevent drug resistance.[448]

Cardiovascular Complications

Cardiovascular complications are frequently encountered in AKI. This organ-organ interaction, also referred to as organ crosstalk, has led to defining the CRS.[449] Type 3 CRS is specifically characterized as worsening of kidney failure leading to heart disease, including acute coronary syndrome, decompensated heart failure, and arrhythmias. Patients with oligoanuria are at risk of developing total body water excess secondary to sodium and water retention, which clinically can be manifested as peripheral edema and ascites. This positive fluid balance can also lead to pulmonary edema and hypertension. Both volume overload and hypovolemia are associated with increased morbidity and mortality in critically ill patients.[450] Thus accurate assessment of the intravascular volume status of these patients is critical to the treatment strategies of either using

diuretics for nonoliguric AKI with volume overload versus IVF for intravascular volume depletion or renal replacement therapies for patients with intractable total body water excess and oligoanuria. Given the heterogeneity of the patient population in the ICU with AKI, goal-directed fluid therapy should be individualized and include serial monitoring using physical examination findings and clinical tools, such as oxygenation, chest radiographs, body weights, urine output, and central hemodynamic monitoring. In addition, use of bedside echocardiography to measure the diameters of both the inferior and superior vena cava may help guide fluid resuscitation in mechanically ventilated patients.[451,452] Several additional cardiovascular complications, such as fatal arrhythmias, myocardial infarction, and pericarditis, can complicate AKI. Hyperkalemia secondary to AKI often requires immediate treatment in the setting of oligoanuria because fatal arrhythmias such as ventricular fibrillation, ventricular tachycardia, and sine wave can develop in patients with severe hyperkalemia.[453] Hypocalcemia often accompanies AKI and can result in prolongation of the QT interval on the ECG and generalized myocardial dysfunction. Uremia itself may also cause myocardial contractility and promote pericardial effusions and pericarditis.[454]

Pulmonary Complications

Volume overload with associated pulmonary edema is a known complication of AKI. This results in impaired gas exchange, and mechanical ventilation often is required in up to 50% of patients with severe AKI. Mechanical ventilation is a risk factor for increased mortality in patients with AKI[20] and is also considered a proinflammatory intervention that contributes to the increased inflammatory load of critically ill patients.[455] Some of the pulmonary alterations in AKI include increased vascular permeability, alveolar edema formation, neutrophil extravasation, and pulmonary microhemorrhages.[456] Avoiding mechanical ventilation whenever possible in patients with AKI in the ICU would seem prudent because this cohort of patients has significantly longer requirements for mechanical ventilation even without oliguria.[457] The development of respiratory failure with AKI has been shown to have additive effects on mortality. In a retrospective, observational cohort study of data of 217,994 patients who underwent high-risk intraabdominal general surgical procedures, in patients in whom both respiratory failure and AKI developed, the 30-day mortality rate was 65.2% versus a 30-day mortality rate of 7.24% and 10.8%, respectively, if only AKI or respiratory failure developed.[458]

Excess volume and infection are major components and etiologies of respiratory failure in AKI, but vigilance is needed for other potential etiologies. In particular, the respiratory system is often involved in patients with the anti-GBM Ab–mediated syndrome, granulomatosis with polyangiitis, microscopic polyangiitis, polyarteritis nodosa, eosinophilic granulomatosis with polyangiitis, SLE, and, less likely, cryoglobulinemia.

Gastrointestinal Complications

Gastrointestinal symptoms, such as nausea, vomiting, dyspepsia, gastroparesis, and poor appetite, are common in advanced AKI and may be the precipitating symptoms that cause RRT to be initiated. Whether CRF and ESRD are associated with an increased risk of peptic ulcer disease has revealed discordant results.[459,460] As such, prophylactic treatment for prevention of peptic ulcer disease in patients with AKI is not recommended. In addition, use of aluminum- and magnesium-containing antacids should be avoided with advanced renal failure given the potential for toxicity in the latter cohort of patients. Many systemic disorders can cause AKI and often have associated gastrointestinal symptomatology. Gastroparesis is common in patients with long-standing diabetic nephropathy and systemic sclerosis. Polyarteritis nodosa is associated with hepatitis B infection and often presents with constitutional gastrointestinal symptoms of nausea, vomiting, abdominal pain, and diarrhea. Henoch-Schönlein purpura is associated with abdominal pain and gastrointestinal bleeding.[461] SLE is associated with mesenteric vasculitis and gastrointestinal bleeding is common with systemic amyloidosis.

Intestinal consequences of AKI have recently been described.[456] During AKI the intestinal integrity is disrupted, potentially causing increased mucosal permeability and translocation of either endotoxin or live microorganisms that can further aggravate the inflammatory process.[462] This loss of barrier function of the intestine may partially explain the increased potential for liver injury in AKI as endotoxins and inflammatory mediators drain into the portal circulation, resulting in Kupffer cell activation and further cytokine release.[463,464] Liver injury may clinically be evident by abnormal liver function test results or physical examination findings such as scleral icterus and jaundice. Jaundice was reported in one prospective study in up to 28% of patients during their ICU course.[465] The mechanism of liver injury and jaundice is usually multifactorial, including sepsis, hypotension, medications, and hepatic congestion. Although AKI often accompanies acute pancreatitis, it is important to note that AKI itself can cause elevations in both serum amylase and lipase without clinical pancreatitis but the elevations typically do not exceed three times the upper limits of normal.[466]

Neurologic Complications

Neurologic complications of AKI are variable and early clinical symptoms may include lethargy, irritability, confusion, and disorientation. Tremors, asterixis, and myoclonus may be noted on physical examination with coma and seizures much less common. The degree of encephalopathy generally is concordant with the degree of renal failure, although variability exists and older patients are generally symptomatic earlier than younger patients. The most common electroencephalographic finding is a prominence of slow waves. Dialysis is indicated for the treatment of uremic encephalopathy and symptom resolution may improve acutely; however, several days are often needed for mental status to resolve to baseline.

Medication Dosing Considerations

Most medications and pharmacologic agents are either metabolized or removed from the circulation by either the liver or the kidney. In patients with AKI, all prescribed medications need to be assessed for appropriate dosing to avoid nephrotoxicity or accumulation of the active drug or its metabolites that could have other organ-specific complications. Certainly, all unnecessary medications should be stopped. Measuring drug levels when available to help prevent nephrotoxicity such as in aminoglycoside use should be performed. Certain cohorts of patients such as the elderly are at increased risk for requiring medication adjustments for renal insufficiency.[467] Multiple resources exist to help practitioners adjust medication dosing in renal failure.[468] Many medications used in the perioperative setting also have been demonstrated to cause AKI and therefore dosing adjustment may deserve special attention.[469] For patients receiving IHD, PD, or continuous RRT, knowledge of pharmacokinetic principles in the latter setting can be challenging but it is important to avoid toxicity and ensure appropriate therapeutic dosing to maintain maximum clinical effect.[470–473]

TABLE 52.2 Nutritional Provisions in Critically Ill Patients With Acute Kidney Injury

Type of Enteral Formulation	Standard, Polymeric Fluid-Restricted Formula[a]
Energy requirements	25–30 kcal/kg per day (actual body weight)
Protein requirements	1.2–2 gm/kg per day (up to 2.5 g/kg per day with frequent continuous renal replacement therapy)

[a]Specialized formulations with reduced electrolyte content may be necessary in patients with electrolyte abnormalities.

Nutritional Considerations

Nutritional support in the critically ill patient with AKI refers to the appropriate administration of calories, protein, electrolytes, vitamins, and fluid to alter the course of critical illness. The optimal nutritional support in critically ill patients with AKI is often influenced by associated multiple comorbidities. Whenever feasible however, enteral nutrition is preferred to parenteral nutrition because enteral nutrition is believed to preserve gut immune function and prevent translocation of gut bacteria.[474] Direct comparisons of enteral versus parenteral nutrition in the critically ill patient have shown that enteral nutrition may be associated with a lower rate of infection but does not reduce mortality.[475,476] However, guidelines discourage enteral nutrition in hemodynamically unstable or prerenal patients given the concern for bowel ischemia.[477,478] Nutritional requirements must be determined once it has been determined that nutritional support will be required in the critically ill patient with AKI (Table 52.2). Although the appropriate goal for critically ill adult patients is unknown, caloric intake is generally recommended to be initially 8 to 10 kcal/kg per day[479] with a goal of 25 to 30 kcal/kg per day but not to exceed 35 kcal/kg per day.[480] Because protein requirements increase with the severity of illness, critically ill patients with AKI are often hypercatabolic and therefore the recommended protein requirement is 1.2 to 2 kcal/kg per day.[481,482] In regard to volume administration with parenteral nutrition, careful examination of the patient is continually warranted to optimize fluid balance by treating intravascular volume depletion yet avoiding excess volume administration. The goals of prescribing parenteral nutrition are to optimize clinical outcome and address electrolyte abnormalities and volume status in the critically ill patient; this requires advanced understanding and training in nutrient metabolism as well as solute compatibility. As such, guidelines have been developed to ensure proper ordering, compounding, labeling, and dispensing of parenteral nutrition.[483] Similarly, a framework to help guide institutions in ensuring and maintaining competency in prescribing parenteral nutrition has also been published.[484]

Renal Replacement Therapy

In patients with severe AKI, RRT is the cornerstone of supportive management (Box 52.3). The goal of RRT is to permit the removal of fluid and solutes that accumulate in renal failure, thereby restoring the composition and volume of the extracellular fluids and preventing the complications of uremia, hyperkalemia, and acidosis.

A detailed technical guide to the performance of RRT is beyond the scope of this chapter. The following discussion provides an overview of RRT with a focus on the key management issues of selection of modality, timing of initiation of dialysis, and appropriate intensity of therapy.

• BOX 52.3 Indications for Renal Replacement Therapy

Hyperkalemia
Volume overload
Acidosis
Uremia (altered mental status, pericariditis)
Certain drug and alcohol intoxications

Modalities of Renal Replacement Therapy

Different modalities of RRT include conventional IHD, PD, continuous RRT (CRRT), and hybrid therapies such as sustained low-efficiency HD (SLED) or extended-duration dialysis or prolonged intermittent renal replacement therapy (PIRRT). The various forms of CRRT include continuous venovenous HD (CVVHD), continuous venovenous hemofiltration (CVVHF), and continuous venovenous hemodiafiltration (CVVHDF).

Solute removal during RRT may occur by diffusion down a concentration gradient from blood, across a semipermeable membrane, into dialysate, or by convective transport of solute across the membrane during ultrafiltration. Fluid removal occurs by ultrafiltration, driven by either a hydrostatic or osmotic pressure gradient across the semipermeable dialyzer or filtration membrane.

IHD is a process of solute clearance by diffusion across the dialysis membrane driven by the concentration gradient between blood and the dialysate. It requires a large-bore double-lumen venous catheter typically inserted in the internal jugular, subclavian, or femoral vein. Because an episode of AKI requiring dialysis may not recover renal function, a subclavian venous catheter should always be avoided whenever possible owing to the risk of subclavian stenosis that would affect functioning of an arteriovenous fistula. Treatment duration and frequency of IHD are variable and usually dependent on factors such as the patient's planned volume removal and metabolic needs.

CRRT is a modality intended to run 24 hours/day in the ICU setting. It provides slower per unit time clearance compared with intermittent therapies. Solute removal is achieved by diffusion (HD), convection (hemofiltration), or both (hemodiafiltration).

CRRT includes CVVHD, CVVHF, and CVVHDF. CRRT is considered to cause less hemodynamic stress than IHD in patients with severe AKI. CRRT was initially described using an arteriovenous extracorporeal circuit (continuous arteriovenous HD) with inflow through a large-bore arterial catheter and return through a venous catheter. It used the patient's own cardiac output to drive blood through the dialysis circuit. It has now been replaced by CVVHD that allows higher blood flow rates and is independent of mean arterial pressure and thus avoids the complications of prolonged arterial cannulation.

As in IHD, CVVHD solute removal occurs by diffusion across the concentration gradient with hydrostatic forces driving ultrafiltration. In addition to the duration of therapy, the other major difference between CVVHD and IHD is the dialysate flow rate. With IHD, the typical dialysate flow rate is 500 to 800 mL/min, which is greater than or equal to the typical blood flow rate allowing for rapid solute clearance. In CVVHD, dialysate flow rate is typically 1 to 2 L/hr, which is slow compared with a blood flow rate of 200

to 300 mL/min, allowing for virtual equilibration of low–molecular-weight solutes between the blood and dialysate. Although CRRT provides slower solute clearance per unit time compared with intermittent therapies, CRRT is typically prescribed over 24 hours and therefore the overall solute clearance with CRRT may even exceed the typical clearances obtained with IHD.

In CVVHF, a high ultrafiltration rate is generated and physiologic replacement fluid is administrated at a rate equal to the difference between the high ultrafiltration rate and the desired rate of fluid removal. Solute removal is achieved by convection and clearance is equal to the ultrafiltration rate. No dialysate is used. In continuous hemodiafiltration, the dialysate flow of continuous HD is added to the convective ultrafiltration of continuous hemofiltration.

Prolonged intermittent RRT is a modification of conventional IHD, using lower blood and dialysate flow rates while prolonging the treatment duration to 8 to 16 hours compared with the usual 3 to 4 hours of IHD. As with CRRT, by prolonging the treatment duration and decreasing the rate of net ultrafiltration, the hemodynamic stress on the patient is minimized.

PD uses the peritoneum as a natural semipermeable membrane through which solute transport and fluid removal occurs via diffusion from the blood to the dialysate. The dialysate is a highly concentrated, typically dextrose-based solution instilled in the peritoneum via a peritoneal catheter. In adults, acute PD is not widely used for many reasons. Acute PD requires surgical placement of a PD catheter, which may not be appropriate for patients with recent abdominal surgery or with an acute intraabdominal process. Solute clearance with PD is not optimal in patients with a hypercatabolic state. Other limitations include the potential for compromising lung volumes in mechanically ventilated patients owing to increased IAP or the development of glucose intolerance from the high dextrose concentration within the dialysate.

Theoretically, CRRT and SLED may provide advantages over IHD such as providing better hemodynamic tolerability, improving control of fluid removal, and offering improved efficiency of solute clearance. However the data do not support either modality as superior to IHD in regard to patient survival or recovery of renal function.

Comparing outcomes of CRRT with IHD has been reported in observational studies and case series.[485–488] However, conclusions from these studies are confounded by a selection bias for an increased number of hemodynamically unstable and higher-acuity patients in the CRRT group. After adjusting for the severity index, there appears to be no survival benefit between patients receiving CRRT or IHD.[486,487]

In a multicenter, randomized, controlled trial comparing continuous hemodiafiltration and IHD, continuous hemodiafiltration was associated with increased ICU mortality (59.5% vs. 41.5%) and in-hospital mortality (65.5% vs. 47.6%). Despite randomization, there was a significant difference in severity scores between the two groups. After adjustment, the odds of death with continuous hemodiafiltration were nonsignificant.[489]

In the Hemodiafe Trial, the largest prospective, randomized, multicenter study consisting of 360 patients, patients were randomly assigned to receive either IHD versus CVVHDF. The primary endpoint was 60-day survival; there was no statistically significant difference in 60-day survival between the two groups: 32% in the IHD group versus 33% in those patients receiving CVVHDF.[490]

Similarly, in another multicenter prospective randomized controlled trial involving 316 patients with AKI, patients were randomly assigned to receive intermittent renal replacement therapy (IRRT, defined as daily dialysis during 4–6 hours per session with a blood flow of 100–300 mL/min and a dialysate flow of 300–500 mL/min) or CRRT (CVVH continued during 24 hours per day with a blood flow rate of 100–250 mL/min, an ultrafiltration rate of 1–2 L/hr). The randomly assigned treatment modality of IRRT or CRRT had to be continued daily for at least 3 consecutive days. Thereafter treatment could be continued according to the needs of the patients. Results demonstrated that duration of ICU stay, hospital stay, and renal recovery at the time of discharge were also comparable between the two groups.[491]

In the CONVINT trial, 252 critically ill patients in the ICU were randomly assigned to receive IHD versus CVVH. The primary outcome measure was survival at 14 days after the end of RRT. Results demonstrated survival rates at 14 days after RRT were not statistically significant (39.5% IHD vs. 43.9% CVVH).[492]

Recent systemic reviews and meta-analyses have confirmed the absence of differences in mortality rate or recovery of renal function across different dialysis modalities.[493–495] Advocates of CRRT claim that it offers better hemodynamic tolerability and greater volume control in critically ill patients.[62,496] In patients with acute brain injury or hepatic liver failure, CRRT is associated with better preservation of cerebral perfusion than IHD and seems to be a more appropriate modality of RRT.[497–501] Based on these data, the KDIGO Clinical Practice Guideline for AKI suggests using intermittent and continuous RRT as complementary therapies in patients with AKI and have suggested that CRRT be used preferentially in hemodynamically unstable patients.[6]

Studies comparing PIRRT and CRRT show similar outcomes. In a prospective, randomized clinical study, 12-hour SLED was compared to 24-hour CVVH. The primary outcome, 90-day mortality, was similar in both groups, although the SLED cohort had reduced nursing time and lower costs.[502] Other studies have shown that SLED demonstrated similar hemodynamic stability and metabolic control compared to CRRT.[503–505] A systematic review and meta-analysis comparing CRRT with extended daily dialysis showed no difference in mortality or recovery of kidney function between the two groups.[506] There are only limited studies comparing PIRRT and IHD.[507]

PD has long been used as a dialytic therapy in AKI, although its use has declined as the use of CRTT has become more common. Single studies have compared PD efficacy with hemofiltration favoring hemofiltration; however, this was not replicated in a larger study demonstrating similar metabolic control, mortality rate, and renal function recovery between both groups.[508–510]

In the absence of data suggesting better survival or recovery of renal function with one particular modality over another, these modalities should be considered complementary. In general, CRTT and PIRRT modalities are more optimal therapies for patients who are hemodynamically unstable but are more expensive.[511] The choice of modality should be based on the local availability, and expertise of practitioners prescribing RRT, and nursing staff delivering the therapy.

Timing of Initiation of Renal Replacement Therapy

The urgent indications to initiate dialysis in patients with AKI include refractory hyperkalemia, fluid overload, severe metabolic acidosis, pericarditis, uremic encephalopathy, and certain drug and alcohol intoxications. In the absence of these acute indications, the timing of initiation of dialysis in AKI is unclear. However, common practice is to start dialysis in patients before the development of these acute indications in severe AKI in whom imminent recovery of renal function is unlikely. Although starting early dialysis

may have benefits, it also exposes patients to RRT risks related to the procedure including increased risk of catheter-related infections.

A number of retrospective and observational studies have suggested that earlier initiation of dialysis may be associated with better survival.[512–523] A recent meta-analysis including 15 studies compared 28-day mortality for early versus late initiation of renal support. An odds ratio of 0.45 was associated with early initiation; however, the methodologic quality of the included studies was low.[524] There was a significant statistical heterogeneity as well as evidence of publication bias toward smaller studies in which early initiation of RRT was associated with a survival benefit.

A recent randomized controlled trial of 620 patients randomly assigned patients to either an early or delayed strategy. In the early group, RRT was initiated immediately after randomization, whereas in the delayed group, RRT was not initiated until at least one of the following criteria was met: oliguria for more than 72 hours, BUN of more than 112 mg/dL, or any of the acute indications for RRT. No significant difference in mortality at 60 days was demonstrated between the two groups. The rate of catheter-related blood infections was significantly higher in the early strategy group and diuresis occurred earlier in the delayed-strategy group, possibly suggesting recovery of renal function.[525] A prospective, open label, randomized trial consisting of 208 patients with AKI in India showed similar results that do not support early initiation of dialysis among patients with AKI.[526]

In contrast, investigators from the ELAIN trial randomly assigned patients to one of three groups: early, late, or no initiation of dialysis. In the early group, dialysis was initiated within 8 hours of diagnosis of KDIGO stage 2 AKI. In the delayed group, dialysis was initiated within 12 hours of stage 3 AKI, whereas 11 patients never initiated dialysis in this group. The primary endpoint was mortality at 90 days, which was significantly lower in the early initiation group compared with the delayed group (39% vs. 54%). More patients with early initiation of RRT had renal recovery (53% vs. 38%) as well as a significantly shorter duration of RRT and length of hospital stay.[527]

The severity of volume overload as an indication for initiation of RRT has gained considerable attention in recent years. Observational studies have shown that fluid overload is associated with increased mortality in patients with AKI in which early initiation of replacement therapy has shown benefit.[63] In another prospective multicenter observational study consisting of 618 patients, fluid overload, defined as more than 10% increase in body weight relative to baseline, was independently associated with mortality in patients with AKI with an odds ratio for death at dialysis initiation of 2.07.[528] Similar results were shown in another observational study from Beijing in which a higher cumulative fluid balance was associated with a higher 28-day mortality after AKI.[529] Although these data provide a strong caution regarding overly aggressive volume administration in patients with AKI, the hypothesis that earlier initiation of RRT to prevent or reverse volume overload still needs to be tested in prospective clinical trials.

Intensity of Renal Support in Acute Kidney Injury

Assessment of the dose of both IHD and PIRRT is dependent on the intensity and the frequency with which these therapies are provided. Intensity of a treatment is usually quantified in terms of urea reduction ratio or the fractional clearance of urea. In one study of 160 patients, daily IHD was beneficial compared with alternate-day intermittent dialysis.[530] However, this result was not reproduced in the large Veterans Affairs (VA)/National Institutes of Health (NIH) Acute Renal Failure Trial Network (ATN) study, a randomized controlled trial involving 1124 patients randomly assigned to either an intensive or less intensive treatment group. In the intensive treatment group, patients received IHD and sustained low-efficiency dialysis 6 times per week and CVVHDF at 35 mL/kg of body weight per hour. In the less intensive treatment group, patients received the corresponding treatments 3 times a week and at 20 mL/kg per hour. There was no statistically significant difference in either recovery of renal function or 60-day mortality between the two groups.[531]

For CRRT, the dose is usually expressed in terms of the total effluent flow (dialysate plus ultrafiltrate) normalized to body weight. In the Randomized Evaluation of Normal versus Augmental Level (RENAL) study (N = 1508), the high-intensity group received CVVHDF with an effluent flow of 40 mL/kg of body weight per hour, whereas the lower-intensity group received CVVHDF with an effluent flow of 25 mL/kg per hour. Ninety-day mortality was similar (44.7%) in both groups.[532] Two meta-analyses confirmed the same results.[533,534] High-dose CVVH was not beneficial in prospective randomized controlled trials in patients with AKI from either septic shock[535] or after cardiac surgery.[536]

These studies show that more intensive renal support does not result in improved outcomes. The 2012 KDIGO guideline for AKI[6] recommends delivering a fractional clearance of urea of 3.9 per week for patients undergoing intermittent therapy. However, more frequent IHD may be necessary for fluid management in extremely hypercatabolic patients and for control of severe hyperkalemia. For CRRT, the recommended delivered dose of therapy is an effluent flow rate of 20 to 25 mL/kg per hour. Achieving this target dose often requires the prescription of a slightly higher dose (25–30 mL/kg per hour) with careful attention to minimization of interruption of therapy.

Prognosis and Outcomes

AKI increases the risk of hospital mortality, development of CKD and ESRD, pulmonary complications, cardiovascular events, and readmission rates. This association is even stronger among patients in whom recurrent and more severe AKI develop.

Many studies have focused on short-term morbidity and mortality rates of AKI in hospitalized patients. Hospital-acquired AKIs have reported mortality rates as high as 62%,[537] and these rates are higher than even those for patients in whom acute lung injury or myocardial infarction develops. Recent studies have focused on long-term outcomes of patients with AKI and results demonstrate that AKI has clearly been associated with development of CKD.[538,539] In a meta-analysis by Coca and colleagues with pooled data involving 13 studies in patients with AKI, the pooled incidence of CKD and ESRD was 25.8 per 100 person-years and 8.6 per 100 person-years, respectively. The more severe the AKI, the greater the risk of adverse outcomes.[537] Similarly, in a large VA health care system study, 20% of patients in whom an episode of ATN developed rapidly progressed to stage 4 CKD.[540] In addition, in a retrospective study by the VA system in hospitalized diabetic patients, the development of each AKI episode up to three doubled the risk of developing stage 4 CKD.[541]

The KDIGO AKI guideline recommends that patients should be evaluated 3 months after AKI for resolution of AKI or worsening of preexisting kidney disease with management according to CKD guidelines for those at increased risk of CKD as appropriate.[6] Despite the potential benefits in optimizing proteinuria reduction, glycemic and blood pressure control in potentially slowing CKD

progression, close follow-up of patients in whom AKI develops has been lacking. Follow-up care should include laboratory assessment of kidney function and referral to a nephrologist. Recent published studies from the U.S. Department of Veterans Affairs demonstrate the need for strategies to ensure closer follow-up. In a retrospective study by Matheny and colleagues of nearly 11,000 patients admitted with AKI and discharged with an estimated GFR less than 60 mL/min per 1.73 m^2, 69% and 85% of patients had a serum creatinine level obtained at 90 days and 365 days, respectively. However, during outpatient follow-up at 90 days and 365 days, only 6% and 12% had quantitative proteinuria; PTH and phosphate were measured in only 10% and 15% of patients, respectively.[542] Siew and colleagues also reported that only a minority of at-risk survivors of an AKI episode in whom an estimated GFR less than 60 mL/min per 1.73 m^2 developed within 30 days of peak stage of AKI were referred to a nephrologist (8.5%) over 12 months.[543] Similarly, the U.S. Renal Data System reported only 13.2% of patients in whom AKI developed saw a nephrologist at 3 months, and only 18.1% of patients saw a nephrologist after a recurrent AKI episode.[544] Given the increased incidence of AKI worldwide with its associated long-term sequelae, more comprehensive and updated strategies to ensure appropriate follow-up will be necessary.

AKI in hospitalized patients is associated with both direct and indirect health care costs and prolonged hospitalization, which increases resource utilization. Despite secular trends demonstrating that AKI-associated mortality may be decreasing,[545] the mortality rate remains exceedingly high. AKI is associated with greater diagnostic monitoring, longer ICU stays, prolonged hospitalization, and an increased risk of early rehospitalization.[544] AKI that is not associated with critical illness has been shown to add $2600 (U.S. dollars) in attributable costs and increased the length of stay by 5 days.[546] Increased health care costs of AKI were also reported by Chertow and colleagues in hospitalized patients with KDIGO stage 2 AKI; there was a 6.5-fold increased odds ratio for death, as well as a $9000 (U.S. dollars) increase in hospital costs and more than 3.5 days of increased length of stay.[547] The development of KDIGO stage 1 AKI after cardiac surgery resulted in a 1.6-fold increase in total postoperative costs compared with patients without AKI.[548] Rehospitalization rates have also been shown to be increased in patients in whom AKI develops but who did not require RRT.[549]

Health-related quality of life (HRQL) and residual disability have been increasingly reported and recognized as patient-centered outcomes after acute illness complicated by AKI. Several small and mostly single-center studies have evaluated HRQL and concentrated on functional disability in patients with critical illness. Overall, HRQL is lower in survivors of AKI requiring RRT compared with the age- and sex-matched general population at both hospital discharge and at 6 months after AKI onset. Older age, greater comorbid disease, higher illness severity, longer durations of ICU and hospital stays, and dialysis dependence are all associated with significantly lower HRQL.[544]

Key Points

- There is general consensus that a standardized definition of AKI has both epidemiologic and clinical benefits.[7]
- The worldwide incidence of AKI in the ICU has been reported to be greater than 50%.[34]
- The most common cause of AKI in the ICU is acute tubular necrosis.[58]
- The MDRD equation in estimating GFR is more accurate in patients with CKD and less accurate in patients with a normal GFR.[151]
- Anuria does signify a likely severe nephrologic emergency requiring immediate evaluation.
- Granular casts are a typical microscopic finding in ischemic ATN, which is the leading cause of AKI in hospitalized patients.[209]
- Intravascular volume expansion has been shown to decrease the risk of AKI for radiocontrast-induced nephrotoxicity.[256]
- Drug-induced nephrotoxicity has been reported to cause between 8% and 60% of in-hospital AKI.[294]
- Medications such as PPIs have been associated with an increased risk of incident CKD, progression of CKD, and ESRD.[309]
- Patients with positive fluid balance after AKI have a higher mortality.[62]
- Infectious complications, however, remain a leading cause of death in patients who develop AKI in the ICU.[445]
- Critically ill patients with AKI are often hypercatabolic; therefore the recommended protein requirement is 1.2 to 2 kcal/kg per day.[481]
- After adjusting for the severity index, there appears to be no survival benefit between patients receiving CRRT and those receiving IHD.[487]
- Development of AKI has clearly been associated with development of CKD.[538]

Review Questions

1. A 25-year-old male pedestrian was struck by a car while riding his bicycle. He was brought to the emergency department by ambulance. Physical examination reveals blood pressure of 130/80 mm Hg, pulse rate of 70 beats/min, and that the patient was afebrile. Cardiac examination reveals S_1, S_2, no S_3, and a I/VI systolic ejection murmur at the left sternal border. Lungs were clear; the abdomen was nontender; extremities revealed tenderness of the left lower extremity but not tense; and pulses in the lower extremity were normal. The patient was not taking any medications at presentation. Laboratory study results included urinalysis: trace protein, large blood; urine microscopy: 0–1 white blood cells (WBCs) per high-power field (HPF), 0–1 red blood cells (RBCs)/HPF, no casts; urine osmolality 295 mOsm/kg H_2O; serum creatinine 2.5 mg/dL; blood urea nitrogen 32 mg/dL; sodium 144 mEq/L; potassium 5.1 mEq/L; bicarbonate 22 mEq/L; glucose 92 mg/dL; aspartate aminotransferase 98 IU/L; alanine aminotransferase 78 IU/L.

What is the best initial management for this patient?

a. Obtain an immediate (stat) renal ultrasound
b. Stat vascular surgical consult
c. Intravenous fluids
d. Obtain urine for eosinophils
e. Obtain a spot urine myoglobin

Answer: c. This patient presented with a history concerning for rhabdomyolysis. The laboratory criteria consistent with the latter diagnosis are urinalysis with no RBCs on microscopy but large dipstick blood as well as elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) and associated renal failure. An elevated creatine phosphokinase level would be expected (value not given). The best initial treatment is intravenous fluids (IVF), normal saline solution with a goal urine volume of 200 mL/hr. At some point, a renal ultrasound will likely be required but the initial treatment is IVF. There is no need to obtain a urine eosinophil level in this setting because the latter is often ordered when there is concern regarding the possibility of acute interstitial nephritis. A urine myoglobin study may help in the diagnosis but results can be normal at initial presentation. A stat vascular surgery consultation is not yet indicated in view of normal lower extremity pulses, but continued vigilance would be necessary to observe for the possibility of a compartment syndrome.

2. A 25-year-old female with a 14-year history of type 1 diabetes mellitus (DM) presents to your office for routine follow-up. She has no new complaints except that her mother, who is a nurse, took her blood pressure on two occasions over the past month and it was elevated at 146/92 mm Hg and 156/98 mm Hg. The patient admits to poor compliance to diabetic control for many years and her hemoglobin A_{1c} is often above 9.0%. One year ago the patient had microalbuminuria and was prescribed an angiotensin-converting enzyme (ACE) inhibitor but she never filled the prescription. On review of systems, the patient denied recent rashes, illicit drug use, shortness of breath, chest pain, or headaches. Physical examination shows blood pressure of 142/98 mm Hg, pulse rate of 88 beats/min, and the patient is afebrile. Results of fundoscopic, cardiac, and pulmonary examinations were normal and there was no lower extremity edema. The patient was not using any medications. Laboratory study results were creatinine 0.9 mg/dL, blood urea nitrogen 24 mg/dL, sodium 140 mEq/L, potassium 4.2 mEq/L, chloride 94 mEq/L, bicarbonate 24 mEq/L, hemoglobin 13.0 gm/dL, WBCs $5.0 \times 10^3/\mu L$, platelets $345{,}000 \times 10^3/\mu L$, aspartate aminotransferase 14 IU/L, alanine aminotransferase 22 IU/L. Chest x-ray and electrocardiogram results were normal. The urinalysis showed 2+ protein, 1+ dipstick blood; urine microscopy showed 3–5 WBCs/HPF, 5–10 RBCs/HPF, 2 dysmorphic RBCs/HPF, 1 RBC cast/HPF, 1 to 3 hyaline cast/HPF. The prothrombin time is PT 12.5 seconds and the partial thromboplastin time is 25 seconds. Renal ultrasound shows normal echogenicity; right kidney 11.0 cm, left kidney 11.6 cm.

Which of the following is the most appropriate first step in caring for this patient?

a. Schedule a renal biopsy.
b. Obtain a renal artery Doppler.
c. Obtain a serum renin/aldosterone ratio.
d. Begin an ACE inhibitor and low-sodium diet with close follow-up in 4 weeks.
e. Refer the patient to a urologist.

Answer: a. This patient has a long-standing history of DM that has been poorly controlled. She has dipstick proteinuria and was not compliant with prescribed ACE inhibitors and is therefore at risk for progressive DM nephropathy. However, the patient has new-onset hypertension in the setting of an active sediment (RBCs, RBC casts, dysmorphic RBCs, and worsening proteinuria). This patient has a normal serum creatinine level *but* her urinalysis is consistent with an active proliferative glomerulonephritis. This essentially is a nephrologic emergency. Any delay in treatment is likely to be harmful to the patient and may result in irreversible renal failure. The first step is to schedule a renal biopsy for definitive diagnosis. Starting the ACE inhibitor (assuming she is not pregnant [i.e., or screening for latter first]) and a low-sodium diet would also be reasonable, but having the patient return in 1 month is not appropriate because an emergent renal biopsy is indicated. The urine sediment is concerning for glomerular injury and therefore urologic evaluation is not indicated. Although new-onset hypertension raises the possibility of fibromuscular dysplasia or other potential secondary causes such as primary hyperaldosteronism to explain her hypertension, her active urine sediment reflects an acute glomerulonephritis and as such, a renal Doppler and renin/aldosterone ratios are not indicated.

3. Which one of the following estimating equations for measurement of glomerular filtrate rate (GFR) is most accurate in patients with normal or near-normal renal function?

a. Cockcroft-Gault formula
b. Modification of Diet in Renal Disease (MDRD) study Eq. (4 variable)
c. MDRD study Eq. (6 variable)
d. Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation
e. Iothalamate clearance

Answer: d. The measurement of an accurate GFR in clinical practice is complex and can be cumbersome with many potential variables that can interfere with the results. The gold standard for measuring GFR is an inulin clearance but it is difficult to perform and mostly not available. The most common methods

to measure GFR are the 24 hour urine for creatinine clearance and three "estimating" equations to assess GFR. Of the clinically used estimating equations, the CKD-EPI equation is the most accurate in those with near-normal GFR. The MDRD equation is more often used in patients with CRF. The Cockcroft-Gault equation has been historically used to assess GFR for drug dosing guidelines and often overestimates the GFR. Iothalamate clearance, which provides a more accurate assessment of GFR than creatinine clearance, is not an estimating equation but rather a measured GFR (using iothalamate).

Summary

Introduction

Chronic kidney disease (CKD) is a common diagnosis in adult medicine.[1–6] To properly identify patients at risk for adverse outcomes and disease progression, extensive work has focused on early and appropriate classification over the past 10 years. In particular, the National Kidney Foundation proposed a classification system for CKD in 2002 using estimated glomerular filtration rate (eGFR) as a method to categorize patients.[7,8] Table 53.1 describes current NKF guidelines of CKD. CKD patients have higher mortality after critical illnesses.[9,10] Understanding this population's physiology and underlying disease state may aid caregivers in attempting to improve outcomes.

This chapter aims to define CKD and discuss the physiology of CKD in terms of blood pressure, electrolytes, mineral disorders, and anemia. An emphasis is given to the ICU management of these problems. When available, evidence-based guidelines are reviewed and discussed. The ICU management of patients with CKD is often not guided by evidence-based therapy.

Definition and Etiology

As shown in Table 53.1, CKD is staged in a five-tier system based on eGFR. The diagnosis relies on abnormal kidney function or urinalysis findings for 3 months or more. The serum creatinine level and age, sex, gender, and race are used to generate an eGFR from a quadratic equation derived from the Modification of Diet in Renal Disease Study (MDRD).[7] Most patients with CKD do not progress to end-stage renal disease (ESRD), however, because of the very high cardiovascular and noncardiovascular mortality associated with this at-risk population.[11–14] Proposals exist to more clearly define elderly subjects with CKD stage 3 disease at risk for disease progression, though this has not become standard.[15–17] In particular, stage 3A CKD (eGFR 45–60 mL/min per 1.73 m^2) does not progress toward ESRD in most elderly subjects if proteinuria is absent, whereas stage 3B CKD (eGFR 30–44 mL/min) may progress.[18]

Etiologies for CKD are broad and often multifactorial. However, frequently diabetes mellitus and hypertension play a major role. Hypertension may lead to kidney damage in the form of nephrosclerosis or chronic renal ischemia owing to atherosclerotic vascular disease. An important recent development is the recognition that the higher prevalence of nondiabetic kidney disease in the African American population may be due to genetic risk conferred by inherited variants in the apolipoprotein L1 gene (*APOL1*).[19] Additional causes of kidney disease in the general population include immune-mediated glomerular diseases, such as systemic lupus erythematosus, immunoglobulin (Ig) A nephropathy, membranous nephropathy, or other previous glomerulonephritides that often are present. Glomerulonephritis may be active as evidenced by hematuria and proteinuria, or it may have occurred in the patient's past, leading to abnormal kidney function but a relatively bland urinalysis. Alternatively, primary tubulointerstitial diseases could exist owing to reflux nephropathy, sarcoidosis, chronic infections, allergic reactions, or side effects from medications such as cyclophosphamide (Cytoxan) and lithium. In general, the diagnosis of CKD should warrant a higher index of suspicion for concurrent, and potentially undiagnosed, cardiovascular disease.

The population with CKD is at risk for deterioration in kidney function during a hospitalization stay, particularly if a critical illness is present. Potential causative factors for this are listed in Box 53.1. Importantly, acute tubular necrosis may occur without obvious hypotension and patients with reduced kidney function are more at risk for this complication.[20]

Diagnosis

Intrinsic to the eGFR formula, as well as other estimates of renal function from the serum creatinine level, is the presumption that a patient's serum creatinine level is stable. This may not be the case in patients in the intensive care unit (ICU); as a result, imprecision should be expected in kidney function estimation in ICU patients.[21] The serum creatinine level is now recognized as potentially providing an underestimated level of renal function in a large population of patients, particularly those with low weight,

TABLE 53.1 Chronic Kidney Disease Stages

Chronic Kidney Disease Stage	eGFR (mL/min per 1.73 m^2)	Urinalysis Findings
1	≥90	Hematuria, proteinuria, or abnormal imaging >3 months
2	60–89	Hematuria, proteinuria, or abnormal imaging >3 months
3	30–59	Above or normal
4	15–29	Above or normal
5	0–14	Above or normal

eGFR, Estimated glomerular filtration rate.

• BOX 53.1 Factors Leading to Deterioration in Kidney Function During Hospitalization in Patients With Chronic Kidney Disease

Volume depletion (prerenal, including "normotensive" sepsis, renal vasoconstriction owing medications or hypercalcemia)
Obstruction
Acute tubular necrosis
Renal vascular disease (atherosclerotic with volume depletion, thrombotic, and/or embolic disease)
Upper urinary tract infection (bilateral or unilateral with single kidney, including a kidney transplant)
Nephrotoxic medications (allergic inflammation, tubular injury)
Glomerular disease (immunoglobulin A or postinfectious related to infection)

• BOX 53.2 Factors That May Alter Serum Creatinine Level

Endogenous Impact on Creatinine Level
Reduced muscle mass
Reduced hyperbilirubinemia

Exogenous
Increased medications inhibiting tubular secretion (trimethoprim and cimetidine)

Medications Interfering With Laboratory Assays[a]
Increased flucytosine and cefoxitin
Reduced catecholamines

[a]*Varies by type of assay used.*

small muscle mass, and liver disease.[22] In addition, both endogenous and exogenous factors can influence the measurement of serum creatinine.[23–26] Box 53.2 describes situations in which serum creatinine measurements may not adequately reflect kidney function. Importantly, some vasoactive substances can impart a negative interference on creatinine values if the creatinine sample is obtained from a central line used for vasopressors.[27] Nonetheless, creatinine variation has improved since values have been standardized to reference values.[28,29]

In general, current guidelines recognize the importance of stage 3 through 5 kidney disease for prognostication in outpatient and inpatient outcomes. Proteinuria is now associated with increased cardiovascular risk at all levels of GFR, including normal GFRs.[30] Even mild kidney dysfunction, defined typically as a serum creatinine level as low as 1.5 mg/dL, is associated with worse outcomes after coronary artery bypass grafting and cardiac valvular and general surgery.[31–35]

Concern exists about the accuracy of the MDRD equation at higher GFRs. For example, the newer creatinine-based Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula equation leads to a lower prevalence rate of stage 3 CKD than the MDRD equation as more patients have an eGFR above 60 mL/min.[36–38] The CKD-EPI formula has been reported to better predict vancomycin dose requirements compared with the eGFR formula.[39]

Measurement of serum cystatin C levels, a protein produced by all nucleated cells and freely filtered by the glomerulus, may provide more accurate estimates of kidney function than creatinine-based equations, particularly when kidney function is close to normal.[40] Cystatin C may also provide prognostic information about future cardiovascular events.[13] In fact, cystatin C has been proposed as a marker of "preclinical" kidney disease based on worse cardiovascular outcomes in elderly subjects with higher cystatin C levels.[41] Despite a growing body of literature, use of cystatin C is not routine in clinical practice.

When the serum creatinine level is stable and the eGFR formula is considered to inaccurately measure kidney function, creatinine clearance can be measured by using a 24- hour urine collection through the following formula:

$$\text{Creatinine clearance (dL/24 hr)} = (\text{Urine creatinine (mg/dL)} \times \text{volume of urine (dL)}) / \text{Plasma creatinine (mg/dL)}$$

In this equation, units will need to be converted from deciliters per 24 hours to milliliters per minute by a conversion factor of 0.0694.

If this measure is pursued, clinicians are counseled to pay close attention to units as well as the expectation that men excrete 1500 to 2500 mg/day of creatinine and women excrete 1000 to 1500 mg/day of creatinine.[42] If a lower amount of urinary creatinine is obtained, the possibility of an undercollection should be considered. It is also worthwhile to note that, historically, drug dosing has been determined by creatinine clearance and *not* estimated GFR.

In summary, estimating kidney function in ICU patients may be challenging owing to the absence of steady-state conditions and irregularities in body size and fluid compartments. Critical care providers need to understand the strengths and weaknesses of measuring kidney function in these patients.

Physiology of Chronic Kidney Disease

Hypertension

More than 80% of CKD patients with eGFRs less than 60 mL/min have hypertension.[5] This has several important impacts on the management of ICU patients. First, long-standing hypertension, if uncontrolled, leads to adaptations in autoregulation. Autoregulation refers to the ability of blood vessels to constrict and dilate in

the presence of hypertension and hypotension, respectively. Consequently, patients become acclimated to blood pressures near their "typical" blood pressure and may not immediately tolerate lower blood pressures, despite these apparent lower values being in the normal range. A consequence of this may be hypoperfusion to the kidneys as well as the brain, heart, intestine, and other critical organs at blood pressure levels that appear normal. If a history of poorly controlled hypertension is obtained, an astute clinician should aim to keep blood pressure close to a patient's prior level. This very much requires individualized attention and thorough history taking.

Second, CKD leads to sodium retention.[43,44] The most notable ICU impact this will have is the potential for volume retention and the need for diuretics to manage hypertension in the CKD population.[45–47] Several mechanisms lead to the development of hypertension in the CKD population. They include upregulation of the renin-angiotensin system, increased sympathetic nervous system activity, and impairment of endothelial-dependent arterial smooth muscle relaxation.[48–54] Owing to these mechanisms, patients with CKD may develop more edema and volume overload with equivalent amounts of intravenous fluids. One worthwhile consideration, however, is that sodium retention associated with CKD may be counterbalanced by sodium loss from excessively high blood pressure levels. This phenomenon, known as pressure natriuresis, may explain the rapid drops observed in blood pressure in hypertension emergencies once excess sympathetic activity is controlled. Finally, volume management may be confounded by the presence of pulmonary hypertension, which is now recognized to occur more frequently is patients with CKD.[55]

Electrolyte Disorders in Chronic Kidney Disease

Sodium

Sodium homeostasis in patients with CKD is abnormal.[56] Although patients with CKD are sodium "avid" and tend toward states of volume overload, they are less able to increase sodium retention in times of need and subsequently are also at risk for volume depletion. In comparison, subjects with normal renal function can quickly increase sodium absorption and avoid volume-depleted states.[57] Patients with tubulointerstitial disease and obstructive uropathy may be particularly at risk for episodes of volume depletion because of their recognized inability to increase sodium reabsorption in times of volume depletion.[58]

Patients with CKD thus are a group at risk for both volume depletion and volume overload. ICU illnesses may confound this because of irregularities in physical examination findings in this population. Specifically, elevated blood pressure and edema in the CKD population are frequently present but may not represent states of intravascular volume overload. In summary, close attention to assessment of volume status and need for supplemental fluids or diuresis is warranted in the CKD population.

When volume overload is present, iatrogenic sources may be playing a role. Potential sources of sodium include maintenance intravenous fluids (including bicarbonate), antibiotics, and nutritional sources including total parenteral nutrition. Tracking fluid intake and output does not clearly differentiate between the electrolyte makeup of the various sources. Consequently, volume overload may develop insidiously. When volume overload develops, the standard approach involves minimizing sodium-containing sources and initiating a diuretic regimen.

Diuretics range from the gentler thiazide diuretics, which are less effective with a GFR below 30 mL/min, to more potent loop diuretics. In general, if significant volume removal is desired, a twice-daily or every 12-hour loop diuretic regimen should be prescribed to avoid excess sodium reabsorption in the period after the major diuretic effect.[59] Chronic administration of diuretics before ICU admission may lead to adaptive processes necessitating higher diuretic doses, combination therapy, or alternative approaches to volume overload states.[60–63] Torsemide is the loop diuretic that may be closest to lasting 24 hours.[64] Doses of loop diuretics need to be increased as renal function declines. Significant variability in loop diuretic kinetics exists; if a dose does not yield an increase in urine output within 2 hours, consideration should be given to increasing the dose. Alternatively, continuous infusion of loop diuretics may provide a better diuresis with less toxicity.[65,66] Typically infusion rates of furosemide are 10 to 40 mg/h. When a loop diuretic drip is ordered, a bolus should be given before initiating therapy to avoid a significant delay in efficacy.

Diuretic failure is common in the CKD population. Potential explanations in an ICU population include acute kidney injury, inadequate dosing, and distal tubular hypertrophy as the result of chronic diuretic use. When high-dose loop diuretics do not achieve adequate diuresis, the addition of metolazone may improve urine output. Historically, metolazone is given 30 minutes before the loop diuretics, although it may be efficacious if given at other times as well. Finally, isolated ultrafiltration or dialysis may be required for volume removal. Recently intraabdominal hypertension has been recognized as a disorder that may negatively affect kidney function as well as response to diuretics.[67–72]

Water

Water concentration and dilution are abnormal in patients with CKD. Normal patients can dilute and concentrate urine within a range of 40 to 1400 mOsm/kg.[73] CKD leads to a narrower range of urine osmolality. Specifically, patients with advanced CKD have a urine osmolality much closer to 300 mOsm/kg; the ability to adjust urine osmolality declines as kidney function worsens.[74] Consequently, patients with CKD are prone to both hypernatremia and hyponatremia. Loop diuretics may further worsen the kidneys' ability to concentrate and dilute urine.[75]

The approach to hypernatremia and hyponatremia is similar to that of other patients. In hypernatremia cases, concurrent illnesses often lead to patients being unable to obtain water for themselves; a high urine output owing to hyperglycemia or a high urea concentration may worsen this. Elevated urea, similar to high serum glucose levels, functions as an osmolar agent in the tubular lumen and creates a state of relative resistance to antidiuretic hormone with the potential for substantial free water loss.[76]

Hypernatremia can lead to significant agitation and should be treated aggressively with increased water either intravenously, in the form of hypotonic intravenous fluids, or enterally. When severe, an estimation of free water deficit is appropriate. Unexplained polyuria with a low urine osmolality, hypernatremia, and CKD in an ICU patient with an unclear history should warrant an investigation for previous lithium use.[77]

Hyponatremia reflects irregularities in water excretion in the vast majority of cases. Patients with CKD are less able to excrete water owing to the inability to lower urine osmolality.[78] Sources of water include intravenous fluids, medications mixed in dextrose, and enteral sources. Patients often are not aware of or not forthcoming about the amount of water they drink, although this is less an issue in ICU patients. The approach to hyponatremia in most patients with CKD is similar to the non-CKD population: looking for and reducing causes of increased water intake. Mild to moderate

CKD is not a contraindication to using antagonists to antidiuretic hormone. Importantly, sodium abnormalities in the patient with CKD, both with and without congestive heart failure, are associated with worse mortality.[79]

Potassium

Potassium (K^+) regulation is an essential function of the kidneys in normal states. Patients with CKD routinely maintain serum potassium in the normal range despite losing up to 90% of renal function.[80,81] Mechanisms underlying the maintenance of normal serum K^+ in advanced CKD include increased K^+ excretion per functioning nephron, increased gastrointestinal elimination of K^+, and increased uptake of K^+ by cells.[82] Diabetes mellitus, however, may exacerbate the development of hyperkalemia owing to the presence of a distal tubular acidosis (type IV) from aldosterone resistance. Hypokalemia may also be present as the result of current diuretic use or renovascular hypertension.[83] Its presence is associated with a higher risk of death and future ESRD needs in the CKD population.[84]

ICU patients with CKD represent a population prone to irregularities in K^+ homeostasis, in particular hyperkalemia.[85,86] Potential causes of hyperkalemia include insulin deficiency, hypoaldosteronism, and a loss of normal intestinal function that plays a role in increased potassium excretion in patients with CKD. Decreased blood flow to muscle and intestines in times of critical illness may impede potassium cellular uptake and excretion, respectively. Tissue ischemia from trauma, hypoxia, or tumor lysis is associated with an elevation in K^+, which may occur quickly.[87] One additional clinical consideration is that patients with CKD who are fasting may develop surprising levels of hyperkalemia without any apparent cause owing to low levels of insulin.[88] Glucose-containing intravenous fluids may avoid this.

The evaluation of hyperkalemia in patients with CKD begins with assessing the cause. Typically, this includes close scrutiny of medications, intravenous fluids, and types of nutritional support. Frequently, ICU patients receive nutrition very different from what the body is accustomed to and cannot manage a higher load of K^+, especially in states of relative tissue perfusion. Importantly, many patients with CKD are using diuretics as part of their routine outpatient medications; simply stopping these medications may lead to states of hyperkalemia. Hyperosmolality leads to a K_+ shift out of cells owing to solvent drag; in its most common presentation, hyperglycemia, this can be reversed quickly with the use of insulin. Metabolic acidosis may be associated with hyperkalemia, although organic acidosis states appear to cause less hyperkalemia than non-organic acid–induced states.[89]

Medications are an important and growing cause of hyperkalemia. Congestive heart failure and proteinuric renal disease remain as indications for possible combination therapy of an aldosterone antagonist with either an angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker. In this setting, hyperkalemia may occur and may be severe.[90] Box 53.3 lists some common causes of hyperkalemia in the CKD population and the associated mechanism.[91] The presence of hyperkalemia should warrant close attention to affected patients as its presence is associated with increased mortality.[92]

Metabolic Acidosis

The kidneys and lungs regulate acid balance in the body. Kidney excretion of acid occurs through two mechanisms: as protons bound to anions such as phosphate and through ammoniagenesis. As kidney function declines below a GFR of 30 mL/min, the excess excretion of protons by each remaining functional nephron is no longer able to keep serum bicarbonate in the normal range. As a result, bicarbonate levels in patients with CKD are frequently in the range of 18 to 22 mmol/L, owing to a modest increase in the serum anion gap.[93] A recent trial showed sodium bicarbonate, supplemented orally, could delay kidney disease progression (Fig. 53.1).[94]

In ICU patients with CKD, serum bicarbonate and anion gaps are often further worsened by concurrent conditions, including lactic acidosis, ketoacidosis, or dilution, as the result of aggressive volume resuscitation. In the latter case, dilutional acidosis, may present with a worsening serum bicarbonate in the days after admission to the ICU and institution of intravenous fluids; the anion gap should not change significantly. In general, an anion gap above 20 mEq/L should warrant a workup for other causes of increased acid generation. Medications may also worsen acidosis in the CKD population because of disturbances in ammonia

• BOX 53.3 Causes of Hyperkalemia in Patients With Chronic Kidney Disease in the Intensive Care Unit

Medications

Trimethoprim—Reduced renal K^+ excretion[141,142]
NSAIDs, ACE inhibitors, ARBs—Decreased renal K^+ excretion
Heparin—Decreased aldosterone synthesis[143]
β-Blockers, nonselective—Decreased cellular K^+ uptake[144]
Triamterene, spironolactone, amiloride—Decreased renal K^+ excretion
Digoxin overdose—Decreased cellular K^+ uptake[145]
Succinylcholine use with trauma/critical illness—Increased K^+ release from cells[146]
Penicillin G—Increased K^+ load[147,148]

Clinical Conditions

Renal tubular acidosis (associated with diabetes)—Decreased renal K^+ excretion
Thrombocytosis—K^+ release *after* phlebotomy[149]
Insulin deficiency—Reduced cellular K^+ uptake
Cell death (tumor lysis, rhabdomyolysis)—Increased K^+ load

ACE, *Angiotensin-converting enzyme;* ARBs, *angiotensin receptor blockers;* K^+, *potassium ion;* NSAIDs, *nonsteroidal antiinflammatory drugs.*

production as well as excess acid production in the form of lactic acid, ketoacids, and pyroglutamic acids.[95,96]

Mineral Bone Disorder

Substantial information has developed in the past several years about the mechanisms leading to abnormal calcium and bone metabolism in patients with CKD. Historically, this disorder was named *renal osteodystrophy.* The current preferred term is *CKD mineral bone disorder*.[97] The main developments reflects the growing importance of fibroblast growth factor FGF-23 on phosphate and parathyroid regulation and the relaxation of guidelines for strict parathyroid hormone (PTH) control in the ESRD population.[98]

FGF-23 is a phosphaturic protein produced by bone. Phosphaturia occurs as a result of decreased expression of sodium-phosphate (NaPi)-2a cotransporters in renal proximal tubular cells.[99] In addition, FGF-23 leads to a reduction in 1,25(OH)2D production by the kidney.[100] Its concentration increases earlier in the course of CKD than PTH. These adaptations initially keep calcium and phosphorus levels well maintained through early to middle stages of progressive CKD.

From the perspective of an ICU patient, hypocalcemia will routinely be encountered owing to the previously mentioned developments. Hypocalcemia, in the absence of other causes, suggests renal disease is chronic. Serum phosphorus levels may similarly be elevated as GFR declines. Dietary phosphorus restriction and phosphorus binders are the primary treatments for this. There is limited prospective data evaluating the best management of CKD mineral bone disorder, and therapy is for the most part dictated by nonrandomized studies and consensus guidelines. Elevations of FGF-23 are associated with a higher risk of mortality across multiple levels of kidney function.[101] Important issues for anyone caring for CKD patients with abnormalities of calcium bone deposition in the ICU include the following:

- Avoidance of phosphorus containing gastrointestinal stimulants owing to risk of systemic absorption and acute kidney injury.
- Recognition that hypocalcemia may be chronic; typically patients adapt to this with a normal ionized calcium owing to concurrent metabolic acidosis. Rapidly raising pH may lower serum calcium levels acutely and predispose patients to arrhythmias.[102]
- Consideration for other causes of hypocalcemia and hyperphosphatemia, in particular cell death from rhabdomyolysis and tumor lysis syndrome.

Anemia and Hematologic Disease

Erythropoietin is produced by the kidney and stimulates hematopoiesis in the bone marrow. CKD is associated with a reduction in erythropoietin levels and consequent anemia. As CKD progresses toward ESRD, anemia becomes more severe.[103] As a general rule, most patients with ESRD receive supplemental erythropoietin to increase their hemoglobin (Hgb) level and avoid transfusions.

Two large trials published in 2006 significantly altered the management of anemia of CKD.[104,105] The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) and Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE) trials both showed, in a well-designed format, that randomization to a normal Hgb did not improve outcomes and increased some adverse events. As a result, goal Hgb levels have dropped closer to 10.0 g/dL in general practice and the use of these medications has fallen substantially. These trials reinforced earlier data showing a normal Hgb, achieved through supplement erythropoietin, in the CKD population was dangerous.[106] Similar results were noted with darbepoietin alfa.[107] These studies clearly show adverse events from supraphysiologic Hgb levels in patients with CKD. The impact of relative reductions in Hgb in critically ill CKD patients is not well studied.

In CKD patients with critical illnesses, the problems of anemia are often magnified. How the anemia of CKD affects hospital course is not well understood. The current preference of minimizing transfusions and keeping Hgb levels in a lower range, based on trials for the most part on patients without CKD, has led to a reduction in Hgb in patients with CKD as well.[108–110] It is important to consider that patients with CKD may not be able to recover Hgb after acute illness as the result of reduced erythropoietin production.

Acute drops in the Hgb level in CKD patients in the ICU should be managed similar to patients without CKD. Chronic anemia should not be presumed to be due to CKD, and routine evaluations should still occur, including stool studies and iron status assessment. CKD patients, when blood urea levels increase above 100 mg/dL, are more prone to bleeding as the result of irregularities in platelet functional activity.[111–113] Dialysis may reduce the risk of bleeding related azotemia and "uremic platelets," although variable data on this point exist.[114–116] Additionally, desmopressin stimulate von Willebrand factor release acutely, although tachyphylaxis develops after the first dose.[117,118] Finally, conjugated estrogens may provide a sustained reduction in bleeding complications in patients with CKD who have recurrent gastrointestinal bleeding from arteriovenous malformations.[119] Low-molecular-weight heparin clearance is reduced in patients with low GFRs. Appropriate dose reductions should occur; currently no guidelines exist for dosing with these medications in patients with a GFR below 15 mL/min, and their use in these settings should be avoided. Similarly, new direct oral anticoagulants (thrombin inhibitors, factor Xa inhibitors) have limited information on safety in subjects with advanced kidney disease. Although patients with ESRD consistently fall into high-risk groups for stroke, their potential benefit from anticoagulation may be limited by a higher bleeding risk.[30,120]

End-Stage Renal Disease

Patients with ESRD represent a large and growing percentage of the CKD population. In the United States, 90% of this population receives renal replacement therapy in the form of in-center hemodialysis at the time of dialysis initiation.[5] Efforts are under way to move more of this care to the patient's home in the form of home hemodialysis or peritoneal dialysis.

Patients with ESRD have a higher mortality when admitted to ICUs.[121,122] This is primarily due to comorbid conditions.[123] Indications for admission may be dialysis specific, such as access complications or volume overload, or may be due to other comorbid illnesses. Most commonly, this includes cardiovascular causes including acute coronary syndromes and strokes, other infectious causes, and gastrointestinal hemorrhages. Commonly used ICU prognostic scoring systems such as Acute Physiology and Chronic Health Evaluation (APACHE) II and III, Simplified Acute Physiology Score, and Sequential Organ Failure provide reasonable prognostication of patients with ESRD.[124]

Attention to a dialysis patient's access for ESRD is essential in the care of any hospitalized ESRD patient. Arteriovenous fistulae and arteriovenous grafts (AVGs) may potentially occlude during hypotension.[125] Loss of dialysis access due to complications from hypotension or potential iatrogenic causes such as restraints could

pose a severe hardship for the patient upon recovery from their current illness.[126–128] A relatively recently recognized issue is the need to avoid brachial and subclavian accesses whenever possible in patient who may currently or imminently need an arteriovenous fistula or AVG. The reason is the frequent development of venous stenosis or thrombosis that could hamper future access maturation; studies show a high prevalence of thrombosis—more than 30%—after placement of a peripherally inserted central catheter.[129] Tunneled intrajugular catheters are an appropriate option in this population.[130] Subclavian lines, even temporarily, pose similar complication risks. Currently the Kidney Disease Outcomes Quality Initiative, sponsored by the National Kidney Foundation, recommends not placing peripherally inserted central catheter lines in patients with CKD.[131]

Common causes of infection in the ESRD population are cellulitis, pneumonia, bacteremia, and pycocystitis.[132] In the absence of a clear cause of infections, a high index of suspicion for access infection should be maintained for ESRD patients presenting with unexplained sepsis if a tunneled dialysis catheter is being used. Generally, catheters do not show signs of infection. Initially, antibiotic therapy should broadly cover gram-positive and gram-negative organisms, as these are the most common organisms associated with infection.[133] Vancomycin and gentamicin, prescribed with a loading dose to achieve therapeutic targets based on local sensitivity data, are standard regimens. Considering the prevalence of methicillin-resistant *Staphylococcal aureus*, a cephalosporin only–based regimen may significantly delay effective therapy.[134] An important consideration is the patient undergoing peritoneal dialysis who still produces urine. If feasible, these patients should not receive aminoglycoside therapy to maintain their important residual renal function. Instead, a third-generation cephalosporin should be used. Whenever possible, old culture results should be used to guide initial treatment as antibiotic resistance is commonplace. When a tunnel infection is suspected in a patient receiving dialysis, as evidence by an erythematous track around the course of the catheter or purulent drainage from the tunnel itself, catheter removal should urgently occur. When an AVG is infected, urgent removal or resection should also occur. Old, occluded AVGs may represent a source for chronic indolent infections and inflammation.[135]

Ideal fluid management in ESRD patients with sepsis requires close monitoring and repeat assessments. Limited data exist to guide the clinician and, in states of classic sepsis, appropriate volume resuscitation should occur. Nonetheless, thoughtful consideration as to when to moderate fluid repletion in the intubated ESRD patient with sepsis may improve subsequent ventilator weaning.

Kidney Transplantation

Patients with a functioning kidney transplant constitute an important and growing percentage of the CKD population. Data from the 2008 U.S. Renal Data System survey show that patients with a functioning kidney transplant make up 30% of ESRD patients.[5] Infectious and cardiovascular complications are the most frequent complications requiring admission to an ICU.

The risk of infection in a kidney transplant patient is complex and related to a number of factors, including the health of the allograft, specific donor and recipient factors (such as cytomegalovirus status and time from transplant), adequate prophylaxis, up-to-date and effective vaccination, and the level of immunosuppression.[136] In the early posttransplant period, generally defined as 1 month or less, typical postoperative complications are most common, including *Clostridium difficile*–associated colitis. In months 1 through 6 after transplantation, opportunistic infections and viral infections are the predominant source of infection owing to the residual effects of induction immunosuppression. After 6 months, typical community-acquired organisms remain the primary source of infection. Infection with cytomegalovirus is an important cause of morbidity in the transplant population and may be present outside the first 6 months. Specific guidelines exist regarding prophylaxis, screening, and treatment for cytomegalovirus in the solid organ transplant patient.[137]

Drug Dosing

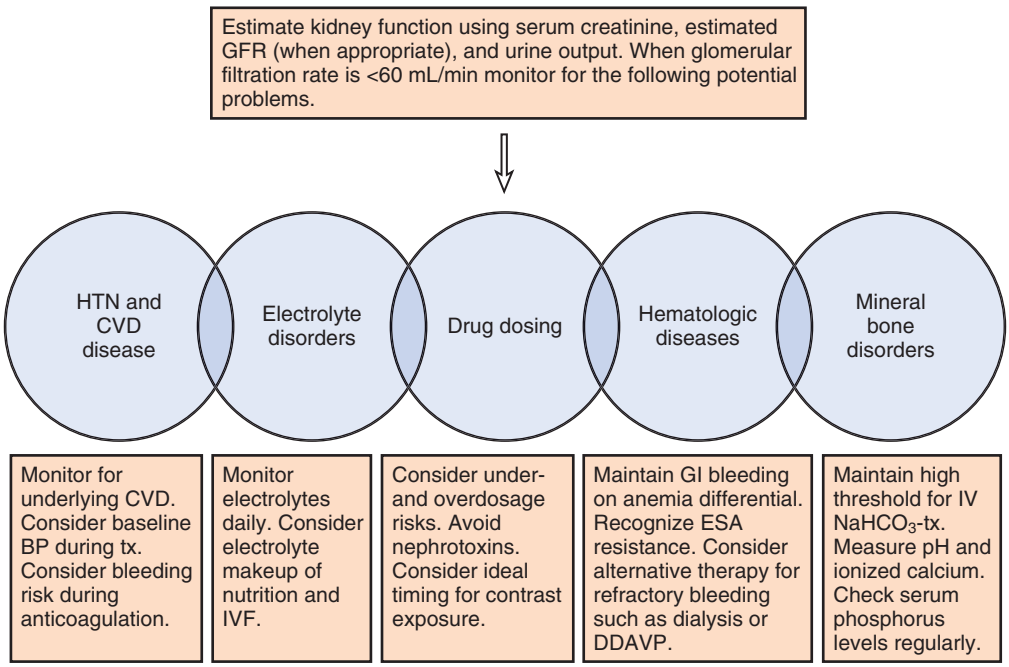
Drug dosing in patients with CKD requires close attention to current levels of kidney function and an understanding of the risks and benefits of the medication prescribed. Two points are worthy of specific attention. First, drug dosing has historically been defined by creatinine clearance and not eGFR.[138,139] The second is that patients with CKD, particularly those with advanced disease, are an understudied population in terms of medication dosing.[140] Antibiotic dosing in the critically ill patient is an area in which the balance between toxicity of overdosage needs to be balanced against the possibility of subtherapeutic dosing. Recognizing that the serum creatinine level may not reflect true GFR is an important part of this process.

Summary

The prevalence of CKD and ESRD in the ICU has increased, and this population is prone to poor outcomes. Ideal care of this population includes the recognition that serum creatinine levels may not reflect GFR, that patients are prone to volume overload and volume depletion, and that abnormalities in Hgb, pH, calcium, and phosphorus may reflect normal and not abnormal physiology. Drug dosing needs to be tailored to individuals with consideration of the risks of both underdosage and overdosage. See Fig. 53.2 for a summary of management principles for CKD.

Key Points

- Patients with CKF frequently die of cardiovascular disease; a high index of suspicion for occult cardiovascular disease should guide caregivers.
- The serum creatinine level frequently does not accurately reflect the current level of kidney function in the ICU patient.



• **Fig. 53.2** Select management principles for patients with chronic kidney disease. *BP,* Blood pressure; *CVD,* cardiovascular disease; *DDAVP,* 1-deamino-8-D-arginine vasopressin; *ESA,* erythropoietin stimulating agent; *GFR,* glomerular filtration rate; *GI,* gastrointestinal; *HTN,* hypertension; *IVF,* intravenous fluid; *$NaHCO^3$*, sodium bicarbonate; *tx,* treatment.

- CKD is associated with sodium retention and a higher prevalence of hypertension. Acute blood pressure control should take into account baseline blood pressure control to avoid tissue under perfusion.
- Electrolyte disorders, particularly hyperkalemia, in the ICU population with CKD, are frequent.
- Acute treatment of chronic metabolic acidosis may lead to iatrogenic falls in serum calcium.
- Brachial and subclavian access is relatively contraindicated in the advanced CKD and ESRD population owing to their future impact on maturing vascular access for dialysis.
- Drug dosing in patients with CKD is poorly studied. Clinicians should be aware of under dosage and over dosage potentials.

Review Questions

1. In the care of a critically ill individual with an abnormal serum creatinine level, which of the following statements *best* describes the assessment of kidney function?

a. An isolated serum creatinine level can be used to calculate the estimated glomerular filtration rate (eGFR) using the Modification of Diet in Renal Disease Study equation.

b. Stage 3a chronic kidney disease (CKD; e GFR 45–60 mL/min) has a high risk of progressing to end-stage renal disease (ESRD).

c. Proteinuria increases cardiovascular risk even at a normal GFR.

d. Serum creatinine is the most accurate measure of kidney function.

Answer: c. The measurement of kidney function using a serum creatinine level may be misleading. Patient-specific issues (size irregularities) and exogenous substances can lead to situations where serum creatinine may inaccurately reflect kidney function; other measures such as 24-hour creatinine clearance may be helpful at times. Kidney function assessment requires steady-state serum creatinine and a single value may provide an inaccurate result. Patients with stage 3a CKD do not have a high risk of kidney disease progression unless significant proteinuria is present. Proteinuria is now a recognized risk factor for cardiovascular disease at all levels of kidney function.

2. A 56-year-old male with stage 3b CKD owing to diabetic nephropathy is recovering from pneumonia. Through the course of the hospitalization he has accumulated 12 kg in weight and is hypertensive and edematous on examination. You believes he needs aggressive diuresis. An initial regimen of furosemide 40 mg intravenously (IV) twice a day (bid) does not yield a negative fluid balance. In reviewing his record, you note his creatinine level is slightly worse than on admission (currently 3.2 mg/dL; 2.4 before admission) and he was taking furosemide 80 mg bid before admission. What is the best additional step in treating his volume overload?

a. Convert furosemide to a thiazide diuretic such as chlorthalidone 25 mg daily.

b. Increase his furosemide to 80 mg IV bid.

c. Convert his furosemide to 80 mg IV daily.

d. Replace furosemide with metolazone 5 mg daily.

Answer: b. Patients with CKD who use moderate- to high-dose diuretics develop compensatory mechanisms to retain additional sodium. As a result they often require higher-dose diuretics or, on occasion, the addition of metolazone to a diuretic regimen to achieve an adequate diuresis. Thiazide diuretics such as chlorthalidone or hydrochlorothiazide are not as effective at initiating a diuresis as loop diuretics. This case illustrates an example of a volume overloaded state in which diuretics are not achieving an adequate diuresis as the result of worsening kidney function and the need for a higher dose. In a volume-overloaded state, most loop diuretics (the exception being torsemide) should be administered twice daily. Metolazone is rarely used alone.

3. You are caring for a 62-year-old male patient with stage 4 CKD (eGFR 22 mL/min) owing to polycystic kidney disease. He was admitted for sepsis attributed to an infected renal cyst. He will be completing an antibiotic course and you are asked to write orders for him to leave the ICU. Which of the following statements is *true* regarding the care of patients with stage 4 CKD?

a. A peripherally inserted central catheter (PICC) line should not be used.

b. Phosphorus-containing gastrointestinal stimulants may be used if serum phosphorus is in the normal range.

c. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) should be avoided.

d. All subjects should follow a renal diet.

Answer: a. In subjects with advanced CKD (all subjects with stage 4 disease) PICC lines are not recommended to avoid damage to the subclavian vein, which may be a site for future vascular access for dialysis. Phosphorus-containing gastrointestinal stimulants should be avoided because of the potential for a large phosphorus load to be absorbed and subsequent acute kidney injury. ACE inhibitors and ARBs are not contraindicated in advanced but stable CKD, although close attention to potassium levels is needed. Although a renal diet may control volume overload and potassium excess states, if subjects are malnourished they may not be necessary.

Acid-base, electrolyte, and metabolic disturbances are common in the intensive care unit (ICU). Indeed, critically ill patients often have compound acid-base and electrolyte disorders. Successful evaluation and management of such patients requires recognition of common patterns (e.g., hypokalemia and metabolic alkalosis) and an ability to dissect one disorder from another. This chapter is intended to provide clinicians with the tools they need for diagnosis and treatment of the acid-base, electrolyte, and metabolic disorders encountered in the care of critically ill patients. By reviewing the elements of normal physiology in these areas and presenting a general diagnostic scheme for each condition, we hope to provide readers with a foundation for approaching not only common, but novel and complex disorders.

Metabolic Disorders of Acid-Base Homeostasis

Normal acid-base balance depends on the cooperation of at least two vital organ systems: the lungs and the kidneys. The gastrointestinal (GI) tract also is implicated in many acid-base disturbances. Multiorgan system involvement, therefore, provides the backdrop for the acid-base disorders commonly seen in critically ill patients.

Normal Acid-Base Physiology

Normal biochemical and physiologic function requires that extracellular pH be maintained within a very narrow range. Although the "normal" range of pH in clinical laboratories is 7.35 to 7.45 pH units, the actual pH in vivo varies considerably less.[1] This tight control is maintained by a complex homeostatic mechanism involving buffers and the elimination of volatile acid by respiration.

The principal extracellular buffer system is the carbonic acid/bicarbonate pair. The equilibrium relationships of the components of this system are illustrated as follows[1]:

$$H_2O + CO_2 \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

From these relationships, the Henderson-Hasselbalch equation is derived:

$$pH = pK + \log_{10} \frac{HCO_3^-}{\alpha_{CO_2} \cdot P_{CO_2}}$$

where CO_2 is carbon dioxide, HCO_3^- is bicarbonate, and Pco_2 is the partial pressure of carbon dioxide. In this equation, α_{CO2} is the solubility coefficient of CO_2 (0.03), and pK is the equilibrium constant for this buffer pair (6.1). Rearrangement yields the Henderson equation:

$$H^+ = 24 \cdot \frac{P_{CO_2}}{HCO_3^-}$$

TABLE 54.1 Expected Compensation for Simple Acid-Base Disorders

Disorder	Primary Disturbance	Compensation	Magnitude	Time to Completion
Metabolic acidosis	↓ $[HCO_3^-]$	↓ PCO_2	1.5 • $[HCO_3^-]$ + 8	12–24 h
Metabolic alkalosis	↑ $[HCO_3^-]$	↑ PCO_2	0.9 • $[HCO_3^-]$ +9	12–24 h
Respiratory acidosis, acute	↑ Pco_2	↑ $[HCO_3^-]$	1 mmol/L/10 torr	<6 h
Respiratory acidosis, chronic	↑ Pco_2	↑ $[HCO_3^-]$	3.5 mmol/L per 10 torr	>5 days
Respiratory alkalosis, acute	↓ Pco_2	↓↓ $[HCO_3^-]$	2 mmol/L/10 torr	<6 h
Respiratory alkalosis, chronic	↓ Pco_2	↓ $[HCO_3^-]$	5 mmol/L per 10 torr	>7 days

HCO_3^-, Bicarbonate; Pco_2, partial pressure of carbon dioxide.

It is apparent from this equation that disturbances in the proton concentration of the extracellular fluid (ECF) (and blood) may be due to perturbation in the numerator, the denominator, or both. Disturbances that affect the Pco_2 primarily are called respiratory disturbances, and those that affect the HCO_3^- primarily are called metabolic.

Acid-base homeostasis depends on compensation for a primary disturbance. Compensation for a respiratory disturbance is metabolic, and compensation for a metabolic disturbance is respiratory. Furthermore, it is clear from the previous equations that to mitigate the change in proton concentration or pH, the direction of the compensation must be the same as the direction of the primary disturbance. Thus consumption of bicarbonate will be accompanied by hyperventilation and a consequent reduction in Pco_2. A simple acid-base disturbance is considered to consist of the primary disturbance and its normal compensation. A complex acid-base disturbance consists of more than one primary disturbance. To detect complex acid-base disturbances, one must be familiar with both the direction and magnitude of normal compensation (shown in Table 54.1).[2] More than one metabolic disturbance may coexist (e.g., metabolic acidosis and metabolic alkalosis), but only one respiratory disturbance is possible at a time.

In this section, we discuss disorders that affect the metabolic component of acid-base homeostasis: metabolic acidosis and metabolic alkalosis. Respiratory disturbances affecting acid-base balance will be discussed elsewhere (see Chapters 9–11, and 34).

Metabolic Acidosis

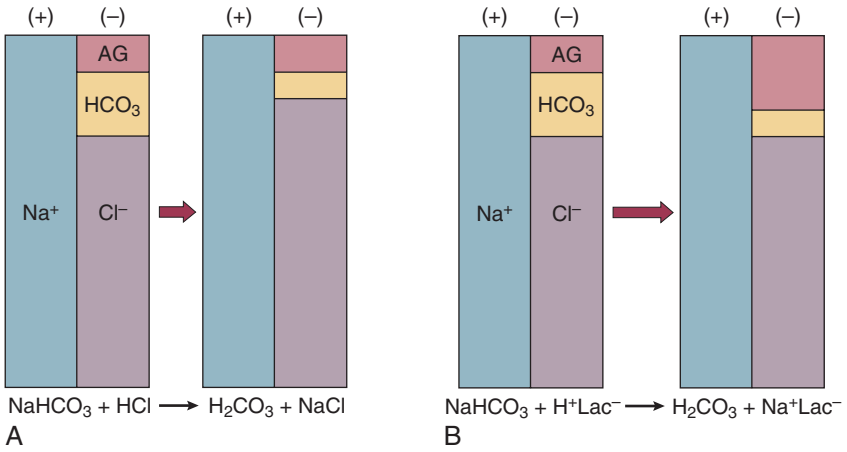
Definition and Classification

A metabolic acidosis is a process that, if unopposed, would cause acidemia (a high hydrogen ion concentration, or low pH, of the blood) by reducing the extracellular bicarbonate concentration. The extracellular bicarbonate concentration may be reduced by either addition of acid and consequent consumption of bicarbonate, or by primary loss of bicarbonate.

An adult eating a normal diet generates 16,000 to 20,000 mmol of acid per day.[3] Almost all of that acid is in the form of carbonic acid, resulting from CO_2 and water generation in the metabolism of carbohydrates and fats. Individuals with normal ventilatory capacity eliminate this prodigious acid load through the lungs, thus the term volatile acid. The remainder of the daily acid load, about 1 mmol/kg body weight per day, derives from metabolism of phosphate- and sulfate-rich protein (yielding phosphoric and sulfuric acid). These nonvolatile, or fixed, acids are buffered primarily by extracellular bicarbonate under normal circumstances. The kidneys are responsible for regenerating the consumed bicarbonate by secreting hydrogen ions (protons) in the distal nephron. These secreted protons must be buffered in the tubule lumen to allow elimination of the daily fixed acid load within the physiologic constraint of the minimum urinary pH. The urinary buffers are composed of the filtered sodium salts of the phosphoric acid, and ammonia, which is synthesized in the proximal tubule and acidified in the collecting duct to form ammonium (NH_4^+). Under conditions of acid loading, the normal kidney reabsorbs all the filtered bicarbonate in the proximal tubule. Urinary net acid excretion therefore consists of phosphoric acid (so-called titratable acidity, because it is quantified by titrating the urine with alkali to pH 7.40) and ammonium, less any excreted bicarbonate.[4]

Many factors modify the kidney's capacity to regulate acid-base balance. For example, renal ammoniagenesis is stimulated by acidemia, and inhibited by alkalemia, and thus participates in a homeostatic feedback loop.[1] Hyperkalemia inhibits and hypokalemia stimulates renal ammoniagenesis. Hypokalemia further stimulates acid secretion by activating the sodium-hydrogen (Na^+-H^+) exchanger in the proximal tubule and the hydrogen ion (H^+), potassium ion–adenosine triphosphatase (K^+-ATPase) in the collecting duct. Finally, aldosterone stimulates both proton and K^+ secretion in the collecting duct. For these reasons, hypokalemia tends to perpetuate a metabolic alkalosis, and hyperkalemia a metabolic acidosis.[1]

Metabolic acidosis can be caused by excessive production of fixed acid, decreased renal secretion of fixed acid, or loss of bicarbonate, either through the kidney or through the intestine.[4] The net effect of any of these processes is a reduction in the blood bicarbonate concentration. The plasma anion gap helps to distinguish among the various causes of metabolic acidosis. Of course, because of charge neutrality, the sum of the concentration of all cations in the plasma is equal to the sum of all the anions. By convention, however, the anion gap is defined as the difference between the plasma sodium concentration and the sum of the bicarbonate and chloride concentrations. It represents the concentration of anions that are normally unmeasured by a basic metabolic chemistry panel.[5] The anion gap normally is about 8 mmol/L, but it varies widely according to the methods used by the clinical chemistry laboratory.[6] The anion gap is composed mainly of albumin, along with phosphates, sulfates, and organic anions.



• **Fig. 54.1** The generation of hyperchloremic and anion-gap *(AG)* acidoses. Blocks represent the ionic composition of the plasma, cations (+) to the left and anions (–) to the right. In each of the panels (A and B), the bar to the left represents the basal or normal state. The anion gap is shown in red. Panel A shows the change in the ionic composition of the plasma when hydrochloric acid *(HCl)* is added. The chloride concentration increases as bicarbonate is consumed. Panel B shows the effect of addition of an organic acid such as lactic acid *(H^+Lac^-),* in which case the bicarbonate is consumed and the AG increases proportionately. *Cl,* Chloride; *H_2CO_3,* carbonic acid; *Na,* sodium; *$NaHCO_3$,* sodium bicarbonate.

There are two important pitfalls in the interpretation of the anion gap. First, because the anion gap is proportional to the plasma albumin concentration, hypoalbuminemia (common in critically ill patients) will lower the "baseline" anion gap (by approximately 2.5 mmol/L for each gram per deciliter decline in the albumin concentration).[7] Thus profound hypoalbuminemia may falsely lower the anion gap, and thus mask a high anion gap acidosis. Second, alkalemia increases the anion gap, by causing lactate generation and by titrating plasma buffers, most notably albumin.[8] (Thus in respiratory alkalosis, the bicarbonate concentration will be low in compensation, and the anion gap may be elevated, giving a false impression of a high anion gap metabolic acidosis by inspection of the electrolytes alone.)

If bicarbonate is lost (e.g., through diarrhea) or hydrochloric acid is gained (e.g., renal tubular acidosis or administration of unbuffered amino acid solutions[9]), the bicarbonate concentration falls with a commensurate increase in the plasma chloride concentration; thus the anion gap is unchanged. If, on the other hand, bicarbonate is lost in buffering an organic acid such as lactic acid or a ketoacid, the decrement in the bicarbonate concentration is more or less matched by an increase in the anion gap. These processes are illustrated in Fig. 54.1.

Box 54.1 lists the causes of hyperchloremic metabolic acidosis. Two diagnoses are of particular interest in the critical care arena. First is the posthypocapnic metabolic acidosis, in which bicarbonate falls in compensation for a chronic respiratory alkalosis. When "normal" ventilation is restored, the pH falls until bicarbonate can be retained, giving the appearance of a hyperchloremic metabolic acidosis. This emphasizes the importance of observation over time in the analysis of acid-base status. The second entity of interest is a so-called dilutional hyperchloremic acidosis. This is seen in patients who are rapidly resuscitated with large volumes of isotonic saline solution. The acidosis traditionally has been attributed to dilution of blood bicarbonate. Analysis based on physical-chemistry principles, however, may better explain the phenomenon (see later text).[10]

The differential diagnosis of high anion gap metabolic acidosis is limited (Box 54.2). The most common cause in critically ill patients is a lactic acidosis. The causes of lactic acidosis are numerous. As shown in Box 54.3, they are divided into type A (imbalance between tissue oxygen demand and supply) and type B (all others).[5] Diabetic ketoacidosis (see Chapter 55) and intoxications (see Chapter 65) are discussed elsewhere. Two causes of high anion gap acidosis recently added to the differential diagnosis, and of particular relevance to intensivists, are pyroglutamic acidosis and intoxication with propylene glycol.

• BOX 54.1 Causes of Hyperchloremic Metabolic Acidosis

Extrarenal Loss of Base
Diarrhea
Pancreatic fistula
Ureteral diversion

Extrarenal Gain of Acid
Ammonium chloride
Hydrochloric acid
Sodium chloride
Toluene inhalation (glue sniffing)

Renal Loss of Base
Type II renal tubular acidosis
Posthypocapnic state
Excretion of organic anions (bicarbonate precursors)

Renal Acid Excretory Defect
Type IV renal tubular acidosis
- Chronic kidney disease
- Hypoaldosteronism
- Urinary tract obstruction

Type I renal tubular acidosis
- Sickle cell nephropathy
- Lupus nephritis
- Renal transplant

• BOX 54.2 Causes of High Anion-Gap Metabolic Acidosis

Ketoacidoses
- Diabetic
- Alcoholic
- Starvation

Intoxications
- Methanol
- Ethylene glycol
- Propylene glycol
- Salicylate

Pyroglutamic acidosis
- Congenital
- Acquired

Lactic acidosis (see Box 54.3)

Uremic acidosis

• BOX 54.3 Causes of Lactic Acidosis

Type A (Tissue Oxygen Supply: Demand Mismatch)

Decreased tissue oxygen delivery
- Shock
- Hypoxemia
- Severe anemia
- Carbon monoxide poisoning

Increased tissue oxygen demand
- Grand mal seizure
- Extreme exercise

Type B

Impaired oxygen utilization
- Cyanide poisoning
- Linezolid
- Metformin
- Antiretroviral agents (nucleosides and nucleoside reverse transcriptase inhibitors [NRTIs])
- Acetaminophen

Excessive lactate production
- Sepsis
- HIV infection
- Alcohols (EtOH, MeOH, ethylene glycol, propylene glycol, sorbitol)
- Propofol
- Diabetes mellitus
- Alkalemia
- Malignancy
- Pheochromocytoma
- Sorbitol/fructose
- Thiamine deficiency
- Congenital enzyme defects (tricarboxylic acid cycle, pyruvate transport)

Decreased lactate metabolism
- Liver failure

D-lactic acidosis

EtOH, *Ethanol;* MeOH, *methanol;* HIV, *human immunodeficiency virus.*

Pyroglutamic acid is a metabolic intermediate in the γ-glutamyl cycle, one product of which is glutathione. Pyroglutamic acidosis may be congenital (caused by one of several enzyme deficiencies) or acquired.[8] The acquired syndrome may be caused by acetaminophen (which depletes glutathione, leading to uninhibited pyroglutamic acid synthesis), certain antibiotics, or glycine deficiency. The acidosis may be profound and the anion gap greater than 30 mmol/L.[11] Definitive diagnosis is made by urinary screening for organic acids. In practice, however, circumstantial evidence suggests the acquired syndrome and the diagnosis are supported by a favorable response to appropriate intervention.

Propylene glycol is a solvent for medications, many of which (such as lorazepam, nitroglycerine, etomidate, and phenytoin) are commonly infused intravenously in critically ill patients. Propylene glycol is metabolized by alcohol dehydrogenase to lactic acid. High anion gap acidosis has been associated with high- and even low-dose infusions, particularly of lorazepam.[7,12] Thus development of a high anion gap acidosis in a critically ill patient should prompt a search for a source of propylene glycol because withdrawal of the agent will promptly alleviate the acidosis.

Consequences of Acidemia

It has been generally accepted that severe acidemia (pH < 7.20) is associated with a variety of deleterious effects. Of particular concern are the cardiovascular effects, including pressure-resistant arterial vasodilation, venoconstriction, diminished myocardial contractility, and impaired hepatic and renal perfusion.[13] (Some controversy exists as to which of these effects are directly caused by acidemia.[4]) A predisposition to malignant arrhythmias has been reported in vitro and in animal models. Finally, numerous metabolic derangements have been attributed to the effect of acidemia on key enzymes in metabolic pathways, resulting in sympathetic hyperactivity with diminished catecholamine responsiveness; insulin resistance and suppressed glycolysis; and reduced hepatic lactic acid uptake and metabolism.[14]

Diagnosis of Acid-Base Disorders

Acid-base disorders are revealed most commonly through the basic metabolic chemistry panel, when the plasma bicarbonate concentration is noted to be outside the normal range. If the bicarbonate is low, and if the anion gap is clearly elevated on that sample, a diagnosis of high anion gap metabolic acidosis can be made with some confidence, keeping in mind the pitfalls in the interpretation of the anion gap mentioned previously.[7]

If the bicarbonate is low and the anion gap normal, two possibilities exist: either a hyperchloremic metabolic acidosis or a respiratory alkalosis with metabolic compensation. These two entities can be distinguished by examination of the blood pH and blood gases; a low pH is diagnostic of the former.

If the bicarbonate concentration is high, again there are two alternative diagnoses requiring blood pH measurement for their differentiation: either a metabolic alkalosis or metabolic compensation for a respiratory acidosis.

Once the primary disturbance has been identified, the astute clinician, recognizing the possibility of a mixed disturbance, is obligated to ask, "Is that all there is?" This question can be answered only by an understanding of the rules of normal compensation for simple acid-base disorders (see Table 54.1).[2] Knowing at least the expected direction of compensation allows the clinician to diagnose the most obvious mixed disturbances. For example, if the pH is low, the bicarbonate is low, and the Pco_2 is above 40 torr, there is clearly a mixed metabolic and respiratory acidosis. Similarly, if the pH is high, the bicarbonate is high and the Pco_2 is below 40 torr, the diagnosis is a mixed respiratory and metabolic alkalosis. More subtle mixed disorders can be diagnosed only by understanding not only the expected direction, but the expected magnitude of compensation. This allows one to conclude, for example, whether the hyperventilation in a patient with metabolic

acidosis is appropriate (expected compensation), inadequate (a separate respiratory acidosis), or excessive (a separate respiratory alkalosis).

The preceding method permits the diagnosis of simple and dual acid-base disorders. Triple acid-base disorders can be diagnosed only by comparing the change in the anion gap with the change in the plasma bicarbonate concentration. Most simply conceived, the fall in the bicarbonate should roughly equal the rise in the anion gap (see Fig. 54.1). If the rise in the anion gap exceeds the fall in the bicarbonate, a metabolic alkalosis is said to be present in addition to the high anion gap acidosis. Conversely, if the fall in the bicarbonate exceeds the rise in the anion gap, mixed hyperchloremic and high anion gap acidoses are said to coexist. Although this analysis is useful in the case of large discrepancies, in more subtle cases it is confounded by theoretical and practical considerations.[5,15]

Note that the plasma bicarbonate concentration may be completely normal in the setting of complex countervailing acid-base disturbances—for example, the high anion gap acidosis and a metabolic alkalosis seen in a patient with diabetic ketoacidosis (DKA) and vomiting. Thus important acid-base disturbances may be overlooked unless clinicians routinely calculate the anion gap when caring for critically ill patients.

The classical approach to acid-base disorders previously described has been challenged recently by proponents of a physical-chemistry approach described originally by Stewart.[16] According to this method, the pH of the blood depends on the ionization of water by the difference in the concentration of so-called strong ions (the strong ion difference [SID]). The SID offers a quantitative approach to measuring the degree of acidosis in hyperchloremic metabolic acidosis. Although there is evidence that this approach may have prognostic capabilities in patients with severe sepsis and septic shock with hyperchloremic metabolic acidosis, the complexity of the equations for calculating the SID makes this method cumbersome in clinical settings.[17] The main utility of this construct in the critical care setting seems to be its explanation of a hyperchloremic metabolic acidosis in patients who receive large volumes of isotonic saline solution.

Treatment of Metabolic Acidosis

Although severe acidemia has not been definitively determined to be deleterious to patients, blood pH < 7.10 leaves little room for additional acid burden without a precipitous fall in pH. Therefore most clinicians favor treating metabolic acidosis with blood pH ≤ 7.10. Any respiratory contribution to the acidemia must be corrected before administering alkali.

Treatment of hyperchloremic metabolic acidosis is straightforward. In cases of acute metabolic acidosis, treatment depends on successful therapy of the underlying cause (e.g., diarrhea) and reduction of the bicarbonate deficit.

Sodium bicarbonate is the alkalinizing agent of choice for most patients with severe acidemia. Alternative alkalinizing agents such as salts of citrate, acetate, and lactate, which under normal circumstances are oxidized in the liver to bicarbonate, should not be used to treat acidemia in patients with suspected or confirmed hepatic impairment or circulatory compromise. Bicarbonate dosing must be empirical because the bicarbonate deficit is not calculable in practice.[18] Rapid infusion of undiluted ampoules of sodium bicarbonate (1000 mmol/L) is recommended for patients with severe acidemia. The goal is to raise the blood pH no higher than 7.20. Excessive bicarbonate administration, or bicarbonate administration to patients with high circulating concentration of metabolizable conjugate bases such as ketones or lactate, runs the risk of overshoot alkalemia. Administration of undiluted ampules will tend to cause hyperosmolality, the risk of which may be mitigated by administration of sodium bicarbonate as an isotonic solution (e.g., 150 mmol sodium bicarbonate in 1 L of water). Large volumes of any bicarbonate solution can lead to volume overload, a reduction in the ionized calcium concentration (see "Hypocalcemia") and increased generation of CO_2. This last effect causes a respiratory acidosis in patients whose ventilation cannot increase. Plasma electrolytes and blood gases must be monitored frequently to guide adjustments in the composition of the solution and its rate of infusion.

Tris-hydroxymethyl aminomethane, or THAM, is an amino alcohol that buffers without generating CO_2. It has the advantage, therefore, of avoiding a superimposed respiratory acidosis. It has been used successfully in animals and humans with various metabolic acidoses.[13,19] It is eliminated by the kidney, and thus should be used with caution in the setting of renal insufficiency. Risks include hyperkalemia, hypoglycemia, and hepatic necrosis (in neonates).[7]

The treatment of choice for lactic acidosis is reversal of the underlying cause of the acidosis (see Box 54.3). Pending resolution of the underlying disorder, however, the intensivist is often confronted with an unstable patient who is profoundly acidemic. Treatment at this stage is controversial.[20] The debate has focused on the potentially deleterious effects of bicarbonate administration in lactic acidosis.[13,21] In addition to the effects already mentioned, bicarbonate in animal models of lactic acidosis has been associated with increased lactate generation, reduction in intracellular pH, increased venous Pco_2, and reduction in cardiac output. (This last effect correlates well with the reduction in ionized calcium concentration.[13]) Studies in humans, though few, likewise show no improvement in cardiac output, morbidity or mortality with bicarbonate.[22] Continuous hemodialysis (e.g., continuous venovenous hemodialysis) may be a promising tool for treating lactic acidosis, because it provides large amounts of bicarbonate without the risks of volume overload or hypocalcemia. Metformin-associated lactic acidosis is particularly amenable to treatment with renal replacement therapy because it removes the culprit toxin.[23] Treatment of DKA and the acidoses associated with other intoxications are discussed in Chapters 55 and 65, respectively.

Metabolic Alkalosis

Definition and Classification

Metabolic alkalosis is a process leading to accumulation of extracellular bicarbonate which, if unopposed, will result in an increase in the plasma pH (alkalemia). In its pure form, it is accompanied by compensatory hypoventilation (CO_2 retention).[2]

From a pathophysiologic perspective, metabolic alkalosis is divided into those factors that generate the alkalosis and those factors that maintain or perpetuate it.[24,25] Metabolic alkalosis is generated by addition of bicarbonate to the blood. This can occur either by loss of acid from the body or by addition of exogenous alkali. Loss of acid may be from the stomach (e.g., vomiting or gastric suction) or kidney. Renal acid loss is enhanced by a high rate of sodium delivery to the distal nephron, high circulating mineralocorticoid levels, potassium depletion, and high rates of renal ammoniagenesis.

Because of the kidney's prodigious ability to excrete bicarbonate, however, addition of bicarbonate to the blood is not sufficient to cause a sustained metabolic alkalosis. Some mechanism(s) to

maintain the alkalosis must prevail. The most common mechanism contributing to the maintenance of metabolic alkalosis is volume depletion, either absolute or relative (e.g., congestive heart failure), which (1) reduces glomerular filtration, (2) enhances tubular bicarbonate reabsorption, and (3) causes secondary hyperaldosteronism, further enhancing urinary acidification. Another common perpetuating factor is potassium depletion, which stimulates proton secretion at several sites along the nephron.

Patients with metabolic alkalosis and signs of volume expansion—especially hypertension—usually have excess mineralocorticoid as the explanation for the metabolic alkalosis. Aldosterone and glucocorticoids (other than dexamethasone) stimulate renal loss of acid and K, and thereby generate and maintain the alkalosis.

Given the pathophysiology described, it is useful to approach the patient with metabolic alkalosis with special attention to the ECF volume status, centering on the history and physical examination, followed by sequential analysis of blood chemistries.[26] Causes of metabolic alkalosis are shown in Box 54.4. One entity unique to critically ill patients is the posthypercapnic metabolic alkalosis. This syndrome is caused by abrupt treatment (usually with tracheal intubation and mechanical ventilation) of a patient with chronic respiratory acidosis. The renal bicarbonate retention that compensated for the chronic respiratory acidosis persists (because of volume depletion) after restoration of a normal Pco_2, resulting in the high pH and high plasma bicarbonate characteristic of metabolic alkalosis. The key to the diagnosis is the history and sequential analysis of blood chemistries.[24]

• BOX 54.4 Causes of Metabolic Alkalosis

Intravascular Volume Depletion, Absolute or "Effective"

Gastrointestinal acid loss
- Vomiting or nasogastric suction
- Villous adenoma
- Chloride diarrhea

Renal acid loss
- Diuretics (loop, thiazide)
- Bartter syndrome
- Gitelman syndrome
- Magnesium depletion
- Posthypercapnic state
- Congestive heart failure
- Hepatic cirrhosis/ascites

Intravascular Volume Expansion

High renin, high aldosterone
- Renal artery stenosis
- Accelerated hypertension
- Renin-secreting tumor

Low renin, high aldosterone
- Primary aldosteronism

Low renin, low aldosterone
- Cushing syndrome or disease
- Exogenous mineralocorticoid
- Apparent mineralocorticoid excess syndrome
- Liddle syndrome

Renal insufficiency
- Exogenous alkali load
- Milk-alkali syndrome

Modified from Gennari FJ. Pathophysiology of metabolic alkalosis: a new classification based on the centrality of stimulated collecting duct ion transport. Am J Kidney Dis. *2011;58:626–636.*

Clinical Consequences

Alkalemia in critically ill patients is associated with increased mortality.[27] Patients with combined metabolic and respiratory alkalosis have a higher mortality than those with respiratory alkalosis alone, and mortality in alkalemia is roughly proportional to the pH.[27] Although no causal relationship between alkalemia and mortality has been established, the pathophysiology of alkalemia is far from benign.[25] First, metabolic alkalosis suppresses ventilation, causing CO_2 retention and relative hypoxemia.[28] Second, alkalemia acutely increases hemoglobin's oxygen affinity (Bohr effect). Third, alkalemia causes vasoconstriction, particularly in the cerebral circulation.[25] All these processes tend to decrease tissue oxygen delivery.[29] (Note that chronic alkalemia inhibits 2,3-diphosphoglycerate synthesis, allowing normalization of the oxyhemoglobin desaturation curve, mitigating tissue hypoxia to some extent.) These alterations in tissue oxygen delivery could be responsible at least in part for some of the clinical manifestations of metabolic alkalosis.

Because alkalemia causes a decrease in ionized calcium concentration (see "Calcium"), many of the neuromuscular manifestations of metabolic alkalosis overlap with those of hypocalcemia, including paresthesias, tetany, and a predisposition to seizures.[1] The acutely diminished tissue oxygen delivery to the brain may contribute to the initial confusion and obtundation seen with metabolic alkalosis.

Metabolic alkalosis often is accompanied by hypokalemia and hypomagnesemia. Thus there is an association between alkalosis and arrhythmias,[24] but an independent effect of the alkalosis on cardiac arrhythmogenesis has not been established.

Increases in blood lactate concentration may occur in patients with metabolic alkalosis owing to upregulation of phosphofructokinase and thus glycolysis, and because of tissue hypoxia (see earlier text).[8] With severe metabolic alkalosis (arterial pH >7.55), the tissue hypoxia may be so marked that compensatory hypoventilation will be overridden by hypoxic drive, resulting in a normal to low arterial Pco_2 and elevated blood lactate levels (so-called lactic alkalosis).[30]

Treatment

Treatment of metabolic alkalosis entails correcting the factor(s) responsible for its maintenance, and, if possible, correcting the factor that generated the alkalosis. Once the underlying diagnosis is clear (see Box 54.4), therapy is usually straightforward. If the metabolic alkalosis is maintained by chloride depletion and ECF volume contraction, the intravascular volume should be restored to normal, usually with intravenous isotonic saline solution.[24,25] Potassium should be given, as potassium chloride (KCl), to replace any deficits (see "Disorders of Potassium Homeostatis") because potassium depletion perpetuates the metabolic alkalosis. If gastric suction cannot be stopped, acid loss can be reduced by the use of histamine H_2 blockers and proton pump inhibitors.

Treating patients with metabolic alkalosis in the setting of volume overload and diminished effective circulating volume (e.g., congestive heart failure, hepatic cirrhosis) is more challenging, because infusion of saline solution is contraindicated. Unless hyperkalemia is present, chloride should be replenished with KCl supplementation. In rare cases of concurrent hyperkalemia and metabolic alkalosis, acetazolamide (a carbonic anhydrase inhibitor) may be of benefit as it produces a bicarbonate diuresis. Acetazolamide should be avoided in patients with hypokalemia, because the alkaline diuresis will cause renal potassium wasting and worsen the hypokalemia.[24] Another potential complication of acetazolamide administration,

particularly in patients with impending ventilatory failure, is worsening of hypercapnia due to inhibition of red blood cell carbonic anhydrase and impaired CO_2 transport.[25] Hydrochloric acid infusion, as a 0.1- to 0.25-N solution, has been used with success in patients with severe metabolic alkalosis (pH > 7.55 and systemic instability such as encephalopathy or cardiac arrhythmia[24]) refractory to conventional measures.[25,31] Correction of the metabolic disturbances has been reported with infusion of 0.25-N HCl at 100 mL/h over about 12 hours.[31] Extreme care must be taken to ensure that the infusion catheter is properly positioned within the vena cava because the solution is highly caustic. Plasma chemistries must be monitored frequently to avoid over-correction. If renal function is severely impaired or medical therapy is not possible, hemodialysis against a low-bicarbonate bath may be used.[24]

In states of primary mineralocorticoid excess, an aldosterone antagonist such as spironolactone should be used until the underlying abnormality can be corrected. Other potassium-sparing diuretics, such as amiloride and triamterene, are useful as well and are essential in managing the rare patient with Liddle syndrome.

Disorders of Potassium Homeostasis

Normal Potassium Physiology

Disorders of potassium homeostasis are common in hospitalized patients and may be associated with severe adverse clinical outcomes, including death.[32,33] Prevention and proper treatment of hyperkalemia and hypokalemia depend on an understanding of the underlying physiology.

The total body potassium content of a 70-kg adult is about 3500 mmol, of which only 2% (about 70 mmol) is extracellular.[34] This uneven distribution reflects the large gradient between the intracellular potassium concentration (K_i ~ 140 mmol/L) and the extracellular potassium concentration (K_e ~ 4.5 mmol/L), a gradient that is maintained by the intrinsic ion permeability of cell membranes and by Na-K ATPase, the sodium-potassium pump.[35] The K_e:K_i ratio largely determines the resting membrane potential of cells and thus is crucial for proper function of excitable tissues (muscle and nerve).[35] Small absolute changes in K_e will perturb the ratio significantly. Therefore disturbances of K_e (measured as changes in plasma potassium concentration, or P_K) may have serious, even lethal, consequences mainly in the form of excitable tissue dysfunction.

It is not surprising, therefore, that the extracellular potassium concentration is tightly regulated. In fact, two separate and cooperative systems participate in potassium homeostasis. One system regulates external potassium balance: the total-body parity of potassium elimination with potassium intake. The other system regulates internal potassium balance: the distribution of potassium between the intracellular and ECF compartments. This latter system provides a short-term defense against changes in the P_K that might otherwise result from total-body potassium losses or gains.

Regulation of Internal Potassium Balance

Internal potassium balance protects against changes in K_e; potassium tends to move out of cells during potassium depletion and into cells following potassium intake. This process tends to mitigate short-term fluctuations in K_e:K_i.[36,37] The factors that influence internal potassium balance include hormones, acid-base status, plasma tonicity, exercise, and cell integrity (Box 54.5).

The direction and magnitude of an acid-base–related change in P_K depend on the nature and the duration of the disturbance.[38]

• BOX 54.5 Factors Affecting Internal Potassium Balance

Factors Causing Cellular Potassium Influx

Insulin
β_2-Adrenoceptor agonist
(Metabolic alkalosis)[a]

Factors Causing Cellular Potassium Efflux

Cell ischemia/lysis
Exercise
Plasma hypertonicity
α-Adrenoceptor agonist
(Metabolic acidosis)[a]

[a]*Factors shown in parentheses have a minor or variable effect. See text.*

The most consistent and pronounced relationship between changes in pH and P_K occurs in acute mineral (hyperchloremic) acidosis, in which there is a strong inverse relationship between these two variables.[39,40] Interestingly, hypokalemia is seen with prolonged mineral acidosis in patients with normal renal function and reflects increased renal potassium excretion.[40] Unlike mineral acidoses, however, even severe acute organic (high anion gap) acidoses are not usually associated with hyperkalemia.[41–44] Nonetheless, factors coincident with the acidosis may alter P_K. For example, mesenteric ischemia may result in both lactic acidosis (from anaerobic metabolism) and hyperkalemia owing to potassium efflux from ischemic tissue. Even the hyperkalemia so commonly seen in patients with DKA does not result from the acidemia; rather, it appears to be a consequence of the characteristic insulin deficiency and hyperglycemia (see the next paragraph on hypertonicity).[44] Respiratory disturbances typically alter P_K less than metabolic disturbances. Alkaloses, respiratory or metabolic, have less effect on P_K than their corresponding acidosis.[39] Bicarbonate administration, which was once thought to reduce the P_K by stimulating cellular potassium uptake,[45] is now known to have very little if any immediate effect on internal potassium balance,[46,47] except perhaps in patients with preexisting severe metabolic acidosis.[41] It is clear, however, that long-standing alkalemia causes urinary potassium losses that may, over time, result in profound potassium depletion.[48]

Hypertonicity, as seen with hypertonic fluid administration[49] or diabetic hyperglycemic states,[50] leads to hyperkalemia, probably as a result of convective potassium efflux from cells by way of solvent drag. Lethal hyperkalemia has been attributed to this phenomenon in diabetic patients with end-stage renal disease.[51]

Exercise causes a transient shift of potassium out of cells. Clinically significant hyperkalemia may result from exercise[52,53] (and clinically misleading local venous hyperkalemia results from fist clenching during phlebotomy[54]).

Regulation of External Potassium Balance

In contrast to the prodigious capacity of the kidney to excrete potassium,[55] renal potassium conservation is imperfect and explains why significant potassium depletion and hypokalemia may result from dietary potassium deficiency alone.[56]

Normally, 90% to 95% of dietary potassium is eliminated through the kidney, and only about 5% to 10% through the intestine. It is the kidney that is almost entirely responsible for matching potassium output to potassium intake to maintain total

body potassium constant.[57] The majority of potassium excreted by the kidney derives from potassium secretion in the distal nephron (late distal tubule and collecting duct).[57] Virtually all regulation of potassium excretion takes place at this site in the nephron, under the influence of two principal factors: the rate of flow and sodium delivery through that part of the nephron, and the effect of aldosterone.[57] Potassium secretion is directly proportional to flow rate and sodium delivery through the distal nephron, explaining in part why diuretic use often is accompanied by hypokalemia.

Metabolic acidosis with acidemia results in inhibition of renal potassium secretion.[41] In contrast, metabolic alkalosis and bicarbonate delivery to the distal nephron stimulate kaliuresis by increasing the electrochemical driving force for potassium secretion.[57] Other anions that are poorly reabsorbed in the distal nephron (e.g., synthetic penicillins) have a similar effect to stimulate potassium secretion.[58]

It is well established that aldosterone participates in a homeostatic feedback loop with P_K such that increases in P_K stimulate adrenal aldosterone production, which in turn reduces P_K primarily by stimulating renal potassium excretion.[57] Hypokalemia is a prominent feature of primary aldosteronism (Conn syndrome) because the high circulating aldosterone levels are accompanied by volume expansion and thus a high rate of sodium delivery to the distal nephron. When circulating aldosterone levels are high owing to volume depletion (secondary aldosteronism), the increase in distal potassium secretion is offset by a decrease in distal nephron flow, thus mitigating renal potassium loss. Indeed, it is usually when patients with secondary hyperaldosteronism (e.g., in congestive heart failure or hepatic cirrhosis) are treated with diuretic drugs that distal nephron flow is increased and hypokalemia may ensue.

The effect of dexamethasone (a pure glucocorticoid) to enhance renal potassium excretion appears to result entirely from hemodynamic changes that cause an increase in glomerular filtration rate and distal flow rate. All other glucocorticoids tend to further stimulate potassium secretion in proportion to their mineralocorticoid activity.[57]

Magnesium deficiency is associated with renal potassium wasting and may result in severe potassium depletion.[59] Because magnesium, like calcium, acts to stabilize excitable membranes, the deleterious effects of hypokalemia on the myocardium are magnified by concurrent hypomagnesemia (see later "Clinical Manifestations of Potassium Imbalance").[60]

Disorders of Potassium Homeostasis

Disorders of potassium homeostasis may be conveniently divided according to the duration of the disturbance: acute (<48 hours' duration) or chronic. Such a distinction is particularly applicable to the medical intensive care setting where blood chemistries are sampled frequently and a patient's condition and therapy may change radically over a short time. In addition, the approach to treatment varies according to the acuity of the disturbance. The treatment of acute disturbances is largely independent of their cause, whereas the rational treatment of chronic disturbances depends on understanding their pathogenesis.

Acute Hyperkalemia (Box 54.6)

Excessive Potassium Intake

Given an acute potassium load, a normal individual will excrete about 50% in the urine and transport about 90% of the remainder into cells over 4 to 6 hours.[61] It is possible to overwhelm the adaptive mechanisms such that if too much potassium is taken in too quickly, significant hyperkalemia will result. Such events are almost always iatrogenic (i.e., overly aggressive potassium replacement therapy).[62] One's ability to tolerate a potassium load declines with disordered internal balance (see later text) and impaired renal potassium excretory capacity.[63] In such circumstances, an otherwise tolerable increase in potassium intake may cause clinically significant hyperkalemia. Doses of oral potassium supplements as small as 30 to 45 mmol have resulted in severe hyperkalemia in patients with impaired external or internal potassium homeostasis.[64]

KCl, used as a supplement, is the drug most commonly implicated in acute hyperkalemia.[63,65] Banked blood represents a trivial potassium load under most circumstances, because a unit of fresh banked blood—either whole or packed cells—contains only about 7 mmol of K.[66] (The potassium concentration in banked blood does increase substantially as the blood ages, however, as a result of potassium egress from older erythrocytes.[67]) Thus severe hyperkalemia would result only from massive transfusion of compatible blood.[67,68] Infants[69] or patients with impaired renal potassium excretory capacity may develop hyperkalemia from an otherwise tolerable transfusion.

Patients undergoing open heart surgery are exposed to cardioplegic solutions containing KC1, typically at about 16 mmol/L,[70] which may lead to clinically significant hyperkalemia in the postoperative period, especially in patients with diabetes mellitus with or without renal failure.[71]

Abnormal Potassium Distribution

Acute hyperkalemia may result from sudden redistribution of intracellular potassium to the extracellular space. If only 2% of intracellular potassium were to leak unopposed from cells, P_K would immediately double. Fortunately, such dramatic circumstances are rarely encountered. Nevertheless, smaller degrees of potassium redistribution commonly result in clinically significant hyperkalemia.

• BOX 54.6 Causes of Acute Hyperkalemia

Excessive Potassium Intake

Oral
Intravenous
Blood transfusion
Cardioplegic solutions

Transcellular Potassium Shift

With acute renal failure
  Rhabdomyolysis
  Tumor lysis syndrome
Tissue infarction
  Mesenteric
  Limb
Hypertonicity
  Hyperglycemia
Metabolic acidosis
Drug-induced
  Digitalis intoxication
  Succinylcholine
Hyperkalemic periodic paralysis
Pseudohyperkalemia
  Thrombocytosis
  Leukocytosis
  In vitro hemolysis
  Fist clenching with phlebotomy

Among the most impressive syndromes associated with acute hyperkalemia are those involving rapid cell lysis. The tumor lysis syndrome results from treatment of chemosensitive bulky tumors with release of intracellular contents, including potassium, into the ECF.[72] Extreme hyperkalemia even causing sudden death[73] has featured prominently in some series of patients. Most such patients were in renal failure from acute uric acid nephropathy, thus impairing their ability to excrete the potassium load.[73] Rhabdomyolysis, either traumatic or nontraumatic, may result in sudden massive influx of potassium to the extracellular space.[74] Hyperkalemia is present in about 40% of patients upon presentation with rhabdomyolysis[75] and is more common among patients whose course is complicated by oliguric acute renal failure.[76] Alcohol[75] and cocaine[77] are commonly implicated in the development of rhabdomyolysis. Extreme hyperkalemia in this latter context has been reported.[78] Statin drugs are frequently associated with rhabdomyolysis,[79] rarely causing extreme hyperkalemia.[80] Other circumstances that may result in redistributive hyperkalemia include severe extensive burns, hemolytic transfusion reactions, and mesenteric ischemia or infarction.

Pharmacologic Agents

Several drugs may rarely cause acute hyperkalemia by redistribution: digitalis glycosides and succinylcholine. Massive digitalis overdose has been associated with extreme hyperkalemia.[81,82] Succinylcholine depolarizes the motor end plate and in normal individuals causes a trivial amount of potassium leak from muscle, resulting in an increase in P_K by about 0.5 mmol/L.[83] In patients with neuromuscular disorders, muscle damage, or prolonged immobilization, however, muscle depolarization may be more widespread, causing severe hyperkalemia.[84] Prolonged use of nondepolarizing neuromuscular blockers in critically ill patients may predispose to succinylcholine-induced hyperkalemia.[85] Owing to a reduction in circulating insulin levels, somatostatin and octreotide may impair normal cellular potassium uptake, particularly in the end-stage renal disease population.[86,87]

Hyperkalemic Periodic Paralysis

This rare syndrome of episodic hyperkalemia and paralysis is caused by a mutation of the skeletal muscle sodium channel, inherited in an autosomal dominant pattern.[88] Attacks may be precipitated by exercise, fasting, exposure to cold, and potassium administration and prevented by frequent carbohydrate snacks. Attacks are usually brief and treatment consists of carbohydrate ingestion. Severe attacks may require intravenous glucose infusions.[89]

Acute Renal Failure

Hyperkalemia accompanies acute renal failure in 30% to 50% of cases. It is seen most commonly in oliguric renal failure. Contributing factors include tissue destruction (e.g., tumor lysis syndrome, rhabdomyolysis) and increased catabolism.[90]

Pseudohyperkalemia

Pseudohyperkalemia refers to a measured potassium that is higher than that circulating in the patient's blood. It has a number of possible causes. First, it may be caused by efflux of potassium out of blood cells in the test tube after phlebotomy. This may be seen in a serum specimen in cases of thrombocytosis[91] or leukocytosis,[92] when the clot causes cell lysis in vitro. These days, many clinical laboratories measure electrolytes in plasma (unclotted) specimens. Even under these conditions, extreme leukocytosis may cause pseudohyperkalemia if the specimen is chilled for a long time before the plasma is separated, leading to passive potassium leak from cells.[93] In chronic lymphocytic leukemia, centrifugation of the blood can cause disruption of the fragile leukemia cells, leading to liberation of intracellular potassium. This can be mitigated by clotting of the specimen before centrifugation as the clot will protect the leukemia cells from damage.[94] Hemolysis during specimen collection will spuriously raise P_K by liberating intraerythrocyte potassium. Second, if the patient's arm is exercised by fist clenching with a tourniquet in place before the specimen is drawn, the sampled blood potassium concentration will rise significantly as a result of local muscle release of intracellular potassium.[54]

Pseudohypokalemia

GM-CSF, *Granulocyte-macrophage colony-stimulating factor.*

Acute Hypokalemia

Hypokalemia that develops over hours is virtually always the result of redistribution of potassium from the extracellular to the intracellular space. The causes of acute hypokalemia are summarized in Box 54.7. A few causes, commonly seen in the critical care context, merit elaboration.

Treatment of Diabetic Ketoacidosis

It is well recognized that patients presenting in DKA are always severely total body potassium depleted, as a result of the glucose-driven osmotic diuresis (and hence, kaliuresis), poor nutrition, and vomiting during the development of DKA.[44] Paradoxically, most patients in DKA have a normal P_K upon admission.[95] Insulin deficiency and hyperglycemia appear to account for the preservation of a normal P_K despite severe total body potassium depletion.[44] Once therapy for DKA is instituted, however, P_K typically plummets as potassium is rapidly taken up by cells under the influence of insulin. Hypokalemia in this setting may lead to respiratory arrest.[96] Potassium replacement at rates up to 120 mmol/h has been reported, with total potassium supplementation of 600 to 800 mmol within the first 24 hours of treatment.[97]

Refeeding

A situation analogous to DKA arises during aggressive refeeding after prolonged starvation or with aggressive "hyperalimentation" of chronically ill patients. The glucose-stimulated hyperinsulinemia and tissue anabolism shift potassium into cells, rapidly depleting extracellular potassium.[98] Death in the setting of refeeding has been reported and may be partly due to rapid cellular uptake of other ions (e.g., phosphorus, magnesium).[99]

Pharmacologic Agents

Specific β_2-adrenoceptor agonists (e.g., albuterol) may cause electrophysiologically significant hypokalemia, especially when given to patients who are potassium depleted from the use of diuretic drugs.[100] Epinephrine, given intravenously (IV) in a dose about 5% of that recommended for cardiac resuscitation, causes a fall in P_K by about 1 mmol/L.[101] Such a dose achieves plasma levels of epinephrine comparable to those seen after acute myocardial infarction and may explain the transient hypokalemia following resuscitation from cardiac arrest even without the use of exogenous epinephrine (postresuscitation hypokalemia).[102,103] A rare cause of severe hypokalemia is poisoning with soluble barium salts, such as the chloride, carbonate, hydroxide and sulfide. Soluble barium salts are used in pesticides and some depilatories, which may be ingested accidentally or intentionally.[104] Thiopentone, a barbiturate used to induce coma for refractory intracranial hypertension, is associated with redistributive hypokalemia in the majority of treated patients within 12 hours of initiating therapy.[105]

Therapeutic Hypothermia

Therapeutic hypothermia is used to improve survival and neurologic outcomes in patients with cardiac arrest and ventricular fibrillation. Hypokalemia has been reported during the cooling phase of this therapy[106] and may be a predictor of polymorphic ventricular tachycardia in these patients.[107] The hypokalemia is generally mild, and there is uncertainty as to whether to treat mild hypokalemia owing to the potential risk of severe rebound hyperkalemia during the rewarming phase.[108,109]

Hypokalemic Periodic Paralysis

Three forms of this rare syndrome have been described: familial, sporadic. and thyrotoxic.[110,111] All have in common attacks of muscle weakness accompanied by acute hypokalemia caused by cellular potassium uptake. Death may occur due to ventilatory failure or cardiac dysrhythmias. The familial variety—resulting from a skeletal muscle calcium channelopathy[88]—is inherited in an autosomal dominant pattern, with onset of clinical manifestations typically in the second decade of life. Attacks may occur after carbohydrate or salt ingestion, or exercise. Administration of potassium orally or IV will abort an acute attack but is ineffective in preventing attacks.[110] The sporadic variety of hypokalemic periodic paralysis is identical to the familial form except for the absence of a hereditary pattern. Thyrotoxic periodic paralysis was first described in Asians but is now recognized to be nearly ubiquitous.[111] The usual onset of symptoms is in the third decade. Severe hypophosphatemia may accompany the hypokalemia.[112] Treatment of the disorder is same as treatment of hyperthyroidism.

Pseudohypokalemia

Severe leukocytosis may cause spuriously low plasma potassium concentrations if blood cells are left in contact with the plasma for a long time at room temperature or higher. This phenomenon results from ongoing cell metabolism in vitro with glucose and potassium uptake.[59] Unexpected hypokalemia and hypoglycemia in the setting of leukocytosis should alert the clinician to this phenomenon.

Chronic Hyperkalemia

Renal Failure

Patients with chronic kidney disease tend to maintain a normal P_K until renal function declines to about 10% of normal.[113] Aldosterone and insulin both appear to play a role in the extrarenal potassium adaptation in chronic kidney disease.[114] This explains why patients with chronic kidney disease who are mineralocorticoid and/or insulin deficient have a particular predisposition to hyperkalemia.[115]

Mineralocorticoid Deficiency

Mineralocorticoid deficiency may result from global adrenal insufficiency (Addison disease) or from selective defects in the renin-angiotensin-aldosterone axis (see Chapter 56). Hyperkalemia in the setting of unexplained hypotension should immediately raise suspicion for adrenal insufficiency. A common setting for isolated mineralocorticoid deficiency is the syndrome of hyporeninemic hypoaldosteronism.[115] This syndrome is most often seen in elderly patients with diabetes mellitus and moderate renal insufficiency. Hyperkalemia is a universal finding. An associated hyperchloremic metabolic acidosis (type IV renal tubular acidosis) is characteristic.[115] In addition to diabetes mellitus, two other systemic diseases are associated with this syndrome: the AIDS[116,117] and systemic lupus erythematosus.[118]

Aldosterone deficiency may be induced by a variety of pharmacologic agents acting at different sites in the renin-angiotensin-aldosterone axis. β-Adrenoceptor blockers and, to a greater extent, cyclooxygenase inhibitors (COX-1 and COX-2), predispose patients to hyperkalemia by suppressing renin release.[119] As a general rule, COX inhibitors should be avoided in patients with renal insufficiency or those who are otherwise prone to hyperkalemia either because of diabetes or the use of other implicated drugs. Converting enzyme inhibitors and angiotensin receptor blockers decrease aldosterone biosynthesis. These drugs are reported to be implicated in 10% to 38% of hyperkalemia in hospitalized patients.[120] Volume depletion and/or hypotension increase the risk of hyperkalemia with all these agents.

High- and low-dose heparin therapy decreases circulating aldosterone levels by selectively inhibiting aldosterone biosynthesis.[121] Hyperkalemia is seen with the use of low–molecular-weight heparins as well, particularly in patients with diabetes mellitus.[122]

Renal Potassium Secretory Defect

An isolated defect in renal potassium secretion (often with a renal tubular acidosis) is associated with sickle cell disease or trait,[123] systemic lupus erythematosus,[118] and after renal transplantation.[124] In this last circumstance, the hyperkalemia is exacerbated by the use of cyclosporine and tacrolimus for immunosuppression.[125,126] A syndrome of hyperkalemic (type IV) distal renal tubular acidosis is seen in patients with urinary tract obstruction.[127]

The so-called potassium-sparing diuretics (spironolactone, eplerenone, amiloride, and triamterene) impair renal potassium excretion by blocking sodium reabsorption in the distal nephron. Two antibiotics, pentamidine[128] and trimethoprim,[129,130] cause hyperkalemia, occasionally severe, by blocking sodium reabsorption in the distal nephron.

Chronic Hypokalemia

Chronic hypokalemia is virtually always the result of altered external balance: insufficient potassium intake, excessive potassium losses, or a combination of the two. Losses most often are either GI or renal.

Inadequate Potassium Intake

Because renal potassium conservation is not perfect, severe dietary potassium restriction causes hypokalemia in 3 to 7 days in normal humans.[56] In one series of hypokalemic hospitalized patients,

inadequate potassium supplementation during IV therapy contributed to the development of severe hypokalemia in 45% of cases and was the sole cause in 6%.[131] Other disorders associated with nutritional hypokalemia include anorexia nervosa, alcoholism, and malignancy.

Excessive Potassium Losses

Hypokalemia may develop as a result of both upper and lower GI fluid losses, but the pathogenesis is quite different in the two situations. With diarrhea, the potassium is lost from the gut.[132] Gastric fluid losses (e.g., vomiting or gastric suction) are associated with hypokalemia. Paradoxically, however, most of the potassium losses are renal, not gastric. Gastric fluid potassium concentration is only 5 to 10 mmol/L. Thus only massive gastric fluid losses would, alone, significantly deplete total body potassium stores. The gastric fluid losses, however, stimulate renal potassium secretion in several ways. First, by generating a metabolic alkalosis and increasing bicarbonate delivery to the distal nephron, potassium secretion is stimulated. The metabolic alkalosis also leads to cellular proton loss and potassium uptake, which in renal epithelial cells, enhances potassium secretion. Finally, the volume contraction which usually accompanies GI fluid losses causes secondary aldosteronism, which further augments urinary potassium losses. Thus in this situation, urinary potassium concentration is typically high while urinary chloride concentration is low owing to volume contraction. (Urinary sodium losses may be high owing to natriuresis obligated by the bicarbonaturia.)

All diuretics work by inhibiting sodium and chloride reabsorption by the nephron. Those drugs that act proximal to the potassium secretory site in the nephron promote a kaliuresis by increasing delivery of fluid distally and causing secondary aldosteronism. Thus hypokalemia frequently accompanies the use of the two most common classes of diuretics: thiazides and loop diuretics.[133] Carbonic anhydrase inhibitors exert an additional kaliuretic effect by shunting bicarbonate-rich, chloride-poor fluid to the distal nephron.[134] Combining two potassium-wasting diuretics for added diuretic effect (e.g., furosemide plus metolazone) can result in severe hypokalemia. In such cases, P_K has been found to fall below 3.5 mmol/L in more than 80% of patients and below 3.0 mmol/L in more than half.[133]

Various antibiotic agents may cause renal potassium wasting and thereby hypokalemia; 90% of patients receiving amphotericin B require potassium supplementation.[135] Penicillin antibiotics, particularly polyanionic derivatives such as carbenicillin and ticarcillin, have been associated with hypokalemia.[136]

Mineralocorticoids predispose to hypokalemia by stimulating renal potassium excretion. Mineralocorticoid excess may be primary[137] (Conn syndrome) or secondary to diminished real or "effective" circulating volume. All glucocorticoid drugs except dexamethasone possess some mineralocorticoid activity. Therefore prolonged administration of these agents can cause severe hypokalemia. In edematous patients with secondary aldosteronism (e.g., congestive heart failure, hepatic cirrhosis) hypokalemia commonly ensues only when diuretic therapy enhances distal nephron flow rate.

Magnesium deficiency is associated with renal potassium wasting and may result in severe potassium depletion (see later text). Because magnesium, like calcium, acts to stabilize excitable membranes, the deleterious effects of hypokalemia on the myocardium are magnified by concurrent hypomagnesemia.[138] The intensive care setting is fraught with potential causes of hypomagnesemia (see "Disorders of Magnesium Homeostasis").

Hypercalcemia causes a salt and water diuresis and is therefore commonly associated with renal hypokalemia (see "Calcium").[139] In one series, one-third of hypercalcemic patients were hypokalemic with no other predisposing factors; the prevalence was 52% in patients with hypercalcemia of malignancy. P_K was inversely proportional to the plasma calcium concentration.[140]

Several inborn tubular transport abnormalities are associated with chronic hypokalemia (and metabolic alkalosis). Bartter and Gitelman syndromes are associated with volume contraction and normal blood pressure, and Liddle syndrome with hypertension.[141]

Clinical Manifestations of Potassium Imbalance

Alterations in P_K have a variety of adverse clinical consequences, the expression of which may be magnified in the critically ill patient. The most serious of these manifestations are those involving excitable tissues.

Clinical Manifestations of Hyperkalemia

Cardiac Effects

Hyperkalemia depolarizes the cell membrane, slows ventricular conduction, and decreases the duration of the action potential. These changes produce the classic electrocardiographic (ECG) manifestations of hyperkalemia, including (in order of their usual appearance) peaked T waves, prolongation of the PR interval, widening of the QRS complex, loss of the P wave, "sine wave" configuration, or ventricular fibrillation and asystole.[142,143] These ECG changes may be modified by a multitude of factors such as ECF pH, calcium concentration, sodium concentration, and the rate of rise of P_K.[142]

ECG changes may not accompany changes in P_K. If present, these ECG changes certainly suggest hyperkalemia. However, in the absence of the classic ECG changes, the clinician should not be lulled into a false sense of security when evaluating a hyperkalemic patient. Normal electrocardiograms occur despite extreme hyperkalemia[144] and the first cardiac manifestation of hyperkalemia may be ventricular fibrillation.[145] Consequently, P_K greater than 6.5 mmol/L, even with a normal ECG, should be treated as an emergency (see "Treatment of Potassium Imbalance").

Neuromuscular Effects

Hyperkalemia may result in paresthesias and weakness progressing to a flaccid paralysis, which typically spares the diaphragm. Reflexes are depressed or absent. Cranial nerves are rarely involved and sensory changes are minimal.[146]

Metabolic Effects

Hyperkalemia decreases renal ammoniagenesis, which by itself may produce a mild hyperchloremic metabolic acidosis,[147] and limits the kidney's ability to excrete an acid load and thus prevent correction of a metabolic acidosis.[148]

Clinical Manifestations of Hypokalemia

Although less immediately life-threatening than hyperkalemia, hypokalemia has many detrimental effects in critically ill patients. Along with cardiac and neuromuscular manifestations are many more subtle effects.

Cardiac Effects

Hypokalemia hyperpolarizes the cell membrane and prolongs the cardiac action potential.[149] These changes are associated with the following ECG manifestations: ST-segment depression,

a decrease in T-wave amplitude, and an increase in U-wave amplitude.[142,143] However, because all of these are nonspecific, the ECG is an even less reliable index of hypokalemia than it is of hyperkalemia.

Hypokalemia may be associated with an increased incidence of arrhythmias and conduction defects. It is well established that potassium depletion increases the cardiac toxicity of digitalis glycosides.[150] However, controversy exists as to whether hypokalemia per se induces ventricular arrhythmias in patients not taking digitalis. There is an increase in benign ventricular ectopy in hypokalemic patients without acute myocardial ischemia.[151] The clinical importance of this observation is unclear. In individuals hospitalized with acute myocardial infarction, however, a correlation between hypokalemia and ventricular tachycardia and fibrillation was observed.[152] Because potassium repletion did not reduce the occurrence of these arrhythmias, it is unlikely that hypokalemia was the sole arrhythmogenic factor.[152] It has been demonstrated that patients presenting with acute myocardial infarction show a U-shaped relationship between mean in-hospital P_K and mortality, such that P_K values less than 3.5 mmol/L or greater than 4.5 mmol/L were each associated with higher in-hospital mortality. The lowest mortality was seen in patients with P_K 3.5 to 4.0 mmol/L, implying that potassium supplementation to achieve higher concentrations was not justifiable.[153]

Neuromuscular Effects

Modest hypokalemia generally presents as weakness, myalgias, muscle fatigue, and "restless" legs. With more severe hypokalemia (<2 mmol/L), paralysis may supervene. This usually involves the extremities but may progress to include the trunk and muscles of ventilation. As with hyperkalemia, cranial nerves typically are spared and sensory function usually remains intact.[59] It is important to note that these manifestations may be masked by concomitant hypocalcemia and may only appear when calcium is replenished. Conversely, in patients with hypokalemia and hypocalcemia, tetany may develop only after potassium replacement.[59] Smooth muscle dysfunction (ileus, gastroparesis) is more commonly seen with hypokalemia than with hyperkalemia.

In addition to the effects of potassium depletion on the electrical properties of the neuromuscular system, profound hypokalemia may result in muscle injury and frank rhabdomyolysis, even in bedbound patients.[154]

Miscellaneous Effects

Hypokalemia and potassium depletion are associated with glucose intolerance,[155] increased protein catabolism, polydipsia and polyuria,[59] and metabolic alkalosis.[156]

Evaluation of Disorders of Potassium Homeostasis

The diagnostic approach to disorders of potassium homeostasis may be focused by dividing them according to their duration: acute (or of unknown duration) versus chronic.

Evaluation of Acute Hyperkalemia

When P_K rises abruptly or if P_K is high (>6.5 mmol/L) on initial presentation of the patient, the first step is to obtain an ECG to look for electrophysiologic evidence of hyperkalemia. In the presence of such signs, treatment for hyperkalemia should begin urgently (see "Treatment of Potassium Imbalance"). At the same time, an unclotted blood sample should be obtained, using meticulous phlebotomy technique, for another set of electrolytes, glucose, blood urea nitrogen and creatinine, and complete blood cell count. Urine should be tested for heme pigments to exclude acute rhabdomyolysis or hemolysis. The patient's list of medications and diet should be reviewed promptly, looking for exogenous sources of potassium and drugs that may impair potassium tolerance (see Box 54.6).

Evaluation of Chronic (Sustained) Hyperkalemia

Fig. 54.2 outlines an approach to the patient with sustained hyperkalemia lasting for days. Failure to stimulate cortisol release with a cosyntropin stimulation test (see Chapter 56) supports a diagnosis of Addison's disease. In the absence of that diagnosis, the patient is likely to have either selective aldosterone deficiency and/or tubular unresponsiveness to aldosterone. Assessment of the renin-angiotensin-aldosterone axis is most simply done by measuring plasma renin activity (PRA) and aldosterone levels in the basal and diuretic/posture-stimulated state.[115] Diabetic nephropathy and chronic tubule-interstitial disease can result in hyporeninemic hypoaldosteronism where both the PRA and aldosterone levels are low. Primary adrenal insufficiency or selective aldosterone insufficiency is associated with low aldosterone levels but a high PRA. Aldosterone resistance, as can be seen with the use of potassium-sparing diuretics, distal renal tubular acidosis, or pseudohypoaldosteronism type I (epithelial sodium channelopathy or loss-of-function mutation of the mineralocorticoid receptor) can result in both high PRA and aldosterone levels.[157] Historically, the trans-tubular potassium gradient (TTKG) had been used to help assess the distal tubular responsiveness to aldosterone; however, owing to incorrect assumptions regarding tubular urea recycling that are beyond the scope of this chapter, the TTKG is now considered an invalid tool in the assessment of sustained hyperkalemia.[158]

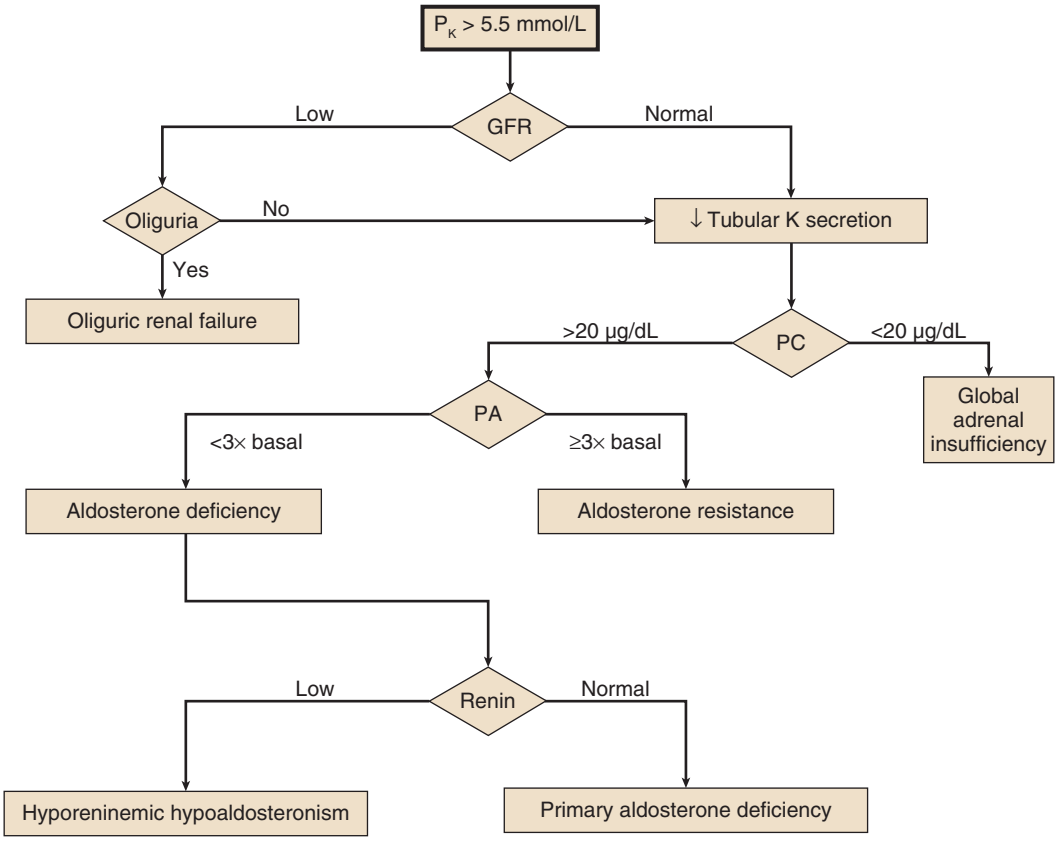
Evaluation of Acute Hypokalemia

Hypokalemia accompanied by serious cardiac or neuromuscular manifestations is an emergency. Likewise, urgent therapy is indicated for profound hypokalemia (P_K < 2.0 mmol/L) even in the absence of clinical complications. In addition, moderate hypokalemia (P_K < 3.0 mmol/L) in patients taking digitalis,[150] and perhaps with acute myocardial ischemia,[152] should be treated urgently because of the risk of ventricular arrhythmias. In all these situations, it is imperative that the blood specimen be obtained and handled properly, especially in patients with leukocytosis, since rapid administration of potassium to a patient with pseudohypokalemia may cause severe hyperkalemia.

The remainder of the evaluation of acute hypokalemia derives mainly from the patient's history with an emphasis on interventions causing cellular potassium uptake (e.g., insulin, β-adrenergic agonists) or a rapid increase in tissue anabolism (e.g., total parenteral nutrition), and a history of periodic paralysis. Patients with hypokalemia upon presentation should be evaluated as though their hypokalemia were acute.

Evaluation of Chronic Hypokalemia

Once acute hypokalemia and transient potassium redistribution have been excluded, one should next determine whether the kidney is responding appropriately to the potassium deficit or whether it is contributing to the problem. This is best done by measuring the 24-hour urinary excretion of potassium during potassium repletion (Fig. 54.3). Potassium excretion less than 20 mmol/day suggests appropriate renal potassium conservation and points to extrarenal



• **Fig. 54.2** Diagnostic evaluation of chronic hyperkalemia. *GFR,* Glomerular filtration rate; *PA,* stimulated plasma aldosterone (see text); *PC,* stimulated plasma cortisol (see Chapter 56).

(lower GI or skin) potassium losses, recovery from diuretic-induced hypokalemia, or chronically potassium-deficient diet. Excretion of greater than 20 mmol/day is evidence of inadequate renal potassium conservation, indicating a renal cause of the hypokalemia. Renal potassium losses associated with normal systemic blood pressure are most commonly seen with the use of thiazide or loop diuretics and are accompanied by a metabolic alkalosis. Other causes of hypokalemia with metabolic alkalosis in a normotensive patient include gastric fluid loss and Bartter and Gitelman syndromes. These are separable most often by history, but if not, the urinary chloride measurement will be helpful, being low with gastric fluid losses. Renal hypokalemia may accompany a renal tubular acidosis, in which case the plasma bicarbonate will be low.

Mineralocorticoid excess may be the cause if the renal potassium loss is associated with systemic hypertension, and the renin-aldosterone axis should be studied with basal and saline solution–suppressed blood hormone measurements. High PRA and aldosterone levels suggest renal artery stenosis, malignant hypertension, or rarely a renin-secreting tumor. Low PRA and high aldosterone levels indicate primary aldosteronism. When both PRA and aldosterone levels are low, one should suspect the syndrome of apparent mineralocorticoid excess, Cushing syndrome, or rarely Liddle syndrome. Note that Cushing syndrome owing to ectopic adrenocorticotropic hormone secretion often is not accompanied by typical cushingoid features.[159]

Treatment of Potassium Imbalance

In general, the initial treatment of acute severe potassium imbalance is independent of the cause of the disturbance, whereas the rational therapy of chronic hyperkalemia or hypokalemia depends on an understanding of its pathogenesis.

Acute Hyperkalemia

In considering when hyperkalemia constitutes an emergency, two points should be kept in mind. First, the electrophysiologic effects of hyperkalemia are directly proportional to both the absolute P_K and its rate of rise.[142] Second, whereas the ECG manifestations of hyperkalemia are generally progressive and proportional to the P_K, ventricular fibrillation may be the first ECG disturbance of hyperkalemia[145]; conversely, a normal ECG may be seen with extreme hyperkalemia.[144] Thus it is apparent that neither the ECG nor the P_K alone is an adequate index of the urgency of hyperkalemia, and that the clinical context must be considered when assessing a hyperkalemic patient. Because most patients manifest hyperkalemic ECG changes at P_K greater than 6.7 mmol/L,[143] hyperkalemia should be treated emergently for (1) P_K greater than 6.5 mmol/L or (2) ECG manifestations of hyperkalemia regardless of the P_K.[160]

Therapy of acute or severe hyperkalemia is directed at preventing or ameliorating its untoward electrophysiologic effects on the myocardium. The goals of therapy, in chronologic order, are as follows (Table 54.2):

1. Antagonize the effect of hyperkalemia on excitable cell membranes.
2. Redistribute extracellular potassium into cells.
3. Enhance elimination of potassium from the body.

Membrane Antagonism

Calcium. Calcium directly antagonizes the myocardial effects of hyperkalemia without lowering P_K.[161] During treatment with

TABLE 54.2 Emergency Treatment of Hyperkalemia

Agent	Dose	Onset	Duration	Complications
Membrane Stabilization				
Calcium gluconate (10%)	10 mL IV over 10 min	Immediate	30–60 min	Hypercalcemia
Hypertonic (3%) sodium chloride	50 mL IV push	Immediate	Unknown	Volume overload Hypertonicity
Redistribution				
Insulin (short-acting)	10 units IV push, with 25–40 g dextrose (50% solution)	20 min	4–6 h	Hypoglycemia
Albuterol	20 mg in 4 mL normal saline solution, nebulized over 10 min	30 min	2 h	Tachycardia Inconsistent response
Elimination				
Loop diuretics				
Furosemide	40–80 mg IV	15 min	2–3 h	Volume depletion
Bumetanide	2–4 mg IV			
Sodium bicarbonate	150 mmol/L IV at variable rate	Hours	Duration of infusion	Metabolic alkalosis Volume overload
Sodium polystyrene sulfonate (Kayexalate, Kionex)	15–30 g in 15–30 mL 70% sorbitol orally)	> 2 h	4–6 h	Variable effect Intestinal necrosis
Hemodialysis		Immediate	3 h	Arrhythmias

calcium, the ECG should be monitored continuously. The dose may be repeated in 5 minutes if there is no improvement in the ECG, or if the ECG deteriorates after an initial improvement.[162] There are several case reports of sudden death in patients given intravenous calcium while also receiving digitalis glycosides.[163] Although these observations do not provide clear guidance, it may be wise to administer intravenous calcium with great caution to patients known or strongly suspected to have toxic levels of digitalis glycosides.

Hypertonic Saline Solution. Intravenous hypertonic sodium chloride has been shown to reverse the ECG changes of hyperkalemia in patients with concurrent hyponatremia.[164] Whether hypertonic saline solution is effective in the treatment of eunatremic patients has not been established. Moreover, the extracellular volume load imposed by hypertonic saline solution argues against its use.

Redistribution of Potassium Into Cells

Insulin. Insulin reliably lowers P_K in a dose-dependent manner. An intravenous dose of 10 units of regular insulin given as a bolus along with an intravenous bolus of dextrose (50 g as a 50% solution) to adult patients lowers the P_K by about 0.8 mmol/L after an hour.[165] After the initial bolus, a dextrose infusion should be started, because a single bolus of 25 g of dextrose has been shown to be inadequate to prevent hypoglycemia at 60 minutes.[166] There seems to be no advantage of a continuous insulin infusion over a bolus injection.[38] Insulin should be used without dextrose in hyperglycemic patients; indeed, the cause of the hyperkalemia in those patients may be the hyperglycemia itself.[50]

Albuterol. P_K has been shown to decline by 0.6 mmol/L after inhalation of 10 mg of albuterol, and by about 1.0 mmol/L after 20 mg in patients with end-stage renal disease.[167] The effect of insulin is additive with that of albuterol, with the combination reported to result in a decline in P_K by about 1.2 mmol/L at 60 minutes.[166] Even among patients not taking β-blockers chronically, as many as 40% appear to be resistant to the hypokalemic effect of albuterol.[166,167] For that reason, albuterol should never be used alone for the treatment of urgent hyperkalemia.

Bicarbonate. The putative benefits of a bolus injection of sodium bicarbonate in the emergency treatment of hyperkalemia pervaded the literature until recently. Ironically, this dogma was based on studies using a prolonged (4–6 hours) infusion of bicarbonate.[45] It has now been clearly demonstrated that short-term bicarbonate infusion does not reduce P_K in patients with dialysis-dependent kidney failure, implying that it does not cause potassium shift into cells.[46,47,160]

Elimination of Potassium From the Body

Enhanced Renal Elimination. Hyperkalemia occurs most often in patients with renal insufficiency. However, renal potassium excretion may be enhanced even in patients with moderate renal failure by increasing distal nephron flow. This may be accomplished with saline or sodium bicarbonate infusions and may be enhanced further by the use of loop diuretics. Diuretic-induced volume contraction must be avoided because this will lead to decreased distal nephron flow and reduced potassium excretion.[162] It must be emphasized that for obvious reasons this treatment strategy is not a consideration for the treatment of acute hyperkalemia in the anuric patient.

Exchange Resin. Sodium polystyrene sulfonate (SPS, Kayexalate, Kionex) is a cation exchange resin that exchanges sodium for secreted potassium in the colon. Each gram of resin binds approximately 0.65 mmol of potassium in vivo, although the effect is highly variable and unpredictable.[38] The resin causes constipation and hence almost always is given with a cathartic. It is more effective when given orally than by retention enema.[38]

There are two concerns with the use of SPS for the treatment of urgent hyperkalemia. The first is its slow effect. When given orally, the onset of action is at least 2 hours and the maximum effect may not be seen for 6 hours or more. One recent study in hemodialysis patients failed to show any effect on P_K after an oral dose of SPS.[168] The second concern with SPS is its possible toxicity. There are numerous case reports of patients who developed intestinal necrosis after exposure to SPS in sorbitol as an enema[169–171] and orally.[172] A retrospective study estimated the incidence of colonic necrosis to be 1.8% among postoperative patients.[172] For these reasons, some authorities consider the use of SPS to be unjustifiable.[173]

A newer cation exchange resin, patiromer sorbitex calcium (Veltassa) binds potassium in exchange for calcium in the GI lumen and is approved for the treatment of chronic hyperkalemia.[174] Because of its delayed onset of action, patiromer is of limited use in the critical care setting; the manufacturer clearly states that it is not indicated for use as an emergency treatment for life-threatening hyperkalemia.

Dialysis. Hemodialysis is the dialytic method of choice for removal of potassium from the body. P_K falls by over 1 mmol/L in the first 60 minutes of hemodialysis and a total of 2 mmol/L by 180 minutes, after which it reaches a plateau.[38] Rebound always occurs after dialysis, with 35% of the reduction abolished after an hour and nearly 70% after 6 hours.[38] There is controversy as to whether dialysis for severe hyperkalemia precipitates serious ventricular arrhythmias; however, in the hemodialysis population, hyperkalemia independently has been associated with adverse outcomes.[175] Because of the possibility of serious ventricular ectopy, patients undergoing dialysis for severe hyperkalemia should have continuous ECG monitoring.[38] The rate of potassium removal with peritoneal dialysis is much slower than with hemodialysis.[38]

Chronic Hyperkalemia

As established previously, chronic hyperkalemia always implies deficient renal potassium excretion. It follows that the therapy of chronic hyperkalemia is primarily directed toward stimulating renal potassium excretion while limiting potassium intake. For all adults with chronic hyperkalemia, daily potassium intake should be restricted to 60 mmol. All drugs known to impair either internal or external potassium balance should be eliminated if possible. Finally, all patients with chronic hyperkalemia should be evaluated for occult urinary tract obstruction.

Further therapy of the persistently hyperkalemic patient should be guided by the diagnostic evaluation outlined in Fig. 54.2. In cases of mineralocorticoid unresponsiveness or when mineralocorticoid treatment is complicated by fluid overload, a thiazide or loop diuretic can be added to the regimen. This will restore normal volume status and enhance renal tubular potassium secretion in many mineralocorticoid-resistant patients. It is crucial to avoid diuretic-induced volume depletion, however, since this will exacerbate the renal potassium secretory defect.

Patients who fail to respond to the previous measures may be given sodium bicarbonate, which will stimulate renal potassium secretion. This is especially appropriate for patients whose chronic hyperkalemia is accompanied by a renal tubular acidosis (type IV renal tubular acidosis). The usual dose is 1 to 2 mmol bicarbonate/kg body weight per day in 3 or 4 divided doses.[162] Lastly, patiromer sorbitex calcium is indicated for use in controlling chronic hyperkalemia.[174]

Acute Hypokalemia

A low P_K almost always indicates a large total body potassium deficit. In fact, P_K decreases by approximately 0.3 mmol/L for each decrement of 100 mmol total body potassium.[176] But if potassium is replenished too quickly, the homeostatic mechanisms that defend P_K will be overwhelmed and P_K will rise abruptly. The rate of rise of P_K with potassium administration can be greatly altered by factors that affect internal potassium balance. For example, during treatment of DKA with insulin, cellular uptake of potassium may be massive, obligating enormous replacement doses of potassium. Conversely, insulin deficiency markedly impairs tolerance to a potassium load.[61]

See "Evaluation of Acute Hypokalemia" for definitions of urgent hypokalemia. Limited information exists on which to base a rational prescription of KCl in an emergency.[61,177,178]

Based on the available literature, we can estimate that nondiabetic patients with normal renal function should respond well to a 1- to 2-hour infusion of KCl at 0.6 mmol/kg per hour given IV in saline solution. In patients with kidney function reduction of any degree, the infusion rate should be halved (0.3 mmol/kg per hour). Patients with diabetes mellitus not being treated for DKA or hyperglycemia should receive no more than 0.2 mmol/kg per hour, or about 0.1 mmol/kg per hour in the setting of renal failure. For severe hypokalemia, the ECG should be monitored continuously and the infusion stopped immediately if signs of hyperkalemia develop. The maximum increase in P_K is seen at the end of the infusion, and about 50% of the increase is lost over the next 2 to 3 hours when a new steady state is achieved. Thus P_K should be measured at the end of the infusion. If the patient is still dangerously hypokalemic at this point, additional potassium may be given. If at the end of the infusion P_K is in an acceptable range, the measurement should be repeated 2 to 3 hours later when disposal of potassium load is complete to determine the need for further treatment.[162]

Hypokalemia in the setting of aggressive "refeeding," and especially in the treatment of severe DKA, should be treated initially as described previously. Frequent monitoring of P_K with rapid laboratory turnaround time is critical for proper management.

Hypokalemia that is not life-threatening is best treated with oral potassium replacement. It is important to recognize that GI absorption of an oral dose of KC1 elixir is essentially complete. Dangerous hyperkalemia can occur in entirely normal individuals following KCl ingestion.[179] The maximum increase in P_K is seen 1.5 to 2 hours after an oral potassium load. Thus a sensible oral dose of KCl in moderate hypokalemia should probably not exceed the hourly IV doses proposed earlier. There is no reason to give a simultaneous oral and IV potassium dose; serious hyperkalemia may ensue.

Chronic Hypokalemia

The treatment of chronic hypokalemia depends entirely on identifying and, if possible, remediating the cause (Fig. 54.3). When the cause of the excessive potassium loss cannot be treated specifically, maintenance potassium supplementation is needed.

Disorders of Water Homeostasis

Hyponatremia and hypernatremia reflect disorders of water homeostasis. They are common disorders in critically ill patients and are associated with increased morbidity and mortality.[180,181]

Physiology of Water Homeostasis

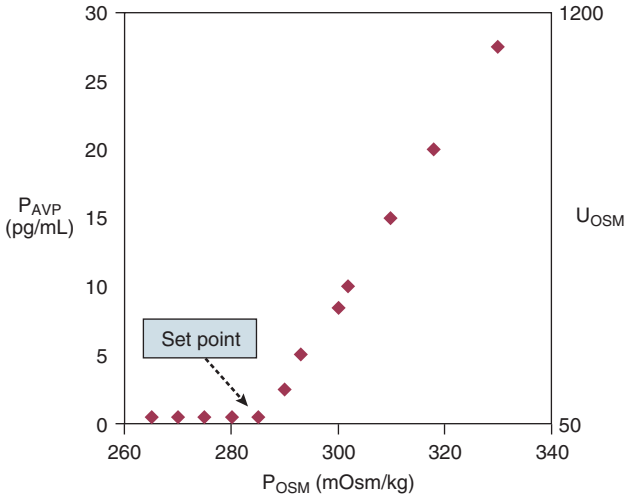
Normal plasma sodium concentration varies very little—even less than the "normal" range of clinical laboratories (135–145 mmol/L). This tight regulation depends on the following elements: (1) pituitary secretion of arginine vasopressin (AVP; also known as antidiuretic hormone, or ADH) that varies over a wide range in response to physiologic stimuli; (2) kidneys that are capable of responding to circulating vasopressin by varying the urine concentration; (3) intact thirst; and (4) access to water.

Tonicity or effective osmolality describes the capacity of particles in solution to effect water movement across a semi-permeable membrane like the cell membrane. The normal response to water ingestion (of sufficient magnitude to lower the plasma osmolality even slightly) is the excretion of maximally dilute urine (urine osmolality <100 mOsm/kg). The underlying physiologic sequence is as follows: the plasma hypotonicity is sensed by the cells comprising the hypothalamic osmostat. These hypothalamic nuclei then proportionately reduce their synthesis of AVP, also known as ADH, leading to diminished AVP release into the circulation by the posterior pituitary. The lower circulating AVP concentration, in turn, results in the insertion of proportionately fewer water channels into the collecting duct of the kidney. This, in turn, creates a more water-impermeable conduit, preventing water reabsorption and allowing excretion of the dilute urine elaborated by the more proximal segments of the nephron.[182]

Conversely, plasma hypertonicity leads to higher circulating AVP concentration and proportionately higher water permeability of the collecting duct, and the excretion of a concentrated urine.[182]

Fig. 54.4 shows the relationship among plasma osmolality, plasma AVP concentration, and urine osmolality. The normal "set point" is a plasma osmolality about 285 mOsm/kg. Notice that the minimum urine osmolality is about 50 mOsm/kg, and the maximum is about 1200 mOsm/kg.[183]

When plasma osmolality rises beyond 290 to 295 mOsm/kg, the thirst center of the hypothalamus is stimulated. At that point, neurologically intact individuals with access to water will drink until the plasma osmolality returns to normal.[183]



• **Fig. 54.4** Typical example of the physiologic relationship between plasma osmolality *(P_{osm})*, plasma vasopressin concentration *(P_{AVP})*, and urine osmolality *(U_{osm})*. P_{AVP} and U_{osm} vary around the *set point* to maintain P_{osm} within the range of normal.

Nonosmotic Vasopressin Release

It is important to recognize that plasma osmolality is not the only determinant of AVP synthesis and release. Low arterial blood pressure and low effective arterial volume powerfully stimulate AVP release.[183] This baroreceptor-mediated AVP release is teleologic, because water retention is an important component in the defense against hypovolemia. So primal is this circulatory defense that the baroreceptor stimulation predominates over any osmolal effect on AVP release.[183] Thus a volume-contracted or hypotensive individual will have high circulating AVP levels even if his plasma osmolality is low. In addition, circulating AVP levels rise with pain, stress, nausea, hypoxia, hypercapnia, and a variety of medications, most notably epinephrine and high doses of narcotic analgesics.[183]

Hyponatremia

Epidemiology and Clinical Manifestations

Hyponatremia (plasma sodium concentration <135 mmol/L) is one of the most common electrolyte disorders, found in approximately 3% of hospitalized patients and as many as 30% of patients in ICUs.[180]

The clinical manifestations of hyponatremia are largely attributed to intracellular volume expansion (cellular edema), which occurs only when hyponatremia is associated with hypotonicity. Intracellular volume expansion is of greatest consequence in the brain, where it is translated into increased intracranial pressure because of the rigid calvarium.[184]

The pathophysiology of hypotonic hyponatremia has important implications for its management. Most cells—especially brain cells—have adaptive mechanisms for mitigating tonicity-related volume changes.[184] Cell volume peaks 1 to 2 hours after the onset of acute hypotonicity. Thereafter solute and water are lost from cells, and cell volume returns toward normal. After several days of sustained hypotonicity, cell volume is restored to near normal.[184]

The morbidity and mortality associated with hypotonic hyponatremia are influenced by several factors, including the magnitude and rate of development of the hyponatremia, the patient's age and gender, and the nature and severity of any underlying diseases.[184] The very young and very old, females, and alcoholics appear to be at particular risk.[185] Cell-volume adaptation to hypotonicity may be deficient in premenopausal women, who have more frequent and more severe neurologic consequences than men with equivalent degrees of hypotonicity.[186]

Neurologic symptoms usually do not occur until the plasma sodium concentration falls below 125 mmol/L, at which point the patient may complain of anorexia, nausea, and malaise. Between 120 and 110 mmol/L, headache, lethargy, confusion, agitation, and obtundation may be seen. More severe symptoms (seizures, coma) may occur with levels below 110 mmol/L.[187] Focal neurologic findings are unusual but do occur, and transtentorial cerebral herniation has been described in severe cases, especially in young women following surgery.[186] In that setting, hypoxemia is common and often is associated with noncardiogenic pulmonary edema.[188] Hypoxia appears to exacerbate the cerebral damage in hyponatremia.[189]

Although symptoms generally resolve with correction of the hypotonicity, permanent neurologic deficits may occur, particularly in acute severe hypotonicity, when the brain's volume-regulatory defenses may be overwhelmed.[186] Profound hypotonicity that develops in less than 24 hours may be associated with residual neurologic deficits and has a 50% mortality rate in some populations.[186] In contrast, when hypotonicity develops more gradually, symptoms are both less common and less severe. Indeed, patients with chronic hyponatremia, even in the range of 115 to 120 mmol/L, may be completely asymptomatic.[184]

Pathophysiology and Differential Diagnosis

Hyponatremia may coexist with a normal, high, or low plasma osmolality. Thus the diagnostic algorithm for hyponatremia (Fig. 54.5) begins with an assessment of the plasma osmolality (P_{osm}). This may be estimated by the following formula:

$$\text{Estimated } P_{osm} = (2 \times P_{Na}) + \frac{P_{gluc}}{18} + \frac{BUN}{2.8}$$

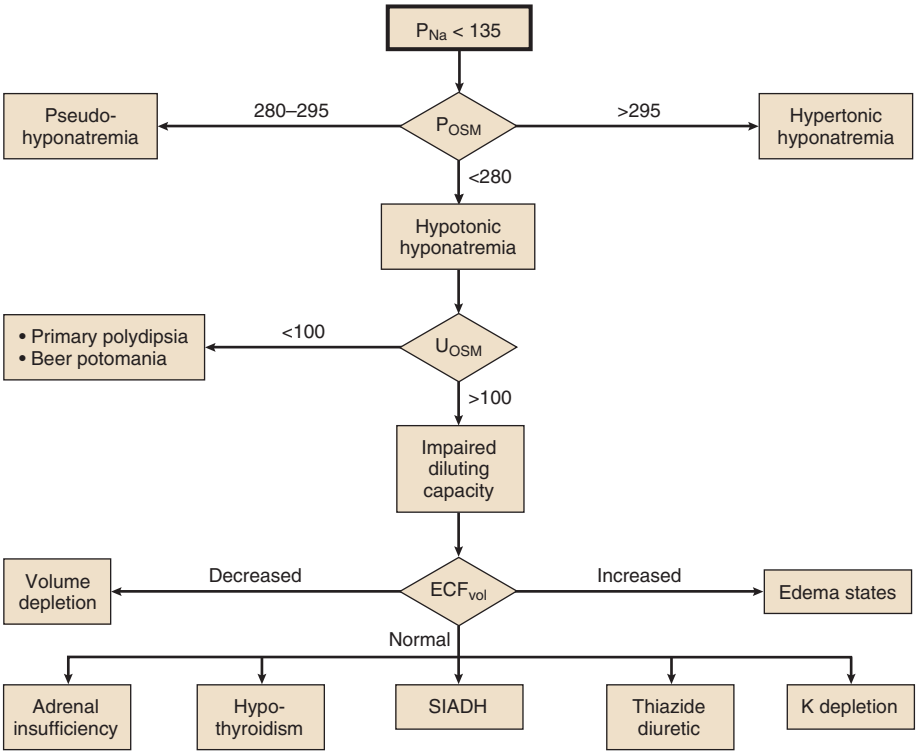
where P_{gluc} is the plasma glucose concentration and BUN is the blood urea nitrogen concentration (both in milligrams per deciliter). If there is a suspicion that an unmeasured, osmotically effective solute may be implicated (e.g., mannitol or glycerol), the P_{osm} should be measured directly.

Isotonic hyponatremia (also known as factitious or pseudohyponatremia) is a laboratory artifact seen with analytic techniques that measure the mass of sodium per unit volume of plasma sampled.[190] It is seen in the presence of marked hypertriglyceridemia or paraproteinemia, when the measurement method involves a predilution step. Direct potentiometry (which uses an ion-selective electrode in undiluted plasma) avoids this problem.[190]

Hypertonic hyponatremia results from the presence in ECF of abnormal amounts of osmotically effective solutes other than sodium (e.g., glucose, mannitol, or glycerol). The osmotic pressure exerted by the nonsodium solute leads to redistribution of water from the intracellular to the ECF compartment, resulting in cellular dehydration and hyponatremia. The hyponatremia is real (not pseudo-), but it is accompanied by hypertonicity and a decrease in cellular volume.

Hypotonic hyponatremia is caused by an inability of the kidney to excrete sufficient electrolyte-free water to match water intake. This may occur either because the normal diluting capacity of the kidney is overwhelmed by excessive water intake or because the diluting capacity of the kidney is impaired. These alternatives usually can be distinguished by measuring the urine osmolality. A urine osmolality less than 100 mOsm/kg in a patient with hypotonic hyponatremia points to excessive water intake as the cause (see Fig. 54.5). It is a prodigious feat for an individual eating a normal diet to overwhelm the normal diluting capacity of the kidney. Estimates are that one can ingest (and excrete) about 20 L of water a day without affecting the plasma osmolality appreciably.[183] Thus patients who develop hyponatremia from so-called psychogenic or primary polydipsia—usually patients with obsessive-compulsive disorder or psychosis—typically have concurrent urinary diluting defects, either in association with the underlying mental illness or perhaps as a side effect of psychotropic or anticonvulsant medications.[191]

Not all patients with hypotonic hyponatremia and dilute urine have primary polydipsia. The patient may be ingesting a diet so deficient in protein and salt that he excretes very little solute in the urine. In that situation (called beer potomania for obvious reasons,[192] although the syndrome has been seen in other patients with very low daily solute intake[193]), the low daily solute excretion limits the total amount of water that can be eliminated even with a maximally dilute urine (i.e., maximum urine volume = solute excretion ÷ minimum U_{osm}). This might reduce the maximum water excretion to only 3 to 4 L/day, a quantity easily exceeded by an enthusiastic beer drinker.



• **Fig. 54.5** Diagnostic evaluation of hyponatremia. *ECF_{vol}*, Extracellular fluid volume status; *K*, potassium; *P_{Na}*, plasma sodium concentration; *P_{osm}*, plasma osmolality (mOsm/kg); *SIADH*, syndrome of inappropriate antidiuretic hormone secretion; *U_{osm}*, urine osmolality (mOsm/kg).

A urine osmolality above 100 mOsm/kg in the face of hypotonic hyponatremia signifies impaired urinary diluting capacity. The concentrated urine usually reflects a high circulating AVP level. Because circulating AVP is affected by systemic hemodynamics as well as osmolality, assessment of the patient's ECF volume status and hemodynamics is crucial at this juncture. Hypotonic hyponatremia may be associated with normal, decreased, or increased extracellular volume.

Euvolemic Hyponatremia

Patients with pure water excess appear clinically euvolemic because the excess water distributes throughout the total body water space; only one-third of total body water is extracellular (and only one-twelfth is intravascular). The only evidence of the slight intravascular volume expansion is low blood urea nitrogen and plasma uric acid concentration.[194] The paradigm of euvolemic hyponatremia with concentrated urine is the syndrome of inappropriate antidiuretic hormone (SIADH). It is characterized by elevated circulating AVP (ADH) levels that are inappropriate to vasopressin's two physiologic stimuli (i.e., osmotic or hemodynamic).[195] Hypotonic hyponatremia in patients with SIADH develops to the extent that water ingestion exceeds water eliminated by insensible, GI, and renal routes. Because the normal response to extracellular hypotonicity is the elaboration of maximally dilute urine (urine osmolality <100 mOsm/kg), the urine need only be inappropriately concentrated (i.e., >100 mOsm/kg) to be compatible with a diagnosis of SIADH.

Because hypothyroidism[196] and glucocorticoid insufficiency[197] may impair urinary dilution, patients in whom a diagnosis of SIADH is entertained should undergo appropriate tests of thyroid and adrenocortical function (see Chapter 60).

Once a diagnosis of SIADH is made, its cause must be established because the cause may have important implications in its own right and may be easily remediable. Box 54.8 lists important causes of SIADH. They fall into five major categories: intracranial abnormalities, intrathoracic abnormalities, tumors, drugs, and idiopathic. An important variant of SIADH is the reset osmostat syndrome,[198] in which vasopressin levels are regulated normally by tonicity, but around a lower set point than normal. This syndrome is seen most often in patients who are severely debilitated (e.g., malnutrition, metastatic cancer, advanced tuberculosis) and may account for up to one-third of cases of SIADH. The diagnosis of reset osmostat syndrome has important therapeutic implications, as discussed later.

Hyponatremia has recently been recognized to occur with some frequency in endurance-sports athletes. The incidence of hyponatremia, with serum sodium levels below 135 mmol/L, is approximately 15% in marathon and triathlon athletes; 0.6% of runners develop severe hyponatremia with serum sodium levels below 120 mEq/L.[199] The 3 major risk factors associated with hyponatremia in this setting include body mass index below 20, racing time exceeding 4 hours, and weight gain owing to excessive fluid intake during the race. Excessive water intake is the most important factor in the development of hyponatremia for runners.[199]

Hypovolemic Hyponatremia

The urinary diluting impairment in hypovolemia is mediated both by decreased delivery of fluid to the diluting segments of the nephron and by hemodynamically stimulated vasopressin release. Thus the volume-contracted patient cannot excrete electrolyte-free

water normally, and even in the face of modest water ingestion may readily become hyponatremic.

The cause of the volume contraction usually is obvious (e.g., hemorrhage, vomiting, diarrhea, diuretics). When it is not, the urine sodium concentration can be helpful in distinguishing between renal and extrarenal solute losses. Renal losses (e.g., as a result of diuretic medications) are usually reflected by sodium wasting, and extrarenal losses are usually accompanied by sodium conservation (urine sodium concentration <10 mEq/L). Exceptions occur in the recovery phase after diuretic therapy and in metabolic alkalosis owing to vomiting. In the latter situation, the urine chloride concentration tends to be very low and is the best indicator of extracellular volume depletion.[200,201]

Cerebral salt wasting may be responsible for hypovolemic hyponatremia in patients with intracranial pathology (e.g., trauma, tumors, hemorrhage). The pathogenesis of the urinary salt wasting is incompletely understood. The mechanism of hyponatremia in this setting is similar to that of other hypovolemic states. As a hyponatremic syndrome in patients with central nervous system disease, cerebral salt wasting is often difficult to distinguish from SIADH, because urinary sodium excretion tends to be high. Particularly confusing in patients with cerebral salt wasting is the finding of hypouricemia, which is thought to reflect impaired solute reabsorption in the proximal tubule.[202] The key features that distinguish cerebral salt wasting from SIADH are volume depletion and urinary sodium excretion inappropriate to the patient's volume status.[202]

The hyponatremia associated with diuretic treatment is multifactorial in origin. Insofar as diuretics produce overt volume depletion, they can cause hyponatremia by the mechanisms discussed earlier. Thiazides have been associated with the development of acute severe, symptomatic hyponatremia, particularly in small, elderly women, in the absence of overt signs of volume depletion.[203] This often precipitous syndrome appears to be caused, at least in part, by increased water ingestion.[204]

Hypervolemic Hyponatremia

Hypervolemic hyponatremia generally is seen in patients who cannot excrete sodium normally because they have either severe renal failure or one of the pathologic edema-forming states (e.g., congestive heart failure, hepatic cirrhosis, the nephrotic syndrome). Patients with advanced chronic kidney disease are predisposed to hyponatremia.[205] Acute oliguric renal failure or end-stage (dialysis-dependent) renal failure will be accompanied by hyponatremia to the extent that water intake exceeds insensible and GI water elimination (see Chapter 52).

Hyponatremia is seen in more than 20% of patients presenting with decompensated congestive heart failure and more than 30% of patients admitted to the hospital with complications of hepatic cirrhosis.[206] The hormonal milieu of such patients is typical of intravascular volume depletion, even though the absolute intravascular volume typically is increased. Thus these disorders are said to be characterized by reduced effective circulating volume.[207] Because of the perceived intravascular volume depletion, renal diluting ability is compromised for reasons similar to those in hypovolemic hyponatremia.

Management and Complications

Hyponatremia per se requires treatment only when it is associated with hypotonicity. Hypertonic hyponatremia responds to the treatment of the underlying disorder, most commonly a hyperosmolar hyperglycemic state (see Chapter 55).

The therapy of hypotonic hyponatremia must be tailored to (1) the patient's signs and symptoms and (2) the duration of the disorder.[185] Severe hyponatremia (plasma sodium concentration <115 mmol/L) can be life-threatening, especially if it develops rapidly.[187,208] The therapy of symptomatic hyponatremia, irrespective of cause, is directed at raising ECF tonicity to shift water out of the intracellular space, thereby ameliorating cerebral edema. The rate of correction, however, must be carefully regulated. Overly rapid correction, particularly in patients with chronic hyponatremia, in whom cell volume adaptations may be complete, can produce osmotic demyelination syndrome (ODS).[209,210] The ODS is associated with a variety of sometimes irreversible neurologic deficits (e.g., dysarthria, dysphagia, behavioral disturbances, ataxia, quadriplegia, coma), which typically develop 3 to 10 days after treatment.[211] Additional

risk factors for osmotic demyelination include hypokalemia, malnutrition, alcoholism, advanced age, female sex, and the postoperative state, particularly after orthotopic liver transplantation.[212–214]

For patients with acute hyponatremia of less than 24 hours' duration (e.g., marathon runners, postoperative patients, users of "ecstasy"), severe, symptomatic hyponatremia is treated as an emergency to reduce intracranial pressure and the risk of herniation. An expert panel has recommended treating this condition with an intravenous bolus of 100 mL of 3% saline infused over 10 minutes. If signs or symptoms of increased intracranial pressure persist, the dose may be repeated twice.[215] In these limited circumstances, there is no recognized harm in allowing the plasma sodium concentration to correct to normal within hours.[215]

For patients with severe, symptomatic chronic hyponatremia (>48 hours' duration) or similar hyponatremia of unknown duration, clinicians should aim to raise the plasma sodium concentration by no more than 6 mmol/L in the first 6 hours and then stop the increase.[215] Correction of severe symptomatic hypotonic hyponatremia, regardless of cause, should be accomplished with hypertonic (3%) saline solution (sodium concentration 513 mmol/L). The volume of 3% saline solution required can be estimated by the following formula:

$$\text{Volume of 3\% saline solution (liters/24 hours)} = \text{Target change } P_{Na} \text{ (mmol/L per 24 hours)} \times \text{TBW (L)}$$

For example, in a 70-kg man with a plasma sodium concentration of 105 mmol/L and total body water of 42 L (60% of body weight), the amount of sodium needed to raise the plasma sodium concentration by 6 mmol/L is 6 mmol/L × 42L, or 252 mmol. Therefore 252 mmol ÷ 513 mmol/L or 0.5 L of 3% saline solution would be required in the first 6 hours, or 83 mL/h. Care should be taken to avoid overcorrecting the plasma sodium concentration, especially in patients at high risk of the ODS.[197,211] It is important to recognize that this calculation provides only a very rough guideline. The plasma sodium concentration must be monitored frequently during treatment to adjust the rate of correction. If the rate of correction begins to exceed the target rate, the hypertonic saline solution infusion should be stopped. It may be necessary to administer water (enteral or IV) with or without desmopressin to prevent overly rapid correction or to reverse overcorrection.[215]

Rapid extracellular volume expansion with hypertonic saline solution may precipitate pulmonary edema, particularly in patients with underlying heart disease. Thus patients receiving 3% saline solution should be assessed frequently for evidence of volume overload. One may administer a loop diuretic if necessary, recognizing that this will enhance electrolyte-free water clearance and accelerate the correction. Rarely, administration of isotonic (normal) saline solution to patients with SIADH paradoxically may lower the plasma sodium concentration if the urine osmolality remains high—a process that has been called desalination.[216]

The treatment of chronic asymptomatic hypotonicity should be directed at correcting the pathophysiologic mechanisms involved in generating the hypotonic state. Because euvolemic hyponatremia represents pure water excess, treatment depends on restricting water intake to less than the daily water output. Patients with SIADH excrete little or no electrolyte-free water in the urine. Therefore if water intake is limited to less than the amount of insensible water losses (~10 mL/kg body weight per day), the plasma sodium concentration will slowly rise. Patients with the reset osmostat variant of SIADH characteristically do not develop progressive hypotonicity and therapy is rarely required.

If the cause of SIADH cannot be corrected and if water restriction is poorly tolerated or ineffective, a specific vasopressin (V_2) receptor antagonist (VRA) can be used. Conivaptan (parenteral) and tolvaptan (oral) were the first VRAs to be approved by the U.S. Food and Drug Administration for clinical use. These agents have changed the management of patients with SIADH.[217] Tolvaptan reliably increases P_{Na}; however, hyponatremia recurs within 1 week after the medication is discontinued.[218] For patients admitted with hyponatremia related to decompensated congestive heart failure, tolvaptan along with diuretic therapy improves most signs and symptoms of heart failure within 1 week,[219] although no effect on 24-month mortality or heart failure morbidity has been demonstrated.[220] Before the introduction of VRAs, demeclocycline (a tetracycline antibiotic that increases electrolyte-free water excretion by inhibiting vasopressin-mediated water reabsorption in the collecting duct) was commonly used to treat patients with SIADH. Demeclocycline is contraindicated in patients with renal disease, hepatic cirrhosis, or congestive heart failure because drug-related kidney injury has been described in these situations.[221] Neither VRAs nor demeclocycline are indicated for the treatment of acute, severe hyponatremia.

Therapy of hypovolemic hyponatremia should be directed at restoring intravascular volume with intravenous isotonic saline solution while identifying and correcting the cause of the excessive solute loss. Volume repletion readily elicits a water diuresis by increasing the delivery of fluid to the renal diluting segments and suppressing vasopressin release. As with all categories of hypotonic hyponatremia, the rate of correction must be carefully controlled.

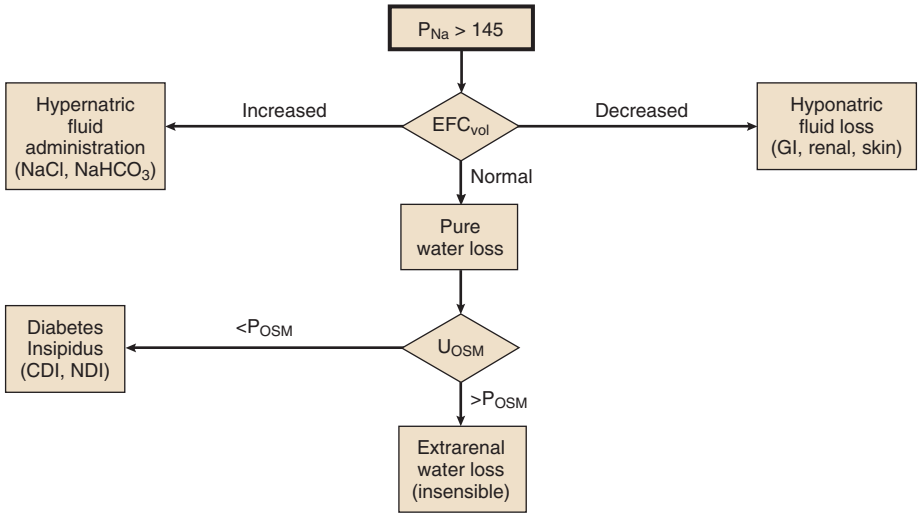
The treatment of diuretic-induced hyponatremia is straightforward: withdrawing the offending drug, liberalizing salt intake, and replenishing body potassium stores usually correct the disorder. Severe symptomatic hyponatremia in this setting should be treated with hypertonic saline solution as detailed earlier. Patients must be watched carefully after correction of the hyponatremia because relapse may occur for up to a week.[222]

Resolution of the hyponatremia associated with any of the pathologic edematous disorders ultimately depends on effective treatment of the underlying disease. Regardless of the specific therapy of the underlying disorder, the mainstay of therapy for the hyponatremic edematous patient remains salt and water restriction. Diuretics are often a double-edged sword in the hyponatremic edematous patient: they may be needed to treat pulmonary vascular congestion, peripheral edema, and ascites, but if used to excess can produce further decrements in effective arterial blood volume and exacerbate water retention. Strategies directed at increasing effective arterial blood volume (e.g., afterload reduction with angiotensin-converting enzyme inhibitors[223,224]) have had some success in increasing electrolyte-free water excretion and ameliorating hyponatremia in patients with congestive heart failure. VRAs are likely to facilitate treatment of hypervolemic hyponatremia (see earlier).[217]

Hypernatremia

Epidemiology and Clinical Manifestations

Hypernatremia is common in critically ill patients; it is present on admission in about 9% of patients and develops during the course of the ICU stay in another 6%.[225] It is associated with a significantly higher mortality than is seen in patients without hypernatremia.[225]



• **Fig. 54.6** Diagnostic evaluation of hypernatremia. *CDI,* Central diabetes insipidus; *ECF_{vol},* extracellular fluid volume status; *GI,* gastrointestinal; *NaCl,* sodium chloride; *$NaHCO_3$,* sodium bicarbonate; *NDI,* nephrogenic diabetes insipidus; *P_{Na},* plasma sodium concentration; *P_{osm},* plasma osmolality; *U_{osm},* urine osmolality.

Sustained hypernatremia develops in patients whose water output exceeds their input. Water ingestion can defend against the development of hypernatremia even when water losses are prodigious. For that reason, hypernatremia upon presentation to the hospital occurs most commonly in patients who are incapacitated: those who have impaired thirst sensation, who cannot access water or who cannot express their need for water (e.g., infants and patients with neurologic impairments). Similar predispositions prevail among critically ill patients. Thus the development of hypernatremia in hospitalized patients is considered iatrogenic, reflecting an incomplete understanding of the factors that lead to hypernatremia.[225] The increased mortality seen in patients with hypernatremia probably is due to their underlying vulnerabilities rather than an effect of the hypernatremia itself.[226]

The clinical manifestations of hypernatremia are proportional to the magnitude and rate of rise of the plasma sodium concentration and are attributable to intracellular volume contraction. To counteract cellular volume contraction, cells begin to adapt within minutes by allowing the influx of electrolytes, thus mitigating cell shrinkage. When hypernatremia lasts more than a few hours, brain cells generate new organic osmolytes. This leads to further water movement back into brain cells, restoring cell volume to near normal after about 3 days.[227] Thus chronic progressive hypernatremia is associated with fewer and milder symptoms than acute severe hypernatremia. Most often, patients with long-standing hypernatremia present with weakness, lethargy, and confusion. Seizure and coma may supervene. Acute severe hypernatremia in infants and small children is associated with intracranial bleeding,[228] presumably caused by brain shrinkage and traction on the penetrating vessels. There is some controversy, however, as to whether the hypernatremia in that situation is the cause or the effect of the intracranial hemorrhage.[229]

Differential Diagnosis

The plasma sodium concentration reflects the ratio of body sodium content to total body water. Thus hypernatremia (plasma sodium concentration >145 mmol/L) can result from loss of pure water alone, loss of hyponatric fluid, or a gain of sodium or hypernatric fluid.* It is important to distinguish among these paths to hypernatremia because they have diagnostic and therapeutic implications (Fig. 54.6).

Euvolemic Hypernatremia

Hypernatremic patients who appear euvolemic most likely have pure water loss as an explanation for their hypernatremia. This is because the water is lost from all body compartments proportionately; only one-twelfth of the water loss is intravascular. For example, a 60-kg woman with a 3-L pure water loss would experience an intravascular loss of only 250 mL (clinically imperceptible) but would develop a plasma sodium concentration of 155 mmol/L.† Pure water can be lost either through the skin and respiratory tract (so-called insensible losses) or in urine.

Insensible losses amount to about 10 mL/kg body weight per day under normal environmental conditions in an afebrile individual with a normal respiratory rate. A hot environment, fever, or rapid respiratory rate may double that rate.[183] Note that a patient supported by mechanical ventilator using humidified gas will lose no water through the respiratory tract.

The loss of large amounts of dilute, electrolyte-free water in the urine is typical of diabetes insipidus (DI). DI may be central (CDI) or nephrogenic (NDI) depending on whether the defect is in vasopressin release from the posterior pituitary or in the renal

*Hyponatric and hypernatric are used here to refer to a fluid with a sodium concentration less than (or greater than) that of plasma.

†The expected change in the serum sodium concentration is calculated as follows: [Initial total body water volume] × [Serum sodium concentration initial] ÷ [Final total body water volume]; 30 L × 140 mmol/L ÷ 27 L = 155 mmol/L.

response to circulating vasopressin, respectively. The causes of DI are shown in Box 54.9. Most cases of CDI, especially those following trauma or intracranial surgery, are self-limited, lasting 4 to 5 days. Of special interest to intensivists is a classic triphasic syndrome that may be seen following severe head trauma:

1. Initially, there is abrupt cessation of vasopressin release from the posterior pituitary, accompanied by polyuria.
2. About a week later, an antidiuretic phase ensues, characterized by urinary concentration and water retention with a tendency toward hyponatremia, lasting 5 to 6 days. This appears to result from the release of stored vasopressin from the degenerating hypothalamic neurons.
3. Persistent CDI recurs when the vasopressin stores are depleted.[230]

Regardless of the cause, patients with DI of either type usually have a plasma sodium concentration within the normal range because their water ingestion matches their urinary water output. They develop hypernatremia only with water deprivation, owing to mental or physical incapacity, and/or neglect. An awareness of the causes of DI, a careful history, and familiarity with the differential diagnosis of polyuria will prevent hypernatremia in these circumstances.

Congenital
  Autosomal recessive: aquaporin-2 water channel gene mutations
  X-linked recessive: arginine vasopressin V_2 receptor gene mutations

Hypovolemic Hypernatremia

The loss of salt and water, with the water loss greater than the sodium loss, will lead to hypernatremia and volume depletion, manifested by orthostatic or persistent hypotension and tachycardia, and evidence of organ underperfusion (e.g., acute renal failure, lactic acidosis). For example, if the 60-kg woman whose plasma sodium concentration rose to 155 mmol/L (see earlier) had lost the equivalent of half-isotonic saline solution instead of pure water, her intravascular volume would have contracted by 750 mL, enough to cause at least orthostatic hypotension and tachycardia.

A common cause of hypovolemic hypernatremia is the loss of GI fluids.[231] Most GI fluids have an electrolyte concentration below that of plasma: The concentration of sodium plus potassium in stool is roughly constant at 110 to 120 mmol/L over a wide range of stool volume.[132] Gastric fluid has an even lower electrolyte concentration: about 40 to 50 mmol/L total cation concentration.[232] Diuresis, either osmotic (glucose-, mannitol- or urea-induced) or medication-induced, causes the loss of urine with an electrolyte concentration less than that of plasma, leading to volume contraction and hypernatremia. The loss of sweat, which contains some sodium, can cause hypovolemic hypernatremia in individuals who exercise vigorously in a hot environment. If the cause of the fluid loss is not apparent from the history or the physical examination, a urinary chloride concentration less than 10 mmol/L in the face of hypovolemic hypernatremia suggests that the electrolyte loss is extrarenal (cutaneous or GI).

Hypervolemic Hypernatremia

Hypervolemic hypernatremia is relatively uncommon. It results most often from the administration of hypertonic sodium salts to patients without free access to water.[231] Patients show signs of extracellular volume expansion (e.g., hypertension, edema, congestive heart failure, and pulmonary edema). In infants, this syndrome has been caused by erroneous preparation of dietary formula using salt instead of sugar; in adult outpatients, it may be caused by ingestion of a concentrated salt solution, usually for its emetic effect.[233] The risk of death is substantial and seems to be proportional to the plasma sodium concentration.[233]

In hospitalized adults, hypervolemic hypernatremia is most often iatrogenic, caused by intravenous administration of undiluted sodium bicarbonate (formulated at 1 mEq/mL or 1000 mmol/L) or sodium chloride (3% [513 mmol/L] or 23.5% [4019 mmol/L]). Not all hypervolemic hypernatremia results from the administration of hypertonic fluids. It may be seen in a volume-expanded patient who then loses hypotonic fluid.[234]

Treatment

The initial treatment of the patient with hypernatremia depends on his or her volume status. For patients with pure water losses (euvolemic), therapy has two goals: (1) reduction and/or replacement of ongoing water losses, and (2) replacement of the existing water deficit.

If the water losses are urinary (see Fig. 54.6) and due to CDI, antidiuretic hormone should be administered. Several formulations are available (Table 54.3). In the acute (postsurgical or posttraumatic) setting, l-AVP may be used either subcutaneously or intravenously, although the latter route may be associated with hypertension and coronary spasm and should therefore be used

TABLE 54.3 Pharmacologic Treatment of Central Diabetes Insipidus

Agent	Total Daily Dose	Frequency of Administration	Onset of Action (h)	Duration of Action (h)	Comments
Arginine vasopressin, 20 units/mL	5–10 units subcutaneously	q2–q4 h	1–2	2–6	Intravenous route may cause vasoconstriction and coronary spasm
Desmopressin acetate (DDAVP)					
10 μg/0.1 mL intranasal	10–40 μg intranasal	Daily or bid	1–2	8–12	
4 μg/mL injection	1–2 μg IV or subcutaneously	Daily or bid	1–2	8–12	

bid, Twice daily; *DDAVP,* 1-deamino-8-D-arginine vasopressin; *q,* every.
Modified from Singer I, Oster JR, Fishman LM. The management of diabetes insipidus in adults. *Arch Intern Med.* 1997;157:1293–1301.

with extreme caution.[235] The advantage of vasopressin in this setting is its short half-life, which allows the physician to repeatedly assess the need for continued hormone replacement, especially when the disorder may be self-limited. Desmopressin (1-deamino-8-d-arginine vasopressin [DDAVP]) is a synthetic analog of vasopressin that has no vasoconstrictor properties, thus avoiding the risks of hypertension and myocardial ischemia. The treatment of the urinary water losses associated with NDI are best treated with thiazide diuretics with or without COX inhibitors. Because most of these agents are orally administered, treatment of NDI in the critically ill patient often consists of urinary water replacement until he or she is able to take medications by mouth.

The rate of water replacement should be proportional to the rapidity with which the hypernatremia developed.[227] Thus if the hypernatremia had developed over only a few hours (such as in salt poisoning, postsurgical or posttraumatic DI), it can be corrected just as quickly. On the other hand, hypernatremia of more than a day's duration, or of unknown duration, must be correctly slowly to avoid cerebral edema. One should aim to lower the plasma sodium concentration by no more than 10 mmol/L per day.[236]

The water deficit to be corrected over 24 hours can be estimated by the following formula:

$$\text{Target positive water balance over 24 h (L)} = \text{TBW}\left(1-\frac{\text{Current } P_{Na}-10}{\text{Current } P_{Na}}\right)$$

where TBW is total body water in liters (estimated as about 0.5 × lean body weight [kg] in women and 0.6 × lean body weight in men). For example, a 60-kg woman presenting with a plasma sodium concentration of 160 mmol/L should be in positive water balance by 30 (1 – 0.94) or 1.9 L to achieve a plasma sodium concentration 150 mmol/L in 24 hours. To achieve this target, all ongoing water losses must be replaced completely and then exceeded by the calculated amount.

Water is best administered enterally as tap water. If that route is unavailable, 5% dextrose in water (D_5W) may be used, with the understanding that the capacity to metabolize glucose is limited to about 15 g/h in a critically ill adult.[237] Thus even in nondiabetic patients, the administration of more than 300 mL/h of D_5W is likely to result in hyperglycemia, which may be relatively resistant to insulin administration. Hyperglycemia will exacerbate urinary water losses by causing an osmotic diuresis. Half-normal (0.45%) saline solution may be a good alternative, as long as one recognizes that only half the administered volume is electrolyte-free water and that the sodium load may cause unwanted volume expansion.

Regardless of the degree of hypernatremia, normal (0.9%) saline solution should be given intravenously to patients who present with obvious volume depletion, manifested by hypotension, tachycardia, and evidence of impaired tissue perfusion. This is consistent with the first principles of emergency and critical care, prioritizing the adequacy of the circulation. Only after the extracellular volume deficits have been largely corrected may the physician direct his or her attention to the total body water deficit (see earlier text).

Patients with hypervolemic hypernatremia need reduction in their extracellular and intravascular volume before their water deficit can be corrected. Failure to do so will exacerbate the volume overload. For patients with adequate renal function, this may be accomplished with the use of diuretic drugs. Loop diuretics tend to cause the excretion of isotonic urine. Replacement of that urine volume with pure water will allow correction of the hypervolemia and the hypernatremia simultaneously.

Because of the imprecision of the estimation formulas and the failure of the foregoing analysis to take account of other fluids and electrolytes both administered and lost, it is crucial that the plasma electrolytes be monitored every 4 to 6 hours during the correction of severe hypernatremia, especially in view of the dire consequences of overly rapid correction.

Calcium

Calcium is required for bone mineralization, muscle contraction, nerve conduction, and blood coagulation. It is required for cell division, hormone secretion, phagocytosis, chemotaxis and activation of numerous intracellular second messengers.[238] Calcium is also responsible for activation of calcium-dependent phospholipases and proteases, generation of free radicals, cytokines release, and inhibition of adenosine triphosphate (ATP) production in the face of ischemic injury. Thus calcium plays a central role in physiologic as well as pathologic conditions.[239]

Normal Calcium Physiology

Calcium is the most abundant cation in the body. The total body calcium content of an average adult is approximately 1 kg, 99% of which is found in bones and teeth, with only 1% in plasma and soft tissues.[240] Calcium homeostasis is achieved with the cooperation of several organs, including the skeleton, the gut, and the kidney, under the influence of several hormones, mainly vitamin D, parathyroid hormone (PTH), and calcitonin.

Calcium Intake and Absorption

The daily dietary intake of calcium for an average adult in North America is 800 to 1000 mg. The main dietary source of calcium is milk and other dairy products; it is also available in the form of fortified food and calcium-containing supplements. Approximately 20% of dietary calcium is absorbed by the intestine. Intestinal absorptive capacity increases with calcium deprivation and under certain physiologic conditions such as growth spurts in children, pregnancy, and lactation.[241] Intestinal absorption occurs via both passive paracellular and active transcellular pathways. Vitamin D increases the active transport of calcium across the intestinal membranes.[240]

Renal Handling of Calcium

The filtered load of calcium (the product of glomerular filtration rate and the plasma concentration of ultrafilterable calcium) is about 10 g/day. Calcium balance is maintained when the kidneys excrete about 200 mg/day (the intestinal absorptive load). Thus the fractional excretion of calcium is only about 2%.[240,241] Of the 98% of filtered calcium reabsorbed along the nephron, 60% is reabsorbed in the proximal tubule. Approximately 15% of the filtered calcium is reabsorbed in the thick ascending limb of loop of Henle (TAL). The reabsorption of calcium in TAL is mostly passive and proportional to the lumen-positive voltage generated by the furosemide-inhibitable Na-K-2Cl transporter and luminal potassium recycling via renal outer medullary potassium channels. There is also some active transcellular transport, which is under the influence of PTH and calcitonin.[240,241] In the distal tubule, approximately 10% to 15% of filtered calcium is reabsorbed via active transcellular pathways. The apical membranes of distal convoluted tubules and connecting tubules contain highly selective epithelial calcium channels (transient receptor potential cation channel subfamily V member 5 [TRPV-5]),[240,241] which facilitates calcium entry into the cells. PTH increases the density and open probability of TRPV-5 channels.[242]

Volume expansion, hypercalcemia, acute and chronic acidosis, and loop diuretics reduce the renal calcium reabsorptive capacity and result in hypercalciuria. Conversely, hypocalcemia, alkalosis, PTH, calcitriol, and thiazide diuretics enhance renal calcium reabsorption and cause hypocalciuria.

Regulation of Plasma Calcium

Normal plasma calcium concentration is 8.8 to 10.4 mg/dL. In plasma, calcium exists in two forms: protein-bound and ultrafilterable (permeant across the glomerular filtration barrier). Approximately 40% of plasma calcium is bound to plasma proteins (predominantly albumin), cannot cross the biologic membranes, and is thus physiologically inert. The ultrafilterable portion of plasma calcium makes up the remaining 60% of plasma calcium and consists of calcium complexed with various anions such as citrate, phosphate, and lactate (about 10%), and free, ionized calcium (Ca^{2+})—the biologically active form, accounting for about 50% of plasma Ca.[243]

Plasma ionized calcium concentration is tightly regulated. Several factors play an important role in maintaining plasma Ca^{2+} concentration within a narrow range (about 4.4–5.2 mg/dL or 1.1–1.3 mmol/L). The principal regulators are PTH, vitamin D_3, and Ca^{2+} itself.

Ca^{2+} acts as a ligand for calcium-sensing receptors (CaSRs) present on the chief cells of the parathyroid glands. A rise in plasma Ca^{2+} concentration results in activation of CaSRs, which in turn inhibits PTH secretion. Conversely, a fall in Ca^{2+} concentration inhibits CaSRs, increasing PTH secretion. PTH mobilizes the calcium from bone stores, stimulates renal calcium reabsorption, and increases the conversion of $25(OH)D_3$ to 1, $25(OH)_2D_3$, the most active form of vitamin D_3. Activated vitamin D_3 increases intestinal calcium absorption. The CaSR is also present on the basolateral surface of TAL cells. Activation of the CaSRs in these cells results in a reduction in tubular calcium reabsorption. All these systems work in concert to keep the Ca^{2+} levels within physiologic levels.[238]

Plasma Calcium Measurement

Ionized calcium is the physiologically important moiety, yet total calcium is the moiety most often measured in clinical laboratories. Under normal circumstances, there is a fairly constant relationship between total and ionized calcium (see earlier text), but in critically ill patients, this relationship may be disturbed such that total calcium no longer provides a reliable index of the physiologically important calcium concentration. The two major factors affecting the ratio of ionized to total calcium are acid-base status and plasma protein concentration.

Acidemia causes displacement of calcium ions from albumin by protons and results in a relative increase in ionized calcium. Conversely, alkalemia increases calcium binding to albumin, causing a relative fall in ionized calcium levels while total plasma calcium concentration remains unchanged.[238,240]

Changes in the concentration of plasma protein, especially albumin, result in alterations in total calcium concentration. Hypoalbuminemia, common in critically ill patients, causes a reduction in total calcium concentration; hyperalbuminemia (e.g., in states of severe volume contraction) tend to cause an increase in total plasma calcium. Numerous formulas have been proposed to adjust the total calcium concentration for changes in plasma albumin concentration.[244] The most commonly used formula is based on the observation that each gram of albumin binds about 0.8 mg calcium at physiologic pH:

$$Ca_{corrected} = Ca_{observed} + (0.8 \cdot [4.0 - albumin])$$

Unfortunately, the corrected calcium correlates very poorly with physiologically active ionized calcium in various critically ill populations, typically with a very low sensitivity for diagnosis of true hypocalcemia.[244–246]

The reasons for this discrepancy are manifold, including concurrent acid-base disorders, high circulating concentrations of free fatty acids,[247] and infusions of heparin, citrate, and bicarbonate.[246] Therefore in critically ill patients, direct measurement of ionized calcium is recommended for assessing physiologic calcium concentration.

Hypocalcemia

Epidemiology

Hypocalcemia is extremely common in critically ill patients. The prevalence of ionized hypocalcemia is reported to be 60% to 85%

among medical, surgical, and trauma ICU patients.[248–251] Risk factors for the development of hypocalcemia in critically ill patients include advanced age, sepsis, acute renal failure, multiple blood transfusion, malnutrition, magnesium deficiency, severe shock, and colloid volume resuscitation.[251,252] Mortality is higher in hypocalcemic patients[249,253,254] but does not appear to be independently associated with hypocalcemia.[250,251]

Causes of Hypocalcemia

Causes of hypocalcemia are shown in Box 54.10. Hypocalcemia may be caused by disorders involving the hormonal regulators of calcium homeostasis, PTH and vitamin D; redistribution of calcium; drugs; and miscellaneous influences. We discuss causes of particular relevance to the critical care setting.

Hypoparathyroidism

Parathyroidectomy, for hyperparathyroidism or "incidentally" with thyroidectomy, may cause postoperative hypocalcemia. Risk factors for developing hypocalcemia include subtotal parathyroidectomy and simultaneous thyroidectomy. Profound, long-lasting hypocalcemia may develop, as part of the "hungry bone" syndrome, in which calcium is sequestered into the rapidly remineralizing bone.[255] Hypomagnesemia may contribute to the hypocalcemia (see "Disorders of Magnesium Homeostasis").

Vitamin D Deficiency

Vitamin D deficiency is common in elderly, institutionalized patients owing to poor dietary intake and inadequate sunlight exposure. Diseases involving liver and small intestine may result in poor absorption of vitamin D. For conversion to its most active form, vitamin D requires hydroxylation in liver and kidney. Frequently, critically ill patients have liver and kidney dysfunction, which results in impaired vitamin D synthesis and predispose to hypocalcemia.[239] Vitamin D deficiency (level < 20 ng/dL) upon admission to a medical ICU has been associated with increased mortality.[256] Whether vitamin D supplementation to critically ill patients will reduce mortality remains to be determined.

Redistribution

Citrate is useful as a preservative and anticoagulant for blood components precisely because it chelates calcium and thereby inhibits the coagulation cascade. The calcium citrate complex is then metabolized in liver, where citrate is converted into bicarbonate, and ionized calcium is released into the circulation. Massive blood transfusion may result in ionized hypocalcemia owing to chelation of calcium by citrate. However, hypocalcemia is transient in patients with normal liver function, and ionized calcium levels return to normal levels within 15 minutes of transfusion.[257] Citrate also may be used for anticoagulation of the dialysis circuit for continuous renal replacement therapy (continuous venovenous hemofiltration and variants). Under those conditions, calcium typically is infused through a central venous line to prevent hypocalcemia. Inadequate calcium replacement or concomitant liver failure may result in clinically significant hypocalcemia. In the latter case, with citrate accumulation, the total calcium may be misleadingly normal, but the ionized calcium is low.[258,259] Hypocalcemia is frequently reported with plasmapheresis where citrate is used for anticoagulation.[260] Sodium bicarbonate to treat metabolic acidosis may cause hypocalcemia from calcium binding to albumin and formation of carbonate complexes. Similarly, abrupt alkalinization from hemodialysis against a bicarbonate bath may precipitate symptomatic hypocalcemia.

Phosphate binds with calcium to form insoluble calcium phosphate complexes. Under normal physiologic conditions, calcium and phosphorus levels are tightly regulated, preventing significant complexation. Any condition that causes an acute increase in phosphate levels, however, can cause complexation and resultant ionized hypocalcemia. Examples include endogenous phosphorus overload as in the tumor lysis syndrome[72] and exogenous phosphorus overload from laxatives and cathartics.[261–264] Patients with impaired renal function are at particular risk[262] (see "Phosphorus").

Hypocalcemia in rhabdomyolysis is multifactorial and involves calcium deposition in injured muscles, formation of calcium-phosphate complex owing to hyperphosphatemia, and acute renal failure causing decreased synthesis of vitamin D.[265]

The presence of ionized hypocalcemia correlates with the development of severe acute pancreatitis[266] and is reported in up to 85% of patients with severe acute pancreatitis.[267] The cause of hypocalcemia in this setting is unclear. Calcium has been shown to accumulate in pancreas, liver, and skeletal muscle in an animal model of acute pancreatitis.[268] Low[269] and high[270,271] levels of PTH have been reported. Experimental elevation in free fatty acids, both circulating[272] (as might be seen in the hypertriglyceridemia of acute pancreatitis) and intraperitoneal,[273] have been associated

- Acute renal failure

with the hypocalcemia of acute pancreatitis. Finally, high circulating endotoxin levels may have a role.[267]

Drugs

Bisphosphonates are used for the treatment of osteoporosis and hypercalcemia. They act by impairing osteoclast function and reducing osteoclast numbers. Bisphosphonate-induced hypocalcemia has been reported in patients with renal failure, hypoparathyroidism, or vitamin D deficiency.[274] Denosumab, a receptor activator of nuclear factor κ (RANK)-ligand inhibitor, is an antibody-mediated antiresorptive drug used in the treatment of postmenopausal osteoporosis, and it has been shown to cause hypocalcemia particularly in individuals with chronic kidney disease.[275] Other drugs such as colchicine, plicamycin (formerly mithramycin), and calcitonin also decrease bone release of calcium.[240] Cinacalcet, a calcimimetic, can cause hypocalcemia by stimulating the parathyroid CaSR.

Sepsis/Systemic Inflammatory Response Syndrome

Hypocalcemia is common in patients with sepsis or systemic inflammatory response syndrome.[249,253] The cause probably is multifactorial.[276] Among the proposed mechanisms are calcium sequestration,[277,278] an effect of inflammatory cytokines,[279] calcitonin precursors,[279,280] hypomagnesemia[281] with inappropriate hypoparathyroidism,[276] and probable PTH resistance.[279,282] Vitamin D deficiency, from malnutrition and inability to hydroxylate vitamin D because of coexisting liver and kidney dysfunction, also has been implicated.[276] The hypocalcemia may serve to protect vulnerable cells from the deleterious effects of calcium during sepsis. Indeed, calcium administration in this setting may be detrimental.[276]

Clinical Manifestations

Hypocalcemia affects predominantly the neuromuscular and cardiovascular systems. Neuromuscular manifestations include paresthesias (perioral and acral), hyperactive reflexes, tetany (carpopedal spasm and other muscle spasm), and seizures.[240] Laryngospasm and bronchospasm may supervene, leading to respiratory arrest.[238] Tetany may be provoked by tapping over the facial nerve and noting ipsilateral facial muscle twitching (Chvostek sign) and transiently occluding the brachial artery with a tourniquet and noting carpal spasm (Trousseau sign), although neither of these signs is specific for hypocalcemia. Prolonged hypocalcemia lasting longer than 36 hours has been associated with the development of critical illness polyneuropathy and myopathy.[283] Psychiatric manifestations include anxiety, irritability, confusion, and psychosis.[238]

Cardiovascular findings include a prolonged QT interval and, in severe hypocalcemia, bradycardia, hypotension refractory to fluids and vasopressors, heart block, heart failure, and cardiac arrest.[239]

Symptoms and signs of hypocalcemia depend on the degree of depression of ionized calcium levels and the rate of decline.[240] Mild hypocalcemia (ionized calcium >3.2 mg/dL) usually is well tolerated.

Diagnosis

When hypocalcemia is suspected in a critically ill patient, the diagnosis should be established by direct measurement of ionized calcium levels (see "Plasma Calcium Measurement"). If ionized hypocalcemia is confirmed, plasma magnesium and phosphorus should be measured. Further diagnostic evaluation derives from the differential diagnosis (see Box 54.10). Without PTH levels and vitamin D levels, the diagnosis of hypocalcemia remains obscure in the majority of critically ill patients.[249]

Treatment

Therapy of hypocalcemia depends on its severity. Hypocalcemia (ionized calcium < 3.2 mg/dL) accompanied by serious cardiovascular or neuromuscular signs should be treated urgently. Calcium gluconate (10% in 10 mL containing 90 mg elemental calcium) can be given over 5 to 10 minutes, followed by calcium gluconate infusion (500–1000 mg in 500 mL 5% dextrose over 6 hours).[240] Calcium chloride (10% in 10 mL containing 272 mg elemental calcium) contains more calcium and can rapidly increase plasma calcium levels; however, it is more irritating to the veins and must be given by a central venous catheter. Patients with renal failure, hyperphosphatemia, and serious hypocalcemia may require dialysis.

Patients receiving intravenous calcium should have frequent measurement of the ionized calcium. They should be monitored for side effects of calcium administration, including hypertension, skin flushing, nausea, vomiting, and chest pain.

Intravenous calcium should be reserved for patients who have severe symptomatic hypocalcemia or who are incapable of taking calcium orally. Administration of intravenous calcium can cause complexing with phosphorus and ectopic calcification.

Critically ill patients with mild hypocalcemia (ionized calcium >3.2 mg/dL) tend to have few if any manifestations. Patients with long-standing or chronic hypocalcemia (e.g., owing to vitamin D deficiency or hypoparathyroidism) should receive oral calcium supplementation. Calcium is available as the carbonate, citrate, phosphate, and lactate salt. Calcium requirement varies between 1 and 4 g elemental calcium daily and must be given in divided doses. Vitamin D can be added with calcium to enhance intestinal absorption.

Several points in the management of hypocalcemia should be borne in mind. First, in cases of concomitant mild hypocalcemia with hyperphosphatemia (e.g., renal failure), the hyperphosphatemia should be corrected using phosphate binders, because that alone often leads to correction of the hypocalcemia. Second, magnesium deficits should be corrected because that may restore normal calcium physiology even without calcium supplementation (see "Disorders of Magnesium Homeostasis"). Finally, concurrent severe metabolic acidosis should await correction of the hypocalcemia, because correction of the acidosis is likely to worsen the ionized hypocalcemia and precipitate tetany.

Hypercalcemia

Hypercalcemia has been reported in 15% to 30% of critically ill patients,[282,284] and thus appears to be less common than hypocalcemia. It is more common in patients with higher severity of illness and in those with concurrent renal failure.[282,284]

Causes of Hypercalcemia

Box 54.11 lists causes of hypercalcemia. About 90% of hypercalcemia in ambulatory and non-ICU patients is caused by only two entities: primary hyperparathyroidism and malignancy.[238] The spectrum is a bit broader in critically ill patients.

Primary Hyperparathyroidism

Primary hyperparathyroidism is the most common cause of hypercalcemia, accounting for more than 50% of cases in ambulatory patients. Specific causes include benign adenoma (80%–90%), hyperplasia (10%–20%), and carcinoma (1%). Biochemical abnormalities include elevated circulating intact PTH, hypercalcemia, and hypophosphatemia.[238]

- Thiazide
- Lithium
- Vitamin D/calcium supplements
- Vitamin A

Malignancies

Hypercalcemia is rarely the presenting sign of a malignancy; most malignancies are advanced at the time hypercalcemia develops. About 40% of hypercalcemia in hospitalized patients has been associated with cancer.[285] Almost 80% of malignancy-related hypercalcemia is secondary to the secretion of parathyroid hormone-related peptide (PTHrP) by the malignant cells.[285] PTHrP is not detected by clinical laboratory assays for PTH. Numerous types of malignancies are associated with PTHrP-mediated hypercalcemia, including breast,[286] renal cell, and ovarian carcinomas[238] and hematologic malignancies.[287]

Increased production of 1,25-$(OH)_2D_3$ by malignant cells is a recognized cause of hypercalcemia in patients with lymphomas.[288,289] Finally, osteolytic bone lesions from advanced cancers such as breast, lung, and multiple myeloma frequently result in hypercalcemia.[238]

Rhabdomyolysis

Rhabdomyolysis associated with acute renal failure commonly produces hypocalcemia during the initial phase (see "Hypocalcemia"). Approximately 30% of patients, mostly young men, develop hypercalcemia during resolution of the acute renal failure.[290] Release from injured muscles of previously sequestered calcium appears to be the basis for the hypercalcemia.[290,291] PTH is appropriately suppressed according to most,[292,293] but not all,[294] studies. Vitamin D levels may be elevated[292,294] or suppressed[265,293]; the contribution of vitamin D to the syndrome is unclear. Regardless of the underlying mechanism, the hypercalcemia is usually mild and self-limited.[290]

Immobilization

Immobilization is associated with hypercalcemia as the result of increased bone resorption. Risk factors include duration of bed rest, spinal cord injury, multiple skeletal fractures, and underlying disorders leading to increase bone resorption (e.g., Paget disease, malignancy).[295,296] Although hypercalcemia is usually modest and completely reversible with activity, calcitonin and bisphosphonates can be used with success if treatment is required.[295]

Medications

A small percentage (5% to 10%) of patients treated with lithium develops hypercalcemia as the result of lithium-induced hyperparathyroidism.[238] Hyperparathyroidism may or may not be reversible on discontinuation of therapy. Thiazide diuretics increase tubular reabsorption of calcium and are well known to cause modest hypercalcemia, which revert back to normal upon discontinuation of therapy. More severe hypercalcemia should prompt an evaluation for occult hyperparathyroidism. Vitamin A may increase osteoclast-mediated bone resorption and causes hypercalcemia.

Milk-Alkali Syndrome

This syndrome consists of hypercalcemia (often extreme), metabolic alkalosis, and acute renal failure. It is seen in patients who ingest large quantities of alkaline calcium salts (e.g., calcium carbonate), often with vitamin D preparations.[297] Because of the increasing use of these medications to prevent or treat osteoporosis, the incidence of this syndrome, once considered rare, appears to be increasing.[298]

Clinical Manifestations

Clinical manifestations of hypercalcemia depend on the rate of increase and absolute level of plasma calcium. The most serious manifestations are neurologic and cardiovascular. Patients may experience muscle weakness, fatigue, depression, and altered mental status. At extremely high levels, stupor and coma may ensue.[238,243] Prolonged hypercalcemia lasting longer than 36 hours has been associated with the development of critical illness polyneuropathy and myopathy.[283] Hypercalcemia causes an increased rate of cardiac repolarization and results in shortened QT interval. Conduction disturbances and malignant arrhythmias have been reported with hypercalcemia.[299,300]

Hypercalcemia may lead to acute renal failure from volume depletion and renal vasoconstriction, and polyuria and polydipsia owing to NDI.[238,243] GI symptoms include anorexia, nausea, vomiting, and constipation. Peptic ulcer disease and acute pancreatitis are exceedingly rare, especially in the acute setting.[238]

Diagnosis

The diagnosis of hypercalcemia often is apparent from the history, with an understanding of the differential diagnosis (see Box 54.11). In cases of sustained or unexplained hypercalcemia, assays for intact PTH and vitamin D metabolites are of great value. An assay for PTHrP rarely is necessary in the evaluation of hypercalcemia in a critically ill patient, because in most patients with hypercalcemia of malignancy, the cancer is advanced and the diagnosis will be obvious when the PTH and vitamin D levels are shown to be suppressed.

Treatment

The treatment strategy for hypercalcemia depends on the severity of the disturbance and on its underlying cause. Identification of the probable cause of the hypercalcemia is important both for the immediate and long-term management.

Mild hypercalcemia (total calcium ≤12 mg/dL or 3 mmol/L) is usually caused by primary hyperparathyroidism, thiazide diuretics, calcium and vitamin D supplements, lithium, and immobilization. Treatment should begin with withdrawal of the offending agent (if possible). Volume deficits should be replaced orally if possible. Early mobilization should be encouraged. Loop diuretics should be avoided in patients with mild asymptomatic hypercalcemia as they may exacerbate the volume depletion, leading to increased renal calcium reabsorption.

The immediate treatment of moderate hypercalcemia (total calcium > 12 mg/dL or 3 mmol/L, and ≤ 14 mg/dL or 3.5 mmol/L)

includes the measures discussed earlier, as well as intravenous volume expansion with isotonic saline solution. A loop diuretic will enhance renal excretion of calcium, but care must be taken to avoid volume depletion.

Severe hypercalcemia (total calcium >14 mg/dL or 3.5 mmol/L), even in the absence of signs and symptoms, should be treated as an emergency. Strategies for treatment include (1) enhanced calcium elimination, (2) reduced bone resorption, (3) decreased gut absorption of calcium, and (4) identification and treatment of the underlying cause.

Enhanced Calcium Elimination

Forced diuresis is the mainstay of treatment. Volume expansion with normal saline solution should be instituted immediately at a rate of 200 to 300 mL/h. The net fluid balance in adults should be positive approximately 2 L in 24 hours. Caution must be taken to avoid symptomatic volume overload in patients with impaired myocardial performance and/or renal insufficiency.

Once the volume deficit is adequately replaced, loop diuretics may be added to enhance renal calcium excretion. A dose of loop diuretic that at least doubles the rate of urine output can be given as often as every 8 hours.

For patients with congestive heart failure unresponsive to diuretics, or with advanced kidney failure, dialysis should be considered. Hemodialysis against a solution containing 2.0 mEq/L calcium is very effective in decreasing plasma calcium levels. Lower calcium baths are likely to cause hypotension[301] and precipitate tetany.

Reduced Bone Resorption

Several agents are available for the management of hypercalcemia. Bisphosphonates inhibit the osteoclast function and number and inhibit bone turn over. They are well tolerated, although nephrotoxicity may develop if administered too quickly.[243] Pamidronate (60–90 mg IV) reduces the plasma calcium in 48 to 72 hours and the effect may last for a month.[243] Zoledronic acid may be even more efficacious.[302] With the advent of bisphosphonates, two older agents have fallen into disfavor. Calcitonin has rapid onset of action but tachyphylaxis occurs within 48 to 72 hours. Plicamycin (formerly mithramycin) has unacceptable liver, renal, and bone marrow toxicity; thus use of this medication has fallen out of favor.

Decreased Gut Calcium Absorption

If endogenous vitamin D overproduction is implicated in the hypercalcemia (e.g., lymphoma, sarcoidosis), corticosteroids will lower the plasma calcium, at least partly by decreasing gut calcium absorption.

Disorders of Magnesium Homeostasis

Disorders of magnesium balance may be the most commonly seen electrolyte abnormalities in the ICU. Hypomagnesemia, the more common disorder, is seen in 12% of hospitalized patients and up to 65% of critically ill patients.[303–305] Because of magnesium's involvement in a host of critical physiologic functions,[306] its derangement can be expected to result in a variety of manifestations.

Normal Magnesium Physiology

The normal adult total body magnesium content is approximately 24 g or 2000 mEq, 50% to 60% of which is found in bones and 40% to 50% is in the intracellular compartment, mainly in the muscles and soft tissues. Only about 1% of total body magnesium is in the extracellular space; the normal concentration range is 1.8 to 2.3 mg/dL (1.5–1.9 mEq/L or about 0.7–1.0 mmol/L).[241] In plasma, 20% to 30% of magnesium is bound to protein, mainly albumin, with the rest (70%–80%) in a form that is filterable across the glomerulus.[241] Magnesium is taken up slowly into cells, under no known hormonal control.

Magnesium is a major constituent of chlorophyll, and therefore green vegetables are a good dietary source. Also, magnesium is found in grains, cereals, seeds, nuts, legumes, meat, and seafood.[241,307] The normal adult diet contains about 300 mg of magnesium.[308] Under normal circumstances, about one-third of that is absorbed in the small bowel; there is some obligatory secretion in that segment as well, along some minor reabsorption downstream in the colon.[303] This results in net absorption of about 100 mg/day. (Magnesium absorption is highly dependent on dietary magnesium content, however, and can increase to up to 70%–80% of dietary intake under conditions of magnesium deprivation.[241]) Unlike calcium absorption, magnesium absorption from the intestine does not seem to depend significantly on vitamin D.[241,309] The small intestinal secretion of magnesium normally amounts to a loss of only about 20 mg/day. With acute or chronic diarrhea, however, GI losses can be substantial.[241]

The filtered load of magnesium (the product of the glomerular filtration rate and the plasma concentration of ultrafilterable magnesium) is about 2500 mg/day. To maintain external magnesium balance, the renal excretion of magnesium must equal the intestinal absorption, or about 100 mg/day. Thus the fractional excretion of magnesium ($Mg_{excreted} \div Mg_{filtered}$) is about 4% under normal conditions.[241] With magnesium depletion, the fractional excretion of magnesium can fall to less than 1%, and with magnesium loading, rise to match the excess in the filtered load.[241] This modulation in magnesium excretion is largely due to changes in plasma magnesium concentration.

The major site of renal magnesium reabsorption (60%–70% of the filtered load) is the TAL. This tubular segment is responsible for most of the modulation in magnesium excretion. Magnesium reabsorption here is largely passive and depends on a lumen-positive voltage generated by the (diuretic-inhibitable) Na-K-2Cl transporter channel and potassium recycling via the renal outer medullary potassium channels.[241] This explains why loop diuretics increase urinary magnesium excretion and tend to cause hypomagnesemia. Other factors that inhibit magnesium reabsorption in the TAL include volume expansion, hypercalcemia, hypophosphatemia, and to a lesser extent, metabolic acidosis. Conversely, volume depletion, hypocalcemia, and metabolic alkalosis increase magnesium reabsorption. About 10% of filtered magnesium is reabsorbed in the distal convoluted tubule. Reabsorption at this site is inhibited by thiazide diuretics and stimulated by potassium-sparing diuretics such as amiloride.[303]

Magnesium plays a vital role in cellular physiology. It catalyzes more than 300 enzymatic reactions and is an integral part of all adenosine triphosphate–dependent reactions.[306] It is involved in synthesis of proteins; energy-rich compounds, electron, and proton transporters; DNA and ribonucleic acid transcription; translation of messenger RNA and regulation of mitochondrial function.[306,310] There is evidence that magnesium helps regulate intracellular calcium concentration, especially in vascular smooth muscle, and thereby affects vascular tone.[310] In vitro studies suggest a role for magnesium in inflammation and immunity, although clinical confirmation is lacking.[310]

Assessment of Body Magnesium Status

Because extracellular magnesium accounts for only about 1% of total body magnesium, plasma magnesium is a poor reflection of body magnesium status. Nonetheless, magnesium status is most commonly assessed by measuring plasma magnesium levels. Like calcium, magnesium circulates in the plasma in bound and free (ionized Mg^{2+}) forms, the latter being the metabolically active form. Determination of ionized magnesium is clinically impractical, and there is no reliable correlation with serum albumin concentration. Moreover, the relationship between low ionized magnesium concentration and increased morbidity and mortality in critically ill patients has yet to be clearly established.[311–313] Thus, the available literature does not support the superiority of the measurement of ionized magnesium over the cheaper and widely available total serum magnesium levels.

The magnesium loading test has been proposed as a more sensitive measure of total body magnesium stores than the plasma magnesium concentration. In theory, magnesium-depleted individuals will translocate more of the administered magnesium load into cells and excrete a lower proportion in the urine over 24 hours.[281,303,310] Because the test requires a 24-hour urine collection and must be limited to patients who have normal renal function and who are not taking medications that affect magnesium excretion (see later text), the test is often impractical in the critical care setting.

Hypomagnesemia

Epidemiology

Patients with malnutrition, chronic alcoholism, those with congestive heart failure using loop or thiazide diuretics, patients in the postoperative period (especially after open heart surgery), and patients with cancer are at higher risk than the general ICU population.[303–305,314]

Causes

The causes of hypomagnesemia can be divided into four main categories: (1) insufficient intake, (2) renal loss, (3) extrarenal loss, and (4) redistribution (Box 54.12).

The renal causes can be distinguished from the others by measuring 24-hour urinary magnesium excretion or, more practically, the fractional excretion of magnesium (FE_{Mg}), calculated as follows[303]:

$$FE_{Mg} = \frac{U_{Mg} \times P_{Cr}}{(0.7 \times P_{Mg}) \times U_{Cr}} \times 100,$$

where U_{Mg} and P_{Mg} are the urine and plasma concentrations of magnesium, respectively, and U_{Cr} and P_{Cr} are the urine and plasma concentrations of creatinine. (P_{Mg} is multiplied by 0.7 as this represents the ultrafilterable fraction of magnesium.) A 24-hour urinary magnesium excretion of more than about 25 mg or FE_{Mg} greater than 2% is consistent with renal hypomagnesemia.[238,303] Most hypomagnesemia in critically ill patients is multifactorial.

Deficient Intake

The prevalence of hypomagnesemia in individuals with chronic alcoholism is approximately 20% to 30%. Hypomagnesemia in alcoholic individuals is multifactorial and results from decreased dietary intake, increased renal loss, and acute pancreatitis.[303] Parenteral nutrition is an important cause of hypomagnesemia in the ICU. Patients receiving parenteral nutrition have a higher daily magnesium requirement for unknown reasons.[238]

• BOX 54.12 Causes of Hypomagnesemia

Deficient Intake
- Magnesium-deficient parenteral nutrition
- Protein-calorie malnutrition
- Alcoholism

Renal Loss
- Drug-induced
  - Loop diuretics
  - Thiazide diuretics
  - Aminoglycosides
  - Amphotericin b
  - Cis-platinum
  - Cetuximab
  - Foscarnet
  - Pentamidine
- Volume Expansion
- Osmotic diuresis (e.g., hyperglycemia)
- Alcohol
- Hypercalcemia
- Tubular dysfunction
  - Recovery from acute tubular necrosis
  - Bartter syndrome
  - Gitelman syndrome

Gastrointestinal
- Small intestine resection
- Inflammatory bowel disease
- Jejunoileal bypass surgery
- Diarrhea
- Steatorrhea
- Malabsorption syndromes
- Proton pump inhibitors

Redistribution
- Acute pancreatitis
- Hungry bone syndrome

Gastrointestinal Losses

Diarrheal fluid contains a high concentration of magnesium—up to 16 mg/dL[238,310]—and hypomagnesemia is a common finding in patients with acute or chronic diarrhea from any cause. Because intestinal absorption of magnesium occurs primarily in jejunum and ileum, conditions such as celiac disease, inflammatory bowel disease, extensive small bowel resection, and jejunoileal bypass surgery for obesity are frequently associated with intestinal magnesium wasting.[303] The prolonged use of proton pump inhibitors increases the risk of hypomagnesemia in the general population[315] as a result of reduced GI absorption; however, the exact mechanism remains unclear.[316]

Renal Losses

Medications are perhaps the most important cause of renal magnesium wasting in critically ill patients. Loop diuretics are commonly used at high doses. Aminoglycosides may cause asymptomatic hypomagnesemia 3 to 4 days after initiation of therapy; typically

it resolves after cessation of therapy.[238,317] Almost all patients who receive cisplatin develop renal magnesium wasting and hypomagnesemia, which may persist for months after discontinuation of therapy.[318] Most patients who receive IV pentamidine therapy develop renal magnesium wasting and hypomagnesemia that may last for 1 to 2 months after cessation of the therapy.[238] The renal magnesium wasting associated with chronic alcohol use may take up to a month to resolve with abstinence.[303]

Redistribution

Hypomagnesemia is reported in up to 20% of patients with acute pancreatitis.[305,310] The proposed mechanism is saponification of necrotic fat with magnesium and calcium. The mechanism of hypomagnesemia with the hungry bone syndrome (following parathyroidectomy for hyperparathyroidism) is rapid bone uptake of magnesium during remineralization.

Clinical Manifestations

Hypomagnesemia in critically ill patients has been associated with a twofold increase in mortality, even after adjustment for severity of illness.[319] (The observation that magnesium supplementation has not been shown to improve outcome[303] suggests that hypomagnesemia may be a marker for pejorative conditions not captured by severity of illness scores.)

The signs and symptoms of hypomagnesemia are cardiovascular, neuromuscular, and metabolic and are shown in Box 54.13.[238,303,306,310] There is little evidence that hypomagnesemia is associated with arrhythmias in otherwise healthy individuals. In the setting of acute myocardial ischemia, however, even mild hypomagnesemia has been associated with increased frequency of ventricular arrhythmias.[303] Results of recent large clinical trials, however, have shown no benefit to magnesium supplementation in this setting in the absence of overt hypomagnesemia.[310] Torsades de pointes is a malignant ventricular arrhythmia associated with magnesium deficiency or drugs that prolong the QT interval. Magnesium is the treatment of choice. Magnesium supplementation after cardiopulmonary bypass may reduce the frequency of ventricular ectopy.

The hypocalcemia associated with hypomagnesemia is caused by both hypoparathyroidism and bone resistance to PTH. Hypokalemia is caused by hypomagnesemia-induced renal potassium wasting and will not resolve until the hypomagnesemia is corrected.[320,321]

Treatment

In patients who have malignant cardiac arrhythmias (ventricular fibrillation or torsades de pointes) or seizure attributed to hypomagnesemia, intravenous magnesium must be given immediately (2 g of magnesium sulfate over minutes).

Less urgent cases, but those in which signs and symptoms are present, may be treated with magnesium sulfate 6 g IV in the first 24 hours followed by 3 to 4 g daily for the next 2 to 6 days.[238,303,310] Because translocation of magnesium into cells is a slow process and because urinary excretion is proportional to the plasma magnesium level, more rapid infusion rates are associated with urinary magnesium wasting that defeats the purpose of the therapy. Effective intravenous infusions should be given over 8 to 12 hours.[303] For patients with impaired renal function, the dose should be reduced by 50% to 75% and serum magnesium levels should be monitored frequently. Patients should be monitored closely for symptoms and signs of hypermagnesemia (see the following text).

Patients with refractory hypokalemia in the setting of hypomagnesemia, who are receiving high doses of potassium, must be monitored closely for the development of hyperkalemia once the magnesium has been replenished.

For mild asymptomatic hypomagnesemia, patients who can tolerate oral medication should receive oral magnesium salts (e.g., magnesium chloride, 500 mg slow-release tablets, 10–12 per day in divided doses). High doses of oral magnesium salts may cause diarrhea.

• BOX 54.13 Clinical Manifestations of Hypomagnesemia

Cardiovascular

Ventricular arrhythmias
- Torsades de pointes
- Ventricular fibrillation; premature ventricular contractions
- Increased digitalis toxicity

Conduction disturbances
- Prolonged QT interval
- Prolonged QRS duration
- ST depression
- Peaked T wave

Neuromuscular
- Muscle weakness
- Tetany
- Horizontal and vertical nystagmus
- Choreoathetoid movements
- Seizures

Metabolic

Hypokalemia, refractory
Hypocalcemia, refractory

Hypermagnesemia

Causes

Hypermagnesemia is much less common than hypomagnesemia. Patients with normal renal function have a prodigious capacity to excrete excess magnesium through the kidneys.[238] Thus hypermagnesemia is seen only in patients with compromised renal function who are receiving enteral or parenteral magnesium, or in patients with normal renal function receiving massive exogenous magnesium (e.g., treatment for preeclampsia and eclampsia).[238] The causes of hypermagnesemia are shown in Box 54.14.

• BOX 54.14 Causes of Hypermagnesemia

Patients With Renal Insufficiency

Magnesium-containing antacids (e.g., magnesium aluminum hydroxide)
Magnesium-containing laxatives or enemas (e.g., magnesium citrate)

Patients With Normal Renal Function

- Asystole

Gastrointestinal
- Nausea and vomiting
- Ileus

Neuromuscular
- Hyporeflexia
- Flaccid skeletal muscle paralysis
- Respiratory muscle weakness and paralysis
- Lethargy
- Coma

Urinary retention

Clinical Manifestations

The clinical manifestations of hypermagnesemia (Box 54.15) are largely due to the effect on the heart, nerve, and smooth muscle. Initial manifestations, with plasma concentrations of 4 to 6 mg/dL, include nausea and vomiting, hypotension, and flushing. More severe effects, including death,[322] are seen with levels exceeding 6 mg/dL.

Treatment

Treatment of hypermagnesemia depends on the severity of symptoms and the patient's renal function. Patients with adequate renal function and mild asymptomatic hypermagnesemia require no treatment except to remove all sources of exogenous magnesium. The half-time of elimination of magnesium is about 28 hours.[238] Magnesium excretion may be enhanced by saline solution infusion and the use of loop diuretics.[238] (Care must be taken to prevent hypokalemia and metabolic alkalosis.) Patients with symptomatic hypermagnesemia, especially those with cardiovascular manifestations, require urgent treatment. The recommended therapy is calcium gluconate 1 g IV over 5 minutes.

Patients with acute or chronic renal failure and symptomatic hypermagnesemia require dialysis to remove excess magnesium. Hemodialysis removes magnesium efficiently, yielding a 30% to 50% reduction in predialysis serum magnesium levels after a 3- to 4-hour treatment.[238]

Phosphorus

Phosphorus has an essential role in normal physiology. It is necessary for skeletal integrity; energy economy (formation of high-energy phosphate bonds); nucleic acid, lipid, and protein structure; cell signaling; and buffering.[241] It is not surprising, therefore, that disorders of phosphorous homeostasis have diverse manifestations.[323–325] Hypophosphatemia is considerably more common in hospitalized and critically ill patients than hyperphosphatemia.

Normal Phosphorus Homeostasis

Total body phosphorus amounts to about 700 g in an adult. About 85% resides in the skeleton, about 15% in soft tissues, and only about 1% in blood.[240] Circulating phosphorus is mostly in the form of inorganic phosphates. The normal plasma concentration of phosphorus is 2.5 to 4.5 mg/dL, also expressed as a phosphate concentration of 0.9 to 1.45 mmol/L. (Phosphate concentration should not be expressed in milliequivalents per liter because the average valence of plasma phosphates, a mixture of HPO_4^{2-} and $H_2PO_4^-$, changes with pH.[326]) Of that circulating phosphorus, about 75% is free and ultrafilterable; 25% is protein bound.[241]

A normal adult diet includes about 1000 mg of phosphorus per day. Stool contains about 300 mg, so the net absorption (mostly in the small intestine under the influence of vitamin D) is about 70%. The dietary and secreted phosphorus may be bound into insoluble, nonabsorbable salts by cations such as Al^{3+}, Ca^{2+}, and Mg^{2+}. Thus the kidney is responsible for excreting about 700 mg phosphorus per day. Almost all phosphorus reabsorption takes place in the proximal tubule. The most important regulators of renal phosphorus excretion are PTH, fibroblast growth factor (FGF)-23, and dietary phosphorus content. PTH increases phosphorus excretion.[240] FGF-23, a phosphatonin released by osteocytes and osteoblasts in bone, increases urinary phosphorus excretion.[327] Renal excretion of phosphorus is proportional to the dietary intake. Other factors that increase renal phosphorus excretion include extracellular volume expansion, acute hypercalcemia, diuretics, and glucocorticoids.[240,241] Acid-base disorders have a variable effect on phosphorus reabsorption depending on their direction and duration[240,241] with one exception: respiratory alkalosis causes a marked decrease in renal phosphorus excretion by causing redistributive hypophosphatemia[324] (see the following text).

Phosphorus homeostasis depends on PTH, FGF-23, and vitamin D. PTH and FGF-23 cause phosphaturia by decreasing renal proximal tubule reabsorption. Active vitamin D inhibits PTH release. Vitamin D activation (1-α hydroxylation) in the kidney is inhibited by FGF-23 and hyperphosphatemia. This, in turn, reduces intestinal phosphorus absorption and allows increased PTH secretion, causing phosphaturia and returning plasma phosphorus toward normal. Hypophosphatemia reverses this physiology, allowing increased gut absorption and reduced renal excretion of phosphorus.

Hypophosphatemia

Hypophosphatemia is common in critically ill patients. It has been reported in 29% of adult surgical patients (and 45% of patients with one or more risk factors for hypophosphatemia), and—liberally defined—in 76% of pediatric ICU patients.[328] Patients with malnutrition, uncontrolled diabetes mellitus, sepsis, and chronic alcoholism are at high risk for hypophosphatemia.[329] It is associated with a marked increase in mortality in patients with sepsis,[330] and serum phosphorus concentration is inversely correlated with APACHE II (acute physiology, age, and chronic health evaluation) score after liver resection.[331] In these situations, the serum phosphorus concentration probably is a marker of severity of illness. If severe, however, hypophosphatemia itself may cause serious complications.

Causes of Hypophosphatemia

The causes of hypophosphatemia classically are divided into three general categories: (1) redistribution from the extracellular to the intracellular space, (2) increased renal excretion, and (3) decreased intestinal absorption (Box 54.16). It is important to recognize that many factors have several different effects on phosphorus homeostasis.

Redistribution
Respiratory alkalosis causes intracellular phosphate shift (by stimulating glycolysis) and can cause severe symptomatic hypophosphatemia. Respiratory alkalosis is commonly encountered in ICU patients owing to sepsis, liver failure, and in patients requiring mechanical ventilation; in the last case, the degree of hypophosphatemia is proportional to the pH.[238,332] Sepsis is commonly associated with hypophosphatemia, probably owing to hyperventilation and respiratory alkalosis. Rapid refeeding of patients with malnutrition may result in significant hypophosphatemia owing to an insulin-mediated intracellular phosphate shift. In one study of ICU patients, refeeding hypophosphatemia developed in 34% of patients after 48 hours of starvation and was predicted by the prealbumin concentration. Profound hypophosphatemia (<1 mmol/dL) occurred in 10% of patients.[333] Patients with anorexia nervosa, uncontrolled diabetes mellitus, chronic malnutrition, and chronic alcoholism are at a particularly high risk of developing refeeding syndrome. Leukemia in the leukemic phase[334] and with rapid leukocyte reconstitution after bone marrow transplant[335] have been reported to cause severe redistributive hypophosphatemia.

Diabetic ketoacidosis is associated with phosphorus efflux from cells and increased urinary phosphate excretion, resulting in severe total body phosphorus depletion (often with a deceptively normal presenting serum phosphorus concentration).[324] Initiation of insulin therapy in such patients results in intracellular phosphate shift and can result in profound, symptomatic hypophosphatemia.[324]

Increased Renal Excretion
Any cause of primary hyperparathyroidism will cause phosphaturia and tend to cause hypophosphatemia. Hyperparathyroidism caused by hypocalcemia or vitamin D deficiency or resistance is similarly associated with hypophosphatemia. The exception is the secondary hyperparathyroidism of chronic kidney disease, in which hyperphosphatemia owing to decreased renal phosphorus elimination is characteristic. Vitamin D deficiency or resistance also causes hypophosphatemia from decreased intestinal phosphate absorption. Extracellular volume expansion increases the filtered phosphorus load and dilutes the luminal concentration of phosphorus, resulting in phosphaturia. Ethanol and glycosuria both decrease proximal tubule phosphate reabsorption.[238,324] All diuretic drugs, but particularly those with proximal tubular effects such as acetazolamide and, to a lesser degree, thiazides, cause phosphaturia.

Decreased Intestinal Absorption
Salts of Al^{3+} and Ca^{2+}, formulated for oral administration as antacids or as phosphate-binding medications, can cause malabsorptive hypophosphatemia. Chronic diarrhea and steatorrhea may cause reduce intestinal phosphate absorption directly and by way of vitamin D deficiency and cause hypophosphatemia.

The hypophosphatemia commonly associated with chronic alcohol ingestion is multifactorial. Dietary phosphorus deficiency, malabsorption, antacid ingestion, hypocalcemia and secondary hyperparathyroidism, hypomagnesemia, and an ethanol-induced renal tubular defect all have been implicated.[324]

Clinical Manifestations

Important clinical manifestations of hypophosphatemia are shown in Box 54.17. Most patients are asymptomatic until plasma phosphorus falls below 1.5 mg/dL or about 0.5 mmol/L. The most severe manifestations, such as hemolysis, spontaneous rhabdomyolysis, seizure, or coma, are not commonly seen with phosphorus above 1 mg/dL (0.3 mmol/L). Acute clinical manifestations are thought to be largely due to altered cellular energy economy.[238,240,323,324]

Treatment

The therapy of hypophosphatemia starts with its prevention. In critically ill patients, this depends on recognition and correction of the factors that lead to hypophosphatemia. The astute clinician will be able to anticipate the development of hypophosphatemia (in refeeding, for example), monitor the patient appropriately, and supplement phosphorus accordingly. Patients receiving total parenteral nutrition should receive adequate phosphorus for their level of renal function (see Chapter 78).[326]

The exact method of phosphorus supplementation in hypophosphatemia depends on the severity of the disturbance and the patient's underlying condition. In mild to moderate hypophosphatemia (>1.5 mg/dL or about 0.5 mmol/L) oral replacement is usually sufficient. Skim milk is an excellent source of phosphorus and provides 900 mg/L of inorganic phosphate. In patients who cannot tolerate milk, oral sodium phosphate, formulated to provide 250 mg of phosphate in each tablet, can be used. (Fleet Phospho soda was once recommended for phosphate supplementation but is no longer available due to safety concerns.[260]) Supplementation should continue for several days to replenish phosphorus deficits adequately. Administration of sufficient doses of oral phosphorus preparations very commonly causes diarrhea, limiting its usefulness.

Patients with severe hypophosphatemia (<1.5 mg/dL), or those for whom the enteral route is not an option, require intravenous phosphorus repletion. In such patients, the recommended dose is 2.5 to 5.0 mg (0.08–0.16 mmol)/kg body weight over 6 hours; doses at the higher end of the range are reserved for profound, symptomatic hypophosphatemia.[240,326] A recent study used a more aggressive, weight-based protocol in critically ill patients and found it to be safe and effective.[336] Clinicians should recognize that the administered intravenous phosphorus can complex with circulating calcium, leading to a decrease in ionized calcium (with attendant hypotension and tetany) and metastatic calcification. The use of potassium salts of phosphate for repletion of phosphorus deficits has been associated with dangerous hyperkalemia. For that reason, potassium deficits and phosphorus deficits should be treated separately.[326]

Hyperphosphatemia

Hyperphosphatemia (plasma phosphorus >5.0 mg/dL or a phosphate concentration >1.6 mmol/L) most often is associated with renal dysfunction. Massive influx of phosphorus into the extracellular space, however, either from endogenous sources or exogenous, can overwhelm normal renal excretory mechanisms and lead to severe hyperphosphatemia.

Causes of Hyperphosphatemia

Hyperphosphatemia may be caused by (1) redistribution of phosphorus from the intracellular to the extracellular space, (2) increased phosphorus intake, and (3) decreased renal excretion of phosphorus (Box 54.18). It is important to recognize that most hyperphosphatemia is multifactorial.

• BOX 54.18 Causes of Hyperphosphatemia

- Redistribution
  - Tumor lysis syndrome
  - Rhabdomyolysis
  - Pancreatitis
  - Respiratory acidosis
  - Lactic acidosis
  - Diabetic ketoacidosis
- Increased Intake
  - Phosphate-containing enemas and laxatives
  - Intravenous phosphate
  - Hypervitaminosis D
- Decreased renal excretion
  - Acute renal failure
  - Chronic kidney disease
  - Hypoparathyroidism
- Pseudohyperphosphatemia

Redistribution

Hyperphosphatemia is a common complication of the tumor lysis syndrome.[72] Similarly, rhabdomyolysis often is associated with hyperphosphatemia, especially when it is complicated by acute renal failure.[74,337] Less commonly recognized causes of redistributive hyperphosphatemia include acute and chronic respiratory acidosis, acute pancreatitis,[338] DKA,[339] and lactic acidosis.[340]

Increased Intake

Exogenous administration of phosphorus is unlikely to cause hyperphosphatemia unless renal function is compromised. Several cases have been reported of potentially life-threatening hyperphosphatemia and hypocalcemia after the use of phosphate-containing laxatives and enemas, especially in children and elderly patients.[261,263,264,341,342] Overly aggressive parenteral phosphorus supplementation can cause hyperphosphatemia. Hypervitaminosis D causes increased intestinal uptake of phosphorus and a decrease in PTH, both of which predispose to hyperphosphatemia.

Decreased Renal Excretion

Acute renal failure is associated with elevated phosphate levels caused by the inability of the kidneys to excrete phosphate load. This is particularly pronounced in patients in whom acute renal failure is caused by the tumor lysis syndrome or rhabdomyolysis. Advanced chronic kidney disease (glomerular filtration rate < 25 mL/min) commonly is associated with hyperphosphatemia. Such patients are particularly susceptible to developing severe and life-threatening hyperphosphatemia if they are exposed to an acute increase in serum phosphate levels. Hypoparathyroidism of any cause is associated with impaired renal phosphorus excretion.

Pseudohyperphosphatemia

Spurious increases in the measured plasma phosphorus concentration are reported to be caused by contamination of the blood sample with phosphate-buffered saline solution as a diluent for heparin[343] or during sample processing by the laboratory.[344] Even microliter volumes of the contaminant can cause significant elevations in the measured phosphorus.[343] Paraproteinemia can also cause psuedophyperphosphatemia.

Clinical Manifestations

Phosphate complexes with circulating calcium, reducing the concentration of ionized calcium. Thus most of the clinical consequences of hyperphosphatemia are those of hypocalcemia (see previous text). In addition, ectopic deposition of calcium phosphate salts can occur, especially when the calcium-phosphorus product exceeds 70 mg/dL.[240] Such ectopic calcification in the heart can cause conduction and rhythm disturbances.[345]

Because phosphate is an "unmeasured ion," hyperphosphatemia causes increases in the anion gap. Extreme hyperphosphatemia can cause shocking elevations in the anion gap. One case of hyperphosphatemia from Phospho-Soda intoxication (serum phosphorus 62.5 mg/dL) was associated with an anion gap of 51 mmol/L.[346] To estimate the contribution of phosphorus to the anion gap, one must know not only the plasma concentration of phosphorus but also the pH, because the valence of phosphate varies with pH—from 1.8 mEq/mmol at pH 7.4 to 1.6 mEq/L at pH 7.0.[326] Because extreme hyperphosphatemia can be caused by lactic or ketoacidosis (see previous text), an elevated anion gap in the setting of hyperphosphatemia should never be attributed to the hyperphosphatemia itself without further investigation.

Treatment

Treatment of hyperphosphatemia consists of reducing the phosphate intake and enhancing the removal of excess phosphate. If the patient is taking an oral diet, dietary phosphate should be restricted to less than 800 mg/day. Oral phosphate binders can be added with meals to decrease intestinal phosphate absorption.

Patients with normal renal function can be treated with saline solution diuresis to increase renal phosphate excretion. Acetazolamide can be added to enhance phosphaturia, taking care to avoid a metabolic acidosis. Patients with severe hyperphosphatemia with coexisting renal failure may require renal replacement therapy in the form of intermittent or continuous hemodialysis.

Key Points

- Acid-base disorders often provide a window into underlying pathology. Optimal diagnosis of acid-base disorders requires familiarity with the rules of normal compensation and the pitfalls characteristic of critical illness.
- Acute hyperkalemia may result from exogenous potassium administration or redistribution from cells. Acute hypokalemia always is caused by redistribution.
- Patients, particularly women, are predisposed to catastrophic hyponatremia if hypotonic fluids are administered in the postoperative period.
- The treatment of acute symptomatic hyponatremia is largely independent of its cause, whereas the treatment of chronic hyponatremia depends critically on the underlying pathophysiology.
- Hypernatremia in hospitalized patients should be considered iatrogenic, reflecting insufficient recognition of the causes of water loss and inadequate water replacement in vulnerable patients.
- Plasma calcium concentration, corrected for the plasma albumin concentration, correlates poorly with ionized calcium in critically ill patients. If possible, ionized calcium should be directly measured when considering disorders of calcium homeostasis.
- The clinical manifestations of many metabolic disorders have common features (e.g., hypocalcemia, hypomagnesemia, hyperphosphatemia, metabolic alkalosis), relating to their overlapping pathophysiology.

Review Questions

1. Which of the following statements regarding the treatment of lactic acidosis with sodium bicarbonate is most accurate?
   a. Administration can result in hypercalcemia.
   b. There is a risk of paradoxical worsening of intracellular acidosis.
   c. Treatment of lactic acidosis in patients with arterial pH less than 7.3 has been shown to improve hemodynamic parameters but not survival.
   d. Administration is likely to reduce lactate production.
   Answer: b. Treatment of lactic acidosis with sodium bicarbonate will cause an increase in carbon dioxide generation, which may lower intracellular pH. By raising extracellular pH, bicarbonate administration will reduce ionized calcium (answer a incorrect). Despite the theoretical appeal of raising extracellular pH, studies have not shown any improvement in hemodynamic parameters or survival (answer c incorrect). By causing systemic alkalinization, bicarbonate administration is likely to cause an increase in lactate generation rate (answer d incorrect).
2. You are evaluating a 50-year-old patient in the intensive care unit (ICU). The patient was admitted with sepsis from a urinary source and has been intubated and receiving pressors (norepinephrine and dopamine) for the past 3 days. His past medical history includes diabetes and benign prostatic hyperplasia.

   On examination his vital signs are within normal limits and he appears to be comfortable and in no distress. His laboratory findings are as follows: sodium 143 mEq/L, potassium 5.8 mEq/L, chloride 108 mEq/L, bicarbonate 24 mEq/L, glucose 90 mg/dL, blood urea nitrogen (BUN) 12 mg/dL, and creatinine 0.9 mg/dL (baseline 0.7 mg/dL). All electrolyte values were normal yesterday. Arterial blood gas shows pH 7.38, partial pressure of carbon dioxide (P_{CO_2}) 41 mm Hg, and partial pressure of arterial oxygen (Pa_{O_2}) 180 mm Hg. Urinary electrolytes include the following: urinary sodium 87 mEq/L, urinary potassium 35 mEq/L, and urinary chloride 110 mEq/L. Which of the following is the most likely explanation for the elevated potassium level?
   a. Norepinephrine treatment
   b. Type 4 renal tubular acidosis (RTA)
   c. Starvation ketosis
   d. Pseudohyperkalemia
   Answer: d. There are various causes for hyperkalemia in critically ill patients, including excessive potassium load, translocation of potassium across cellular membrane, and inability to eliminate excess balance. Norepinephrine treatment has not been associated with hyperkalemia (as opposed to succinylcholine or digitalis) (answer a incorrect), and the presence of normal laboratory findings on the previous day makes intravenous (IV) RTA less likely (answer b incorrect). There is no evidence of ketosis with no acidosis, no anion gap, and normal serum glucose (answer c incorrect). Pseudohyperkalemia is the most likely explanation because of normal laboratory findings the day before without change in clinical status. Pseudohyperkalemia has several possible causes, including hemolysis and fist clenching with a tourniquet in place during phlebotomy (answer d correct).
3. A 55-year-old man with small cell lung cancer and syndrome of inappropriate antidiuretic hormone secretion (SIADH) was admitted with seizure and hyponatremia with a sodium level of 107 mmol/L on admission. A 3% sodium chloride (NaCl) infusion is started at 80 mL/h and after 6 hours the sodium level is 122 mmol/L.
   Which of the following next steps is most appropriate at this point?
   a. Stop the 3% NaCl infusion and monitor sodium level every 4 hours.
   b. Stop the 3% NaCl infusion and start a 0.9% infusion at 160 mL/h.
   c. Stop the 3% NaCl and give hydrocortisone 100 mg 3 times a day.
   d. Stop the 3% NaCl, start 5% dextrose in water (D_5W) and desmopressin to lower the sodium level.
   Answer: d. Patients with acute symptomatic hyponatremia need to be treated with an infusion of 3% saline solution to rapidly increase the plasma sodium concentration and prevent cerebral edema. The sodium goal is 6 mmol/L in the first 24 hours as a more rapid rise is unnecessary and can induce osmotic demyelination syndrome. This patient had a very rapid increase in the sodium level; therefore, the sodium concentration must be lowered. This can be best achieved using desmopressin and D_5W (choice d). Monitoring chemistry (choice a), administration of normal saline solution (answer b) may result in even more rapid increase in sodium. Hydrocortisone (answer c) has no role.
4. Which of the following is not a preferred treatment for hypercalcemia?
   a. Plicamycin
   b. Calcitonin
   c. Hemodialysis
   d. Zoledronic acid
   Answer 4: a Treatment of hypercalcemia includes calcium elimination and reduced bone resorption. Zoledronic acid is one of the most efficacious bisphosphonates used to treat hypercalcemia (answer d incorrect). Calcitonin rapidly reduces calcium levels but its effects dissipate within 72 hours (answer b incorrect). Hemodialysis can be used in certain cases to treat refractory hypercalcemia (answer c). Despite its effect on calcium level, the use of plicamycin is discouraged because of its side effect profile (renal liver and bone marrow toxicity) (answer a correct).
5. Which of the following electrolyte abnormalities can cause an elevated anion gap?
   a. Hypercalcemia
   b. Hypernatremia
   c. Hyperphosphatemia
   d. Hypermagnesemia
   Answer: c. The anion gap is the difference between measurements of positively charged and negatively charged particles. In cases of elevated calcium (answer a), sodium (answer b), or magnesium (answer d), there is a concomitant increase in measured negative charges, thus not increasing the anion gap. The presence of hyperphosphatemia can cause large elevations in the anion gap because it is an unmeasured anion.
6. A cachectic homeless man is admitted to the intensive care unit (ICU) obtunded, hypotensive, and hypoxemic. Initial plasma laboratory findings are as follows: sodium 130 mmol/L, potassium 3.6 mmol/L, chloride 96 mmol/L, bicarbonate 13 mmol/L, glucose 62 mg/dL, blood urea nitrogen (BUN) 48 mg/dL, creatinine 1.8 mg/dL. A chest x-ray demonstrates

several spiculated nodules within both lung fields. He is intubated and treatment with intravenous normal saline solution containing dextrose, thiamine, and folic acid is started. Which of the following electrolyte disturbances would the patient be at the highest risk of developing with the described treatment?

a. Hypernatremia
b. Hyperkalemia
c. Hypermagnesemia
d. Hypercalcemia
e. Hypophosphatemia

Answer: e. This patient has risk factors and physical findings of long-standing malnutrition and is at risk of developing the refeeding syndrome as a result of endogenous insulin secretion in response to dextrose. Hypernatremia is unlikely to develop with isotonic fluids (answer a incorrect), and insulin-mediated potassium entry into cells would most likely result in hypokalemia rather than hyperkalemia (answer b incorrect). Hypermagnesemia would likely not occur without excessive magnesium ingestion (answer c incorrect), and as the metabolic acidosis (likely ketoacidosis) corrects, the blood pH will rise, thus placing him at risk for hypocalcemia owing to displacement of albumin-bound protons with calcium (answer d incorrect). Hypophosphatemia can occur as the result of insulin-mediated phosphorus entry into cells (answer e correct), and this may be life-threatening if appropriate replenishment is not provided.

- Hypoglycemia in Patients Without Diabetes

Diabetes Mellitus: Epidemiology and Classification

In 2015, 415 million people worldwide were living with diabetes mellitus (DM) with a projected increase to over 642 million by 2040.[1] Twelve percent of the global health expenditure is spent treating DM and its complications,[1] yet despite this expenditure on health care, 5 million people died from DM in 2015.[1] In the United States, 29.1 million people have DM but more than 25% of them are not yet diagnosed.[2] An additional 86 million people have prediabetes, and 90% of these patients are unaware of the 15% to 30% risk of developing DM over the next 5 years.[2] The medical costs for those in the United States with DM are 2.3 times higher than for those who do not have DM.[3] Diabetes remains the primary cause of all new cases of kidney failure and nontraumatic lower extremity amputation and is the seventh leading cause of death in the United States.[4,5]

The 2016 American Diabetes Association Guidelines classified diabetes into the following categories[6]:

1. Type 1 diabetes
2. Type 2 diabetes
3. Gestational diabetes
4. Specific types of diabetes related to other causes

Patients with DM have a relative insulin deficiency (type 2 DM) or absolute insulin deficiency (type 1 DM). Type 1 DM is caused by autoimmune β-cell destruction, which typically leads to absolute insulin deficiency. Type 2 DM is caused by insulin resistance in the liver, skeletal muscle, and adipose tissue along with a decline in insulin secretion that results in a state of relative insulin deficiency. This accounts for 90% to 95% of DM in the United States. Obesity, lack of physical activity, and unhealthy diet increase the risk of type 2 DM. Although most type 2 DM is diagnosed in adults, children are at increased risk as well owing to the formerly stated risk factors. The rise of type 2 DM in those younger than 20 years of age parallels the increased prevalence in obesity in children.[4,7] Low socioeconomic status and members of minority races and ethnic groups—African Americans, Native Americans, Hispanics, Pacific Islanders, and Asian Americans—are at greatest risk for developing type 2 DM and have a higher risk of developing the microvascular complications of diabetes.[8]

Gestational diabetes (GDM) represents diabetes diagnosed in the second or third trimester of pregnancy that is not overt DM,[6] whereas women detected to have DM in their first trimester would be considered to have pregestational type 2 DM.[6] Women with GDM have up to a 69% risk of GDM with subsequent pregnancies[9] and a 17% to 63% risk of developing type 2 DM within 5 to 16 years.[9,10] All women with a history of GDM should undergo lifelong screening for type 2 DM[6, 9,10] beginning with glucose testing at 6 to 8 weeks postpartum and continuing every 3 years.[10]

Other forms of diabetes include neonatal diabetes, maturity-onset diabetes of the young, diabetes related to abnormalities in the exocrine pancreas, such as cystic fibrosis, drug-induced diabetes, partial or total pancreatectomy, or pancreatitis.[6]

Insulin deficiency can be absolute resulting from β-cell destruction (autoimmune, pancreatitis, or surgical excision) or relative resulting from insulin resistance.[11] In the absence of insulin (relative or absolute deficiency) tissues are unable to use glucose and sense a state of "starvation," leading to further increase in glucose through stimulation of glycogenolysis and gluconeogenesis. In this setting, amino acids and free fatty acids (FFAs) serve as fuel for gluconeogenesis resulting in ketogenesis.[12] The actions of insulin are shown in Box 55.1.

Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar State

Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar state (HHS), the two hyperglycemic emergencies in patients with diabetes,[13] are states of decompensated hyperglycemia. In DKA, insulin deficiency and increased counterregulatory hormones lead to abnormal lipid and carbohydrate metabolism that results in hyperglycemia and ketosis.[13] The diagnosis of DKA is made when the following criteria are met: serum glucose above 250 mg/dL, serum pH less than 7.3, bicarbonate less than 18 mEq/L, positive ketones, and anion gap above 10 mEq/L.[13]

HHS is a state of relative insulin deficiency with adequate insulin to prevent lipolysis and ketogenesis. A decrease in pH related to ketone formation causes the lethargy and nausea of DKA. Without these symptoms, patients with HHS present with more pronounced hyperglycemia, dehydration, and hyperosmolality.[13] The diagnosis of HHS is made when the following criteria are met: plasma glucose greater 600 mg/dL, pH greater than 7.3, bicarbonate greater than 18 mEq/L, small or negative ketones, and serum osmolality greater than 320 mOsm/kg.[13] Table 55.1 lists the diagnostic criteria for DKA and HHS.

Epidemiology

DKA is a possible fatal complication of uncontrolled DM, particularly type 1 DM. Mortality for DKA has decreased to less than 1% but reaches 5% for elderly adults or those with life-threatening illnesses.[13,14] DKA account for 500,000 hospitalizations per year with patients younger than 45 years of age having far higher hospitalization rates compared with older patients.[15,16] The 3.4-day average length of hospital stay for DKA causes a significant economic

• BOX 55.1 Actions of Insulin on Target Organs

Adipose Tissue
Increased glucose entry
Increased fatty acid synthesis
Increased glycerol phosphate synthesis
Increased triglyceride deposition
Activation of lipoprotein lipase
Inhibition of hormone-sensitive lipase

Liver
Decreased ketogenesis
Increased protein synthesis
Increased lipid synthesis
Decreased glucose output via increased glycogen synthesis and decreased gluconeogenesis

Muscle
Increased glucose entry
Increased glycogen synthesis
Increased amino acid uptake
Increased protein synthesis in ribosomes
Decreased protein catabolism
Decreased release of gluconeogenic amino acids
Increased ketone uptake
Increased K^+ uptake

General
Increased cell growth

burden with an estimated annual direct and indirect cost of $2.4 billion.[16,17] DKA is the most common cause of death in children and adolescents with type 1 DM.[13,18,19]

DKA is most common in patients with absolute insulin deficiency such as type 1 DM or pancreatogeneous diabetes, although it can also occur in type 2 DM in two scenarios: (1) acute glucose toxicity and (2) ketosis-prone (or "flatbush") diabetes. About 35% of cases of DKA occur in patients with type 2 DM and in 50% of these patients, it was the initial manifestation of diabetes.[16]

Acute hyperglycemia causes glucose toxicity that leads to reduced β-cell insulin secretion. As the β-cell production of insulin falls, glucose levels further increase, exacerbating the process.[20] Insulin secretion recovers as the glucose levels are lowered, thereby correcting the toxicity. Ketosis-prone diabetes occurs more commonly in African Americans and Hispanics[12,13,16,20] who are obese and have a strong family history of DM.[21–23] Although patients with ketosis-prone type 2 diabetes present in a ketotic, insulin-deficient state, many patients are able to restore insulin secretory capacity and discontinue insulin within a few months of treatment.[21]

HHS, formally known as hyperglycemic hyperosmolar nonketotic state, is the most serious diabetic emergency in type 2 DM. It is characterized by severe dehydration, hyperglycemia and hyperosmolality.[13,24] HHS most commonly occurs in elderly adults with type 2 DM but it can also occur in younger adults and even children. Although the incidence of HHS is 1 in 1000 or less than 1%, the severity of the illness is better characterized by the 10% to 20% mortality rate.[12,16,24] Severe dehydration, advanced age, and other comorbid conditions are associated with increased mortality.[13]

Pathophysiology

DKA is a result of insulin deficiency and elevated counterregulatory hormones (glucagon, growth hormone, cortisol, and catecholamines). In the absence of insulin the liver, adipose tissue, and skeletal muscle are unable to use glucose and sense a state of "starvation." The resulting gluconeogenesis and glycogenolysis worsen the hyperglycemia.[12,13,25] The combination of insulin deficiency and increased counterregulatory hormones leads to an increase in lipolysis and release of FFAs into the circulation. Ketone bodies (acetoacetate and β-hydroxybutyrate) are formed by hepatic oxidation of these FFA.[13] Ketone bodies are weak acids that deplete the body of bicarbonate, leading to development of acidosis.[16]

Hyperglycemia-induced osmotic diuresis causes a net loss of potassium, chloride, sodium, and phosphate. Potassium is shifted to the extracellular space but cannot reenter the cell in the setting of insulinopenia as insulin is needed to drive potassium intracellularly. Despite an increase in extracellular potassium, net potassium balance is negative because of renal losses[16] (Fig. 55.1).

HHS, as DKA, is characterized by insulinopenia and an increase in counterregulatory hormones. However, unlike DKA, there is adequate insulin to prevent lipolysis and the development of ketone bodies and acidemia.[25,26] In contrast to DKA, the higher hepatic and circulating insulin and lower glucagon levels prevent ketogenesis.[24] Owing to the lack of ketoacidosis, hyperglycemia manifests over days, leading to osmotic diuresis and severe dehydration.[25] Glucosuria initially prevents severe hyperglycemia but a decrease in glomerular filtration rate from hypovolemia reduces the ability to eliminate glucose in the urine. The result is severe hyperglycemia and hyperosmolality.[24]

Precipitating Factors

The most common precipitating factors for DKA and HHS are infection and omission of antidiabetic therapy, although a precipitating factor may not be identified in up to 20% to 30% of cases.[27] New-onset type 1 DM or discontinuation of insulin in an established patient with type 1 DM is the precipitating factor in up to 50% of admissions for DKA.[27] In addition, omission or reduction of insulin as a means of weight control may account for up to 20% of recurrent DKA in young women with DM[13,28]—a condition termed "diabulimia."[29]

Forty percent to 60% of HHS is caused by infection, most commonly pneumonia (40%–60%) and urinary tract infection (5%–16%).[24] Other medical illness, such as stroke, myocardial infarction (MI), or trauma, can lead to HHS by increasing counterregulatory hormones and/or decreasing access to water. Drugs such as glucocorticoids, atypical antipsychotics, and thiazide diuretics may lead to metabolic decompensation resulting in HHS.[24] Up to 20% of patients presenting with HHS do not have a previous diagnosis of DM.[24] The precipitating factors of DKA are listed in Table 55.2.

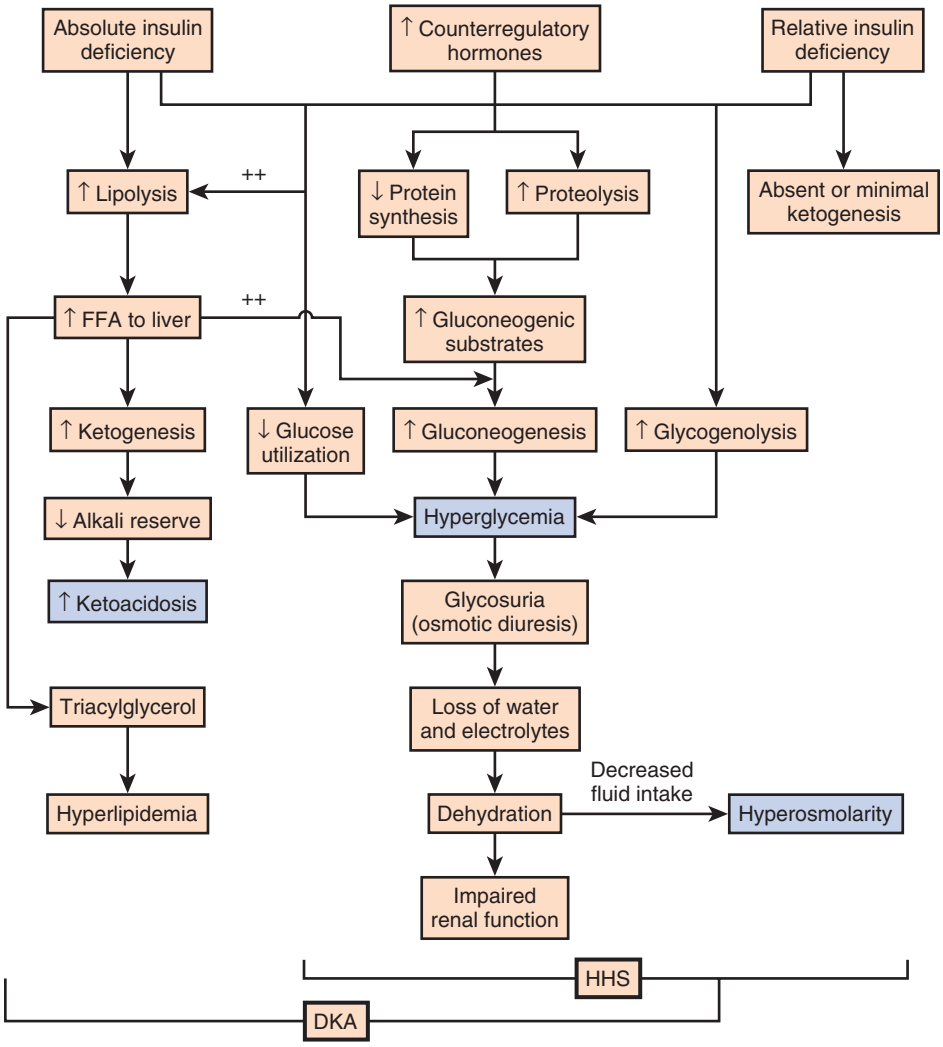
Presentation

Patients with DKA and HHS present with classic symptoms of hyperglycemia: polyuria, polydipsia, and blurry vision, along with symptoms of volume depletion: weakness, fatigue, somnolence, headache, and anorexia related to volume depletion.[30] In addition, patients with DKA also have ketosis-related symptoms: nausea, vomiting, and abdominal pain.[27] DKA develops quickly, frequently within 24 hours, whereas HHS develops insidiously over days or weeks.[12] Both can be subtle or fulminant. Because DKA and HHS can be the presenting signs of DM, a high clinical suspicion is needed to make the appropriate diagnosis and institute timely treatment. Mental status can be normal or altered in DKA if acidosis is severe, whereas the severity of mental status change in HHS can vary from lethargy and somnolence to coma. Clinical signs of DKA and HHS are those of volume depletion and include hypotension, tachycardia, and dry mucous membranes.[30] Patients with DKA may have Kussmaul respirations (rapid deep breathing) and a fruity odor to their breath as a result of acetone (derived from acetoacetate).

Diagnosis

The diagnosis of DKA is made by a pH less than 7.3, bicarbonate less than 18 mEq/L, anion gap greater than 10 mEq/L, glucose level greater than 250 mg/dL, and ketonemia.[24] Diabetic ketoacidosis must be differentiated from other causes of anion-gap metabolic acidosis without ketosis (lactic acidosis, hyperchloremic acidosis, and salicylate toxicity) as well as from other ketotic states (ketotic hypoglycemia, alcoholic ketosis, starvation ketosis, isopropyl alcohol, and hyperemesis).[16]

Although most patients will have a glucose level above 250 mg/dL, DKA can occur in the setting of lower or even euglycemic glucose levels, including pregnant patients owing to increased counterregulatory hormones[27,31,32] and those with poor oral intake and dehydration. Similarly, in patients with gastric losses of hydrogen ions (H^+), bicarbonate can be normal in DKA.[33] Euglycemic DKA has been noted with sodium glucose cotransporter inhibitors used to treat type 2 DM.[34] Patients at greatest risk are those with type 2 DM who are using insulin along with a sodium glucose



• **Fig. 55.1** Pathogenesis of diabetic ketoacidosis *(DKA)* and hyperglycemic hyperosmolar state *(HHS)*: stress, infection, or insufficient insulin. *FFA,* Free fatty acid. TABLE 55.2 Causes of Diabetic Ketoacidosis and Hyperglycemic Hyperosmolar Syndrome[12,13,16,25]

Etiologic Factor/Condition	Diagnoses With Comments
Inadequate insulin	Nonadherence, inadequate insulin regimen, insulin pump failure or omission of insulin, new-onset diabetes
Infections	Any moderate to severe infectious process Most commonly, pneumonia, urinary tract infection, sepsis
Acute medical conditions	Myocardial infarction, pancreatitis, cerebrovascular accident
Interference with glucose metabolism or insulin secretion	Thiazide diuretics, corticosteroids, second-generation (atypical) antipsychotics, FK506 (tacrolimus), glucagon, sympathomimetic agents (albuterol, terbutaline, dobutamine)
Endocrine disturbance	Pheochromocytoma, hyperthyroidism, acromegaly, hemochromatosis
Substance abuse	Cocaine
Nutritional factors	Parenteral nutrition

cotransporter inhibitor who omit insulin and those with an acute illness or decreased oral intake.[34] Additional causes of euglycemic DKA include hepatic insufficiency, starvation ketosis, alcoholic ketoacidosis, and reduction in the glucose before resolution of the acidosis.

Ketones are most often measured in the laboratory by the nitroprusside method, which reacts with acetoacetate and acetone, the less prominent ketones in DKA.[35] β-Hydroxybutyrate is converted to acetoacetate as DKA is treated; hence the nitroprusside method of measuring ketones can result in false-negative ketone levels at presentation and false-positive ketone levels during recovery. By definition, ketone levels are positive in DKA, whereas ketone levels are mildly elevated or absent in HHS. (A serum β-hydroxybutyrate level greater than 3.8 mmol/L is consistent with DKA.[36]) Serum β-hydroxybutyrate is useful for diagnosis and determination of recovery of DKA but serial measurements do not aid management.[12,35]

Serum sodium is often low on presentation because of the osmotic shift of water from the intracellular to extracellular space, causing dilutional hyponatremia. The sodium level should be corrected for glucose by adding 1.6 mEq/L to the sodium for every 100-mg/dL increase in glucose above 100 mg/dL. This estimates the sodium level once the glucose level is corrected.[13] A normal or elevated admission serum sodium level in the setting of hyperglycemia is indicative of profound dehydration and water deficit.[13]

The diagnosis of HHS is based on a glucose level greater than 600 mg/dL, serum osmolality greater than 320 mOsm/kg, and the absence of significant ketosis.[24] A significant number of patients with HHS present with normal mental status; therefore alteration in mental status is no longer part of the diagnostic criteria for HHS.

Osmolality can be calculated using glucose and sodium: [2(measured Na) + glucose/18].[17,24,35] Previous equations included urea; however, the osmotic contribution of urea is not significant.[24] Serum osmolality is generally normal in DKA but is often profoundly elevated in HHS because of the marked volume depletion that results from osmotic diuresis.

The serum potassium level may be low, normal, or elevated in DKA and HHS.[13] Insulin deficiency and acidosis decrease cellular uptake of potassium, although hyperosmolality enhances cellular efflux of potassium.[13] Large amounts of potassium shift from the intracellular space to the extracellular space and are then lost in the urine. Regardless of the serum potassium level, all patients with DKA and HHS have substantial depletion of total body potassium.

Evaluation of DKA and HHS should include measurement of electrolytes, phosphorus, blood urea nitrogen, creatinine, urinalysis, complete blood cell count, hepatic enzymes, hemoglobin A_{1c} (HbA_{1c}), serum ketones, and electrocardiogram. A thorough history should be taken to determine the precipitating cause. A chest radiograph should be considered because of the high incidence of pneumonia as a precipitating factor of HHS.[12,24] Additional workup testing should be based on the clinical evaluation.

Serum amylase and lipase levels can be elevated in up to 25% of patients with DKA,[16] although clinicians should be aware that acute pancreatitis does occur in 10% to 15% of cases of DKA.[37] Leukocytosis, present in up to 50% of patients who present with DKA and HHS owing to increased catecholamine release,[38,39] is proportional to the degree of acidosis, hypercortisolemia, and elevated catecholamines.[16] Although leukocytosis does tend to correlate with the severity of DKA, an elevated white blood cell count should prompt evaluation for infection.[12,38]

Management

DKA and HHS require management of fluids, electrolyte replacement, and insulin. DKA in pregnancy is a medical emergency with up to a 9% fetal death rate.[27] The management of DKA and HHS in adults is detailed in Fig. 55.2.

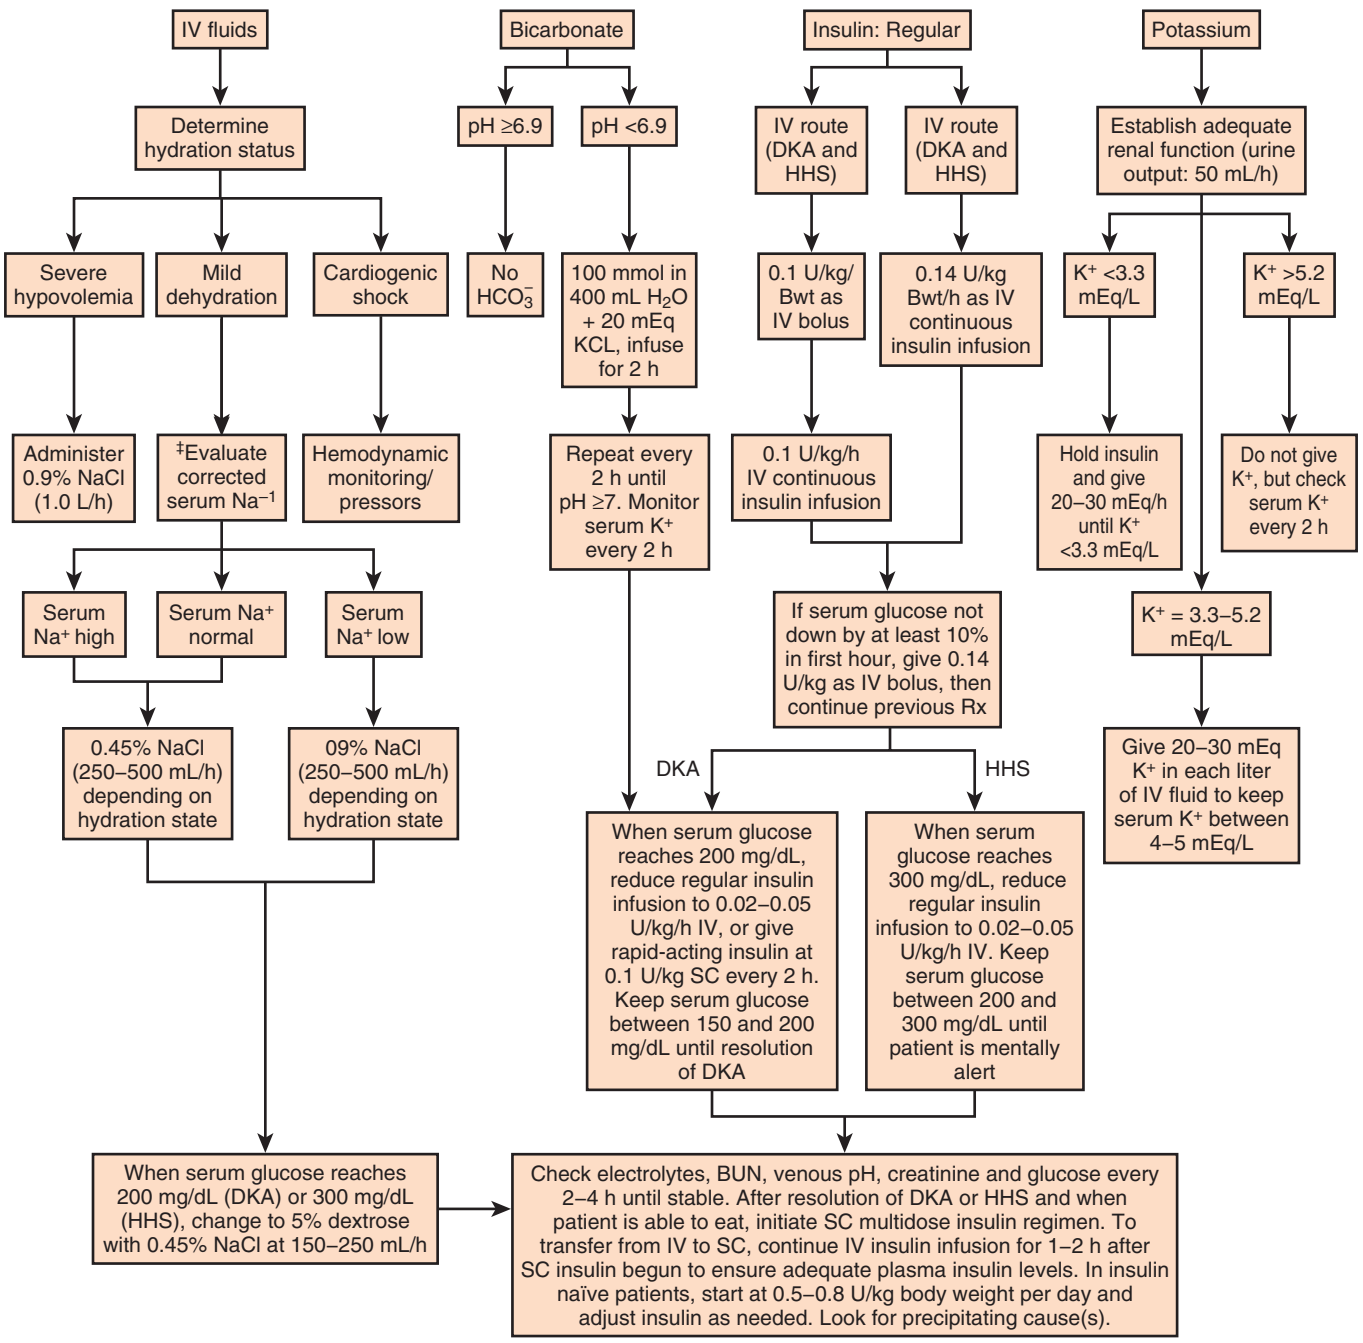
Fluid Replacement

Fluids are essential in the treatment of DKA and HHS to restore tonicity, replete intravascular volume, improve renal and tissue perfusion, and help to reduce the plasma osmolality.[25] Normal saline solution is infused at 15 to 20 mL/kg per hour over the first 2 hours with the subsequent rate of fluid resuscitation based on the state of hydration, serum electrolytes, and assessment of hemodynamic status. Patients with HHS will have a larger fluid deficit than those with DKA and may require fluid rates maintained at 500 mL/h to correct 50% of the fluid deficit within the first 12 hours.[25] Higher rates have not proven beneficial.[25] Saline solution should be continued if the patient is hypotensive. In patients who are hypernatremic or eunatremic, 0.45% normal saline solution can be used at a rate of 250 to 500 mL/h for subsequent fluid.[13,25,35] Patients who remain hyponatremic should continue to receive normal saline solution; 50% of the fluid deficit should be replaced within the first 12 hours and the remainder over the ensuing 12 hours.[25,35] Patients with congestive heart failure or risk of volume overload may need more cautious fluid replacement and appropriate monitoring. Dextrose is added to the fluids once the plasma glucose level falls below 200 to 250 mg/dL. This allows continued infusion of insulin for correction of the ketoacidosis.[13,25,35]

Insulin

In patients with moderate to severe DKA or DKA with mental status changes, intravenous insulin is the treatment of choice. Serum potassium must be greater than 3.3 mEq/L before initiating insulin. A continuous intravenous infusion is usually initiated with a bolus of 0.1 U/kg followed by a rate of 0.1 U/kg per hour.[40] Alternatively, the rate may be started at 0.14 U/kg per hour[16,35] without a bolus. Subcutaneous insulin may be used while intravenous (IV) access is being obtained. In the setting of anasarca, intramuscular insulin may be preferred until the IV access is established. Trials of rapid-acting subcutaneous insulin administered every 1 to 2 hours for DKA have proven the effectiveness of subcutaneous insulin regimens in the non-ICU setting for mild DKA. Subcutaneous and intramuscular insulin in mild DKA produces similar resolution of ketoacidosis and restoration of euglycemia, although trial data for more severe ketoacidosis and DKA in ICU patients are lacking.[13,41] Subcutaneous and intramuscular insulin may be appropriate for mild DKA but should not be used in the setting of moderate or severe DKA.[13,41] During an insulin infusion, point of care (POC) glucose should be monitored hourly initially and then decreased to every 2 hours as the patient's hyperglycemic and acidosis stabilize. The infusion should result in reduction of glucose by 50 to 75 mg/dL per hour. More rapid correction is not necessary and may be harmful. When the plasma glucose level falls below 200 to 250 mg/dL, the infusion rate should be reduced to 0.02 to 0.05 U/kg per hour and dextrose added to the IV fluids to allow time for resolution of the acidosis.[13] The insulin rate should be titrated to maintain the glucose level between 150 and 200 mg/dL until DKA is resolved.[13]

Resolution of DKA is defined by a glucose level less than 200 mg/dL with two of the following: anion gap 12 mEq/L or



• **Fig. 55.2** Protocol for the management of adult patients with diabetic ketoacidosis *(DKA)* or hyperglycemic hyperosmolar state *(HHS).* DKA diagnostic criteria: blood glucose 250 mg/dL, arterial pH 7.3, bicarbonate 15 mEq/L, and moderate ketonuria or ketonemia. HHS diagnostic criteria: serum glucose greater than 600 mg/dL, arterial pH greater than 7.3, serum bicarbonate greater than 15 mEq/L, and minimal ketonuria and ketonemia. Notes: †15 to 20 mL/kg/hour; ‡serum Na should be corrected for hyperglycemia (for each 100 mg/dL glucose, add 1.6 mEq to sodium value for corrected serum value). *BUN,* Blood urea nitrogen; *Bwt,* body weight; *HCO_3^-,* bicarbonate; *IV,* intravenous; *K^+,* potassium ion; *Na^+,* sodium ion; *NaCl,* sodium chloride; *SC,* subcutaneous. (From Kitabchi AE, Umpierrez GE, Miles JM, et al. Hyperglycemic crises in adult patients with diabetes. *Diabetes Care.* 2009;32:1335–1343.)

lower, serum bicarbonate 15 mEq/L or higher, and venous or arterial pH greater than 7.3. Resolution of HHS is defined by normalization of effective serum osmolality to less than 310 mmol/kg and return to normal mental status.[13,17] Once DKA or HHS is resolved, insulin is transitioned to a subcutaneous regimen. To avoid recurrence of DKA, subcutaneous insulin must be overlapped with the insulin drip for at least 2 hours. The home insulin regimen may be restarted in individuals with controlled DM before admission.[13] Previous diabetes control can be assessed with HbA_{1c} testing. In patients not previously using insulin, the subcutaneous insulin dose should be extrapolated from the last 6 to 8 hours of the insulin infusion rate. It is important that the patient is at a steady state and not taking pressors before making this estimation.[42,43] The subcutaneous insulin regimen is calculated from the mean insulin rate during the steady-state period. To find the total daily dose of insulin, the mean insulin rate is multiplied by 20 to allow for a 20% reduction in the calculated dose. Half of the total daily dose should be administered as long-acting (basal insulin) such as NPH, glargine, degludec, or detemir and 50% should be administered as short-acting insulin such as regular, aspart, glulisine, or lispro to control meal-related hyperglycemia.[43] A detailed guide for successful transition to subcutaneous insulin is listed in Box 55.2.

Potassium

Serum potassium concentration is often elevated as a result of extracellular shift of potassium. This shift is a result of insulin deficiency, acidemia, and hypertonicity.[16] Patients with low or low-normal serum potassium levels on presentation have a severe total-body potassium deficit.[13,16,25] Insulin should not be given unless the serum potassium is greater than 3.3 mEq/L to avoid cardiac arrhythmias.[17] Patients who present with hypokalemia require cardiac monitoring, aggressive potassium replacement, and close monitoring of potassium levels.[13] During treatment of DKA and HHS with insulin and fluids, serum potassium levels rapidly fall. Potassium repletion begins when the serum potassium falls below 5.0 mEq/L[24] by adding 20 to 30 mEq KCl in each subsequent liter of IV fluids to maintain the potassium level between 4 and 5 mEq/L.[17,25] More cautious replacement is necessary in the setting of renal insufficiency. Electrocardiography at evaluation and cardiac monitoring is important in DKA and HHS owing the multiple cardiac effects of both hyperkalemia and hypokalemia.

Bicarbonate

Replacement of bicarbonate is rarely recommended in the management of DKA, and even suggestions for use in patients with pH of 6.9 or lower lack evidence from randomized clinical trials. Bicarbonate may worsen hypokalemia and increase the risk of cerebral edema.[16,17] Replacement is achieved by administering 100 mmol (2 ampules) of sodium bicarbonate in 400 mL of water with 20 mEq KCL at a rate of 200 mL/h.[16,17,35] This may be repeated every 2 hours until the pH is above 7.[35] In patients with a pH above 7.0, replacement of bicarbonate offers no improvement in outcomes or rate of recovery and is not recommended.[17]

• BOX 55.2 Important Steps in Transition From Insulin Infusion to Subcutaneous Insulin

Step 1: Is the patient stable enough for transition?

Hypotension, active sepsis, use of pressors, and intubation are contraindications to transition because these factors are recognized to be associated with unreliable subcutaneous insulin absorption, with continued need for the most flexible dosing because of frequently changing insulin requirements.

Step 2: Does the patient need to switch to scheduled subcutaneous insulin?

Yes:	No:
Type 1 DM—all patients	Type 2 DM in patients with a recent mean infusion rate <0.5 unit/h
Type 2 DM in patients on home insulin regimen	Stress hyperglycemia or previously unrecognized DM if infusion rate <1 unit/h or if HbA_{1c} is near normal
Type 2 DM in patients with a recent mean infusion rate ≥0.5 unit/h	

Step 3: If transition is needed, calculate a TDD of insulin. The TDD is an estimate of the 24-h insulin requirement when the patient is receiving full nutrition.

- Determine mean insulin infusion rate from last 6 to 8 h.
- Calculate 24-h insulin dose based on this rate, and reduce the 24-h dose by 20%.
  - Multiply hourly insulin infusion rate by 20 (80% of 24) to arrive at a safety-adjusted 24-h insulin dose.
- Determine if this total is the TDD or basal dose based on current nutrition.
  - If the infusion was providing both the basal and nutritional needs of the patient (i.e., continuous tube feeds), this will be the TDD.

OR

  - If the infusion was not covering significant nutrition, this *could* be the basal insulin dose.

Step 4: Construct a basal/bolus regimen tailored to the patient's nutritional situation, building safeguards for any changes in nutritional intake and uncertainties about reliability of intake. Several options are again available.

- *Basal*: glargine, detemir, degludec, or NPH
  1. Dose is 40% to 50% of TDD.

  OR

  2. Adjusted 24-h intravenous requirement can be given as all basal.
- *Nutritional*: The remainder of TDD is scheduled nutritional insulin in divided doses. In general, these doses need to be adjusted down for <100% nutritional intake, and the orders should allow for administering nutritional insulin just AFTER observed meal to allow an assessment of intake. Several options are available for estimating the initial doses:
  1. Use 50% of the TDD as nutritional coverage, and divide this amount by 3 to determine the scheduled meal dose. Hold if patient does not eat more than 50% of each meal.
  2. Use a more conservative start of 0.1 to 0.2 × basal dose for each meal.
  3. Use carbohydrate counting to cover nutritional intake.

Step 5: Be sure to give subcutaneous insulin BEFORE the infusion stops.

- Basal glargine and detemir ideally are given at least 2 h before infusion is discontinued.
- Shorter lead times (30 min) are possible if rapid-acting insulin is given with basal insulin.

DM, *Diabetes mellitus;* HbA_{1c}, *hemoglobin A_{1c} (glycosylated hemoglobin);* TDD, *total daily dose.*

Phosphate

Like potassium, phosphate is shifted to the extracellular space in the response to acidosis and osmotic diuresis leads to urinary phosphate loss.[16] Despite total-body phosphate deficits, phosphate levels are often normal or elevated on presentation because of the extracellular shifts.[13,16] As insulin therapy allows phosphate to reenter the cell, hypophosphatemia develops.[16] Complications of hypophosphatemia are rare but include respiratory and skeletal muscle weakness, reduced cardiac output, and decreased tissue oxygen delivery.[16,35] Although routine replacement of phosphate is not recommended or supported by trial data, serum phosphate should be monitored and replaced if the phosphate concentration falls below 1.0 mg/dL or in those with possible complications of hyperphosphatemia such as cardiac dysfunction, anemia, or respiratory depression.[13,16] Replacement is usually achieved by administering potassium phosphate, 20 to 30 mEq/L added to replacement fluids. Other potassium replacement requires adjustment if potassium phosphate is added to avoid overzealous correction of potassium. Serum calcium should be monitored in patients receiving phosphate owing to the risk of hypocalcemia.[35] The maximal rate of phosphate repletion should not exceed 4.5 mmol/h.[13]

Complications of the Management of Hyperglycemic Emergencies

The most common complications of the management of DKA and HHS in adults are hypoglycemia, hypokalemia, and hypophosphatemia. Frequent monitoring of glucose and addition of dextrose to the IV fluids once glucose falls below 250 mg/dL helps to prevent hypoglycemia. Frequent monitoring, and appropriate fluid and electrolyte replacement help prevent any complications related to electrolyte disturbances and volume depletion.

In children with DKA, cerebral edema is a feared complication that occurs in less than 1% of children. The mortality rate is 20% to 50% and 15% to 35% of survivors are left with permanent neurologic sequelae.[44] The pathophysiology is poorly understood.[44] Postulated mechanisms for cerebral edema include osmotically driven intracellular water shift when plasma osmolality declines too rapidly, ketone bodies affecting vascular integrity, and hypoxemia.[16] Risk factors include higher osmolality and serum urea nitrogen at presentation, pH less than 7.1, partial pressure of carbon dioxide less than 20 mm Hg, greater than 50 mL/kg of fluid administered within the first 4 hours of treatment, initiation of insulin before rehydration bolus, and treatment with bicarbonate.[12,13,25] Early symptoms are headache and vomiting that progress to decreased arousal and altered mental status.[25] Special attention to rate and tonicity of fluids is especially important in the pediatric population as DKA is treated to avoid rapid correction of glucose and osmolality.[44]

Prevention

Many cases of DKA and HHS are preventable through proper education and effective communication with a health care provider. Education regarding sick day management for all patients with DM and caregivers is paramount to preventing DKA (Box 55.3). In contrast, held basal insulin, less frequent glucose monitoring, a lack of correction scale insulin, and dehydration facilitate the onset of DKA. Ketones should be monitored by urine dipstick if glucose is greater than 240 mg/dL. This allows recognition of impending ketoacidosis, which may guide insulin therapy and prevent hospitalization.[13,45] Patients with insulin pumps require a prescription for basal insulin in the event of a pump failure. Patients should have printed instructions about when to contact their treating physician.

Unfortunately, cessation of insulin because of its high cost is also a common cause of DKA. Insulin discontinuation and poor adherence to therapy account for more than half of DKA in minority populations.[13,46] This may be due to the high cost of insulin, limited access to health care, and low health literacy. Improving diabetes care in this population requires recognition of the many barriers that affect health care in these populations.

• BOX 55.3 Sick Day Management Protocol for Diabetic Patients[120,121]

Examples of "Sick Day" Scenarios

- Feeling sick or presence of fever for 2 days or longer without getting better
- Vomiting or diarrhea for more than 6 h

Management

General Measures

- Check blood sugar levels at least every 4 h, but when values are changing quickly, check more often.
- Check urine or blood ketones.
- Modify usual insulin regimen according to a plan developed by the diabetes physician or team.
- Maintain adequate food and fluid intake. If your appetite is poor, aim for consumption of 50 g of carbohydrate every 3–4 h. If you are nauseous, high-carbohydrate liquids, such as regular (not diet) soft drinks or juice, or frozen juice bars, sherbet, pudding, creamed soups, or fruit-flavored yogurt usually are tolerated. Broth also is a good alternative.

Taking Medications When You Are Sick

- If you are eating: Continue taking your pills for diabetes or your insulin. Your blood sugar may continue to rise because of your illness.
- If you are nauseous or vomiting or otherwise cannot take your medicines:
  - Continue to take your long-acting insulin (Lantus, Levemir, NPH).
  - Call your doctor and discuss whether you need to adjust your short- or rapid-acting insulin dose (regular, lispro [Humalog], aspart [Novolog], glulisine [Apidra]) or your other diabetes medicines.

Examples of When to Call Physician or Diabetes Team

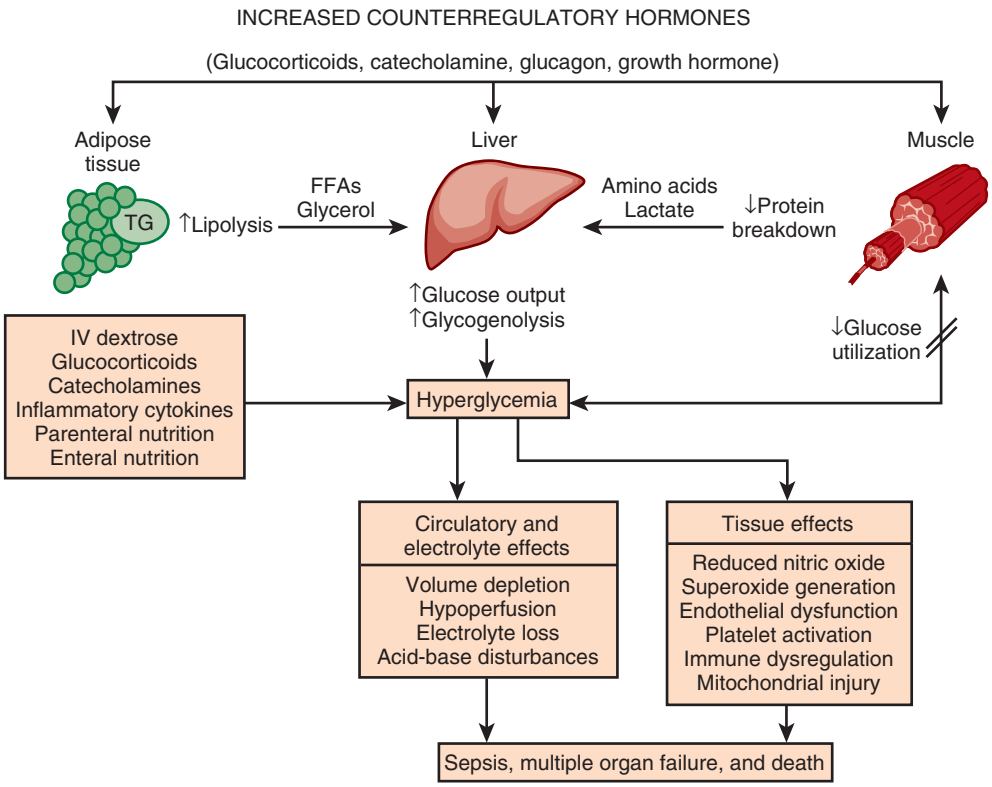
- If glucose levels are higher than 240 mg/dL despite taking extra insulin according to a sick day plan
- If you take diabetes pills and blood sugar is still above 240 mg/dL before meals and remains there for more than 24 h
- If symptoms/signs develop that might signal diabetic ketoacidosis or dehydration, such as dizziness, trouble breathing, fruity breath, or dry and cracked lips or tongue

DKA, *Diabetic ketoacidosis.*

Glycemic Control in the ICU

Epidemiology and Significance of Hyperglycemia

Mortality follows a J-shaped association for glucose levels in the hospital with increased mortality in those with hyperglycemia and those with hypoglycemia.[47,48] Acute hyperglycemia was once regarded as an adaptive response to critical illness, though this idea was challenged by several reports of an increased risk associated with hyperglycemia[49,50] and the noted benefits of improved glucose control in patients with acute MI, stroke, coronary artery bypass surgery, and critical illness.[49,51,52,53]



• **Fig. 55.3** Pathogenesis of stress hyperglycemia. Stress hyperglycemia results from increased hepatic glucose production and impaired glucose utilization in peripheral tissues. Excess counterregulatory hormones (glucagon, cortisol, catecholamines, and growth hormone) increase lipolysis and protein breakdown (proteolysis), and impair glucose utilization by peripheral tissues. Hyperglycemia causes osmotic diuresis that leads to hypovolemia, decreased glomerular filtration rate, and worsening hyperglycemia. At the cellular level increased blood glucose levels result in mitochondrial injury by generating reactive oxygen species and endothelial dysfunction by inhibiting nitric oxide production. Hyperglycemia increases levels of proinflammatory cytokines such as tumor necrosis factor-α and interleukin 6, leading to immune system dysfunction, and increases plasminogen activator inhibitor-1 and fibrinogen, causing platelet aggregation and hypercoagulable state. These changes can eventually lead to increased risk of infection, impaired wound healing, multiple organ failure, prolonged hospital stay, and death. *FFA,* Free fatty acids; *TG,* triglycerides. (From Farrokhi F, Smiley D, Umpierrez GE. Glycemic control in non-diabetic critically ill patients. *Best Pract Res Clin Endocrinol Metab.* 2011;25:813–824.)

Hyperglycemia in hospitalized patients occurs in those with known or undiagnosed DM. Stress hyperglycemia is seen in up to 17% of critically ill patients with previously normal glucose tolerance (Fig. 55.3).[54–56] Hyperglycemia from any source is associated with increased in-hospital mortality compared with those with normoglycemia.[48] Although glucose typically normalizes after resolution of the acute illness in those with stress-induced hyperglycemia, patients with stress-induced hyperglycemia are almost twice as likely to develop DM in the future compared with those with normoglycemia.[55,56]

Synopsis of Trials of Glycemic Control

Early observational studies of patients with MI, stroke, and critical illness revealed that acute hyperglycemia is associated with increased in-hospital mortality in patients with and without DM.[50,52,57] Results of the first randomized controlled trial confirmed observational studies in patients with DM with MI[53] showing improved prognosis with insulin-glucose infusions compared with conventional therapy.[53] The landmark prospective randomized controlled trial, published by Van den Berge in 2001, evaluated intensive insulin therapy (IIT) (glucose target 80–110 mg/dL) versus conventional treatment (glucose target 180–200 mg/dL) for hyperglycemia in a surgical intensive care unit.[58] IIT was associated with a dramatic reduction in mortality, septicemia, length of stay in the ICU, and number of transfusions required.[58] However, results of this single-center study were not able to be reproduced in randomized, controlled multicenter trials or in the medical ICU setting,[59–61] suggesting that the effects seen in the Van den Berge study may be specific to surgical ICU patients.

Hypoglycemia, the foremost obstacle in the use of IIT, increases mortality.[60–63] In the NICE-SUGAR (Normoglycaemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation) study, a multicenter international randomized trial of intensive glucose control in the ICU, those treated to intensive targets had increased mortality.[64] The VISEP (Efficacy of Volume Substitution and Insulin Therapy in Severe Sepsis) trial stopped early because of an increased rate of severe hypoglycemic events and a trend toward prolonged ICU stay in the IIT-treated group.[61]

In addition, patients with larger glycemic variability have an increased odds ratio of hospital mortality, particularly in nondiabetic patients with sepsis.[65] Advances in glucose monitoring and delivery may play a future role in minimizing variability.[66–68] Fig. 55.4 summarizes key studies that have evaluated inpatient intensive glycemic control.

Based on the analysis of the available studies, it is suggested to initiate insulin in critically ill patients when glucose levels exceed 180 mg/dL and to treat to a target glucose level of 140 to 180 mg/dL.[47] Certain populations, including those with acute ischemic cardiac or neurologic events and those undergoing coronary artery bypass grafting, may benefit from more intensive targets such as 110 to 140 mg/dL if this can be achieved without significant hypoglycemia.[47,54] More recent studies have been unable to demonstrate a reduction in perioperative complications in patients undergoing coronary artery bypass grafting who are treated with IIT (glucose goal 100–140 mg/dL).[69] Some of these discrepancies may be partially accounted for by evidence that those without a previous history of DM may benefit from IIT intensive insulin therapy, whereas patients with known preexisting DM have little to no significant benefit from IIT.[69,70]

Intravenous Insulin Protocols

An insulin infusion is the preferred way to manage persistent hyperglycemia in the majority of critically ill patients in the ICU, whereas subcutaneous insulin may be appropriate in those critically ill patients who are able to eat. IV insulin should be started when the glucose level reaches 180 mg/dL.[54] Insulin infusion protocols should be developed by an interdisciplinary team involving endocrinologists, intensivists, nurses, and pharmacists and should allow for hourly adjustment of insulin based on POC glucose readings.[71,72] POC glucose levels should be measured every 1 to 2 hours while an insulin infusion is used to allow titration of the infusion with an upper target of glucose of 180 mg/dL. Once the glucose level and insulin rate are stable, glucose can be measured every 4 hours.[73] An insulin infusion must also be adjusted for nutrition status. Patients receiving an insulin infusion are usually not eating or drinking (NPO) or are receiving total parenteral nutrition or continuous tube feeds. If total parenteral nutrition or tube feeds are withheld, the infusion should be reduced by 50%.[72] In the rare instance when a patient is eating, consideration should be given to use of subcutaneous rapid-acting insulin with meals. This avoids titration of the insulin drip related to postprandial hyperglycemia.[72] When used properly, insulin infusion protocols have a low rate of hypoglycemia.[72]

Technical Issues in Measuring Glucose

Control of hyperglycemia and prevention of hypoglycemia in the ICU is largely dependent on our ability to accurately measure glucose levels. Glucometers have a 15% error compared with laboratory glucose at euglycemic ranges with higher errors at the low range of glucose values (<50 mg/dL) and at the high range of glucose values (>500 mg/dL).[74–76] Changes in pH, anemia, hypothermia, and hypoperfusion affect glucometer accuracy.[77–79] Peripheral vasoconstriction from pressors decreases peripheral glucose values compared with laboratory glucose values.[77,80] Anemia falsely elevates POC measurements, thereby increasing the risk of missing hypoglycemia in up to 10% of patients.[81] POC glucose from arterial blood correlates best with central laboratory glucose testing with decreasing accuracy for venous and the greatest variability for capillary samples.[77,79,81]

Continuous glucose monitors (CGMs) may offer another modality for measuring glucose in the ICU. CGMs use an electrochemical sensor placed subcutaneously to measure glucose every 1 to 10 minutes in the interstitial space in the outpatient setting. The accuracy of CGMs in the ICU and hospital setting may make them more effective in identifying asymptomatic hypoglycemia compared with POC glucose monitoring,[82–85] although without large randomized trial data, there is insufficient evidence to support use of CGMs in critically ill patients.[86,87]

Current Guidelines for Glycemic Control

Several medical associations, including the American Association of Clinical Endocrinologists, Endocrine Society, American Diabetes Association, and Surviving Sepsis Campaign, recommend maintaining glucose between 140 mg/dL and 180 mg/dL in ICU patients, and initiating insulin in the ICU for a glucose level higher than 180 mg/dL.[54,73]

The Effect of Parenteral Nutrition, Enteral Nutrition, and Glucocorticoids on Glycemic Control

Critically ill patients are particularly susceptible to hyperglycemia related to parenteral and enteral nutrition owing to the high concentration of carbohydrates in the feeding preparations combined with altered carbohydrate metabolism in the setting of increased stress and increased levels of counterregulatory hormones.[88]

Because total parenteral nutrition (TPN) and peripheral parenteral nutrition (PPN) are likely to cause hyperglycemia in those with previously controlled DM, IV or subcutaneous insulin should be initiated when TPN/PPN is started.[54] Adding insulin to parenteral nutrition prevents hypoglycemia if the nutrition is discontinued but is impractical for frequent insulin adjustments. When nutrition is held, the IV or subcutaneous insulin should be reduced or dextrose-containing intravenous fluids should be started to prevent hypoglycemia. Although nonstandardized amounts of dextrose are often initiated, when nutrition is held or discontinued, the rate of dextrose-containing IVF can be calculated based on the glucose concentration in the nutrition to minimize hypoglycemia.

Glucose levels should be monitored for at least 48 hours in all patients receiving glucocorticoids.[89,90] In those already using insulin, early insulin adjustments are necessary to avoid hyperglycemia.[54] An insulin infusion is appropriate for moderate to severe steroid-induced hyperglycemia, whereas initiation of subcutaneous insulin at a dose of 0.3 to 0.5 units/kg body weight can be used for less severe hyperglycemia.[91] To avoid hypoglycemia, insulin doses need to be reduced as steroid doses are lowered.[54]

Subcutaneous Insulin Use in the Hospitalized Patient

Insulin is the treatment of choice for hospitalized patients with hyperglycemia. Oral agents and noninsulin injectables are not appropriate in the hospital because of alterations in nutrition and various contraindications. An insulin infusion is preferable in the ICU for moderate to severe hyperglycemia, although subcutaneous insulin regimens can be ordered based on the nutritional status of the patient. Table 55.3 lists the onset, peak, and duration of action of available subcutaneous insulin preparations.

TABLE 55.3 Onset, Peak, and Duration of Action of Currently Available Insulin Preparations

Insulin Preparation	Onset of Action	Peak Action	Duration of Action
Lispro	5–15 min	1–2 h	4–6 h
Aspart	5–15 min	1–2 h	4–6 h
Glulisine	5–15 min	1–2 h	4–6 h
Regular	30–60 min	2–3 h	6–10 h
NPH	2–4 h	4–10 h	12–18 h
Detemir	2 h	Relatively peakless	12–24 h
Glargine	2 h	Relatively peakless	20–24 h
Degludec	2 h	Relatively peakless	33–42 h

In patients who are NPO, a long-acting basal insulin such as detemir, glargine, or degludec is appropriate. Insulin degludec is one of the newer ultralong-acting basal insulins. It lasts longer than 24 hours and is dosed once daily similar to glargine.[92,93] Detemir is dosed every 12 to 24 hours given its shorter duration of action. NPH can be dosed every 12 hours or every 8 hours with or without a small dose of regular insulin as an acceptable basal insulin regimen for a patient who is NPO, although because of its greater peak effect, it may increase the risk of hypoglycemia. Glucose should be monitored every 4 to 6 hours and insulin and fluids with dextrose adjusted as needed.

Patients who are eating should have prandial insulin added to one of the previous basal insulin regimens. Lispro, aspart, and glulisine are the preferred prandial insulins as opposed to regular insulin because of their shorter onset and duration of action, which better mimics physiologic insulin.

For patients with preexisting DM who are using oral hypoglycemic and/or noninsulin agents, the total daily dose of insulin should be calculated based on the age, glomerular filtration rate, and weight of the patient. Patients older than 70 years or those with a glomerular filtration rate less than 60 mL/min should be started on a regimen 0.2 to 0.3 U/kg body weight per day, whereas those younger than 70 years and with normal renal function can be started on 0.4 to 0.5 U/kg body weight per day.[91] The total dose should be split to give 50% as basal insulin and 50% as nutritional insulin.[91] Alternatively, if a patient had previously adequate glucose control before hospitalization with a basal bolus insulin regimen, the patient's previous insulin regimen may be started. Premixed insulin should not be continued in the hospital owing to lack of flexibility. If a patient had good control with a premixed regimen as an outpatient, this can be converted to a basal bolus regimen by adding the total daily dose of insulin and administering 50% as basal insulin and 50% as nutritional insulin. If a patient previously used an insulin drip, this could also be used to calculate the total daily insulin regimen (see Box 55.2). It should be noted that when transitioning from glargine or levemir to insulin degludec or NPH, patients may require up to 20% to 30% less basal insulin.[94]

For patients receiving TPN or PPN, regular insulin may be added to the TPN/PPN at a dose of 1 unit of insulin per 15 g of carbohydrate.[95] Alternatively, basal insulin can be administered with rapid-acting correction every 4 hours.[54,91] This same regimen can be used for continuous enteral feeds. Patients receiving bolus enteral feeds generally require a basal insulin, such as glargine, detemir, degludec, or NPH, along with rapid-acting insulin with each bolus feeding as well as correctional insulin before each feeding. The bolus insulin and feeding should be no more frequent than every 4 hours.[54] Patients with nocturnal or cycled feeds should receive basal insulin in combination with a rapid-acting insulin at the start of tube feeds with rapid-acting insulin every 4 to 6 hours during feeding. The last dose of rapid-acting insulin should be at least 4 hours before discontinuation of the enteral feeds.[91]

Although correctional insulin is an important adjunct to a basal-bolus insulin regimen, it should not be used alone to manage hyperglycemia in the hospital.[96] Correctional insulin should be proportional to the total daily dose of insulin. Patients who require less total insulin also require less aggressive sliding scale regimens. The "rule of 1500" or the "rule of 1800" for more insulin-sensitive patients (type 1 DM, renal or hepatic insufficiency, elderly patients, and those with a body mass index less than 25 kg per m^2) can be used to estimate the glucose-lowering effect of 1 unit of insulin. The rule of 1500 formula estimates the correction using the total daily dose (TDD) of insulin. It is calculated as follows: 1500/TDD = expected mg/dL decrease in glucose from 1 unit of rapid-acting insulin.

TABLE 55.4 Clinical Symptoms of Hypoglycemia

Sympathoadrenal	Neuroglycopenic
Tremor	Tiredness or drowsiness
Palpitations	Difficulty thinking
Diaphoresis	Confusion
Nervousness	Blurred vision
Anxiety or apprehension	Slurred speech
Hunger	Dizziness, weakness
Pallor	Abnormal or belligerent behavior
	Seizure
	Coma or death

Hypoglycemia

Hypoglycemia is documented by Whipple's triad: symptoms and signs of hypoglycemia, a low plasma glucose concentration, and resolution of symptoms or signs after the plasma glucose is corrected. In the ICU, hypoglycemia, defined as a glucose level less than 70 mg/dL, leads to increased mortality hence limiting ability for tight glycemic control.[97–100] Severe hypoglycemia, defined by a blood glucose level less than 40 g/dL,[99] is common in intensive insulin protocols, occurring in 6.8% of patients in the NICE-SUGAR study.[64]

Physiologic Response to Hypoglycemia

Symptoms of hypoglycemia can be divided into sympathoadrenal and neuroglycopenic responses. Sympathoadrenal activation causes tremulousness, palpitations, and anxiety from norepinephrine release[101,102] and sweating, hunger, and paresthesias from cholinergic stimulation.[101,102] As the glucose level drops below 50 mg/dL, the risk and severity of neuroglycopenic symptoms—warmth, weakness, fatigue, confusion, emotional lability, loss of consciousness, and seizures—increases[101] (Table 55.4).

The evolutionary importance in avoiding hypoglycemia is appreciated in the multiple redundant responses to signal and mount a response to a low blood glucose level. As glucose levels approach 81 mg/dL, insulin secretion is reduced. This reduction in insulin results in decreased glucose uptake by skeletal muscle and adipose tissue along with reduced inhibition of glucagon, leading to increased glycogenolysis in the liver, increased gluconeogenesis in the liver and kidney, and lipolysis in the adipose tissue.[102] At glucose levels of 65 to 70 mg/dL, there is an increase in glucagon and epinephrine secretion as well as an increase in cortisol and growth hormone. Increases in glucagon stimulate glycogenolysis and gluconeogenesis in the liver, providing a primary role in preventing hypoglycemia.[101,102] Epinephrine further reduces glucose utilization and stimulates hepatic gluconeogenesis and glycogenolysis as well as renal gluconeogenesis.[101–103] Epinephrine also mobilizes gluconeogenic substrates such as amino acids, lactate, and glycerol.[101] Epinephrine is a critical defense against hypoglycemia when glucagon secretion is deficient, such as in patients with prolonged type 1 DM.[101,102] Although glucagon and epinephrine act quickly—within minutes—cortisol and growth hormone limit glucose utilization over hours. Both cortisol and growth hormone prevent prolonged hypoglycemia by limiting glucose utilization and increasing glucose production.[101,104] When these mechanisms fail, hypoglycemia ensues and at glucose levels of 50 to 55 mg/dL, neurogenic and neuroglycopenic symptoms are present (Fig. 55.5).[101,105]

Hypoglycemia in Patients With Diabetes or Who Receive Insulin

Hypoglycemia that occurs in insulin-treated patients is the result of insulin excess in combination with altered carbohydrate availability, increased sensitivity to insulin, reduced clearance of insulin, increased glucose utilization, or compromised glucose counterregulation.[101]

Insulin secretagogues such as a sulfonylureas or meglitinides (glinides) stimulate endogenous insulin release through binding of adenosine triphosphate–sensitive potassium channels on the sulfonylurea receptor, resulting in depolarization of the β-cell membrane, opening of the voltage-gated calcium channels, calcium

influx, and eventually secretion of insulin.[106] Peak plasma concentrations of sulfonylureas occurs in 1 to 8 hours but the duration of action has a very wide range. Chlorpropamide, a long-acting sulfonylurea with 30% renal clearance, can have a duration of action of up to 60 hours in the setting of reduced renal clearance in kidney failure.[106] Glyburide, another long-acting sulfonlylurea, has a duration of action of 12 to 24 hours in therapeutic doses, although the half-life is prolonged in the setting of renal dysfunction owing to reduced renal clearance of active metabolites.[106] Second-generation sulfonylureas such as glipizide and glimepiride are less affected by renal dysfunction as they are metabolized to inactive metabolites that do not cause further hypoglycemia.[106] Glinides (repaglinide and nateglinide) have a more rapid onset and shorter duration of action and are therefore associated with less prolonged hypoglycemia.[107] Diabetes medications that affect insulin resistance and carbohydrate metabolism (metformin, thiazolidinediones, α-glucosidase inhibitors, dipeptidyl peptidase 4 inhibitors, amylin, incretin mimetics, bile acid sequestrants, or bromocriptine) typically do not cause hypoglycemia unless used in combination with insulin or an insulin secretagogue.

Hypoglycemia Unawareness (Hypoglycemia-Associated Autonomic Failure)

Recurrent hypoglycemia, particularly in the setting of exercise and sleep, blunt the normal adrenomedullary and sympathetic neural counterregulatory responses to hypoglycemia. This condition is known as hypoglycemia-associated autonomic failure (HAAF), or hypoglycemic unawareness.[103] This establishes a vicious cycle of recurrent hypoglycemia and further reduced hypoglycemic awareness.[102,108] The risk of severe hypoglycemia is markedly increased in patients with HAAF. Furthermore, the response to glucagon and epinephrine may already be blunted in the critically ill patient, further increasing the hypoglycemic risk in patients with HAAF.[108]

Loss of autonomic response to hypoglycemia is particularly important in patients with type 1 DM who lose α-cell production of glucagon over time.[102] The inability to regulate β-cell (insulin) and α-cell (glucagon) secretion increases the risk of iatrogenic hypoglycemic 25-fold. This is highlighted in the significant glycemic instability in patients after pancreatic surgery or severe pancreatitis.[11]

Management of Hypoglycemia in Diabetes

Appropriate treatment of hypoglycemia in the hospitalized patent requires standardized treatment regimens and protocols to avoid prolonged exposure to low glucose or rebound hyperglycemia. In a person who can tolerate oral intake, documented hypoglycemia should be treated with a measured amount of readily absorbable glucose (fruit juice, glucose tabs, or gel). For glucose levels of 50 to 69 mg/dL, the "rule of 15" applies; 15 g of glucose is administered with a repeat glucose measured in 15 minutes. Additional 15-g doses of glucose are given until the glucose level is greater than 70 mg/dL. If the initial measured glucose is less than 50 mg/dL, 20 to 30 g of readily absorbable glucose should be given.[109] Parenteral therapy with 25 g of 50% dextrose is necessary when neuroglycopenic symptoms are present or the patient is NPO.[101,109] Patients whose status is postbariatric surgery may have an ineffective response to oral glucose and should be treated with parenteral glucose. Because α-glucosidase inhibitors delay the breakdown and absorption of polysaccharides from the small intestine, patients taking these medications require oral glucose (a monosaccharide) rather than sucrose or lactose (disaccharides) to correct hypoglycemia.[110] Glucagon should be used in those with neuroglycopenic symptoms and no IV access, although it should be noted that those with depleted glycogen stores cannot respond to glucagon.

Appreciating the etiology of the hypoglycemia will help prevent further episodes. When hypoglycemia is secondary to a long-acting insulin, patients require dextrose-containing IVFs to prevent recurrent hypoglycemia. In the case of hypoglycemia secondary to a long-acting insulin secretagogue overdose, particularly glyburide, correction of glucose with carbohydrate intake alone commonly results in recurrent hypoglycemia. In this setting, octreotide, which reduces pancreatic insulin secretion, is a useful therapy and results in less recurrent hypoglycemia than conventional therapy (glucagon and dextrose).[106] The suggested dose of octreotide in this setting is 1 μg/kg every 12 hours to reduce insulin secretion.[106] In most cases, treatment can be stopped after 12 to 72 hours, but glucose monitoring should continue for at least 12 to 24 hours after cessation of treatment.[106]

Prevention of Hypoglycemia

Many episodes of hypoglycemia in the ICU are preventable with attention to changes in nutritional status, glucocorticoid adjustments, changes in pressor requirements, and the clinical status of the patient. Pressors, such as norepinephrine, result in hyperglycemia by reducing glucose utilization and stimulating hepatic gluconeogenesis and glycogenolysis,[101–103] whereas glucocorticoids increase glucose by decreasing skeletal muscle uptake of glucose and increasing glucose production.[101,104] Therefore reduction or cessation of pressors or glucocorticoids is expected to result in improvement in hyperglycemia and reduction in insulin requirements. Similar improvements in glucose are seen when a patient's clinical status improves, resulting in reduced endogeneous production of cortisol and epinephrine.

The single best predictor of hypoglycemia in the hospital is decreased nutrition.[111] Lowering or discontinuing nutrition without adjusting insulin is highly associated with hypoglycemia.[100] The hypoglycemia is exaggerated if a long-acting insulin is used to cover nutritional insulin requirements.[111] In addition, oral agents and premixed (i.e., 70/30 or 75/25) insulin should not be used in the hospital to treat hyperglycemia owing to interruptions in nutrition. Patients with poor oral intake require lower mealtime insulin doses, or mealtime insulin may be given within 15 minutes of completing the meal when the amount of oral intake is uncertain. Holding parenteral or enteral nutrition requires a decrease in basal insulin requirements and/or supplemental IV dextrose. Patients who are insulin dependent (i.e., those with type 1 DM) will progress to DKA without basal insulin; therefore basal insulin should be continued and IV dextrose supplemented as needed to avoid hypoglycemia. Nutrition can be calculated for precise dosing. For example, Glucerna 1.5 tube feeds (TF) has 133.1 g of carbohydrates per liter compared with 50 g of dextrose in 1 liter of 5% dextrose IVF. Allowing for differences in fiber, the D_5 IVF should be infused at approximately 2.7 times the TF rate to offer an equivalent amount of carbohydrates. Table 55.5 lists risk factors for hypoglycemia in hospitalized patients.

Hypoglycemia in Patients Without Diabetes

Because of counterregulatory mechanisms, hypoglycemia is very rare in patients without DM.[104] The differential diagnosis for hypoglycemia in patients without DM differs according to the clinical status of the patient: those who are otherwise healthy and those with an underlying illness (Table 55.6). Medications are the most common cause of hypoglycemia. Other etiologies include

TABLE 55.5 Risk Factors for Hypoglycemia in the Hospitalized Patient[111]

Risk Factor	Prevention
Initiation of insulin	Individualized insulin dosing
Inappropriate timing of mealtime insulin	Mealtime insulin boluses up to 15 min before or 15 min after meal
Overuse or overdosing of correctional doses of insulin	Individualized insulin dosing based on total daily insulin requirements
Change in nutrition	Standardized orders to adjust insulin or add intravenous fluids with dextrose
Reduction in corticosteroid dose	Adjust insulin doses as steroid dose is tapered

Autoimmune	Isoniazid, interferon alfa, hydralazine, procainamide, sulfhydryl-containing drugs
Interactions with sulfonylureas	Phenylbutazone, colchicine, paracetamol
β-Cell toxicity	Pentaminide
Unknown mechanism	Sulfonamide, salicylates, warfarin, octreotide

critical illness, hormone deficiency, non–islet cell tumors, endogenous hyperinsulinemia, and accidental hypoglycemia (see Table 55.6). A list of drugs and suspected mechanisms of hypoglycemia can be found in Table 55.7. Patients with Whipple's triad (symptoms and signs of hypoglycemia, a low plasma glucose concentration, and resolution of symptoms or signs after the plasma glucose is corrected) require further evaluation.[104] A detailed history, examination, and clinical evaluation are required to elucidate the etiology of the hypoglycemia.

Habitual drinkers often consume alcohol over other forms of nutrition, depleting glycogen stores and forcing the body to rely on gluconeogenesis. Acute alcohol consumption reduces endogenous glucose production owing to inhibition of hepatic gluconeogenesis. This effect is worsened in patients with hepatic insufficiency. Despite these mechanisms, hypoglycemia occurs in few adults because of alcohol (1%–4%), although children who present with acute alcohol ingestion are at higher risk for hypoglycemia.[112,113]

Cortisol deficiency is associated with increased insulin sensitivity, reduced glucose production, and increased glucose disposal.[114] The pathophysiology that increases the risk of hypoglycemia in patients with untreated adrenal insufficiency is mitigated with doses of glucocorticoids concomitant to the level of illness.

Hospitalized patients are at risk for hypoglycemia related to poor nutrition, renal failure, heart failure, liver disease, advanced age, infections, and intensity of treatment regimens.[114–117] Hypoglycemia in hospitalized patients is associated with excess mortality.[115,116] In sepsis, the rate of glucose use exceeds that of production.[118] Initially, hyperglycemia results from an increase in stress hormones including glucagon and epinephrine, resulting in stimulation of insulin release and increased glucose utilization by skeletal muscle and adipose tissue. Hypoglycemia eventually develops as the result of reduced hepatic gluconeogenesis.[118] Malnutrition, and renal and liver failure further exacerbate the risk of hypoglycemia in sepsis. Renal failure leads to reduced renal gluconeogenesis and reduced clearance of insulin and secretagogues.[114,117] Similarly, liver failure reduces hepatic gluconeogenesis and glycogenolysis.[114] Thus multiorgan failure dramatically increases the risk of hypoglycemia.

Insulinomas are a rare cause of hypoglycemia with an annual incidence of 0.7 to 4 cases per million population.[114] Their incidence is highest in the fifth decade and 5% to 10% occur as part of multiple endocrine neoplasia type 1.[114] Patients typically present with recurrent spontaneous fasting hypoglycemia.[114] In contrast, patients with post–gastric bypass hypoglycemia have postprandial hypoglycemia.[119] Although the mechanism of post–gastric bypass hypoglycemia has not been completely established, it is thought to be at least partially related to rapid gastric emptying, which results in an excessive rise in glucose. The subsequent elevation in glucose stimulates an exaggerated glucagon-like peptide 1 response, which in turn stimulates insulin release and hypoglycemia.[119]

Approach to the Nondiabetic Patient With Hypoglycemia

Only patients with Whipple's triad should be evaluated for a hypoglycemic disorder.[104] A thorough review of the patient's clinical and laboratory data can often lead to the reason for hypoglycemia without a prolonged and costly workup. When the cause is identified, steps should be taken to avoid recurrent episodes of hypoglycemia. Hypoglycemia related to critical illness should be a diagnosis of exclusion.

When the cause of hypoglycemia is not evident, laboratory evaluation during an episode of spontaneous hypoglycemia is required. This includes measurement of plasma glucose, insulin, C-peptide, proinsulin, β-hydroxybutyrate, and a screen for oral hypoglycemic agents.[104] Insulin antibodies should be measured when antibody-induced hypoglycemia is suspected. Once samples for laboratory tests are drawn, 1 mg of glucagon should be administered IV to observe the response of plasma glucose.[104] Some patients may require a 72-hour fast to induce spontaneous hypoglycemia, although this is not recommended in a critically ill patient. A 72-hour fast protocol is listed in Fig. 55.6.

Once laboratory test results are received, they must be interpreted to determine the cause of hypoglycemia. Table 55.8 shows interpretation of the laboratory results. Patients with documented endogenous fasting or postprandial hyperglycemia with a negative screen for oral hypoglycemic agents and no circulating insulin antibodies should have computed tomography or magnetic resonance imaging scans or transabdominal ultrasonography to localize an insulinoma.[104]

Suggested protocol for a prolonged diagnostic fast

- Date the onset of the fast as the time of the last food intake.
- Discontinue all nonessential medications.
- Allow the patient to drink calorie-free beverages. Ensure that the patient is active during waking hours.
- Collect samples for plasma glucose, insulin, C-peptide, proinsulin, and beta-hydroxybutyrate every 6 h until the plasma glucose concentration is <60 mg/dL; at that point the frequency of sampling should be increased to every 1–2 h.
- Samples for plasma insulin, C-peptide, and proinsulin should be sent for analysis only in those samples in which the plasma glucose concentration is <60 mg/dL.
- End the fast when the plasma glucose concentration is <45 mg/dL and the patient has symptoms and/or signs of hypoglycemia (or if 72 h have elapsed without symptoms).
- The decision to end the fast before 72 h should not be based on a low plasma glucose concentration alone, in the absence of symptoms or signs, because some healthy individuals, especially women and children, have low glucose levels during prolonged fasting.
- Alternatively, the fast can be ended when the plasma glucose concentration is <55 mg/dL without symptoms or signs if Whipple's triad was documented unequivocally on a prior occasion.
- A low plasma glucose concentration is a necessary, albeit not in itself sufficient, finding for the diagnosis of hypoglycemia. Therefore, the decision to end the fast should be based on laboratory-measured plasma glucose concentrations, not those estimated with a point-of care.

• **Fig. 55.6** Suggested protocol for a prolonged diagnostic fast. (From Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab.* 2009;94:709–728.)

TABLE 55.8 Patterns of Clinical and Serum Chemistry Findings After Fasting or a Mixed Meal

Symptoms/ Signs	Glucose (mg/dL)	Insulin (μU/mL)	C-peptide (nmol/L)	Proinsulin (pmol/L)	β-Hydroxy-Butyrate (mmol/L)	Glucose Increase After Glucagon (mg/dL)	Circulating Oral Hypoglycemic Agent	Antibody to Insulin	Diagnostic Interpretation
No	<55	<3	<0.2	<5	>2.7	<25	No	No	Normal
Yes	<55	≫3	<0.2	<5	≤2.7	>25	No	Negative (positive)	Exogenous insulin
Yes	<55	≥3	≥0.2	≥5	≤2.7	>25	No	Negative	Insulinoma, post–gastric bypass hypoglycemia
Yes	<55	≥3	≥0.2	≥5	≤2.7	>25	Yes	Negative	Oral hypoglycemic agent
Yes	<55	≥3	≫0.2	≫5	≤2.7	>25	No	Positive	Insulin autoimmune
Yes	<55	<3	<0.2	<5	≤2.7	>25	No	Negative	IGF-mediated
Yes	<55	<3	<0.2	<5	>2.7	<25	No	Negative	Not insulin (or IGF)-mediated

IGF, Insulin-like growth factor.

Key Points

- Despite advances in the management of critical illness, DKA and HHS remain life-threatening diabetic emergencies.
- DKA and HHS are often precipitated by interruption of insulin treatment, infection, or other acute illness, but may also be the initial presentation of diabetes.
- IV insulin is the treatment of choice for hyperglycemia in critically ill patients as it allows for frequent dose adjustments as necessary for the successful management of hyperglycemic emergencies.

- Attention to potassium replacement is essential to successful management of hyperglycemic emergencies.
- Target glucose in critically ill patients is 140 to 180 mg/dL, with attention given to avoidance of hypoglycemia.
- An HbA_{1c} test on admission distinguishes between stress hyperglycemia and previously unrecognized DM and helps guide therapy and the need for insulin therapy at the time of discharge.
- A physiologic insulin regimen, rather than oral hypoglycemics or sliding scale insulin alone, is the appropriate strategy for glucose control in the hospitalized patient.
- Recurrent hypoglycemia blunts the normal counterregulatory response in patients with type 1 DM and predisposes to severe hypoglycemia.

Review Questions

1. A 64-year-old man presents to the emergency department with dizziness, nausea, vomiting, and abdominal pain. His past medical history is significant for type 2 diabetes, hypertension, and hyperlipidemia. Medications include insulin glargine 25 units nightly, metformin 1000 mg bid, lisinopril 10 mg daily, atorvastatin 10 mg daily, and canagliflozin 100 mg daily. He reports a recent upper respiratory tract infection with reduced appetite over the past several days. During this time, he held insulin glargine but continued his other medications. Laboratory evaluation is provided in the following table:

Evaluation	Level
Sodium	135 mmol/L
Potassium	5.3 mmol/L
Chloride	97 mmol/L
Carbon dioxide	12 mmol/L
Creatinine	1.3 mg/dL
Glucose	210 mg/dL
Lactate	2 mg/dL

Physical examination is significant for blood pressure of 110/60 mm Hg and heart rate of 113 beats/min. Cardiovascular examination reveals tachycardia. Lungs are clear, and the abdomen is mildly tender to palpation diffusely. There is reduced skin turgor and dry mucous membranes.

Which of the following medications should not be restarted upon discharge?

a. Metformin
b. Lisinopril
c. Canaglifozin
d. Glargine

Answer: c. Canaglifozin is the correct answer as the patient's presentation is consistent with euglycemic diabetic ketoacidosis (DKA) from sodium glucose cotransporter (SGLT-2) inhibitor. Metformin (answer a) is not the correct answer as the patient's creatinine is 1.3. Once his DKA is treated, this will likely improve further and metformin can be restarted safely. In addition, given that his lactate level is normal, his anion gap metabolic acidosis is not related to lactic acidosis from metformin. Lisinopril (answer b) is not correct as his blood pressure is likely low-normal owing to DKA and dehydration. He should safely be able to restart this upon discharge. Glargine (answer d) is incorrect as most patients with euglycemic DKA from SGLT-2 inhibitors have relative insulin deficiency and develop DKA in the setting of insulin cessation. This patient will need to be taking insulin after discharge.

2. A 56-year-old obese man was admitted and treated in the intensive care unit (ICU) for pneumonia and sepsis. On admission, his glucose level was elevated, requiring an insulin infusion during his ICU stay. A hemoglobin A_{1c} (glycosylated hemoglobin; HbA_{1c}) measured on admission was 8.5%, although he had no known history of diabetes. His current insulin infusion rate is 2 units/h and has been stable for the past 2 hours. Renal function has normalized. He passed a swallow study and is tolerating a full diet, although he has had more fluctuation in glucose since he started eating.

Which of the following is the most appropriate way to transition him away from the insulin drip?

a. Stop the insulin drip and start insulin on a sliding scale.
b. Stop the insulin drip and start metformin.
c. Start lantus 48 units nightly and stop the insulin drip 2 hours after it is given.
d. Start 0.4 units/kg body weight insulin divided as 50% long-acting and 50% short-acting and stop the insulin drip 2 hours after long-acting insulin.

Answer: d. Patients younger than 70 years of age with a normal glomerular filtration rate not previously on a stable insulin dose should be started on basal bolus insulin at a dose of 0.4 to 0.5 U/kg body weight divided as 50% basal and 50% mealtime insulin. Answer a is not correct because sliding scale only insulin is never appropriate for managing diabetes in the hospital. Answer b is not correct because oral agents and premixed insulin are not appropriate in the hospital because of potential changes in nutrition and medical status. Answer c is not correct because the patient's insulin dose should not be calculated based on his insulin drip as his insulin drip has not been stable for at least 6 hours. In addition, basal insulin therapy without mealtime insulin is not appropriate in this patient given that he is eating.

3. A 75-year-old man is admitted to the ICU after a Whipple procedure performed for pancreatic cancer. He has a history of preexisting diabetes using metformin and glipizide before admission. After surgery, his glucose levels remained below 150 mg/dL until tube feeds were started. Blood sugars levels have been controlled for the past 48 hours with NPH 14 units every 8 hours while receiving Glucerna 1.5 at 60 mL/h (about 191 g carbohydrates over 24 hours). This morning he developed abdominal distention and tube feeds were held an hour ago (at 9 am) with plans for a computed tomography scan of the abdomen. He received his morning dose of NPH at 8 am. The current glucose level is 100 mg/dL. Which of the following is the most appropriate plan to prevent hypoglycemia?

a. Give an ampule of 50% dextrose (D50) now and monitor glucose hourly until tube feeds can be restarted.
b. Start D5 normal saline solution at 160 mL/h.
c. Start D10 at 45 mL/h.
d. No intervention is needed because the glucose level is currently normal.

Answer: b. The patient is receiving Glucerna 1.5 with 191 g carbohydrates over 24 hours. This is about 7 to 8 g of carbohydrates per hour. The equivalent amount of carbohydrates should be delivered with dextrose-containing fluids to prevent hypoglycemia given that the patient has already received insulin. Administering D5 in normal saline solution at 160 mL/h will provide the equivalent amount of carbohydrates per hour. Answer a is not correct as the patient is not hypoglycemic and so does not require D50 now. In addition, if no further glucose is given, he is very likely to develop hypoglycemia. Answer c is not correct as D10 at 45 mL/h would provide only 4.5 g of glucose per hour. Answer d is not correct as the patient is at significant risk of hypoglycemia with the change in nutrition.

Etomidate

Summary

Adrenal insufficiency (AI) is by far the most common adrenal disorder seen in the intensive care unit (ICU) and is the focus of this chapter. It occurs more frequently in critically ill patients than in general hospitalized patients and represents a true emergency that requires rapid diagnosis and treatment. If missed, the condition can be fatal. In addition, because critical illness is often the precipitant of overt AI, the intensivist may have the first and only chance to make the diagnosis.[1]

Primary AI results from a subtotal or complete destruction of the adrenal cortex (>90%) and results in cortisol, aldosterone, and androgen deficiency. Multiple causes of primary AI include autoimmune destruction (Addison disease), polyendocrine deficiency syndrome, infections (e.g., tuberculosis, fungus), vascular compromise, primary or metastatic cancer, amyloidosis, and surgical removal of the adrenal glands.

Secondary AI is much more common than primary AI and can be traced to a lack of adrenocorticotropic hormone (ACTH). Without ACTH to stimulate the adrenal glands, production of cortisol falls but aldosterone secretion remains intact. The most common cause of secondary AI is the inadvertent abrupt withdrawal of therapeutic exogenous corticosteroids. Another cause of secondary AI is the surgical removal of benign or noncancerous, ACTH-producing tumors of the pituitary gland (Cushing syndrome). In this case, the source of ACTH is suddenly removed, and replacement hormones must be taken until normal ACTH and cortisol production resumes.

Less commonly, secondary AI occurs when the pituitary gland reduces or ceases production of ACTH. This can occur for a variety of reasons, including tumors or infections of the area, loss of blood flow to the pituitary, radiation for the treatment of pituitary tumors, total or subtotal removal of the hypothalamus, and surgical removal of the pituitary gland.

The term "relative adrenal insufficiency" has been replaced in recent literature by "critical illness–related corticosteroid insufficiency" (CIRCI),[2,3] which is characterized by corticosteroid activity that is inadequate for the severity of the illness of a patient.

Patients at risk of AI vary from young athletes using steroids to persons taking adrenal extracts for "adrenal fatigue syndrome." Also at risk are those receiving chronic topical glucocorticoid treatment for dermatologic disorders. Patients who are using glucocorticoids and inhibitors (such as itraconazole, diltiazem) of cytochrome 450 (CYP) 3A4 are at risk as well.[4] For all these reasons the intensivist must understand clinical problems associated with the hypothalamic-pituitary-adrenal (HPA) axis and the use of glucocorticoid hormones.

Incidence and Prevalence

The actual incidence of acute AI is unknown. The incidence of HPA axis failure varies depending on the criteria used to make the diagnosis and the patient population studied. At least 90% of both adrenal glands must be destroyed before clinical and biochemical manifestations of AI occur. The overall incidence of AI is estimated to be as high as 60% in patients with severe sepsis and septic shock.[5] Secondary AI may be more common than primary AI. The clinical presentation of secondary AI is relatively nonspecific and often resembles other conditions common in the ICU. Hence

it is not uncommon to attribute the clinical features resulting from acute AI to commonly seen medical conditions in the ICU.[6]

Pathophysiology

To understand the pathogenesis of adrenal diseases one must understand the physiology of the adrenal glands and the causes that result in the disruption of the physiologic process.

The adrenal glands are pyramid-shaped, each weighing about 5 to 10 g, and are located just superior to their respective kidneys. The left adrenal gland is usually slightly more cephalad than the right gland. Each adrenal gland is composed of an inner medulla and outer cortex. These layers are embryologically, anatomically, and physiologically distinct. The adrenal cortex is responsible for the secretion of multiple steroid hormones. The adrenal medulla is responsible for the secretion of catecholamines.

The adrenal cortex is composed of three zones: the outer zona glomerulosa, inner zona fasciculata, and zona reticularis. The zona glomerulosa secretes the mineralocorticoid aldosterone in response to angiotensin, ACTH, and a high circulating potassium concentration. The zona fasciculata and zona reticularis secrete glucocorticoids and adrenal androgens.

The principal mineralocorticoid is aldosterone, which is regulated not only by ACTH but also by serum sodium and potassium levels and by the renin-angiotensin system.[7,8] Mineralocorticoids exert their primary effect on distal renal tubule cells, resulting in renal sodium retention at the expense of potassium loss in the urine. A third major class of adrenal steroids is the sex hormones: dehydroepiandrosterone (DHEA), DHEA-sulfate, and androstenedione. Like the glucocorticoids, ACTH primarily regulates these steroid hormones. They function mainly as precursors for the primary circulating androgen, testosterone, and may also undergo separate conversion to estrogen hormones. In critically ill patients, glucocorticoids are the steroid hormones of greatest concern and therefore remain the focus of the remainder of this discussion.

Glucocorticoid Synthesis

Glucocorticoid synthesis is regulated by (1) a negative feedback mechanism involving cortisol and adrenal steroids, (2) a diurnal rhythm, and (3) stress. The hypothalamus and the pituitary gland closely regulate adrenal hormone production. Corticotropin-releasing hormone (CRH) is produced in the hypothalamus and acts on specialized cells in the pituitary, stimulating production of ACTH, which serves, in turn, to stimulate adrenal cortical cells to produce numerous steroid hormones, including cortisol. Adrenal hormones have a negative influence at the level of the hypothalamus and the pituitary, inhibiting CRH and ACTH release. The adrenal gland in turn ceases its secretory activity until the cortisol concentration returns to normal. When serum cortisol levels are below normal, secretion of CRH and ACTH increases, stimulating the adrenal glands to produce cortisol until its level normalizes. Therefore abnormalities in circulating serum levels of adrenal steroid hormone can be caused by either adrenal or hypothalamic pituitary disease. Because ACTH possesses α-melanocyte–stimulating hormone activity, excessive production of ACTH is associated with hyperpigmentation.

Cortisol is normally secreted in a diurnal pattern. The circulating cortisol level is increased in the morning hours, at approximately 8 a.m. Serum cortisol concentrations decrease throughout the remainder of the day.[9] Similarly, the serum cortisol response to ACTH stimulation also varies in a circadian rhythm. Afternoon responsiveness is much greater because of the decreased circadian level of cortisol at that time. In addition, cortisol is secreted in a series of pulses rather than in a continuous fashion. These factors contribute to make interpretation of a random cortisol level and the ACTH-stimulated value difficult.

"Stress" (exemplified by sepsis, major surgery, or trauma) also affects glucocorticoid synthesis.[10–12] The *stress response* is characterized by continuous ACTH secretion despite a high serum cortisol concentration. Stress overrides all other regulatory mechanisms of cortisol secretion by the adrenal cortex and increases cortisol secretion irrespective of the time of day or the current serum cortisol concentration. The mechanism by which the HPA axis is regulated during stress is not clearly understood. Periventricular neurons in the hypothalamus respond to stress by increasing the levels of CRH messenger ribonucleic acid.[13,14] It has been shown that production of the cytokines interleukin 1 (IL-1), IL-6, and tumor necrosis factor α also plays an important role in the regulation of the HPA axis.[15–19] The cortisol secretion that occurs because of the activation of the HPA axis causes an inhibitory effect not only on the secretion of CRH and ACTH but also on the liberation of interleukins.[20] Thus there is a functional loop between immune activation and regulation of the HPA axis during stress.

The stress response is biphasic, consisting of an early phase in which both ACTH and cortisol are elevated and a late phase in which the serum cortisol level is elevated but the serum ACTH level is paradoxically low.[8] This is explained by the fact that endothelin and atrial natriuretic peptide are both elevated in severe illnesses. Endothelin increases cortisol production by the adrenals, whereas the atrial natriuretic peptide inhibits ACTH production by acting at the hypothalamic-pituitary level. Vasopressin and angiotensin II can increase ACTH secretion during stress conditions, such as sepsis and septic shock.

Acute respiratory failure causes a 50% to 100% rise in serum cortisol concentration. A twofold to sixfold rise occurs with septic shock and after surgical procedures and trauma. The rise in serum cortisol correlates positively with severity of illness[6] and negatively with survival.[7]

The normal daily output of cortisol by the adrenal glands is 20 to 30 mg. The normal adrenal gland secretes about 10 to 12 times the normal daily output of cortisol when under maximal physiologic stress. Hence approximately 200 to 300 mg of hydrocortisone or its equivalent is considered a daily "stress dose" of glucocorticoid.

Glucocorticoid Actions

After uptake of free hormone from the circulation, the effects of cortisol and aldosterone are mediated by binding to intracellular receptors termed the glucocorticoid receptor and the mineralocorticoid receptor.

Cardiovascular Effects

Glucocorticoids help to maintain vascular tone and cardiac contractility. The presence of glucocorticoids is important to the physiologic effects of catecholamines on vascular smooth muscle. Glucocorticoids affect blood pressure by different mechanisms, including direct action of glucocorticoids on the vasculature, permissive effects of the glucocorticoids on the vasopressor action of catecholamines, glucocorticoid-induced decrease in the levels of prostaglandin E_2 and kallikrein (vasodilators), and reduction of nitric oxide–mediated endothelial dilatation. Angiotensinogen synthesis is increased by glucocorticoids.[21] Glucocorticoids increase the synthesis of β-adrenergic receptors, reverse β_2-adrenergic receptor

dysfunction, and increase the coupling of the receptor with the second messenger system.[22]

Two hemodynamic states have been described during acute AI:

1. Low cardiac output, high systemic vascular resistance shock is caused by both decreased myocardial contractility and decreased preload.
2. High cardiac output, low systemic vascular resistance shock mimics septic shock.[23] It appears that patients with AI present initially with a combination of cardiogenic shock and hypovolemic shock. Intravascular volume expansion with intravenous (IV) fluids results in an increase in cardiac output and a lowering of systemic vascular resistance. The hemodynamic profile that one observes is dependent on the timing of hemodynamic assessment during the course of treatment in an individual patient. Thus the hypotension of AI can mimic cardiogenic, hypovolemic, or septic shock (depending on when the hemodynamic assessment was made) and may be poorly responsive or unresponsive to treatment with fluids and vasopressors in the absence of glucocorticoid therapy.

Metabolic Effects

Glucocorticoids increase blood glucose concentrations through their action on glycogen, protein, and lipid metabolism. A major action is on gluconeogenesis. Glucocorticoids increase hepatic glycogen and glucose by inducing the synthesis of hepatic enzymes and increasing the availability of gluconeogenic substrates. This is because of glucocorticoid-induced proteolytic activity on peripheral tissues, which causes mobilization of glycogenic amino acid precursors from peripheral supporting structures, such as bone, skin, muscle, and connective tissue, because of protein breakdown and inhibition of protein synthesis. Glucocorticoids decrease the peripheral uptake and utilization of glucose. They have a permissive effect on other hormones such as glucagon and catecholamines, thus serving to increase the circulating glucose concentration, which in turn increases insulin secretion, at the expense of protein and lipid catabolism.

Glucocorticoids increase lipolysis both directly and indirectly by action on other hormones. Glucocorticoids regulate fatty acid mobilization by enhancing activation of cellular lipase by lipid-mobilizing hormones (e.g., catecholamines, pituitary peptides). They elevate free fatty acid levels in the plasma and enhance any tendency to ketosis. Glucocorticoids stimulate peripheral protein metabolism, using the amino acid products as gluconeogenic precursors. Muscle protein synthesis is reduced, and thus glucocorticoids cause muscle atrophy.

Renal Effects

Glucocorticoids bind to the mineralocorticoid receptors in renal tubules and increase sodium reabsorption and excretion of potassium and hydrogen ions. Glucocorticoids increase the glomerular filtration rate, proximal tubular epithelial sodium transport, and free water clearance. Hyponatremia during AI can be secondary to the glucocorticoid inhibitory effect on vasopressin.[21]

Immunologic Effects

Glucocorticoids suppress immunologic responses, and this is the basis for their use in the treatment of autoimmune and inflammatory disorders. In the peripheral blood, they redistribute lymphocytes from the intravascular compartment to the lymphoid pool in the spleen, lymph nodes, and bone marrow. They therefore decrease lymphocyte counts, but neutrophil counts increase after glucocorticoid administration. Eosinophil counts fall as the result of eosinophil apoptosis. Glucocorticoids inhibit immunoglobulin synthesis and cytokine production from lymphocytes. Glucocorticoids also inhibit monocyte differentiation into macrophages.[21] Glucocorticoids mediate antiinflammatory effects by decreasing the release of inflammatory mediators such as histamine, cytokines, and prostaglandins. The immunologic actions of glucocorticoids are significant only in circumstances in which they are present in supraphysiologic amounts, such as markedly increased endogenous production or exogenous administration.

Gastrointestinal Effects

It has been postulated that CRH inhibits the release of motilin, a duodenal hormone that is responsible for the initiation of peristaltic contractions, which begin in the stomach and propagate distally. Glucocorticoids decrease CRH production and thus inhibit gastric and intestinal motility. This could explain the vomiting, constipation, and abdominal pain observed in cortisol deficiency. Glucocorticoids can also increase risk of peptic ulcer disease and pancreatitis.

Calcium Metabolism

Glucocorticoids lower serum calcium levels by several mechanisms. They inhibit calcium absorption from the gut, decrease renal calcium reabsorption (which results in hypercalciuria), and promote a shift of calcium from the extracellular compartment to the intracellular compartment. Glucocorticoids inhibit osteoblast function and cause osteoporosis, which occurs in approximately 50% of patients who require long-term use of glucocorticoids.[24] Avascular necrosis is a dreaded complication. It mainly affects the femoral head and causes pain and collapse of the bone, often necessitating hip replacement. Glucocorticoid-induced osteocyte apoptosis has been implicated in the pathogenesis of the condition, and the lack of a direct role for an interrupted blood supply suggests that the term osteonecrosis may be preferable to avascular necrosis.[21]

Other Effects

Glucocorticoids have many other effects, including the ability to produce significant mood changes and even psychosis in some patients. Glucocorticoids have been associated with neuronal death, especially in the hippocampus. Glucocorticoids have an association with cataract formation and increased intraocular pressure both by increasing aqueous humor production and decreasing drainage. They also negatively affect the production and action of a number of other hormones, including insulin, thyroid hormones, and gonadal hormones.

Aldosterone secretion is regulated mainly by the renin-angiotensin system. The most potent modulator of this system is renal perfusion. Hyperkalemia inhibits production of renin but increases the synthesis of aldosterone. Aldosterone increases sodium reabsorption in the collecting tubules and at the same time causes potassium and hydrogen ion excretion. This is mediated by the sodium ion–potassium ion (Na^+/K^+) pump in the presence of the enzyme Na^+/K^+-adenosine triphosphatase (ATPase) and results in sodium and water retention and an increase in intravascular volume.[21]

Hyperkalemia, hyponatremia, non–anion gap metabolic acidosis, hemoconcentration, and hypovolemia provide important clinical clues to the diagnosis of primary AI. Because ACTH is not a potent regulator of aldosterone secretion, secondary AI is usually not associated with hyperkalemia. Hyponatremia and hypovolemia may be present in secondary AI but not to the degree found in primary AI. The renin-angiotensin system is activated during AI and serves as a defense mechanism to improve the low intravascular

volume and the altered vasomotor tone that results from aldosterone and cortisol deficiency.[25,26]

Etiology and Pathogenesis

Causes of primary AI are shown in Box 56.1.

Autoimmune Disease

Autoimmune adrenalitis (Addison disease) is currently the most common cause of primary AI in the Western world and accounts for up to 80% of cases.[21] AI may occur as isolated disease or as part of a polyglandular autoimmune syndrome associated with thyroiditis, diabetes mellitus (Schmidt syndrome), hypogonadism, vitiligo, and pernicious anemia.[27,28] Autoimmune AI is more common in women than men and usually occurs in the third to fifth decades of life. The mean duration of symptoms before diagnosis is approximately 3 years. In this disorder high levels of circulating autoantibodies attack the cytoplasm of adrenal cortical cells and inhibit synthesis of glucocorticoids.[27,29]

• BOX 56.1 Causes of Primary Adrenal Insufficiency

- Autoimmune (idiopathic) 80% (most common cause)
- Infections
  - Tuberculosis (second most common cause)
  - *Pneumococcus* infection

  - Phenobarbital
  - Rifampin
  - Etomidate
  - Fluorouracil
  - Metyrapone
- Miscellaneous
  - Irradiation
  - Bilateral adrenalectomy
- Congenital conditions

Infectious Disease

Worldwide, infectious diseases are the most common cause of primary AI.[21]

Tuberculosis

Primary AI results from adrenal gland destruction by *Mycobacterium tuberculosis*. This infection currently accounts for less than 20% of cases.[30] This usually occurs in the presence of tuberculosis elsewhere in the body, especially with involvement of the lungs, genitourinary system, and gastrointestinal system. AI is usually manifest years after the initial presentation of tuberculosis.[31] The mean duration of symptoms of AI before diagnosis is 6 to 9 months. AI secondary to tuberculosis occurs with equal frequency in men and women. In contrast to autoimmune adrenalitis, tuberculosis-induced adrenal disease is not associated with other endocrine diseases. In addition, with tuberculosis the adrenal glands are enlarged and may be calcified. In contrast, the adrenal glands in autoimmune adrenalitis are usually atrophied and noncalcified.

Fungal Disease

Fungal disease can also cause primary AI. *Histoplasma capsulatum* is the most common organism. As seen in tuberculosis, fungal infection is usually disseminated and involves organs other than the adrenal glands. Adrenal involvement may be seen during the active phase or may develop years later after the disease has become "inactive." Sarosi and colleagues[32] reported that more than 50% of patients with disseminated histoplasmosis had AI, and AI was the most common cause of death.

Acquired Immunodeficiency Syndrome

Patients with AIDS are at risk of developing AI by several different mechanisms. Fungal infections are more common in this patient population, and disseminated disease may involve the adrenal glands. Similarly, mycobacterial infection, cytomegalovirus infection, and Kaposi sarcoma may cause involvement of the adrenal glands in up to 50% of patients.[3] In addition, sepsis and spontaneous adrenal hemorrhage are also seen in this group of patients. Because patients with human immunodeficiency virus infection now survive longer, an increased incidence of AI is likely.

Neoplasia

Neoplastic metastasis to the adrenal glands has been found on autopsy in 27% to 40% of patients who die of malignancy.[33–36] Yet metastatic carcinoma accounts for less than 1% of cases of primary AI.[33] This finding is explained by the tremendous functional reserve possessed by the adrenal glands. More than 90% of the adrenal gland must be destroyed before hypofunction occurs. Many patients with metastasis to the adrenals do not develop hormonal deficiency.[37] The most common neoplasms involving the adrenal glands are lung cancer, breast cancer, melanoma, and lymphoma.[35] AI usually occurs in the setting of widespread metastatic disease and is rarely the initial manifestation of malignancy.

Medications

Certain medications can cause AI. Of particular interest to the intensivist are ketoconazole, phenytoin, phenobarbital, rifampin, and etomidate. Ketoconazole decreases glucocorticoid synthesis and is also a glucocorticoid receptor antagonist. Although some

of the newer antifungal drugs (e.g., itraconazole and fluconazole) tend to be safer, AI that occurs after treatment with high doses has been reported, especially during states of increased glucocorticoid requirement, such as the severe stress associated with critical illness. Etomidate decreases glucocorticoid production even after a single injection. Phenytoin, rifampin, and barbiturates increase the catabolism of glucocorticoids. These medications can precipitate acute AI by decreasing glucocorticoid production or function in a patient who has compromised adrenal reserve.[28]

Adrenal Hemorrhage

Adrenal hemorrhage is an important but uncommon cause of AI in the ICU. The association of adrenal hemorrhage with fulminant sepsis was first described with *Neisseria meningitidis* (Waterhouse-Friderichsen syndrome). Infections with *Streptococcus pneumoniae, Staphylococcus* species, *Pseudomonas* species, and *Haemophilus influenzae* type b can also cause this syndrome.[28]

Besides the infectious causes, other conditions may predispose to adrenal hemorrhage, including severe illness (particularly cardiac disease), coagulopathy, anticoagulant therapy, thromboembolism, burns, and trauma.[38] Under these circumstances the typical signs and symptoms of AI are often mistaken for those of other common conditions. Typical settings include the patient who is in the first or second postoperative week or a patient who has recently started anticoagulation therapy. Common findings include abdominal, back, flank, or chest pain; nausea; vomiting; fever; altered mental status; orthostatic hypotension; and a sudden drop in the hematocrit level. The hemodynamic crisis associated with adrenal hemorrhage occurs 1 to 3 days after the initial hemorrhage.

Etiology of Secondary Adrenal Insufficiency

Causes of secondary AI are shown in Box 56.2. Secondary AI occurs because of a decrease in ACTH caused by either hypothalamic-pituitary disease or suppression of the HPA axis as a result of glucocorticoid therapy. The most common cause today is discontinuation of corticosteroid therapy. Nearly 1% of people in the general population (2.5% of those who are older than 70 years of age) are treated with long-term regimens of glucocorticoids for inflammation related to chronic disease.[28] Chronic glucocorticoid therapy leads to HPA axis suppression with resulting secondary AI if glucocorticoids are abruptly discontinued. With the exception of AI because of discontinuation of chronic glucocorticoid therapy, secondary adrenocortical insufficiency is much less common than primary AI. Isolated ACTH deficiency is rare, and ACTH is the last pituitary hormone to be impaired by enlarging sellar and suprasellar tumors.

Most patients admitted to the ICU with secondary AI have recently received steroid therapy or have taken steroids within the year before admission. No clear evidence indicates that detailing the duration or dose of steroid therapy predisposes patients to adrenal suppression. Doses of 25 mg of prednisone twice a day for 2 days, 12.5 mg/day for 6 months, or 5 mg/day for 5 years have all been shown to cause adrenal suppression. On the other hand, studies have shown that prednisone in doses less than 40 mg/day given every morning for 5 to 7 days did not cause adrenal suppression.[39]

As a practical guideline, in anyone who has received more than 20 mg of prednisone a day for more than 3 weeks adrenal function should be considered suppressed until proved otherwise.[40] If glucocorticoids have been given to a patient for more than 1 to 2 weeks, the regimen should be tapered to allow time for the adrenal glands to recover function. AI can occur in response to stress as long as 1 year after steroids are discontinued. All such patients should be evaluated for adrenal function and should be treated with stress doses of steroids during the interim period.

Patients with liver diseases may have AI. Signs of AI are present in 33% of patients with acute liver failure, 65% of patients with chronic liver disease and sepsis, and 92% of patients who have undergone a liver transplantation.[41] In patients with cirrhosis, AI is reported during sepsis and septic shock and is associated with increased mortality. Consequently, the term "hepatoadrenal syndrome" was proposed. Corticosteroid replacement in this patient population has yielded conflicting results, however. Patients with liver diseases should be carefully monitored for symptoms and signs of adrenal insufficiency.[42]

Another potential problem is hypopituitarism related to brain injury. Pituitary dysfunction occurs in up to 30% of patients with brain injury and may not appear until months or years after the traumatic incident.[43]

• BOX 56.2 Causes of Secondary Adrenal Insufficiency

Glucocorticoid therapy (most common cause of secondary adrenal insufficiency)
Neoplastic
- Pituitary adenoma
- Meningioma
- Craniopharyngioma
- Metastatic carcinoma
- Breast
- Lung
- Gastrointestinal
- Lymphoma
- Leukemia

Vascular
Pituitary apoplexy
Sheehan syndrome
Sickle cell disease
Intracranial aneurysm
Cavernous sinus thrombosis
Vasculitis
Eclampsia
Infection
- Tuberculosis
- Fungal infection
- Malaria
- Actinomycosis
- Viral infection

Autoimmune disorders
Infiltrative disorders
Sarcoidosis
Hemochromatosis
Irradiation
Head trauma and pituitary surgery
Isolated adrenocorticotropic hormone deficiency

Clinical Features

Common symptoms and signs of AI are shown in Box 56.3. The symptoms, signs, and general laboratory findings seen in AI are nonspecific. However, when taken together they form a pattern of findings that should suggest the possibility of AI. Clinical features can be divided into acute AI and chronic AI. Patients with acute

• BOX 56.3 Common Symptoms and Signs of Adrenal Insufficiency

Symptoms

- Weakness
- Fatigue
- Anorexia
- Gastrointestinal symptoms (nausea, vomiting, abdominal pain, diarrhea, constipation, and weight loss)
- Orthostatic symptoms
- Myalgias
- Arthralgias

Signs

- Weight loss
- Orthostatic hypotension
- Hyperpigmentation
- Vitiligo
- Confusion/psychosis

AI share many characteristics with patients who have chronic AI, but the symptoms are usually more severe in the acute setting.

The most common complaints associated with chronic adrenal insufficiency are fatigue, weight loss, and gastrointestinal complaints, including nausea, vomiting, and diarrhea. More than half of patients with chronic AI experience postural hypotension. Less commonly patients may develop arthralgias, myalgias, and psychiatric disease, including depression, memory impairment, delirium, and psychosis. Decreased axillary and pubic hair as well as amenorrhea can be seen in women of childbearing age. Patients with primary AI may have hyperpigmentation of the tongue, buccal mucosa, palmar creases, and scar tissue. This is caused by increased production of melanocyte-stimulating hormone, a cleavage product of proopiomelanocortin, which is the precursor for ACTH. Hyperpigmentation is notably absent in secondary AI. The classic presentation of acute AI is a patient with unexplained hemodynamic instability who is unresponsive to intravascular volume resuscitation and use of vasopressors. The associated symptoms are generally nonspecific and are the same as chronic AI. Abdominal pain is common and in the case of adrenal hemorrhage or infarct may mimic an acute surgical abdomen. If the underlying problem is autoimmune adrenalitis, the patient may have vitiligo, pernicious anemia, or one of the other associated endocrinopathies.

Diagnosis

The diagnosis of AI demands a high index of suspicion. The classic symptoms, signs, and laboratory findings of AI are not commonly seen. The consequences of missing the diagnosis can be lethal, but if the diagnosis is made the condition can usually be treated easily. If the diagnosis of AI is being considered, the patient's history should be carefully reviewed for use of steroids (including inhaled corticosteroids), exposure to tuberculosis, use of anticoagulant therapy, presence of sepsis, or history of cancer that may have metastasized to the adrenal glands. Patients taking high doses of steroids can develop AI when subjected to stress. Given that the major manifestations of acute adrenal crisis (i.e., shock) are related primarily to mineralocorticoid deficiency, it is important to recognize that patients receiving glucocorticoid therapy can still develop adrenal crisis if mineralocorticoid supplementation is inadequate.

• BOX 56.4 Common Laboratory Findings in Adrenal Insufficiency

- Hyponatremia
- Hyperkalemia
- Acidosis
- Prerenal azotemia
- Hypoglycemia
- Lymphocytosis
- Eosinophilia

Laboratory Findings

Although the laboratory evaluation of patients with suspected AI is essential, the utility of this evaluation is variable. In a patient with acute worsening of a chronic hypoadrenal state, the common laboratory findings shown in Box 56.4 are more likely to be present and are likely to be more pronounced. In a patient with acute adrenal insufficiency as the result of adrenal infarct or hemorrhage the classic laboratory abnormalities are unlikely to be seen. Although their absence does not exclude the diagnosis, when the typical laboratory abnormalities are present the possibility of adrenal insufficiency should be entertained. Electrolyte abnormalities depend on the type of deficiency: a combined glucocorticoid and mineralocorticoid deficiency (typically seen in primary AI) or an isolated glucocorticoid deficiency (characteristic of secondary AI).

Patients who have a combined deficiency may show hyponatremia, hyperkalemia, decreased serum bicarbonate, and increased blood urea nitrogen. This is primarily caused by the mineralocorticoid deficiency, which leads to renal sodium loss, potassium retention, and dehydration with acidosis and prerenal azotemia. In patients with concomitant kidney injury hypercalcemia may also be seen. It has been suggested that eosinophilia may serve as a marker for adrenal insufficiency; however, this finding is neither sensitive nor specific for AI and should not be relied upon. Patients with secondary adrenocortical deficiency usually have milder electrolyte abnormalities. Their normal adrenal glands are able to produce sufficient amounts of mineralocorticoid even in the absence of ACTH stimulation. They usually have mild hyponatremia with normal potassium levels, and they show little evidence of dehydration. Patients with AI may also have hypoglycemia, which occurs as a result of increased utilization of glucose and decreased gluconeogenesis in the face of glucocorticoid deficiency.

Diagnostic Tests

When there is a high suspicion of AI, hormonal testing is necessary to confirm the diagnosis. The utility of hormonal testing, particularly in the setting of critical illness, is controversial. Furthermore, in the setting of suspected adrenal crisis treatment and testing should be performed concomitantly; however, treatment should not be delayed to allow for testing. The laboratory evaluations most commonly used to detect AI in critically ill patients are the random serum cortisol level and the rapid ACTH stimulation test.

Serum Cortisol Level

The biochemical diagnosis of AI is controversial and is based on the demonstration of decreased cortisol production. Potential pitfalls in the measurement of cortisol levels arise when considering the

effects of critical illness on cortisol production, transport, and utilization. Most clinical laboratories routinely measure total cortisol levels, which may not accurately reflect the physiologic activity of cortisol. Critical illness results in a loss of cortisol-binding globulin with a subsequent decrease in the physiologically inactive protein-bound cortisol and an increase in the physiologically active free cortisol. Experts have recently suggested that measurement of free cortisol levels makes more physiologic sense, but studies have not helped establish diagnostic thresholds for free cortisol levels.[44] To further complicate the matter tissue levels of cortisol measured by microdialysis do not appear to strongly correlate with either free or total serum cortisol levels.[45] In addition, variability of cortisol assays can confound the diagnosis of AI.[46]

Given the controversy in diagnosis, the following recommendations have been suggested. A randomly measured serum cortisol level that exceeds 44 μg/dL makes the diagnosis of adrenocortical deficiency unlikely.[5] This information alone may be insufficient as it has been suggested that patients with septic shock who have high baseline cortisol levels (>34 μg/dL) and an increase of less than 9 μg/dL have a high mortality risk.[47] Serum cortisol levels should increase significantly in patients with normal adrenal function who are in shock and critically ill. The finding of a random serum cortisol level of less than 10 μg/dL in this setting is highly suggestive of compromised adrenal function and should prompt treatment or a confirmatory ACTH stimulation test.[5]

The interpretation of random serum cortisol levels can be effected by several commonly used drugs in the ICU. Antifungal agents such as fluconazole have the ability to impair cortisol synthesis. Propofol produces a temporary reduction in serum cortisol levels but does not seem to inhibit adrenal responsiveness to ACTH. Etomidate, on the other hand, is associated with a reduced serum cortisol concentration despite ACTH stimulation.[48] Treatment with hydrocortisone or cortisone can alter measurements as these agents are detected by most assays used for the measurement of cortisol. Dexamethasone is not detected by most assays and should not interfere with measurements. Treatment with any corticosteroid for more than 2 to 3 days may cause suppression of the HPA axis and thus may alter the outcome of biochemical measurements.

Rapid ACTH Stimulation Test

The ACTH stimulation test measures the response of the adrenal gland to stimulation by exogenous ACTH. This test can be performed at any time of the day because the normal diurnal variation of cortisol is lost in the setting of critical illness. Two major forms of this test are used: low-dose (1 μg) and high dose (250 μg). Clinically, the majority of testing is accomplished using high-dose ACTH stimulation. For both methods the procedure is the same. A baseline serum cortisol level is obtained. Cosyntropin (synthetic ACTH) is then administered intravenously followed by a sample for cortisol level drawn 60 minutes after ACTH administration.

Many recommendations have been made regarding interpretation of ACTH stimulation testing results. When used in the evaluation primary adrenal insufficiency peak cortisol levels less than 18 μg/dL at 30 or 60 minutes after the administration of ACTH are indicative of adrenal insufficiency.[49] It has been suggested that a rise in serum cortisol of less than 9 μg/dL is indicative of AI; however, studies have been unable to consistently demonstrate that this adequately predicts a response to treatment with steroids in critically ill patients.[5]

A few studies have compared low-dose and high-dose ACTH stimulation tests in critically ill patients; however, these study sizes are small.[50,51] Further research is required before definitive recommendations regarding the use of low-dose versus high-dose ACTH stimulation testing can be made.

Interpretation of the results from an ACTH stimulation test performed in critically ill patients who may have sustained recent injury to the hypothalamus or pituitary gland (traumatic brain injury, intracerebral hemorrhage, cerebrovascular accident, postpartum hypopituitarism, and so on) should be done with caution. In these situations the adrenal glands may continue to exhibit a normal response to exogenous ACTH administration for up to 3 weeks after the injury.[43]

The rapid ACTH stimulation test is a relatively simple test for evaluating AI; however, it does not differentiate between primary and secondary AI. To differentiate between primary and secondary AI, a basal plasma ACTH determination is made. An ACTH level more than two times the upper limit of normal is consistent with primary AI.[49] Historically, a 24- to 48-hour infusion of ACTH has been used to distinguish primary and secondary AI. Failure of the adrenal glands to appropriately increase cortisol production after prolonged infusion of ACTH is indicative of primary AI as the atrophic adrenal glands should still be capable of increasing production in response to the prolonged stimulus. Given the availability and accuracy of ACTH measurements, the prolonged stimulus is not often necessary or recommended in the critically ill patient.

After the diagnosis of primary AI is established, appropriate investigation for mineralocorticoid insufficiency should be pursued. Simultaneous measurements of plasma renin activity and aldosterone levels can provide valuable information regarding mineralocorticoid insufficiency.[49] These tests are technically challenging, however, and it is often not feasible to correctly perform these measurements in the intensive care setting.

Critical Illness–Related Corticosteroid Insufficiency

The term critical illness–related corticosteroid insufficiency (CIRCI) describes HPA axis dysfunction in critical illness, which is defined as a cellular corticosteroid activity that is inadequate for the severity of the patient's illness. The use of the term relative adrenal insufficiency is no longer recommended by some authors.

Despite no conclusive evidence of benefit, in the 1950s, 1960s, and into the 1970s cortisol at low doses over days was often used in patients with severe manifestations of sepsis to counter the AI that was assumed to be present. This practice was based on autopsy studies that revealed adrenal necrosis in patients with severe infections. The subsequent recognition of the systemic effects of inflammation in sepsis and the discovery that the majority of patients in septic shock had normal or increased cortisol levels led to a paradigm shift in treating septic shock with massive doses of steroids given for a short period of time. This practice was based on animal studies showing that large doses of steroids given before boluses of endotoxin prevented death.[46] Clinical trials testing the utility of several large doses of steroids in patients with septic shock failed to show benefit.[52,53] One study in patients with septic shock demonstrated that regardless of baseline cortisol level, the inability to raise the cortisol level following ACTH stimulation by at least 10 μg/dL signified poor prognosis.[47] In this poor prognostic group, the higher the baseline cortisol level with failure to produce a 10-μg/dL increase, the worse the prognosis. There is currently no consensus regarding the diagnostic criteria for CIRCI.

Management

Once the diagnosis of AI is made, a search for the cause should be initiated as the patient is being stabilized. Appropriate evaluation for a potential infectious etiology (tuberculosis, fungal infections, and so on) should be pursued as indicated by the patient's history and exposures. An abnormal prothrombin time, partial thromboplastin time, or platelet count may point to an unsuspected coagulopathy suggesting the possibility of adrenal hemorrhage. Antiadrenal antibodies are found in about 70% of patients with autoimmune adrenal disease and in less than 0.1% of normal subjects.[54] Adrenal calcification can be seen in 53% of cases of tuberculosis and can be identified via computed tomography (CT) scan of the abdomen.[55]

Management of AI can be best accomplished by identifying the degree of acuity and severity of the patient's illness at the time of presentation.[56]

Preexisting Adrenal Insufficiency

Patients who are known to have AI or who have received glucocorticoid therapy in the past year should receive stress doses of corticosteroids during critical illnesses and during surgical procedures. The typical regimen is administration of a hydrocortisone 100-mg IV bolus followed by 200 mg/24 h (either as continuous infusion or in divided IV doses). Attention should be paid to providing adequate intravascular volume expansion with isotonic crystalloid solutions. Five percent dextrose in isotonic saline solution may be used in the hypoglycemic patient. Once the acute insult has resolved, the hydrocortisone should be tapered to a maintenance dose. The typical replacement dose is 15 to 25 mg of hydrocortisone or 3 to 5 mg prednisolone daily.[49] If concurrent mineralocorticoid deficiency is present, 50 to 100 μg/day of fludrocortisone should be prescribed.

Patients with known AI scheduled for operation should continue the existing steroid dose before surgery. The morning of the procedure hydrocortisone 100 mg is given intravenously. During the operation a 100-mg hydrocortisone infusion is given. After surgery 100 mg of hydrocortisone is administered intravenously every 8 hours during the first postoperative day. The dose is then tapered to the baseline steroid dose over the next 3 to 4 days.

Adequate instruction is important in this group of patients. Patients with AI should be advised to wear a medical alert bracelet. These patients should be provided with a parenteral form of glucocorticoid and taught to self-administer the drug in case of emergency. They should be taught about the clinical situations in which increased amounts of glucocorticoids are required.

Hemodynamically Stable Patient

A patient who is suspected of having AI and who is hemodynamically stable should be managed in the following manner. A serum cortisol level and a rapid ACTH stimulation test should be performed before initiation of stress doses of corticosteroids. Hypovolemia should be treated with isotonic saline solution. If the diagnosis of AI is confirmed, hydrocortisone 50 to 100 mg should be administered as an IV infusion every 6 to 8 hours.

Hemodynamically Unstable Patient

Acute AI is a life-threatening emergency and requires immediate and aggressive therapy. The treatment of a patient with suspected AI and who is hemodynamically unstable should not be delayed to allow for biochemical testing of adrenal function. Patients should be resuscitated with isotonic fluids, vasopressors as indicated, and receive parenteral glucocorticoids. Blood samples should be obtained for assessment of baseline serum cortisol concentration, electrolytes, glucose, blood urea nitrogen, and creatinine.

The dose of hydrocortisone is 100 mg IV bolus followed by 50 to 100 mg IV every 6 hours. After the patient's condition has stabilized, the hydrocortisone is tapered at 25 to 50 mg/day until a maintenance dose of 30 mg/day is achieved.

Vigorous intravascular volume expansion with isotonic saline solutions is recommended. Volume resuscitation is usually initiated with 0.9% normal saline solution. Dextrose 5% in saline solution can be added to prevent hypoglycemia. The patient's fluid, electrolyte, and glucose status should be carefully monitored during resuscitation. In general, patients with acute AI have a deficit that is approximately 20% of their extracellular space. The rapidity of infusion depends on the patient's hemodynamic status and the presence or absence of underlying cardiovascular disease. Typical methods of assessing volume responsiveness including physical examination, noninvasive cardiac output monitoring, focused critical care echocardiography, and frequent assessment of markers of perfusion (lactic acid, urine output, and so on) should be used. Vasopressors may be necessary in the initial stages to maintain an adequate blood pressure to ensure tissue perfusion. In general, if the hypotension is caused by AI, improvement in blood pressure should be seen within 6 hours of corticosteroid therapy.

Mineralocorticoid administration is usually not required initially during acute AI, because the large doses of hydrocortisone provide adequate mineralocorticoid activity. Once the acute event has resolved and the hydrocortisone is tapered to less than 100 mg/day, mineralocorticoids may need to be started. Fludrocortisone is recommended at a dose of 0.05 to 0.20 mg/day. Excess mineralocorticoids can cause congestive heart failure, hypokalemia, and metabolic alkalosis.

In patients with concurrent hypothyroidism, glucocorticoid replacement should begin before thyroid hormone replacement. Administration of thyroid hormone increases the metabolism of glucocorticoids. Thus treatment with thyroid hormone before glucocorticoid therapy might worsen the hypoadrenal state and precipitate AI.

Reversal of the underlying cause of adrenal dysfunction is an important aspect of treatment. The precipitation of acute adrenal failure is provoked by another acute process and thus the causes of both primary and secondary AI should be sought. Prophylactic use of antibiotics is not beneficial, but specific infections should be treated aggressively with appropriate antibiotic therapy.

Severe Sepsis and Septic Shock

Six randomized clinical trials suggest that replacement of moderate-dose hydrocortisone (200–300 mg/day) decreases the need for vasopressor support in patients with septic shock.[2,57] Among them, the two larger trials were better powered to detect a survival difference but had differing results. These differences were attributed in part to varying demographics and other factors. In the Corticosteroid Therapy of Septic Shock (CORTICUS) study, hydrocortisone did not decrease the mortality rate in either responders or nonresponders to ACTH, but the patients who received hydrocortisone had more rapid resolution of shock, which has also been seen in other studies. These results were different from those

in the Annane study, in which the nonresponders to ACTH had both a reduction in mortality rate and reversal of shock.[57] The differences were attributed in part to the fact that in the Annane study, the patients enrolled were sicker, patients had higher Simplified Acute Physiology (SAPS II) scores, and time to enrollment differed (8 hours vs. 72 hours in the CORTICUS study). The CORTICUS study was published some years after the Annane study; it is possible that variations in the supportive care of the critically ill with advances in the care of the patients with sepsis could have made it difficult to show a mortality rate difference in the CORTICUS study. More patients in the CORTICUS study had a surgical source of sepsis, and thus source control may have played a bigger role in improving outcomes. In addition, fludrocortisone was not administered in the CORTICUS study. The duration of steroid therapy was different in the two studies, and this could have caused the dissimilar results. In addition, the CORTICUS study had a higher rate of superinfection. Compounding all these issues is the difficulty surrounding the accurate diagnosis of AI.[57,58] However, in a recent study, the addition of enteral fludrocortisone did not result in a significant improvement in hospital mortality rates.[59]

In the trials previously mentioned, there was resolution of shock in both responders and nonresponders to ACTH stimulation. As such the most recent Surviving Sepsis Guidelines available at the time of this writing recommend that the ACTH stimulation test not be used to determine who to treat with glucocorticoids. These guidelines recommend that patients with shock unresponsive to adequate fluid resuscitation and vasopressor support should be treated with IV hydrocortisone.[60]

Once initiated, hydrocortisone should ideally be continued for about 7 days. At the present time, the optimum duration of therapy is not clear, but data from studies would suggest that abrupt discontinuation of hydrocortisone could precipitate a rebound inflammatory response and recurrent shock. The ideal dose of steroid should help decrease the proinflammatory responses and at the same time minimize adverse effects, such as interference with wound healing, and decrease any negative impact on immune function. From studies, it appears that adverse effects of myopathy and superinfections are more common with doses greater than 200 to 300 mg/day of hydrocortisone. Hydrocortisone can be administered as a bolus dose or as a continuous infusion. Continuous infusions tend to cause less glycemic fluctuations.

To date, no studies document an improved outcome with corticosteroid use in the absence of septic shock. The recently published Hydrocortisone for Prevention of Septic Shock (HYPRESS) trial investigated the use of hydrocortisone to prevent the development of septic shock in patients with sepsis. In this multicenter, randomized, placebo-controlled trial, there was no difference in the rate of development of septic shock between patients treated with a 50-mg bolus followed by a 200-mg continuous infusion of hydrocortisone and those who received placebo. This study also failed to demonstrate any difference in mortality, ICU length of stay, total days of mechanical ventilation, and organ dysfunction.[61]

Etomidate

Etomidate is a drug increasingly used as an induction agent for endotracheal intubation. It has the advantage of not causing hemodynamic instability. This drug inhibits the 11β-hydroxylase enzyme that converts 11-deoxycortisol into cortisol in the adrenal gland and can cause AI. This adverse event has been described with single-bolus and continuous infusions.

A 2015 Cochrane Library systematic review and meta-analysis concluded that a single induction dose of etomidate was associated with AI as evidenced by the results of ACTH stimulation testing. The review also concluded that there is no strong evidence that the use of single-dose etomidate increases mortality in critically ill patients. Furthermore, etomidate was not found to be associated with increased ICU length of stay, hospital length of stay, duration of mechanical ventilation, or duration of vasopressor use.[62] The authors of this review judged the conclusions to be based on a moderate quality of evidence and recommend that further trials be designed to better answer this question.

Summary

Management of acute AI involves prompt diagnosis and immediate treatment to prevent cardiovascular collapse and death. A high index of suspicion is necessary because the condition can be lethal if missed. Therapy with stress doses of corticosteroids should be initiated when there is a high index of suspicion. The side effects of a short course of high-dose corticosteroids in a critically ill patient are minor compared with the possible consequence of cardiovascular collapse and death.

Key Points

- AI is a true emergency and requires rapid diagnosis.
- Common symptoms of AI include weakness, fatigue, and loss of appetite.
- The classic presentation of acute AI is a patient with unexplained hemodynamic instability who is unresponsive to intravascular volume resuscitation and use of vasopressors. AI can mimic cardiogenic, hypovolemic, or septic shock.
- Secondary AI is more common than primary AI. The most common cause of secondary AI is discontinuation of corticosteroid therapy.
- Patients who have taken 20 mg of prednisone per day or its equivalent for a period longer than 3 weeks during the past year should be considered to be adrenal insufficient until proven otherwise.
- Autoimmune disease is currently the most common cause of primary AI and accounts for approximately 80% of cases. The second most common cause of primary AI is adrenal gland destruction by *Mycobacterium tuberculosis*.
- Ketoconazole, phenytoin, phenobarbital, rifampin, and etomidate can cause AI.
- Therapy with stress doses of corticosteroids should be initiated even before the confirmation of the diagnosis when there is a high index of suspicion. The side effects of a short course of high-dose corticosteroids in a critically ill patient are minor compared with the possible consequence of cardiovascular collapse and death.

Review Questions

1. What is the most common cause of secondary adrenal insufficiency?
- **a.** Infection
- **b.** Exogenous steroid administration
- **c.** Surgical adrenal gland removal
- **d.** Pituitary gland dysfunction

Answer: b. Secondary adrenal insufficiency is due to a decrease in adrenocorticotropic hormone (ACTH) production caused by either hypothalamic-pituitary disease or by suppression of the hypothalamic-pituitary-adrenal (HPA) axis as a result of glucocorticoid therapy. Worldwide, infectious disease is the most common cause of primary adrenal insufficiency (AI). Surgical adrenal gland removal is an exceedingly rare clinical occurrence and would result in primary AI. Although pituitary gland dysfunction results in secondary AI, exogenous steroid administration is the most common etiology for secondary AI. The correct answer is choice b. A thorough medication history and reconciliation should be performed for every intensive care unit (ICU) patient searching for past or present steroid exposure.

2. What is the primary mechanism of the shock syndrome associated with AI?
- **a.** Direct glucocorticoid action on vascular smooth muscle
- **b.** Permissive glucocorticoid effect on the vasopressor action of catecholamines
- **c.** Glucocorticoid alteration of prostaglandin levels
- **d.** Glucocorticoid up regulation of β-adrenergic receptors
- **e.** All of the above

Answer: e. The shock syndrome associated with AI is complex and multifactorial. The complete or relative deficiency of glucocorticoids affects the volume status, vascular tone, and cardiac contractility directly and indirectly. The cardiovascular effects of AI are related but not limited to the direct actions on the vascular smooth muscle, the permissive glucocorticoid effect on the vasopressor action of catecholamines, alteration of prostaglandin levels, and the upregulation of β-adrenergic receptors. Therefore choice e (all of the above) is the correct answer.

3. Which of the following patients would be most likely to have AI after a complex abdominal surgery?
- **a.** Patient with asthma receiving inhaled steroids
- **b.** Patient with seborrheic dermatitis receiving topical steroid cream
- **c.** Patient with chronic obstructive pulmonary disease that requires pulse-dose prednisone several times a year
- **d.** Patient with recurrent anaphylaxis requiring short-course steroids twice a year

Answer: c. Exposure to systemic steroids places patients at risk for adrenal insufficiency. This includes exposure via several routes, including dermal, inhaled, or enteral. All of the answers listed may place a critically ill or injured patient at risk for developing AI. Increased potency and duration of exposure to glucocorticoids likely increases the risk for CI. Therefore the patient described in choice c is most likely to develop AI.

4. What is the most appropriate sequence of care for a hemodynamically unstable patient with suspect adrenal insufficiency?
- **a.** Isotonic fluids, vasopressors, parenteral steroids, serum cortisol testing
- **b.** Vasopressors, isotonic fluids, serum cortisol testing, parenteral steroids
- **c.** Serum cortisol testing, parenteral steroids, isotonic fluids, vasopressors
- **d.** Parenteral steroids, isotonic fluids, vasopressors, serum cortisol testing

Answer: d. Of the sequences listed, choice d is the most appropriate sequence of care. The administration of parenteral steroids and isotonic fluids should be performed concomitantly. The decision regarding the administration of vasoactive medications will be dependent on the patient's response to parenteral steroids and fluids. Serum cortisol testing should never take priority over resuscitation of a patient with documented or suspected AI.

5. Which of the following medications has not been shown to cause adrenal insufficiency?
- **a.** Ketoconazole
- **b.** Propofol
- **c.** Etomidate
- **d.** Rifampin

Answer: b. Ketoconazle, etomidate, and rifampin have all been documented to cause AI. Propofol may interfere with the actual cortisol measurement. However, patients receiving propofol maintain the response to the cosyntropin stimulation test. Therefore the correct answer is choice b.

- Emergency Treatment of Thyroid Storm
- Prognosis in Thyroid Storm

In a Colorado screening study involving more than 25,000 participants, the prevalence of hypothyroidism and hyperthyroidism was 0.4% and 0.1%, respectively, after excluding subclinical cases.[1] Although patients receiving long-term thyroid hormone supplementation are seen frequently in the intensive care unit (ICU), patients with active or newly diagnosed thyroid disease are not commonly confronted in this setting. The extreme forms of decompensated thyroid disease are even less common in the ICU. Based on survey and administrative data obtained in Japan between 2004 and 2008 the annual incidence of thyroid storm was estimated at 0.20 per 100,000.[2] The annual incidence of myxedema coma has been estimate at 0.22 per million.[3,4] Survey data from Germany obtained between 1993 and 1995 uncovered only 12 cases of myxedema coma.[5] Although rare, both of these life-threatening thyroid conditions will likely be encountered by intensivists on multiple occasions during their career.

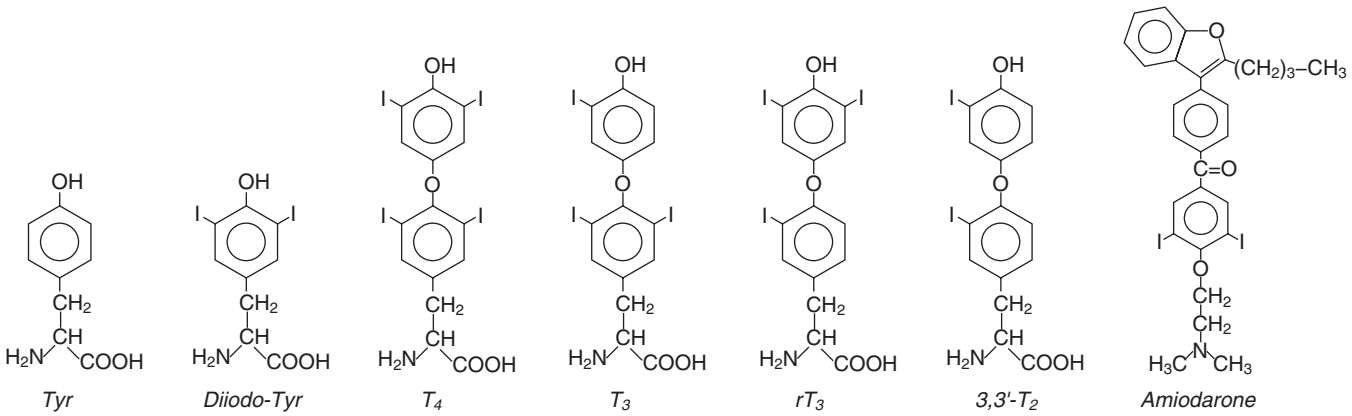
This chapter briefly reviews thyroid physiology, provides an overview of thyrotoxicosis and hypothyroidism, examines the nonthyroid illness (NTI) syndrome, and focuses on the emergency recognition and initial ICU management of patients with thyroid storm and myxedema coma.

Thyroid Physiology

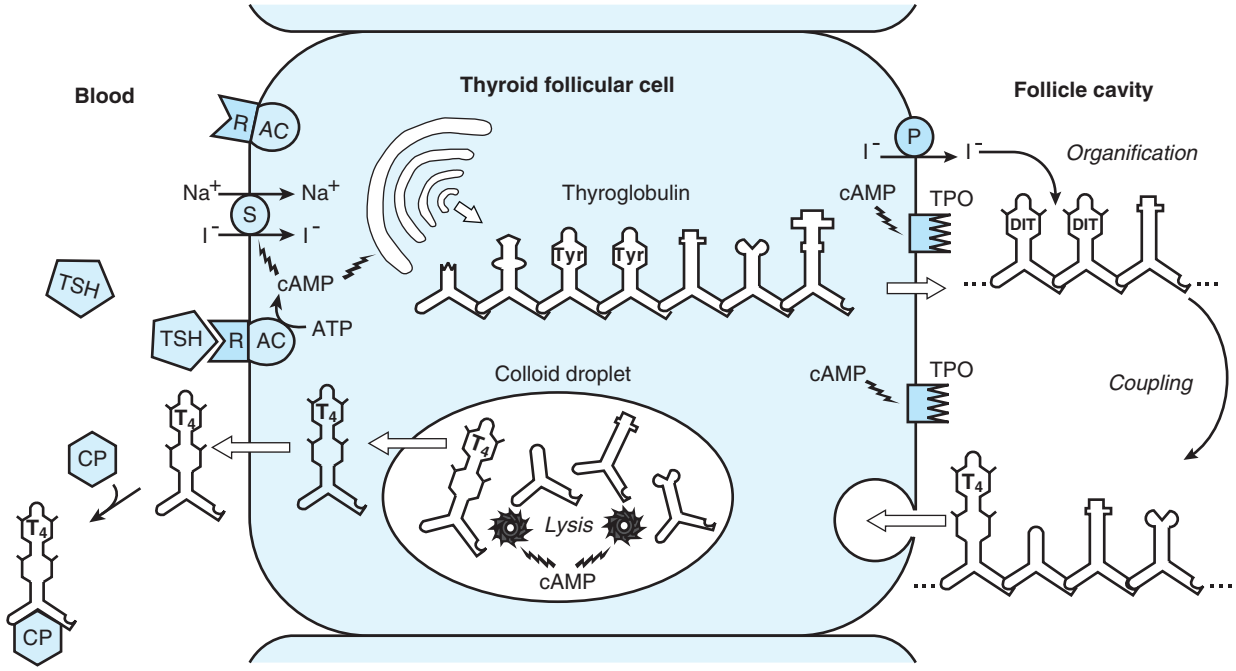
Thyroid Hormone Synthesis

Thyroid tissue consists of spherical cavities called follicles, each lined with epithelial cells (follicular cells or thyrocytes) that surround a cavity containing a colloidal suspension of a protein called thyroglobulin.[6] Two hormones are produced by the thyroid: thyroxine (tetraiodothyronine or T_4) and triiodothyronine (T_3), both of which are iodinated derivatives of the amino acid tyrosine (Fig. 57.1). Because T_4 can be converted in vivo into T_3, and because T_3 has substantially greater biological activity, T_4 can be considered a prohormone. Both T_3 and T_4 are amino acids, but they are not among the 20 amino acids included in the standard genetic code.

The synthesis of T_3 and T_4 begins with the production of thyroglobulin, a 660-kDa homodimeric glycoprotein synthesized and processed at the endoplasmic reticulum and Golgi apparatus of thyroid follicular cells and secreted by exocytosis into the follicle cavities (Fig. 57.2).[7] Among the 2768 amino acids that comprise each thyroglobulin monomer are 66 tyrosine units. The aromatic rings of a fraction of these tyrosine units are subsequently iodinated by the enzyme thyroperoxidase (or thyroid peroxidase, TPO) to form either monoiodotyrosyl or diiodotyrosyl residues, a process called *organification*.[8] Iodide ions enter the thyrocyte by way of sodium-iodide symporters located on the basolateral cell membrane. Iodide egress at the apical membrane has been ascribed to an anion transporter called pendrin.[9] TPO also catalyzes a coupling reaction that combines two iodotyrosyl residues to form either a triiodothyronyl or tetraiodothyronyl residue. At that point the inchoate



• **Fig. 57.1** Molecular structures for the amino acid l-tyrosine *(Tyr)*; diodo-l-tyrosine *(diiodo-Tyr)*; the (pro-) hormone l-thyroxine *(T_4)*; the active hormone triiodo-l-thyronine *(T_3)*; and the inactive deiodination products reverse triiodo-l-thyronine *(rT_3)* and 3,3′-diiodo-l-thyronine *(3,3′-T_2)*. The molecular structure for the drug amiodarone is also shown.



• **Fig. 57.2** Production of thyroxine by follicular cells of the thyroid. The pituitary hormone thyrotropin *(TSH)* interacts with TSH receptors *(R)* on the basolateral surface of follicular cells, activating adenylyl cyclase *(AC),* resulting in intracellular generation of cyclic adenosine monophosphate *(cAMP)* from adenosine triphosphate *(ATP).* cAMP stimulates (depicted by lightning bolt icons) activity of the sodium-iodide symporter (S), allowing uptake of circulating iodide by the cell; stimulates cytoplasmic synthesis of thyroglobulin; and stimulates activity of the enzyme thyroid peroxidase *(TPO),* which is located on the apical surface of the cell. Iodide is transported from the cytoplasm to the follicle cavity by the anion transporter pendrin *(P).* Among the 2768 amino acid residues comprising each monomer of the dimeric protein thyroglobulin are 66 tyrosine moieties, 2 of which are depicted in the thyroglobulin segment shown within the follicular cell. Ellipses represent the remainder of the thyroglobulin peptide backbone, which is not shown. Thyroglobulin is secreted into the cavity of the thyroid follicle where it undergoes organification (the covalent addition of iodine) by TPO, converting selected tyrosyl residues to either monoiodotyrosyl (not shown) or diiodotyrosyl *(DIT)* residues (shown at upper right). TPO also catalyzes oxidative coupling (i.e., joining an aromatic moiety of one iodinated tyrosyl residue to another, forming an ether linkage) of certain tyrosine residues to form thyroxyl residues. The iodinated thyroglobulin is then taken back up by the follicular cell via pinocytosis and subjected to digestion by proteolytic enzymes (depicted by *saw-toothed circular icons*) after merger of the colloid droplet with intracellular lysosomes. The thyroxine molecules *(T_4)* molecules thus derived from thyroglobulin then enter the blood stream where they are largely bound to plasma carrier proteins *(CPs)*—namely, thyroxine-binding globulin, transthyretin, and albumin. The thyroid also produces a proportionately smaller amount of triiodothyronine in a similar manner (not shown). *I^-,* Iodine ion; *Na^+,* sodium ion; *T_4,* tetraiodothyronine (thyroxine).

hormone is still covalently bound to the thyroglobulin molecule as a newly derived, posttranslational amino acid residue. The follicle thus serves as a reaction chamber for the developing thyroid hormones and also serves as a colloidal storage reservoir of hormone precursor. Each thyroglobulin molecule contains several T_4 residues, but typically either one or no T_3 residues. Via pinocytosis, follicular cells can then absorb the modified thyroglobulin protein molecules, forming intracellular vesicles (colloid droplets) that fuse with intracellular lysosomes, thereby subjecting thyroglobulin to proteolytic enzymes that hydrolyze the protein into its constituent amino acids, releasing finished T_3 and T_4 molecules in the process.[7] The T_3 and T_4 molecules are then secreted by the thyrocytes into surrounding capillaries. Iodide inhibits both this intrafollicular cell breakdown of thyroglobulin and the subsequent release of thyroid hormones into the blood.

Thyrotropin

T_3 and T_4 production and release by the thyroid are largely under control of thyrotropin, also known as thyroid-stimulating hormone (TSH), which is a heterodimeric glycoprotein synthesized and secreted by thyrotroph cells of the anterior pituitary and consisting of α- and β-subunits.[10] The α-subunits are common to luteinizing hormone, follicle-stimulating hormone, and human chorionic gonadotropin (hCG), but the β-subunit is unique to TSH. Pituitary secretion of TSH is stimulated by thyrotropin-releasing hormone (TRH), a tripeptide produced by neurons in the paraventricular nucleus of the hypothalamus, released into the hypophyseal portal circulation, and thereby delivered to the anterior pituitary where it serves as one of a number of determinants of the set point for thyroid hormone production.[11] Pituitary secretion of TSH is normally pulsatile with a diurnal variation.[12] Circulating TSH binds to transmembrane receptors expressed on the basolateral membrane of thyroid follicular cells, triggering a series of reactions that ultimately stimulate thyroglobulin synthesis and thyroid hormone release (see Fig. 57.2). hCG can also stimulate TSH receptors and is responsible for a transitory form of hyperthyroidism in early pregnancy called gestational transient thyrotoxicosis.

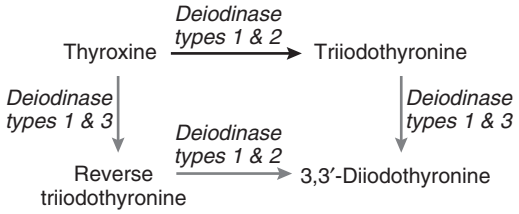
Follicular cell TSH receptors are coupled to a G protein that activates the enzyme adenylyl cyclase, which catalyzes the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP).[13] cAMP in turn stimulates intracellular synthesis of thyroglobulin and activates both TPO and the sodium-iodide symporter (see Fig. 57.2). TSH receptors normally have a minimal degree of constitutive activity—that is, the ability to catalyze the generation of intracellular cAMP even without TSH agonism at the TSH receptor. This constitutive secretion of hormones by thyroid tissue in the absence of TSH or TSH-receptor–stimulating antibodies is called *thyroid autonomy*. Inherited or sporadic mutations in the gene for TRH receptor can occur that alter this constitutive activity, and such mutations may not be expressed until later adulthood. These mutations promote thyroid autonomy, in which the thyroid constitutively secretes hormone even in the absence of TSH.[14] Normal feedback inhibition of pituitary TSH secretion by high levels of circulating T_3 and T_4 still occurs if there is autonomous thyroid tissue, but thyroid hormone production does not decrease as a result.

Thyroid Hormone Transport and Metabolism

Circulating T_3 and T_4 are largely protein bound, mostly (~70%) to thyroxine-binding globulin (TBG), but also to albumin (~15%) and transthyretin (~10%), with a small fraction (<5%) bound to circulating lipoproteins.[15,16] Transthyretin, so-called because it serves to transport both thyroid hormone and retinol, is also called thyroxine-binding pre-albumin. Approximately 0.3% of T_3 and 0.04% of T_4 circulate as unbound (free) molecules. The half-life of T_4 and T_3 are about 1 week and 2 days, respectively. Free T_3 and free T_4 are absorbed by most tissues throughout the body by way of monocarboxylate transporters located on the cell membranes.

After T_3 enters peripheral cells it binds to intracellular thyroid hormone receptors, which act in the nucleus to promote or inhibit transcription of genes that broadly control basal metabolic rate, affect carbohydrate and lipid metabolism, regulate heat production, and influence a host of other systemic and vital organ processes, including body temperature, ventilation, heart rate, cardiac output, and protein metabolism.[17] T_4 is converted by peripheral cells, mainly in the liver, to the active T_3 by a reductive deiodination reaction catalyzed by either of two isoforms of the selenium-containing enzyme iodothyronine monodeiodinase (Fig. 57.3).[18,19] These two activating isoforms are known as type I and type II deiodinase (or D1 and D2, respectively). Because D2 can remove only one iodine atom from the outer aromatic ring (specifically designated as the 5′-carbon position), this enzyme is also referred to as 5′-deiodinase. D1 shares this 5′-deiodination ability but can also remove one iodine atom from inner aromatic ring of T_3 or T_4. D1 is located on the plasma membrane of peripheral cells, whereas D2 (the major activating isoform) is intracellular and localized to the endoplasmic reticulum.[17] A third isoform, known as type 3 deiodinase (D3), is not expressed in the liver of healthy individuals, but hepatic induction of D3 occurs in critically ill patients, particularly those with perfusion failure.[20] The D3 isoform deactivates T_4 by removing one iodine atom from the inner aromatic ring of the molecule (5-deiodination), forming reverse T_3 (rT_3, see Fig. 57.1). D3 also deactivates T_3 by removing an inner ring iodine atom to form 3,3′-diiodothyronine (3,3′-T_2).

D1 and D2 can also convert rT_3 to 3,3′-T_2. Both rT_3 and 3,3′-T_2 are essentially devoid of known biological activity. The deiodinases thus serve to regulate peripheral production of T_3 from circulating T_4 and also regulate intracellular T_3 and T_4 concentrations by controlling the initial steps of their catabolism. Less than 20% of T_3 is produced by the thyroid, whereas 80% to 90% is produced in peripheral tissues by monodeiodination of T_4. Thyroid hormones and their deiodination products are also metabolized by nondeiodination reactions, including cleavage of the ether bond to form diiodotyrosine, glucuronidation or sulfation of the phenol moiety to form inactive conjugates, and oxidative deamination to form tetra- or triiodothyroacetate.[21,22]



• **Fig. 57.3** Activating and deactivating thyroid hormone reactions catalyzed by the three isoforms of selenodeiodinase. The horizontal *black arrow* represents activating reaction; the vertical *gray arrows* represent deactivating reactions.

Thyroid Function Tests

Although recommendations have varied regarding screening of both asymptomatic ambulatory subjects and unselected hospitalized patients for thyroid disease, routine or unselected screening of acutely ill hospitalized patients should not be recommended because the true positive yield is low and because the probability of a false positive result is relatively high.[23–25] Attia and colleagues showed that the positive likelihood associated with an abnormal sensitive TSH test is an order of magnitude lower in hospitalized patients compared with ambulatory patients.[26] Nevertheless, thyroid function testing can be of value in hospitalized patients with known thyroid disease and in cases where there is specific pretest suspicion of a possible thyroid disorder.

TSH Measurement

In primary hyperthyroidism, high levels of circulating thyroid hormone act by feedback inhibition to suppress TSH secretion at the pituitary. Historically, laboratory assays for TSH were insufficiently sensitive to differentiate these low TSH levels from normal levels found in healthy subjects. Thus the clinical utility of TSH measurement was limited to the diagnosis of primary hypothyroidism, where TSH levels are abnormally high and could be readily quantified by those first generation assays. Since that time, second- and then third-generation TSH assays have become widely available, with each generation essentially signifying an order of magnitude increase in sensitivity, allowing TSH measurements to serve as a first-line screening test for disorders of thyroid function. Third generation TSH assays have been defined as those with a functional sensitivity of less than 0.02 mIU/L.[27]

One such family of methods for sensitive TSH measurement is the immunometric assay.[28] One variant employs an enzyme-linked immunosorbent assay (ELISA) in which a sample of the patient's serum is added to a plastic surface to which prepared anti-TSH antibodies have been affixed. The TSH molecules are thus captured by the fixed antibodies and the excess serum can be rinsed away. A different anti-TSH antibody is then added; this one has a specific enzyme covalently linked to it. The reaction chamber is then rinsed again to remove the excess enzyme-linked antibody and a substrate reagent is then added. The remaining enzyme-linked antibody catalyzes the conversion of the added substrate to a reaction product that can be detected and quantified (e.g., by a change in color, fluorescence, or other means). The method is referred to as a *sandwich* ELISA assay because each TSH molecule is trapped between the two types of antibodies.

As with older TSH assays, results above the upper normal limit point to primary hypothyroidism, but the increased sensitivity of immunometric assays allows values well below the lower normal limit to be quantified, thus conferring the ability to detect primary hyperthyroidism as well. In secondary hypothyroidism or hyperthyroidism, however, the interpretation is reversed, with low circulating TSH levels observed in secondary hypothyroidism owing to lack of TSH production by the pituitary and high TSH levels seen in secondary hyperthyroidism owing to excessive TSH production.[4,29] However, these secondary forms of thyroid disease are considerably less common than the primary varieties, and the secondary forms are even more unlikely to lead to the extreme expressions of thyroid disease—namely, thyroid storm or myxedema coma.

TSH measurement and interpretation are not foolproof. Abnormal TSH results can occur in patients who are neither hypothyroid nor hyperthyroid (e.g., in patients with nonthyroidal illness syndrome as discussed in following text). Asymptomatic individuals with subclinical hypothyroidism or hyperthyroidism have abnormal TSH levels. but thyroid hormone measurements are within normal limits.[23,24] Therapeutic administration of dopamine or pharmacologic doses of glucocorticoids can acutely suppress TSH levels and thus spuriously suggest hyperthyroidism.[28] Another potential cause is TSH assay interference caused by circulating heterophile antibodies. These are antibodies produced by the body against nonhuman antigens, such as can occur after exposure to biological pharmaceutical products derived from animal proteins. A common example can occur after a patient is given a therapeutic monoclonal antibody derived from a murine cell line, to which the patient subsequently produces human anti-mouse antibodies. Some heterophilic antibodies, particularly human anti-mouse antibodies, may cross-react with the antibodies used in sandwich ELISA assays, forming a bridge between the capture antibody and the enzyme-linked antibody and thus competing with TSH molecules for anti–TSH-binding epitopes.[30] If the linked enzyme is not disabled in the process, a falsely high TSH value will result. If the active site of the linked enzyme is compromised by the bound heterophile antibody, a falsely low TSH value occurs.

T_3 and T_4 Measurement

Laboratory assessment of plasma T_4 can be accomplished by assessing either the total concentration or the free concentration. The free T_4 concentration (FT_4) represents only those T_4 molecules that are unbound to their plasma carrier proteins. The total T_4 concentration (TT_4) includes all T_4 molecules, bound and free, but because the proportion of free molecules is so low, the total and bound concentrations are essentially equal. Similarly, T_3 can be assayed as either total T_3 (TT_3) or free T_3 (FT_3). The bound molecules serve as a reservoir of thyroid hormone within the circulation, but those molecules are not directly available for uptake by the peripheral cells. Thus the free levels can be considered more physiologically relevant. If circulating carrier protein concentrations remain normal, and the number of hormone-binding sites remains normal, then TT_4 and FT_4 will remain proportional and either test could be used to assess whether T_4 concentration is physiologic or abnormal. However, the plasma concentrations of carrier proteins can be altered by various factors, including drugs, hormone levels, pregnancy, and various disease states, thereby altering the relationship between free and total hormone levels and confounding interpretation of total hormone values (Tables 57.1 and 57.2). In practice, there are two available methods of overcoming these common influences. The most common contemporary means of negotiating this problem is to focus on free hormone levels, if they are available.

Using free thyroid hormone levels as second-tier tests after assessing TSH generally works well but there are potential problems. First, some hospital laboratories may not perform free hormone assays on-site, necessitating sending serum specimens to a distant reference laboratory with the attendant delays involved. Some patients develop autoantibodies against thyroid hormones and these antibodies can interfere with certain free hormone assays to cause falsely elevated results.[31] This interference seems to affect hospitalized patients more so than ambulatory patients and also depends on the particular assay used.[32] Repeating the measurement with a different free hormone assay may show a markedly different result and suggest that this type of interference is occurring.

TABLE 57.1 Diseases Influencing Plasma Thyroxine-Binding Globulin Concentrations

Decrease Plasma TBG	Increase Plasma TBG
Hyperthyroidism	Hypothyroidism
Systemic illness	Pregnancy
Cirrhosis	Infectious hepatitis
Alcoholism	Primary biliary cirrhosis
Acromegaly	AIDS
Cushing disease	Adrenal insufficiency
Congenital TBG deficiency	Genetically determined
Diabetic ketoacidosis	Malnutrition
Nephrotic syndrome	Acute intermittent porphyria
Sepsis	Small cell lung cancer

TBG, Thyroxine-binding globulin.

TABLE 57.2 Drugs That Can Either Alter Plasma TBG Concentration or Interfere With Thyroid Hormone Binding to TBG

Decrease Plasma TBG	Increase Plasma TBG	Interfere With TBG Binding
Glucocorticoids	Oral contraceptives	Furosemide
Androgens	Estrogens	Heparin
Anabolic steroids	Tamoxifen	Sulfonylureas
Testosterone	Raloxifene	Salsalate
Danazol	Clofibrate	Salicylates
Phenytoin	Methadone	Phenytoin
Nicotinic acid	Heroin	Dinitrophenol
L-Asparaginase	Perphenazine	Phenylbutazone
Salicylates	Fluorouracil	Mefenamic acid
	Mitotane	Fenclofenac
		Thiocyanate
		Perchlorate

Resin Uptake Testing

An alternative to free hormone measurement is to use an older method that preceded the clinical availability of FT_3 and FT_4—namely, to assess plasma binding protein capacity and take it into account when interpreting the total hormone levels. To do this, a laboratory assay commonly referred to as either the T_3 resin uptake (T_3RU) or T_4 resin uptake (T_4RU) has been widely used to evaluate binding protein capacity.[16,33] Note that although the term *T_3* or *T_4* appears in the name of the assay and in commonly used abbreviations, these terms do not refer to the patient's thyroid hormone but rather signify exogenous thyroid hormone that is used solely as a reagent for performing the test. The term *T_3RU* was more commonly used historically because T_3 was the reagent in widespread past use to perform the test, although T_4 was later used in more modern versions of the assay. Whichever reagent hormone is used, the test yields a result that is inversely proportional to the available binding sites in the specimen, and that result can be used to correct the patient's TT_3 or TT_4 level for changes in binding protein levels using the following formulas:

$$FT_3I = TT_3 \times \frac{T_3RU_{patient}}{T_3RU_{control}} \quad \text{and} \quad FT_4I = TT_4 \times \frac{T_3RU_{patient}}{T_3RU_{control}},$$

where FT_3I is the free T_3 index and FT_4I is the free T_4 index. These indices serve as surrogate measures for more direct assay determinations for the free hormone levels. Because the T_3RU and total hormone assays have been widely available for many years, smaller clinical laboratories that do not perform FT_3 or FT_4 assays may be able to substitute the index measurements as a useful surrogate.

Discordance Between TSH and Thyroid Hormone

In straightforward cases of primary hyperthyroidism with thyrotoxicosis, serum TSH is low and measurements of T_3 or T_4, or both, are elevated, whereas in primary hypothyroidism, TSH is high and the thyroid hormone levels are low. However, discordant results can be seen in some cases.[34] Because plasma TSH levels can take time to respond to therapy,[35] patients with hypothyroidism who have recently started taking thyroid hormone supplementation may continue to have abnormally high TSH levels (sometimes markedly elevated) while their total and free T_4 levels more quickly normalize from the prescribed hormone supplement. Monitoring during this transitional phase can yield seemingly paradoxical discordance. Similarly, if a hypothyroid patient who is chronically noncompliant with prescribed levothyroxine decides to take a few doses just before undergoing phlebotomy for thyroid function testing, serum T_4 levels may be within normal limits while the TSH level remains substantially elevated. The opposite phenomenon can occur in patients who recently started thionamide therapy for hyperthyroidism, showing paradoxical analyte discordance owing to the relatively rapid normalization of thyroid hormone levels but persistently suppressed TSH levels.[28] Other factors that can lead to discordance include central hypothyroidism or hyperthyroidism, the nonthyroidal illness syndrome, drug effects, and assay interference.[30]

Normal thyroid hormone levels in the face of an abnormally low or abnormally high TSH value are termed subclinical hyperthyroidism or hypothyroidism, respectively. However, elevated T_4 levels can be seen in some euthyroid patients under a variety of circumstance (Box 57.1).

Thyroid Antibody Testing

Antithyroid antibody testing can help differentiate autoimmune-mediated thyroid disease from nonautoimmune causes of hyperthyroidism or hypothyroidism. The percentages indicated in the following text are approximate and may vary because thyroid antibody assays tend to be method dependent.

Autoantibodies directed against TSH receptors (TRAbs), specifically those types that are capable of activating the TSH receptor, are the cause of Graves disease and are present in most patients (~90%) with the disease. Testing for TRAbs is recommended in

• BOX 57.1 Causes of Euthyroid Hyperthyroxinemia

Thyroid hormone resistance syndromes
Idiopathic

guidelines issued by the American Thyroid Association (ATA) to assist in the diagnosis of Graves disease, especially in thyrotoxic patients who do not have orbitopathy.[36] In addition to Graves disease, TRAbs are seen in some cases of autoimmune thyroiditis. Modern assay methods (e.g., ELISA) have high sensitivity and specificity[37]; false-positive results (positive test results in patients without autoimmune thyroid disease) are uncommon. False-negative TRAb assay results can occur in mild Graves disease, but are unlikely in patients with Graves disease who present with severe thyrotoxicosis or thyroid storm. Some patients have TRAbs that occupy the receptor but do not activate it. These blocking antibodies thus compete with TSH for TSH receptors, thereby causing circulating TSH levels to rise. TRAb assays do not differentiate stimulating from blocking antibodies; however, specific thyroid-stimulating immunoglobulin assays are available.[38]

Thyroperoxidase antibodies (TPOAbs) are autoantibodies directed against TPO. They were formerly known as antimicrosomal antibodies, a term that is sometimes still used. TPOAbs are detectable in nearly all patients with Hashimoto thyroiditis and in about 75% of patients with Graves disease. They are also seen in patients with postpartum thyroiditis. Positive TPOAb test results can be seen in patients with destructive autoimmune thyroid disorders; however, they are positive in some patients with nondestructive thyroid disease, in some patients with nonthyroidal autoimmune disorders, and even in individuals without apparent thyroid disease (~11%), especially among the elderly.[39] The presence of TPOAbs in a euthyroid patient may indicate that the patient is at future risk for thyroid disease.

Autoantibodies against thyroglobulin (TgAbs) are detectable in most patients with autoimmune thyroiditis (~85%), in most patients with Graves disease (~60%), and in about 10% of the general population.[39] Most patients with TgAbs present will also have positive results for TPOAbs, but measuring both may increase the diagnostic sensitivity. TgAb assays are also used in conjunction with thyroglobulin monitoring to follow patients with differentiated thyroid cancer.

Other Thyroid-Related Measurements

Thyroglobulin is normally produced only in the thyroid and therefore serves as a marker for functioning thyroid tissue. High levels of thyroglobulin are seen in patients with hyperthyroidism, goiter, thyroid trauma, and thyroid inflammation, as well as in pregnancy and in patients with differentiated (follicular cell) thyroid tumors. Low serum thyroglobulin levels, as well as decreased radioactive iodine uptake, are seen in patients with lack of functional thyroid tissue and in surreptitious chronic thyroid hormone ingestion[40]; however, thyroglobulin assay results can also be low in patients with TgAbs. TgAb testing should therefore be done in conjunction with thyroglobulin measurement. Sex hormone–binding globulin levels are increased in thyrotoxicosis but may take a matter of days to increase following a one-time overdose in otherwise healthy subjects.[41]

TBG can be directly measured by means of immunoassays. Abnormal TBG levels, whether the result of concomitant nonthyroidal conditions (see Table 57.1) or pharmacotherapy (see Table 57.2) alter the relationship between total and free thyroid hormone levels and can be used to interpret TT_4 measurement results. In conjunction with TT_4 measurement, the TBG result can serve as an alternative to resin uptake testing, allowing calculation of a form of FT_4I or hormone-binding ratio ($TT_4 \div TBG$).

Radioactive iodine uptake (RAIU) testing assesses the ability of the thyroid to actively absorb iodine from the blood, thereby allowing differentiation of hyperthyroidism from other forms of thyrotoxicosis.[42] For example, uptake is expected to be high in Graves disease and low in thyrotoxicosis owing to exogenous thyroid hormone ingestion. Although typically low, the results can be variable in patients with hypothyroidism. The patient is given an oral dose of ^{123}I and RAIU is determined at intervals using a stationary radiation detector. A related procedure is nuclear thyroid scanning, in which the radioactive iodine isotope is given intravenously (IV) and scintigraphic imaging is performed using a gamma camera to localize hypofunctioning and hyperfunctioning areas of the thyroid. RAIU and nuclear imaging are not performed in ICU patients but may be indicated after ICU discharge for further assessment of thyroid function.

Levels of rT_3 are elevated or normal in patients with severe illness and NTI syndrome and low in patients with hypothyroidism.[43] Although it is logical to assume that rT_3 measurement would allow distinction between NTI syndrome and actual thyroid disease in critically ill patients, the test appears to have limited ability to differentiate the two situations in practice. Elevated rT_3 levels have been described in patients taking propranolol, dexamethasone, or amiodarone and following the use of halothane. In addition, the test is not widely available. As a result, the test generally is not indicated or recommended in ICU patients.

Drug Effects and Thyroid Function

A number of drugs can interfere with thyroid function, and some drugs are capable of causing overt hypothyroidism or hyperthyroidism or aggravating existing thyroid disease.[30,44,45] Certain drugs can cause transient changes in thyroid hormone levels that later correct even when the drug is continued. Some drugs can cause systematically spurious thyroid test values as an analytical artifact, in which case in vivo hormone levels are actually normal and the patient remains euthyroid. Other drugs actually stimulate or inhibit release of TSH or thyroid hormone. Others increase or decrease metabolic degradation or inactivation of thyroid hormone. Others alter the concentrations of thyroid hormone–binding proteins, and still others displace T_3 or T_4 from these carrier proteins. This section elaborates on some of these effects for selected drugs relevant to the ICU setting.

Iodide

Exposure of a euthyroid subject to excessive iodide, including iodide derived from dietary sources (e.g., kelp or iodide-containing dietary supplements), iodinated radiocontrast media, or other pharmaceuticals containing inorganic iodide or iodine-containing organic compounds, results in decreased thyroid iodide uptake,

decreased thyroid hormone synthesis, and decreased release of hormones from the thyroid. These are all normal physiologic effects known as the Wolff-Chaikoff effect. FT_4 levels decrease as a result, and as a consequence the plasma TSH level increases. This effect, which can exacerbate hypothyroidism, is temporary, followed typically within 2 weeks by an escape phenomenon in which thyroid hormone synthesis renormalizes. However, in patients with even low-grade or latent preexisting thyroid autonomy (e.g., compensated Graves disease or multinodular goiter), excessive iodine may provoke overt thyrotoxicosis or thyroid storm by the Jod-Basedow effect.[30] In this situation plasma free T_4 will increase and TSH will be suppressed.

Amiodarone

The antiarrhythmic drug amiodarone is used frequently in the ICU setting. A portion of the amiodarone molecule bears a structural resemblance to T_4 (see Fig. 57.1) and has complex effects on thyroid hormone metabolism, potentially affecting thyroid function. More than 50% of patients taking amiodarone on a long-term basis have abnormal results on thyroid function testing, but the majority are actually euthyroid.[46] Amiodarone is 37.7% iodine by weight and when metabolized the iodine is released from the drug, usually resulting in a large increase in plasma iodide levels. As noted earlier, exposure to large amounts of iodide will decrease synthesis and release of thyroid hormones by the Wolff-Chaikoff effect. Amiodarone can also inhibit deiodination of T_4 and rT_3 by interfering with D1 activity. In the euthyroid patient this inhibition (see Fig. 57.3) itself leads to a rise in plasma FT_4 and TT_4 levels, with corresponding decreases in FT_3 and TT_3 levels (modestly decreased or to the low reference range), along with an increase in rT_3 levels. In response, TSH levels transiently rise, albeit to less than 20 mIU/L. Within a few months of continued amiodarone therapy, TSH levels usually renormalize. Although the FT_4 and TT_4 levels can remain above the upper normal limit, this by itself does not signify that the patient is hyperthyroid. However, amiodarone may also interfere with cellular uptake of T_3 and T_4 and noncompetitively inhibits the binding of T_3 to intracellular β_1-thyroid hormone receptors.[47]

The reported incidence of thyroid dysfunction in patients taking amiodarone varies from 2% to 50%. This wide range is in part due to how the thyroid dysfunction is defined—for example, by abnormal laboratory values alone versus by clinical assessment of thyroid disease—as well as the screening procedures used and variations owing to statistical sampling. There is also a prominent geographic variance that depends on the regional prevalence of iodine deficiency.[46,48–50] Both hypothyroidism and hyperthyroidism can occur, with high dietary iodine predisposing to hypothyroidism and low iodine intake predisposing to hyperthyroidism. There does not appear to be a clear relationship between the daily or cumulative amiodarone dose and the risk for developing either hypothyroidism or hyperthyroidism.[46] In view of the possibility of causing an actual thyroid disorder, baseline TSH, FT_4, T_3, and thyroid antibody assays should be obtained before initiating the long-term amiodarone therapy in stable patients. In the setting of critical illness, thyroid function test results may not represent baseline thyroid status if NTI syndrome is present. Periodic thyroid function test monitoring has been recommended (e.g., at 3- to 6-month intervals), for patients receiving long-term amiodarone to help identify development of hypothyroidism or hyperthyroidism.

It is important to note that mild TSH elevations (<10 mIU/L or so) can be seen in patients who are taking the drug but remain euthyroid. Nevertheless, actual hypothyroidism from amiodarone has been reported in 1% to 32% of patients taking the drug, most often in patients taking the drug for less than 2 years, and TSH is usually above 20 mIU/L in these cases.[44,46,48,49] The presence of anti-TPO, antithyroglobulin, or antithyrotropin receptor antibodies before receiving amiodarone is associated with an increased risk for amiodarone-induced hypothyroidism.[51] Elevated antibody titers can also develop after amiodarone use in patients who develop hypothyroidism.[52,53] The mechanism is likely related to an inability to escape from the Wolff-Chaikoff effect, often in patients with preexisting Hashimoto thyroiditis. The general approach to treating amiodarone-induced hypothyroidism is to either discontinue the drug, if feasible, or provide thyroid hormone supplementation, or both.

Overall, hyperthyroidism is less common and may develop rapidly or after several years of amiodarone treatment, with thyrotoxicosis reported in less than 1% to 23% of patients taking the drug.[48,54] Amiodarone-induced thyrotoxicosis can be divided into two types. Type 1 occurs in patients with previous autoimmune thyroid disease and thyroid autonomy (e.g., Graves disease or nodular goiter), may be iodine-induced (the Jod-Basedow phenomenon), and results in hyperthyroidism similar to Graves disease. Antithyroid antibodies are often present in patients with preexisting thyroid disease but are uncommon otherwise.[55] Type 2 amiodarone-induced thyroid dysfunction is a form of subacute thyroiditis that occurs in patients with previously normal thyroid function. This is a destructive, inflammatory process in which cytotoxicity causes release of preformed thyroid hormone. Type 2 amiodarone toxicity predominates in North America; type 1 is more often seen in iodine-deficient regions.

Treatment of both types includes stopping amiodarone, if possible. That decision involves a benefit-risk consideration taking into account the individual patient's underlying cardiac disease and potential alternatives to amiodarone therapy. In general, additional first-line treatment for type 1 is a thionamide drug, whereas a trial of glucocorticoid therapy is used in type 2. Perchlorate treatment, and in refractory cases, radioactive iodine ablation or thyroidectomy have also been used in selected cases.

Phenytoin and Carbamazepine

Phenytoin and carbamazepine displace thyroid hormones from their plasma carrier proteins, increasing FT_3 and FT_4 levels in patients who are euthyroid. This effect, however, is transient because the resulting elevation of the free hormone concentrations causes TSH to decrease by feedback inhibition. As a consequence, TT_3 and TT_4 decrease, resulting in normalization of FT_3 and FT_4. A new steady state subsequently ensues in which TSH renormalizes. At that point, in attempting to measure FT_4 using assays that require dilution of the serum sample, the presence of therapeutic levels of phenytoin or carbamazepine interferes with FT_4 determination and causes a falsely low result.[56] The low free hormone level in this case is an in vitro artifact resulting from the increased availability of hormone-binding sites as the anticonvulsant drug separates from the carrier proteins after dilution; the patient otherwise remains euthyroid.

Apart from their effects on thyroid hormone assays, phenytoin and carbamazepine use can also increase the metabolism of thyroid hormones such that patients who require chronic levothyroxine therapy may need to have their T_4 supplement dose increased after starting either anticonvulsant. This occurs because both T_3 and T_4 can undergo conjugation with glucuronic acid in reactions

catalyzed by the enzyme uridine 5′-diphosphate (UDP) glucuronosyl transferase acting at the phenolic hydroxyl group of the hormones to form T_3- and T_4-glucuronides. These glucuronides are inactive, water-soluble metabolites that are excreted in bile with a degree of enterohepatic recirculation.[21,22] Intestinal bacteria produce enzymes that cleave off the glucuronide, leaving some of the free thyroid hormones to be reabsorbed and thus constituting a form of enterohepatic thyroid hormone recirculation. UDP-glucuronosyltransferase also metabolizes and inactivates a number of drugs, including phenytoin, carbamazepine, phenobarbital, and rifampin. Treatment with these drugs induces synthesis of UDP-glucuronosyltransferase, augmenting glucuronide formation and thereby potentially lowering thyroid hormone levels in patients with hypothyroidism.

Other Drugs

Dopamine can suppress secretion of TSH by stimulating type 2 dopaminergic receptors on pituitary thyrotroph cells. However, the resulting low-TSH state is often transient and probably does not cause central hypothyroidism, at least in most cases.[30] Mild decreases in FT_4 may occur in some cases, but this may represent NTI syndrome given that dopamine use is commonly restricted to critically ill patients. Like dopamine, both the somatostatin analog octreotide and high-dose glucocorticoids also can suppress TSH secretion. Amphetamine use can result in increased endogenous dopamine release, thereby indirectly lowering plasma TSH levels. Metoclopramide at doses greater than 1 mg/kg can slightly raise TSH levels, usually no higher than 10 mIU/L.[44]

A number of drugs commonly used in the ICU setting can affect circulating thyroid hormone levels by interfering with hormone binding to plasma proteins (see Table 57.2). Unfractionated heparin and low–molecular-weight heparin increases the activity of lipoprotein lipase, causing an increase in plasma free fatty acid levels, which in turn displace T_4 from its plasma carrier proteins. The result is an increase in FT_4 levels, with the degree of the effect depending on the plasma heparin level, the plasma triglyceride level, and the preanalytical delay period. In one study, FT_4 levels increased by up to 171% in samples obtained 2 to 6 hours after enoxaparin administration.[57] In patients receiving intermittent subcutaneous injections of unfractionated or low–molecular weight heparin, blood sampling for FT_4 analysis should be deferred until the heparin administration is discontinued or the sample can be obtained during the heparin trough period (i.e., just before the next scheduled heparin dose). Specimens from patients who have received heparin should also be analyzed promptly because the length of preanalytical delay correlates with the magnitude of artifactual FT_4 elevation. Furosemide at doses greater than 80 mg, especially in the presence of renal dysfunction, can cause a transient fall in TT_3 and TT_4, with concomitant rises in FT_3 and FT_4, as the result of interference with hormone binding to TBG, albumin, and prealbumin.[58] Nonsteroidal antiinflammatory drugs, including salicylates, also displace T_3 and T_4 from TBG and transthyretin.[59] A variety of drugs may influence total circulating thyroid hormone levels by increasing or decreasing plasma TBG concentration (see Table 57.2).

Chronic treatment with lithium carbonate can lead to hyperthyroidism in 1% to 5% of patients and either subclinical or overt hypothyroidism in 5% to 50% of patients.[44,60] Lithium inhibits thyroid hormone synthesis and release, inhibits deiodinase activity and thereby decreases peripheral conversion of T_4 to T_3, and promotes thyroid autoimmunity by stimulating lymphocyte activity. Diffuse goiter can occur in some patients. Hyperthyroidism secondary to lithium use is less common than hypothyroidism but can occur. It usually manifests as painless thyroiditis that is self-limited. The mechanism may involve lithium-induced thyroid autoimmunity.

By inhibiting 5′-deiodinase, propranolol and dexamethasone can reduce circulating T_3 levels. Corticosteroids can also decrease T_4, TSH, and TBG levels by other mechanisms,[61,62] whereas propranolol can decrease FT_4 and TT_4 levels.[63] Thyroid dysfunction, including a pattern of autoimmune thyroiditis, has been noted in some patients after treatment with recombinant granulocyte-macrophage colony-stimulating factor, sargramostim.[64] Sucralfate, colestipol, and cholestyramine can cause malabsorption of levothyroxine.[65,66]

Nonthyroidal Illness Syndrome

Significance

Abnormal levels of circulating thyroid hormones are frequently observed in patients with acute and chronic systemic illness who otherwise have no manifestations suggesting thyroid disease. This state has been called NTI syndrome or the euthyroid sick syndrome, and it is particularly common in the ICU setting. Whether this condition represents a normal response to any underlying severe illness versus a maladaptive pathologic response has long been debated, but the prevailing view is that it is more likely a physiologic adaptation.[67] Other endocrine abnormalities are also commonly observed in conjunction with critical illness, such as alterations in prolactin and cortisol levels, high endogenous catecholamine concentrations, glucose intolerance, and increased protein catabolism, all of which could be considered elements of a generalized systemic endocrine response to critical illness or injury.[68] As an adaptive acute-phase response, these changes could have protective or beneficial effects, but substantiating data are lacking. The practical value to recognizing the syndrome in the ICU setting is that it can present serious difficulties in the interpretation of thyroid function test results, thus interfering with detection of actual hypothyroidism or hyperthyroidism.

Plasma Hormone Patterns

In a study analyzing autopsy samples obtained from 12 patients dying from NTI and 10 previously healthy individuals dying suddenly from trauma, mean serum T_3, T_4, and FTI values were lower by 79%, 71%, and 49%, respectively, in the NTI group compared with the comparison group, but serum TSH values did not differ significantly.[69] The earliest and most consistent change in plasma thyroid hormone levels that is commonly observed in patients with an acute critical illness or undergoing surgery is a decrease in plasma T_3 level.[70] This fall in T_3 is characteristic of the NTI syndrome, hence the synonym *low T_3 syndrom*e. This is sometimes paralleled by a rise in rT_3 levels. Plasma TT_4 concentrations may also decline early in critical illness. FT_4 levels are often maintained in the normal range during NTI, but they tend to decline if the patient's condition is protracted or worsens. Total and free T_4 levels sometimes transiently rise before this decline.[70] Thus a low plasma FT_4 concentration serves as a marker of disease severity and a prognostic sign for poor outcome. Circulating TSH levels typically remain normal but sometimes show an early transient rise, usually mild, at the onset of critical illness.[71] TSH levels then usually remain within normal limits despite progression of the

NTI. However, in some patients TSH declines, particularly with more severe and prolonged illnesses. In those patients who recover, a transient rebound overshoot in TSH may occur during their recovery phase, with plasma TSH levels commonly rising to slightly above the upper normal limit, but occasionally peaking to 20 mIU/L or so.[72] At this point, the elevated TSH level (potentially in conjunction with low T_4 levels, low T_3 levels, or both) can suggest hypothyroidism, but most of these patients have no signs of thyroid disease after recovery from their acute illness. Severe illness is also associated with a decrease in the pulsatile amplitude of TSH secretion by the pituitary. In addition, the usual relationship between the biological effect of TSH and immunogenic response can vary in some patients with critical illness, affecting accuracy of the assay.[33]

The previous hormone patterns present a challenge in differentiating ICU patients with NTI syndrome from those who actually have hypothyroidism or hyperthyroidism. Although there are no criterion standard biochemical tests that differentiate these conditions, there are some practical points that are helpful.[33] TSH levels assessed by a sensitive TSH assay remains the single best measurement for discriminating NTI syndrome from real thyroid disease. TSH levels above 20 mIU/L are more likely to represent actual (permanent) hypothyroidism. Using a third-generation TSH assay, TSH levels below 0.01 mIU/L in a critically ill patient most likely mean the patient has hyperthyroidism. On the other hand, a low but still detectable TSH in a severely ill ICU patient more likely indicates NTI syndrome.[73] Because T_3 levels are usually low in critically ill patients, the finding of elevated TT_3 or FT_3 in such patients suggests hyperthyroidism. Although rT_3 levels in principle should be increased in NTI syndrome and diminished in patients with hypothyroidism, this relationship has not proved to be helpful in practice. Although the test is available through some clinical reference laboratories, few hospital laboratories perform the test on-site. In addition, Burmeister showed that although rT_3 may be elevated in patients with NTI syndrome, rT_3 levels can also be low in euthyroid patients, and hypothyroid patients can have normal rT_3 levels.[74]

Pathophysiology

A putative mechanism that provides an explanation for the decrease in plasma T_3 and increase in plasma rT_3 levels in NTI is inhibition of deiodinase isoforms D1 and D2, induced either by a phenotypic change brought on by the systemic illness,[75,76] the presence of circulating endogenous inhibitors (e.g., oleic acid and other free fatty acids),[77–80] or the effects of pharmacotherapy used to treat the NTI (e.g., amiodarone, propranolol, or corticosteroids).[62] In support of this contention, low tissue activity levels of D1 and D2 have been observed in biopsy specimens from ICU patients succumbing to critical illness, whereas hepatic D3 activity is induced in patients with poor tissue perfusion.[20,81]

Peeters and colleagues examined deiodinase expression in tissue samples from 80 ICU patients.[20] TSH, T_4, and T_3 levels in these patients were significantly lower, and rT_3 higher, compared with normal subjects ($P < 0.0001$). Hepatic D1 activity was downregulated while liver and muscle D3 activity was induced. The ratio of serum T_3:rT_3 was directly correlated with liver D1 activity ($P < 0.001$). In another report Peeters et al. examined 451 patients receiving intensive care for longer than 5 days, assaying thyroid hormone levels on days 1, 5, 15, and their last day, and also obtaining liver and muscle biopsies from 50 of the 71 nonsurvivors.[81] rT_3 levels on day 1 were higher in nonsurvivors compared with survivors ($P = 0.001$), whereas TSH, T_4, and T_3 levels were all lower in nonsurvivors from day 6 until their last day ($P < 0.001$). TSH, T_4, and T_3 levels increased over time in survivors but decreased or did not change in nonsurvivors. Serum rT_3 and T_3:rT_3 correlated with postmortem tissue deiodinase activities.

Laboratory studies have shown that lipopolysaccharide (endotoxin) from gram-negative bacteria administered to rats induces D2 expression in the mediobasal hypothalamus.[82] The resulting increase in T_3 at the level of the hypothalamus could augment normal feedback suppression of TRH secretion. Extrapolation of these findings to critically ill patients could explain low circulating levels of TSH, T_4 and T_3 in critically ill patients with sepsis. In a murine model, Boelen and coworkers found that serum T_3 and T_4 levels declined 24 hours after administering endotoxin, but those changes were preceded by increased D2 expression at the level of the hypothalamus, decreased TSH production and pituitary D1 activity, and decreased D1 messenger RNA in liver. In the hypothalamus, D2 messenger RNA expression was strongly increased.[83]

In addition to changes in deiodinase activity and suppression of TRH release by the hypothalamus, other mechanisms have been postulated to explain NTI syndrome. Given that the deiodinases are selenium-containing enzymes, and D1 and D2 activity is required to convert T_4 to T_3, selenium deficiency has similarly been postulated as a mechanism for NTI. Alterations in thyroid hormone binding to plasma proteins, effects stemming from starvation, and various cytokine-mediated effects on thyroid hormone levels have also been implicated.[84–87] A study in healthy volunteers showed that fasting induced a decline in mean serum T_3 concentrations from 140 to 93 ng/dL with a concomitant rise in mean rT_3 from 51 to 106 ng/dL, but with no significant changes in TSH, TT_4, or FT_4.[88] That investigation also showed that the rate of conversion of T_4 to T_3 decreased by 50%, whereas T_4 to rT_3 conversion increased by 146% in fasting subjects compared with a control group. Stouthard and associates infused recombinant human interleukin 6 (IL-6) over 4 hours to patients with renal cell cancer and compared the patients hormone levels to those obtained after a saline solution control infusion given on another day.[84] No effects were seen on TT_4 or FT_4, but there was a significant decrease in plasma TSH and an increase in rT_3 compared with the saline solution placebo. When recombinant human IL-6 was given daily for 42 days, weekly assays showed a decrease in T_3 and a transient increase in rT_3 and FT_4. On the other hand, Michalaki et al. showed that serum T_3 declines within minutes of elective abdominal surgery and anesthesia, preceding the rise in endogenous IL-6 induced by operation.[70]

In a study by van der Poll and associates, tumor necrosis factor (TNF) was administered to six healthy men to examine the effects on circulating T_3, T_4, rT_3, and TSH.[86] T_3 and TSH fell significantly, rT_3 rose, and FT_4 was essentially unaffected (except for a small nonsignificant rise in a few subjects), changes that are commonly observed early in the NTI syndrome. Nagaya et al. showed that activation of nuclear factor κB (NF-κB) by TNF-α inhibits T_3-dependent induction of the D1 gene in a hepatic cell line, suggesting a possible molecular basis for euthyroid sick syndrome. The macrolide antibiotic clarithromycin, which blocks activation of NF-κB by TNF-α, was shown to restore hepatic D1 expression.[85]

Prognosis

Multiple investigations has demonstrated that the euthyroid sick state is associated with an increased fatality rate in critically ill

patients.[89–91] Slag et al. studied thyroid function tests in 86 ICU patients, excluding 2 who were determined to have hypothyroidism.[92] Of the 22% of patients that had hypothyroxinemia with normal TSH levels, the associated mortality rate was 84%. They also showed an inverse correlation between the serum T_4 level and mortality. In an observational study of 480 consecutive ICU patients without known thyroid disease, Wang and colleagues measured TT_4, FT_4, TT_3, FT_3, rT_3, and TSH and found that FT_3 levels had the strongest association with mortality, followed by TT_3, then TT_4, then FT_4, then TSH, and finally rT_3.[93] In another study, Chinga-Alayo and colleagues studied thyroid hormone patterns in 113 ICU patients.[94] After adjusting for severity of illness using Acute Physiology and Chronic Health Evaluation (APACHE) II scores and adjusting for TSH levels, they found a 49% rise in odds of dying in the ICU for every 10-ng/dL decrease in TT_3.

Alevizaki and associates found low TT_3 levels were present in 56% of 737 acute stroke patients, with low TT_3 levels proving to be an independent predictor of early and late mortality.[95] A study of 49 consecutive medical ICU patients receiving mechanical ventilation found that severely low TT_4 levels (<3 μg/dL) were associated with a 75% mortality compared with 19% mortality in patients with TT_4 levels of 3 μg/dL or higher. Low TT_4 levels had an 80.5% specificity for predicting death.[96] Tas et al. studied more than 400 patients and found that low FT_3 was a better predictor for mortality than either FT_4 or TSH, but they also showed that combined suppression of FT_3, FT_4, and TSH had higher predictive value than any individual measure.[97] In both of the preceding studies, however, the area under the receiver operating characteristic curve for FT_3 was less than that for the patients' APACHE II scores.

Plikat and coworkers reviewed thyroid hormone patterns in 227 ICU patients with complete thyroid hormone assay results available and who were not receiving either thyroid hormone supplementation or antithyroid drugs.[67] Ninety-seven patients (41%) had low FT_3 levels, consistent with NTI syndrome, 6 patients had hypothyroidism, and 1 had hyperthyroidism. Of the 97 patients with low FT_3, TSH levels were normal in 24% and reduced in 21%, whereas 23% had both low FT_3 and low FT_4 concentrations. NTI syndrome was significantly associated with APACHE II scores, mortality, length of stay, and use of mechanical ventilation. Patients with the combination of low FT_3 and low FT_4 levels had a significantly higher mortality rate compared with those with low FT_3 levels alone.

Treatment

There are limited studies examining whether therapeutic thyroid hormone supplementation influences outcome in patients with the euthyroid sick syndrome. A randomized, placebo-controlled trial testing IV levothyroxine supplementation (1.5 μg/kg per day for 2 weeks) failed to show any survival benefit in 23 medical ICU patients with NTI syndrome and TT_4 concentrations less than 5 μg/dL, despite significant increases in serum T_3 levels.[98] A randomized, double-blind study of 59 patients with acute renal failure treated with either levothyroxine (150 μg IV every 12 hours for 48 hours) or placebo showed significant suppression of TSH levels in the treatment group.[99] The levothyroxine-treated patients also had a significantly higher mortality rate (43% vs. 13%, $P = 0.01$).

In a placebo-controlled study of patients with thermal burn injury, treatment with T_3 did not affect survival.[100] Sirlak and associates studied 80 patients undergoing coronary artery bypass surgery with preoperative left ventricular ejection fractions below 30%, randomly assigning 40 patients to receive oral T_3 (125 μg/day for 7 days before surgery and from postoperative day 1 until discharge) and the other 40 patients to receive placebo.[101] Postoperative cardiac index was significantly higher in the treatment group ($P < 0.01$) and inotropic requirements lower ($P < 0.001$) compared with the placebo group, but the mortality rate was equal (three patients died in each group).[102–104]

In a prospective controlled study Spratt and colleagues studied patients undergoing coronary artery bypass surgery and found that serum T_3 fell from a mean value of just over 140 μg/L to less than 50 μg/L at the time of aortic cross-clamp removal.[105] At that point patients were randomly assigned to receive a 24-hour IV infusion of either placebo or T_3, using a dose previously shown to maintain preoperative T_3 levels. Over the next 36 hours, serum T_3 levels remained essentially unchanged from the value measured at cross-clamp removal in the placebo group. The T_3 group had only a transiently higher cardiac index at 6 hours after operation (3.0 vs. 2.5 L/min per m^2, $P < 0.002$), but there was no significant difference at 1, 12, or 18 hours.[105]

In NTI syndrome, the finding of normal values for TSH and either FT_4 or FT_4I are reassuring that thyroid function is likely normal. Markedly abnormal TSH (e.g., TSH values that are either >20 mIU/L or undetectable using a third-generation assay), even in critically ill patients, are suggestive of real thyroid disease because NTI syndrome usually causes only mild abnormalities in TSH.[28]

Hypothyroidism and Myxedema Coma

Hypothyroidism is the pathologic state that occurs when there is inadequate hormone secretion by the thyroid. Patients with this disorder span a spectrum of severity of illness ranging from a compensated state that is asymptomatic, clinically undetectable, and discernable only by specific laboratory testing to a severely decompensated state resulting in critical illness. The latter is known as myxedema coma, an uncommon, extreme degree of hypothyroidism that results in a characteristic syndrome associated with life-threatening organ dysfunction and requiring prompt recognition and urgent initiation of treatment.

Etiologies of Hypothyroidism

The two most common causes of hypothyroidism are Hashimoto thyroiditis and noncompliance with thyroid hormone replacement therapy. Hashimoto thyroiditis is an autoimmune disorder that can result in thyroid destruction by circulating antithyroid antibodies. If the destructive process is sufficiently severe, lifelong thyroid hormone supplementation is necessary to prevent hypothyroidism. Patients who have undergone thyroidectomy or radioactive iodine ablation are also treated with thyroid hormone replacement. Discontinuation of replacement therapy in these patients can lead to progressive hypothyroidism that can eventually lead to myxedema coma. Secondary hypothyroidism occurs when the thyroid is functional but lack of TSH owing to pituitary dysfunction results in inadequate thyroid hormone production. Secondary hypothyroidism is uncommon, probably occurring in about 5% or so of patients with hypothyroidism.[106] Secondary hypothyroidism has rarely led to myxedema coma.[4,107] The term *tertiary hypothyroidism* has been used to describe hypothyroidism resulting from hypothalamic dysfunction with inadequate TRH. Common causes of drug-induced hypothyroidism include amiodarone and lithium. Myxedema coma caused by amiodarone is not common, but multiple cases have been reported in the literature, including with a duration of use

• BOX 57.2 Etiologies of Hypothyroidism

Congenital Primary Hypothyroidism
- Endemic iodine deficiency
- Thyroid agenesis
- Thyroid dysplasia
- Iodine utilization defect
- Organification defect
- Thyroglobulin synthetic defect
- Iodine transport defect
- Iodotyrosine dehalogenase deficiency
- Thyrotropin receptor defect
- Idiopathic thyrotropin unresponsiveness
- Type 1a pseudohypoparathyroidism
- Excessive maternal iodine ingestion
- Maternal antithyroid drug ingestion

Drug-Induced Hypothyroidism
- Lithium
- Amiodarone
- Thionamides
- Iodine and iodides
- Sulfonamides
- Sunitinib
- Interferon alfa
- Phenylbutazone
- Aminoglutethimide
- Resorcinol
- Interleukin 2
- Thalidomide
- Perchlorate
- Sulfonylurea agents
- Ketoconazole

Acquired Primary Hypothyroidism
- Hashimoto disease
- Thyroidectomy
- Radioactive iodine (^{132}I) ablation therapy
- Neck or whole-body irradiation
- Endemic iodine deficiency
- Hemangioma, hemangioendothelioma
- *Transient hypothyroidism:*
  - Postsubacute thyroiditis
  - Painless thyroiditis
  - Postpartum thyroiditis
- *Infiltrative diseases:*
  - Amyloidosis
  - Sarcoidosis
  - Scleroderma
  - Lymphoma
  - Other neoplasms
  - Hemochromatosis
  - Cystinosis

Acquired Secondary Hypothyroidism
- Hypopituitarism
- Head trauma
- Infiltrative diseases (see earlier)
- Sheehan syndrome
- Bexarotene, dopamine, other drugs

Congenital Secondary Hypothyroidism
- Thyrotropin deficiency
- Thyrotropin structural defect

Tertiary Hypothyroidism
- Hypothalamic dysfunction

• BOX 57.3 Precipitating Factors in Myxedema Coma

- Amiodarone
- Cold exposure
- Congestive heart failure
- Diabetic ketoacidosis
- Gastrointestinal hemorrhage
- Hypoglycemia
- Iatrogenic withdrawal of thyroid replacement therapy
- Infection or sepsis
- Noncompliance with thyroid replacement
- Opioid drugs
- Raw bok choy ingestion
- Sedative-hypnotic drugs
- Stroke
- Sunitinib
- Surgery
- Trauma

less than 6 months.[108,109] Other causes of hypothyroidism are listed in Box 57.2.

Precipitating Factors in Myxedema Coma

In addition to noncompliance with thyroid replacement therapy, a variety of intercurrent illnesses and circumstances can serve to trigger myxedema coma in patients with underlying compensated hypothyroidism (Box 57.3). Common precipitants include infection, stroke, surgery, trauma, and use of sedative, hypnotic, or opioid drugs.[110,111] As an example of a rare precipitating factor, myxedema coma has been described after ingestion of excessive amounts of raw bok choy (Chinese white cabbage, *Brassica rapa chinesis*), metabolites of which are apparently goiterogenic, inhibiting iodine uptake by the thyroid.[112]

Manifestations of Hypothyroidism

A wide variety of symptoms and physical findings can be seen in patients with hypothyroidism (Table 57.3). The sensitivity and specificity for the occurrence of various symptoms in association with hypothyroidism was examined in a cross-sectional survey involving more than 25,000 subjects participating in the Colorado Thyroid Disease Prevalence Study.[1] Among the 9.5% who were found to have elevated TSH levels, 26% of them had TSH levels higher than 10 mIU/L. Based on questionnaire data, symptoms with the highest sensitivity for hypothyroidism were dry skin (28%); memory difficulty (25%), slowed mentation (22%), weakness (22%), tiredness (18%), and muscle cramps (18%), whereas those with the highest specificity were deepening voice (98%), hoarseness (95%), constipation (95%), periorbital puffiness (90%), and feeling cold (88%).

Bradycardia is common, but not always present; tachycardia is much less common.[113] The electrocardiogram frequently shows abnormalities, most commonly sinus bradycardia and low QRS voltage, but various degrees of heart block, prolonged QT interval, and nonspecific ST-segment and T-wave abnormalities can also be seen. Imaging studies may reveal the presence of pericardial or pleural effusions.

In overt primary hypothyroidism, with or without myxedema coma, serum T_4 levels are low and TSH levels are high. There are no TSH or T_4 threshold values that distinguish those patients with myxedema coma. In secondary and tertiary hypothyroidism the TSH concentration is low or undetectable. In addition to these

TABLE 57.3 Manifestations of Hypothyroidism

System	Symptoms	Signs
Integument	Skin texture change Thinning hair Facial puffiness Brittle nails Swelling	Coarse, dry skin Coarse, dry, brittle hair Periorbital edema Transverse nail ridges Peripheral, nonpitting edema Pallor Alopecia Yellow skin Loss of sweating
Neurologic	Generalized weakness Poor concentration Daytime sleepiness Memory impairment Headache Insomnia Tinnitus Auditory impairment Dizziness Paresthesia	Mental slowness Apathetic affect Daytime somnolence Impaired intellectual function Lethargy Slow speech Hyporeflexia Dementia Psychosis, paranoia Hallucinations Neuropathy Ataxia Seizures
Cardiovascular	Dyspnea	Diastolic hypertension Distant heart sounds Hypotension Bradycardia Conduction disturbances Pericardial effusion Cardiac tamponade (rare)
Gastrointestinal	Constipation Anorexia Abdominal pain Nausea, vomiting Bloating Dysphagia	Weight gain Obesity Paralytic ileus Ascites Fecal impaction

specific thyroid function tests, a variety of nonspecific laboratory findings tend to be associated with hypothyroidism. Serum creatine kinase activity is commonly elevated in patients with untreated hypothyroidism owing to secondary myopathy.[114,115] Elevated serum transaminase activity may give the appearance of hepatic dysfunction when the enzymes are actually secondary to hypothyroidism-related myopathy.[114,116] Similarly, elevated plasma ammonia concentration and ascites have been reported in myxedema coma, giving the impression of hepatic coma.[117–120] A subset of untreated patients with hypothyroidism have been demonstrated to have a blunted ventilatory response to both hypercarbia and hypoxemia.[121] This impaired respiratory response was reversed within 1 week of initiating hormone replacement therapy. Macrocytic anemia, hypercholesterolemia, and both hypoglycemia and hyperglycemia have been described in hypothyroid patients.[1,110,113,122]

An association between hypothyroidism and hyponatremia has long been described, although it is not common and the validity of a relationship has been debated.[113,123–125] Reports have indicated findings consistent with a purely renal mechanism rather than inappropriate antidiuretic hormone secretion.[113,126–128] Hyponatremia has also been specifically reported in patients with myxedema coma.[124] Berndt and associates retrospectively reviewed emergency department and medical ICU admissions over a 44-month period at a university hospital in Germany and compared serum sodium levels in the 132 patients with overt hypothyroidism (TSH >10 mIU/L and FT_4 <2 pmol/L) to 1253 control patients with normal TSH.[129] Serum sodium in the hypothyroid patients averaged 137.8 compared with 137.4 mmol/L in the control group ($P = 0.2$), with no correlation between TSH and serum sodium in the hypothyroid group ($r = -0.07$, $P = 0.3$).

Diagnosis of Myxedema Coma

The term *myxedema coma* is somewhat of a misnomer. Although the term implies that all patients with this diagnosis are unresponsive, current usage of this nomenclature encompasses a broader range of acute alterations in sensorium and mental status, such as lethargy, somnolence, disorientation, psychosis, obtundation, and stupor.[4,110,130] Patients with this disorder tend to be older adults. They often, but not invariably, have a prior diagnosis of hypothyroidism or some other past history of a thyroid disorder.[130] Any of the symptoms or physical findings of hypothyroidism can occur in patients with myxedema coma. In addition to disturbances in sensorium, key clinical findings in myxedema coma include hypothermia, bradycardia, hypotension, periorbital edema, abdominal and bladder distention, delayed relaxation phase of deep tendon reflexes, and myxedematous skin changes.[110] The presence of a neck scar consistent with thyroidectomy can be an important physical finding.

Individually, the clinical manifestations of hypothyroidism and myxedema coma are for the most part nondiagnostic or nonspecific, particularly when encountered among patients with critical illness. Thus a constellation of findings from the patient history, physical examination, and routinely available test results is often critical to making a clinical diagnosis before obtaining specific thyroid function test results.[2] Even so, uncertainty in the clinical diagnosis is commonly present. A diagnostic scoring system has been devised to assist with the early identification of patients with myxedema coma.[113] The system assigns points for body temperature, heart rate and certain other cardiovascular findings, central nervous system (CNS) effects, gastrointestinal findings, any identified precipitating factor, and certain laboratory findings (but not thyroid function

test results) to arrive at a score that could range from zero to 230. In 21 patients retrospectively studied, the area under the receiver operating characteristic curve for the scoring instrument was 0.88. Sensitivity and specificity for myxedema coma were 100% and 43%, respectively, using a threshold score of 45. The authors concluded that a score or 60 or higher is potentially diagnostic in the appropriate clinical context, but that further validation is required. A simpler tool was developed by Chiong and colleagues, using the Glasgow Coma Scale score, TSH and FT_4 levels, and the presence or absence of hypothermia, bradycardia, and a precipitating event, with the score potentially ranging from zero to 10.[131]

Treatment of Hospitalized Patients With Hypothyroidism

Several points commonly arise regarding the treatment of hospitalized patients with previously diagnosed hypothyroidism who are not critically ill and do not have myxedema coma.[132] If TSH is measured and found to be elevated, consideration should be given to initiating or adjusting the dose of levothyroxine supplementation. Before initiating hormone supplementation in noncritically ill patients, the possibility of adrenal insufficiency should be considered and, if indicated, either excluded by laboratory testing or empirically treated by administering a corticosteroid.

The approach is more difficult in critically ill patients because the TSH abnormality may be a reflection of NTI syndrome. Chronic levothyroxine supplementation is generally continued in the ICU setting, although parenteral administration may be required. If used, IV dosing for levothyroxine is given at 75% of the established oral or enteral dose. Mild TSH elevations can be seen in critically ill patients during their recovery phase as a manifestation of NTI syndrome and do not require treatment. During the acute phase of critical illness, a significant TSH rise in a patient receiving chronic replacement could indicate inadequate supplementation and consideration should be given to increasing the patient's thyroid hormone dose.

Emergency Treatment of Myxedema Coma

Patients with myxedema coma should be treated in an ICU where their level of consciousness, airway control, gas exchange, and hemodynamic status can be closely monitored. Inadequate airway control owing to an altered sensorium can lead to acute respiratory failure. Respiratory failure can also develop, in some cases rapidly, because of impaired ventilatory responses to hypoxemia and hypercapnia.[121,133] Secure IV access is established and continuous electrocardiographic and pulse oximetry monitoring are used. Adequate systemic perfusion is ensured. Hypoglycemia should be excluded and periodic monitoring of blood glucose is instituted. Hypothermia is treated with passive rewarming, as active warming measures pose a risk of provoking or worsening hypotension by causing vasodilation. Any underlying precipitating factor, as well as any chronic or complicating comorbid conditions, should be identified and treated, as appropriate. Assessment and treatment of any concomitant fluid and electrolyte disorders are addressed. If not already available, plasma TSH and T_4 measurements are evaluated.

The specific treatment of myxedema coma is hormone supplementation (Table 57.4). Levothyroxine is the preferred hormone. The optimal initial dosing is unknown,[134] but typical initial doses recommended in the literature range from 200 to 500 μg, given IV and typically followed by daily doses of 50 to 200 μg.[4,106,135–137] The ATA recommends giving 200 to 400 μg IV of levothyroxine initially and then 1.2 μg/kg per day IV (or 1.6 μg/kg per day orally).[132] IV dosing is preferred for initial dosing because of the possibility of ileus or otherwise impaired gastrointestinal absorption. Whether concomitant liothyronine (pharmaceutical T_3) should be administered has long been debated. The theoretical rationale is that T_3 is the active hormone and unlike T_4 does not require endogenous conversion. If used as a supplement to levothyroxine in patients with myxedema coma, liothyronine can be given at a dose of 5 to 20 μg initially, and then 2.5 to 10 μg at 8-hour intervals.[132] If used, the lower ranges of liothyronine dosing are appropriate for smaller patients, older patients, and patients with cardiac dysrhythmias or coronary artery disease. Higher initial doses of liothyronine (75–100 μg) have been reported to be associated with lower survival in myxedema coma, although the data are very limited.[134,138]

TABLE 57.4 Initial Pharmacologic Treatment of Myxedema Coma

Drug	Dosage
Levothyroxine	Give a loading dose of 200–400 μg IV, followed by daily maintenance doses of 100 μg IV and later 50–200 μg orally.
Liothyronine	Give an initial dose of 5–20 mg IV followed by 2.5–10 mg IV every 8 hours until stabilized (optional adjunct to levothyroxine therapy).
Hydrocortisone	Give 100 mg IV before above and every 8 hours for possible adrenal insufficiency (see text).

IV, Intravenously.

An association exists between adrenal insufficiency and hypothyroidism, both for the primary forms of both diseases as well as their secondary (central) forms. Type 2 polyglandular disease (Schmidt syndrome) is a reflection of this relationship. There is agreement that thyroid hormone supplementation given to patients with myxedema poses a risk for provoking adrenal crisis because some of these patients have underlying adrenal insufficiency.[106,132,139] To avoid precipitating an acute adrenal crisis with its attendant hemodynamic derangements, corticosteroid treatment should precede thyroid hormone administration in patients with myxedema coma. This can be accomplished by giving hydrocortisone (e.g., 100 mg IV every 8 hours). When individual circumstances are present in which the use of corticosteroids could pose significant risk, a potential alternative is to perform rapid cosyntropin testing to exclude adrenal insufficiency. Initial steroid dosing is still required (in this case using dexamethasone initially so as not to interfere with plasma cortisol assay), but dosing could be stopped if post-stimulation cortisol levels demonstrate adequate adrenal reserve. Testing also provides baseline information regarding the patient's adrenal function.

It is reasonable to follow serum hormone levels at intervals of 1 to 2 days in the ICU to ensure that TSH is declining and T_4 normalizing. If T_3 is measured and found to be elevated, consideration can be given to reducing the daily dose of thyroid hormone.[132,138]

Prognosis in Myxedema Coma

The mortality rate of untreated myxedema coma approaches 100%, but contemporary management has lowered the risk of fatal outcome to the range 20% to 50%.[4,106,110,111,140,141] Older age, persistently low heart rare or body temperature, and higher doses of thyroid hormone administration have been identified as possible factors predisposing to fatality. Common mechanisms of death include respiratory failure, myocardial infarction, gastrointestinal and cerebral hemorrhage, circulatory shock, and severe sepsis.[106,111,138]

Thyrotoxicosis and Thyroid Storm

Thyrotoxicosis is a syndrome caused by supraphysiologic levels of circulating thyroid hormones. Patients with this disorder span a spectrum of severity of illness ranging from a compensated state that is asymptomatic, clinically undetectable, and discernable only by specific laboratory testing to a severely decompensated state resulting in critical illness. The latter is known as thyroid storm, an uncommon, extreme degree of thyrotoxicosis that results in life-threatening organ dysfunction. In common with myxedema coma, prompt recognition and urgent initiation of treatment are vital.

Etiologies of Thyrotoxicosis

Of the various etiologies of thyrotoxicosis (Box 57.4), hyperthyroidism is the most common. Hyperthyroidism is a pathologic state of excessive thyroid hormone production by the thyroid. The most common cause of hyperthyroidism is Graves disease, an autoimmune disorder in which antibodies directed at TSH receptors are produced. These antibodies bind to and stimulate TSH receptors, mimicking the effects of TSH on the thyroid, and thereby stimulating production and release of T_4 and T_3 by the thyroid. Stimulatory TRAb can also result in thyroid nodules, lead to growth of existing nodules, and promote thyroid autonomy. In addition, TRAb is the mediator of some of the extrathyroidal manifestations of Graves disease, such as the characteristic orbitopathy.[142,143] Graves disease is the most common cause of thyrotoxicosis and is also the most common cause of thyroid storm. Another common etiology of thyrotoxicosis is nodular thyroid disease, which includes solitary toxic nodules and toxic multinodular goiter.[144,145] Toxic multinodular goiter is the second most common cause of thyroid storm,[106] but solitary toxic nodules may also cause thyroid storm.[146,147]

In patients with underlying thyroid disorders that confer abnormally high levels of thyroid autonomy, iodine administration can stimulate thyroid hormone synthesis and elaboration, and can precipitate thyrotoxicosis or thyroid storm (the Jod-Basedow phenomenon). This has occurred after administration of radioactive iodine for the treatment of hyperthyroidism and also after administration of iodinated contrast for radiographic procedures.[148–152]

All of the preceding etiologies are categorized as primary hyperthyroidism. Secondary (central) hyperthyroidism occurs when the thyroid produces excessive hormones owing to the stimulatory effects of pituitary TSH on thyrotropin receptors at the surface of thyroid follicular cells (see Fig. 57.2). Thus pituitary adenomas that secrete excessive TSH are therefore a potential, albeit uncommon, cause of thyrotoxicosis. Thyroid storm caused by pituitary adenomas have been reported, but the condition is exceedingly rare.[153]

Thyrotoxicosis, including thyroid storm, can occur in patients with embryonal cell carcinoma, choriocarcinoma, and hydatidiform moles[154–158] as the result of high circulating levels of hCG. The hCG molecule shares sufficient structural resemblance to TSH that it can stimulate TSH-receptors on the thyroid. Physiologic levels of hCG have little or no effect, but the high levels that can occur in trophoblastic disease or germ cell neoplasms can cause thyrotoxicosis. In this case the thyrotoxicosis can be considered a form of hyperthyroidism because the thyroid is being stimulated, albeit inappropriately, to a hyperfunctional state of hormone production.

Thyrotoxicosis existing without hyperthyroidism can occur in destructive forms of thyroiditis.[145,159] These include trauma- or radiation-induced thyroiditis, Hashimoto disease, which is an autoimmune disorder causing thyroiditis, Riedel thyroiditis, bacterial (also known as acute or suppurative) thyroiditis, and various forms of subacute thyroiditis. Included among the latter are viral (de Quervain), postpartum, silent, and painless thyroiditis. Iodine uptake studies in these disorders reveal that the thyroid is not hyperfunctional. Instead, the underlying mechanism involves release of stored hormone from the thyroid as a consequence of the attendant injury or inflammation. Depending on the amount of hormone released, the resulting thyrotoxicosis can range from asymptomatic to thyroid storm, but the latter is rare.[106,160] The inflammatory (thyrotoxic) phase of subacute, postpartum, and painless thyroiditis tends to be mild and self-limited. The patient may progress through a hypothyroid phase, which is usually transient but in some cases the destruction process is sufficient to render the patient permanently hypothyroid.

• BOX 57.4 Etiologies of Thyrotoxicosis

Graves disease
Toxic multinodular goiter
Toxic adenoma
Thyroiditis (early phase)
  Hashimoto disease (early autoimmune thyroiditis)
  de Quervain thyroiditis
  Reidel thyroiditis
  Silent thyroiditis
  Postpartum thyroiditis
  Painless or silent thyroiditis
  Inherited nonautoimmune hyperthyroidism
  Sporadic nonautoimmune hyperthyroidism
  Iodine-induced hyperthyroidism (Jod-Basedow disease)
  Drug-induced thyroiditis
Thyrotropin-secreting pituitary adenoma
Excessive hypothalamic thyrotropin-releasing hormone production
Excessive thyrotropin production due to pituitary thyrotropin resistance
Gestational hyperthyroidism
Trophoblastic disease
Hyperthyroid thyroid carcinoma
Metastatic thyroid neoplasm with ectopic thyroid hormone production
Struma ovarii and other teratomas
Thyrotoxicosis factitia (excessive exogenous thyroid hormone ingestion)
  Ingestion of ground beef with excessive bovine thyroid gland inclusion ("hamburger thyrotoxicosis")
  Administration of pharmaceutical thyroid hormone preparation
    Iatrogenic overdose
    Intentional or accidental self-ingestion

Struma ovarii is a rare ovarian teratoma or dermoid that in some cases can contain functional thyroid tissue. The ectopic thyroid tissue operates autonomously and may elaborate sufficient amounts of hormone to cause thyrotoxicosis or even thyroid storm.[161] TSH secretion is thus suppressed and thyroid hormone elaboration by the thyroid gland itself essentially ceases. This neoplasm represents another potential cause of thyrotoxicosis that occurs in the absence of hyperthyroidism. Another is metastatic differentiated thyroid cancer, in which ectopic hormone production originates from the metastases.

Factitious thyrotoxicosis occurs when there are pathologically high levels of circulating thyroid hormone that are not produced by the body but instead represent exogenous hormone from either intentional or unintentional ingestion or administration.[162] Intentional overdose of pharmaceutical thyroid hormone can occur as a means of attempting suicide.[163–165] Intentional ingestion can also occur in patients who surreptitiously use thyroid hormones on a chronic basis either irrationally or owing to psychiatric disease, or as a misguided attempt at inducing weight loss.[166–168] Accidental overdoses are usually benign, particularly in pediatric patients, but thyroid storm can occur.[169–171] Thyroid storm has occurred from massive iatrogenic overdoses as a result of pharmacy compounding errors.[172–174] Dietary supplements or food products containing thyroid hormones or processed animal thyroid tissue have been reported.[175–177] Thyroid storm from thyrotoxicosis factitia is rare, but fatalities have occurred.

Precipitating Factors in Thyroid Storm

Thyrotoxic patients who do not receive treatment can develop progressive worsening and eventually develop a thyrotoxic crisis, a synonym for thyroid storm. More commonly, the disease may not appear progressive but transitions suddenly from an untreated, well-compensated state. This transition is usually triggered by some acute illness, injury, or other intervening physiologic stress that causes decompensation of the underlying thyroid disorder and rapidly leads to the development of thyroid storm. Either course can also be seen in patients who were previously diagnosed and pharmacologically treated for hyperthyroidism but later discontinued that treatment.[2] An uncommon precipitating cause of thyroid storm has occurred in some patients who were known to have hyperthyroidism and were prescribed radioactive iodine ablation therapy, but in whom the iodine administration caused worsening thyrotoxicosis by the Jod-Basedow effect.[151,152] Other examples of precipitating events that can trigger thyroid storm in susceptible patients are given in Box 57.5.[2,178–181]

• BOX 57.5 Precipitating Factors in Thyroid Storm

- Amiodarone
- Bowel infarction
- Cerebrovascular accident
- Congestive heart failure
- Cytotoxic chemotherapy
- Diabetic ketoacidosis
- Emotional stress
- Gastrointestinal hemorrhage
- Hypoglycemia
- Infection or sepsis
- Iodinated contrast administration
- Nonthyroidal surgery
- Organophosphate intoxication
- Pharmaceutical thyroid hormone overdose
- Preeclampsia
- Pregnancy or parturition
- Pulmonary thromboembolism
- Radioactive iodine (^{132}I) administration
- Salicylate overdose
- Thermal burn injury
- Thionamide withdrawal or noncompliance
- Thyroid surgery
- Trauma
- Vigorous thyroid palpation

Manifestations of Thyrotoxicosis

Thyroxicosis is a constellation of clinical manifestations that results from excess circulating thyroid hormone. Table 57.5 lists the wide variety of clinical manifestations that can be found in patients with thyroxicosis.[142,146,180,182] Among the most common complaints in patients with any degree of manifest thyrotoxicosis are heat intolerance, increased appetite, weight loss, increased frequency of defecation, generalized weakness, irritability, and emotional lability. Vital signs may reveal resting tachycardia and systolic hypertension with a widened pulse pressure. The skin tends to be warm and moist, the hair thin, and a fine tremor is often present. Goiter may be present or absent. Neuropsychiatric abnormalities may be evident.

Thyrotoxic patients may show characteristic ocular findings, acropachy, and cutaneous myxedema. However, these particular manifestations are ascribed to TRAbs, so they rarely occur in etiologies other than Graves disease, and even then are often not present.[142] Nevertheless, their appearance can facilitate clinical recognition of an underlying thyroid disorder in patients presenting without a prior diagnosis of hyperthyroidism. There can be a history of decreased visual acuity or diplopia, while the examination may show some of the characteristic findings of Graves orbitopathy, including thyroid stare with lid retraction or findings of lid lag, chemosis, corneal ulceration, proptosis, or extraocular muscle involvement. Myxedema occurs in a minority of patients with Graves disease, and may also occur in patients with Hashimoto thyroiditis. The term refers to bilateral, nonpitting, nodular induration, often with a yellow-brown, erythematous, or violaceous coloration. The most common distribution is pretibial, but the lesions may also be seen to involve the dorsal surfaces of the shoulders, elbows, knees, and feet.[183] Both the orbitopathy and the skin lesions are due to soft tissue accumulation of glycosaminoglycans generated by fibroblasts in response to stimulating TRAbs. Orbitopathy is seen in about 30% of patients with Graves disease, whereas 4% or less have dermopathy and less than 1% develop acropachy.[184]

Among the cardiovascular findings, sinus tachycardia and atrial fibrillation with rapid ventricular response occur commonly. Rarely, conduction disturbances may be seen, including third-degree heart block with bradycardia. A high-output form of congestive heart failure (CHF) can occur, which is in effect a potentially reversible form of cardiomyopathy.[185,186] Severe hypertension can occur, but hypotension is also possible. In some cases of thyroid storm the heart failure is sufficiently severe to lead to acute pulmonary edema or circulatory shock. Acute coronary syndrome can occur from the hypermetabolic effects of thyrotoxicosis in association with underlying coronary artery disease or from associated coronary artery spasm. Sudden cardiac death has also been reported, both in patients with hyperthyroidism and in patients abusing pharmaceutical thyroid hormone.[167,185]

Other than specific thyroid function tests, several nonspecific laboratory tests may reveal abnormalities. For example, associations between thyrotoxicosis and hypercalcemia, hyperglycemia, low cholesterol, abnormal liver function tests, and neutropenia have been reported.[1,114,117,151,187–193]

TABLE 57.5 Manifestations of Thyrotoxicosis

System	Symptoms	Signs
Integument	Excessive perspiration	Diaphoresis

Diagnosis of Thyroid Storm

Thyroid storm is more common beyond the sixth decade and there is a female preponderance.[194] Essentially any of the symptoms or physical findings of thyrotoxicosis can potentially occur in the patient with thyroid storm, but qualifying for the designation of storm implies the presence of an acute, life-threatening condition with significant organ system dysfunction, particularly neurologic, cardiovascular, or both. A frequently cited triad of characteristic physical findings of thyroid storm that are indeed present in many cases includes hyperthermia, severe tachycardia, and CNS derangements, but many cases have deviated from this rule.[179] Either significant neurologic or cardiovascular dysfunction (or both) could be considered diagnostic requirements. The presence of CNS involvement appears to be of major importance in distinguishing patients with thyroid storm from patients with lesser degrees of thyrotoxicosis.[195] The neurologic findings commonly include restlessness, agitation, and delirium, but frank psychosis, coma, or seizures may be present. Apathetic thyroid storm—that is, cases in which neurologic hyperactivity is lacking—can occur and is more common in the elderly.[2,196]

The diagnosis of thyroid storm rests on an underlying diagnosis of thyrotoxicosis. In some cases information from the history and physical examination provides convincing evidence of thyrotoxicosis and specific laboratory testing of thyroid function serves as corroboration. In other cases the clinical diagnosis of underlying thyrotoxicosis (and therefore thyroid storm) is uncertain or only suggestive. For acutely ill, hospitalized patients in whom either thyroid storm or lesser degrees of thyrotoxicosis are considered, thyroid function testing is important. Minimum testing ideally should include serum TSH and FT_4 assays. Where FT_4 assays are not immediately available, FT_4I is substituted. The majority of patients with thyroid storm either have underlying Graves disease or multinodular goiter.

Given that thyrotoxicosis occurs as a result of excessive thyroid hormone, supraphysiologic levels of thyroid hormone are expected and are indeed present in most patients. Free and total thyroid hormone levels will often be elevated and the TSH level will be suppressed. Less commonly thyrotoxicosis can occur in which either T_3 alone (T_3 thyrotoxicosis) or T_4 alone (T_4 thyrotoxicosis) are elevated. Other patterns may be seen in certain of the more rare forms of thyrotoxicosis than can result in thyroid storm. For example, where thyroid crisis is due to acute ingestion of exogenous T_3, serum T_4 levels may not be elevated and TSH not suppressed. In rare cases of pituitary adenoma causing secondary hyperthyroidism and thyrotoxicosis or storm, the TSH level is elevated instead of suppressed. In the aggregate, patients with thyroid storm may have higher T_4 levels than thyrotoxic patients without storm. However, in an individual patient the two conditions cannot be distinguished from one another on the basis of the degree of T_4

TABLE 57.6 The Burch-Wartofsky Scoring System

Diagnostic Parameter	Scoring Points
Body Temperature	
<99.0°F (<37.2°C)	0
99.0°F–99.9°F (37.2°C–37.7°C)	5
100.0°F–100.9°F (37.8°C–38.3°C)	10
101.0°F–101.9°F (38.3°C–38.8°C)	15
102.0°F–102.9°F (38.9°C–39.4°C)	20
103.0°F–103.9°F (39.4°C–39.9°C)	25
≥104.0°F (≥40°C)	30

of T_3 elevation.[2,197,198] Thus there are no threshold hormone levels that are diagnostic for thyroid storm. Although patients with storm tend to have higher thyroid hormone levels on average than thyrotoxic patients without storm, there is substantial overlap.

The Burch-Wartofsky (BW) scoring system[179] (Table 57.6) was proposed in 1993 and has been widely advocated. This severity scoring instrument uses readily available clinical information to derive an integer score that can range from zero to a maximum of 145 points. It was designed for evaluating patients with biochemical evidence of thyrotoxicosis to assess the likelihood of thyroid storm. A total score less than 25 is unlikely to represent thyroid storm, a score of 25 to 44 is suggestive of impending storm, and a score or 45 or higher is highly suggestive of thyroid storm. For patients with intermediate BW scores (25–44 points), the decision to use aggressive therapy is a clinical judgment.[36]

A newer scoring system was developed by the Japan Thyroid Association (JTA) that classifies patients into category 1 (definite) and category 2 (suspected).[2] In addition to requiring thyrotoxicosis, this system specifies requirements from among 5 criteria: (1) fever (≥38°C), (2) tachycardia (≥130 beats/min), (3) CHF (Killip class III or New York Heart Association class IV), (4) gastrointestinal or hepatic (nausea, vomiting, diarrhea, or serum total bilirubin >3 mg/dL), and (5) Glasgow Coma Scale score less than 15 (with lethargy, delirium, psychosis, seizures, or coma). Category 1 requires that the CNS criterion and at least 1 other criterion are met, or alternatively that at least 3 of the 4 non-CNS criteria are met. Category 2 requires 2 of the non-CNS criteria. Patients in whom FT_3 or FT_4 values are not available to confirm thyrotoxicosis are classified as category 2 if they meet category 1 criteria and there is preceding information that supports the diagnosis of thyrotoxicosis.

From a cohort study of 150 hospitalized patients with thyrotoxicosis, 25 of whom were deemed to have thyroid storm, retrospective application of the BW and JTA systems found that 20 of the patients with storm (80%) had BW scores higher than 44 and met category 1 or 2 JTA criteria.[195] The remaining 20% of patients with thyroid storm had intermediate (25–44) BW scores. However, accepting BW intermediate scores as indicative of thyroid storm would have resulted in 66% of the cohort cases being labeled as thyroid storm. These results suggest that including BW intermediate scores as indicative of storm yields greater diagnostic sensitivity than the JTA system, but with a large cost in terms of specificity.

The ATA recommends that severely thyrotoxic patients with systemic decompensation and BW thyroid storm scores or 45 higher or JTA category 1 or category 2 thyroid storm receive aggressive therapy.[36] For thyrotoxic patients with intermediate BW scores (25–44 points), the decision to use aggressive therapy is a clinical judgment.[36] These scoring instruments can be useful; however, the variables used are largely nonspecific and can be seen in many patients with critical illness unrelated to thyroidal illness. Thus thyroid storm ultimately remains a clinical diagnosis and blind application of scoring systems cannot supplant clinical judgment.[36,146,195,199]

Emergency Treatment of Thyroid Storm

Thyroid storm is an emergency that necessitates ICU monitoring and prompt treatment Because of attendant risks, thyroidectomy and radioactive ablation have little place in the emergency management of thyroid storm, although surgery has been used in highly selected cases. Specific treatment begins with a thionamide drug to inhibit hormone synthesis. The mechanism of action of thionamide drugs involves interference with TPO-mediated iodination of tyrosyl residues on thyroglobulin.[200] Of the two thionamides available in the United States, methimazole (MMI) and propylthiouracil (PTU), both are effective (Table 57.7). MMI is preferred for most cases of hyperthyroidism treated with a thionamide because it has a better side effect profile. However, there are several situations in which PTU is preferentially advocated, at least in adults, and one of these is thyroid storm. A rationale is that PTU not only inhibits hormone synthesis in the thyroid, but it also inhibits peripheral conversion of T_3 to T_4, an effect that MMI lacks. The 2016 ATA guidelines recommend PTU over MMI for most patients with thyroid storm.[36] PTU and MMI are available in the United States only as oral formulations. A parenteral formulation is marketed in Japan and some other countries.[201] There are reports

TABLE 57.7 Initial Specific Pharmacologic Treatment of Thyroid Storm

Agent	Dosage
1. Give One Thionamide Agent to Inhibit Thyroid Hormone Synthesis	
Propylthiouracil	Give 400–1000 mg oral or rectal loading dose followed by 200 mg q4h to 400 mg q6h.
Methimazole	Give 20 mg orally or per rectum q4h
2. Give One Agent to Inhibit Thyroid Hormone Release (Starting 1 to 2 h After Above)	
Lugol solution	Give 1 mL orally q8h
Sodium ipodate[a]	Give 0.5 g orally q12h.
Iopanoic acid[a]	Give 0.5 g orally q12h
Potassium iodide	Give 5 drops of saturated solution orally q6h
Sodium iodide	Give 250 mg IV every 6 h to 1 g IV q8h
Lithium carbonate	Give 300–450 mg orally q8h (see text).
3. Give One β-Adrenergic Receptor Blocker to Blunt End-Organ Effects	
Propranolol	Give 2–10 mg or more IV in incremental doses, then give 40–120 mg orally q6h titrated to effect
Metoprolol	Give 5–15 mg or more IV in incremental doses, then give 5–15 mg IV q4–6 h
Esmolol	Give 500 μg/kg IV over 1 min, followed by 50–200 μg/kg per minute by continuous IV infusion, titrated to effect
4. Give One or More Agents to Inhibit Peripheral Conversion of T_4 to T_3	
Dexamethasone	Give 2 mg IV q6h
Propranolol	Give 40–60 mg orally q6h
Sodium ipodate[a]	Give 0.5 g orally q12h
5. If Not Already Given as Above, Give a Corticosteroid	
Dexamethasone	Give 2 mg IV q6h
Hydrocortisone	Give 100 mg IV q8h
6. Augment Clearance by Administering a Bile Acid Sequestrant	
Cholestyramine	Give 5 g orally q6h
Colestipol	Give 5 g orally q6h

[a]Currently off market in the United States.

IV, Intravenously; T_4, thyroxine; T_3, triiodothyronine.

of reformulating oral preparations of PTU and MMI and administering the drugs both rectally (as retention enemas or suppositories)[202–205] and IV.[206,207]

The most common side effects of thionamides are rash, usually macular or urticarial, and arthralgias. Agranulocytosis is a potential complication of either thionamide, and the appearance while taking one thionamide contraindicates use of the other agent. Hepatotoxicity can occur with either drug. With PTU, this toxicity takes the form of a rare allergic hepatitis with hepatocellular necrosis, often with high levels of serum transaminase activity.[208] The hepatic dysfunction can potentially progress despite discontinuation of PTU, and fatal cases of hepatic failure or requirement for liver transplantation have been reported.[209] Fatalities have occurred in all age groups but may be more common in children (1 in ~2000) than adults (1 in ~10,000).[208,210] These adverse reactions led the U.S. Food and Drug Administration to issue a boxed warning in 2010 advising physicians on the risk of liver failure and death from PTU.[208,210] With MMI the hepatic effects are more likely cholestatic. Rarely, an antineutrophil cytoplasmic antibody–positive vasculitis can occur, particularly with PTU use, and can be associated with a drug-induced lupus-like picture, exfoliative dermatitis, hemoptysis, and rapidly progressive glomerulonephritis.

Both PTU and MMI have been labeled as class D drugs by the U.S. Food and Drug Administration, carrying risk to the developing fetus, but when necessary PTU has been recommended as the thionamide of choice.[200] PTU is preferred over MMI in the first trimester of pregnancy because the latter drug appears to be teratogenic.[208] MMI, on the other hand, has been advised over PTU in the second and third trimesters to avoid the risk of PTU-induced hepatotoxicity. PTU is also avoided in patients who have previously had prior adverse reactions to it.

Colloid stored in the thyroid follicles serves as a reservoir of hormone that can continue to be released from the thyroid even after thyroglobulin synthesis is completely inhibited by administered thionamide. This process of thyroglobulin degradation and thyroid hormone release can potentially continue for weeks after blocking synthesis. By a process defined as the Wolff-Chaikoff effect, supraphysiologic doses of iodine can temporarily halt this release process for a variable period, typically 10 to 14 days.[211] Iodine should therefore be administered routinely to patients with thyroid storm. Various forms of iodine have been available clinically for this purpose. Off-label use of the radiocontrast agents sodium ipodate and iopanoic acid, formerly in common use as oral cholecystographic agents, has been used as a highly effective means of providing this effect.[212,213] However, marketing of these agents was curtailed around the year 2000 in the United States, making them widely unavailable, but they may still be available from some compounding sources.[213–216]

Lugol solution, which contains potassium iodide (KI) (100 mg/mL or 0.6 mEq/mL) and iodine (50 mg/mL), has been widely available and used for decades to treat hyperthyroidism and prepare patients for thyroidectomy. It has also been used to treat thyroid storm. A safety concern with this preparation has been raised because of reports of dosing errors stemming from incorrectly ordering the drug or misconstruing administration orders. The drug is only to be administered orally, and it is frequently ordered as a number of drops to be given per dose. In the hospital setting multidose bottles have often been dispensed along with a bulb pipet (eyedropper). Lethal doses have been accidentally administered when the pharmacy dispensed a multidose bottle of the drug, which was then assumed to be a single dose and the entire bottle administered.[217] In at least one case Lugol solution was mistakenly instilled topically into a patient's eye. Hospitals should have a protocol for handling this solution to ensure that only safe doses are dispensed and that clear instructions are included. Another available formulation is KI oral solution, USP, a saturated solution of KI that contains 1 g (6 mEq) of KI per milliliter of solution and has been used as an expectorant. This solution has also been administered sublingually.[204] For patients who cannot take oral or enteral iodine, parenteral formulations of KI can be given as an IV infusion.

Regardless of the form of iodine administration, its timing is important. The iodine formulation should be administered 1 to 2 hours after the thionamide is given. If given before thionamide, the administered iodine will further stimulate thyroid hormone synthesis (the Jod-Basedow effect) and thereby potentially exacerbate the thyroid storm.

For patients who cannot tolerate a thionamide, lithium has been used therapeutically.[218] The element both interferes with thyroid hormone synthesis and inhibits hormone release from the thyroid. Its use to treat thyroid storm is infrequent because of its narrow therapeutic index. To help prevent lithium toxicity, serial plasma lithium levels should be obtained aiming for a therapeutic concentration of 0.6 to 1.0 mmol/L. Potassium perchlorate competitively inhibits iodide uptake by follicular cells and has also been used when thionamides cannot be given.[219] However, perchlorate can cause agranulocytosis and nephrotic syndrome.[220–222]

Thyroid hormones and their hepatic metabolic products are excreted in bile as sulfate and glucuronide conjugates. The conjugates can undergo hydrolytic deconjugation within the intestinal lumen, and both the secreted and hydrolyzed free hormone can be reabsorbed through the intestinal mucosa. Cholestyramine, an anion exchange resin, strongly binds thyroxine and thereby interferes with this physiologic enterohepatic recirculation of thyroid hormone.[66] Cholestyramine, as well as colestipol, another bile acid sequestrant, have been shown to significantly lower circulating T_3 and T_4 levels in patients with Graves disease.[147,216,223–226] They have been used off-label in the general treatment of thyrotoxicosis and thyroid storm, and specifically in cases of thyroid hormone overdose.

Although thyroid hormones and the endogenous catecholamines superficially would appear to have similar physiologic properties, thyroid hormones are not catecholamines and do not activate adrenergic receptors. Coulombe and colleagues examined norepinephrine secretion rate in normal, hypothyroid, and hyperthyroid subjects.[227] They found no difference between the healthy subjects and the patients with hyperthyroidism. Norepinephrine secretion rates were slightly, but statistically significantly, higher in the patients with hypothyroidism. Holt and associates studied the effects of thyroid hormone on cardiac β-adrenergic responsiveness in conscious baboons, showing that thyroid hormones produce inotropic and lusitropic effects, and the mechanism appears to be up-regulation of both β_1- and β_2-adrenergic receptors, with the latter predominating.[228] Several of the clinical manifestations of thyrotoxicosis can be ameliorated by therapeutic β-blockade, including tremor, tachycardia, hypertension, palpitations, diaphoresis, and eyelid retraction. β-Blockers are therefore used to treat thyrotoxicosis and thyroid storm. The ability of these drugs to lower the heart rate in severe sinus tachycardia and other supraventricular dysrhythmias, as well as to control the ventricular response to atrial fibrillation, positions them as an essential component of treatment in most cases of thyroid storm. Nevertheless, caution is indicated in their use because some patients in thyroid storm progress to severe heart failure, hypotension, and circulatory collapse.

Both propranolol and metoprolol have been shown to be about equally effective at accomplishing the above cardiac and systemic improvements.[229] However, the conventional agent of choice for this purpose has been propranolol, in part because it is one of the oldest available agents in this class and most of the clinical experience in thyroid storm has been with this drug. Another reason is that propranolol, unlike other tested β-blockers, is known to be a strong inhibitor of 5′-deiodinase. Shulkin and coworkers tested the ability of various β-blockers to inhibit T_3 production in rat liver homogenates and showed that propranolol is much more potent than pindolol, timolol, atenolol, metoprolol, and nadolol.[230] They also showed that this effect does not appear to be related to β-adrenergic antagonism but correlates with lipid solubility. Thus an additional effect of propranolol may be an ability to lower T_3 levels through a membrane-stabilizing effect in addition to its β-blocker and deiodinase inhibiting effects. From a Japanese inpatient administrative database containing *International Statistical Classification of Diseases and Health-Related Problems,* 10th revision (ICD-10) diagnostic codes, medications, outcome, and other information, patients spanning a 3-year period with the diagnosis of thyroid storm who received β-blockers were compared to those who did not.[231] Of the 65% of patients listed as receiving β-blockers, their mortality rate was 7.5%, compared with 15.1% in those not given β-blockers ($P < 0.001$).

For patients with reactive airway disease, a relative contraindication to propranolol, a cardioselective β-blocker such as metoprolol can be considered. In patients with a more concerning relative contraindication, consideration can be given to using esmolol, an ultrashort acting β-adrenergic antagonist. Esmolol is given by continuous IV infusion, which can be discontinued if adverse effects are noted, and has been used to treat patients with thyroid storm.[232–234] With a half-life of about 9 minutes, its effects can be expected to dissipate within 30 minutes or so.[235] For patients with an absolute contraindication to β-blockade, the options are more limited. The nondihydropyradine calcium channel–blocking drug diltiazem can be given IV, including by continuous IV infusion, and is commonly used to control the ventricular response in critically ill patients with atrial fibrillation. However, it has no adrenergic blocking effects and it has vasodilator properties that can pose a risk in hemodynamically unstable patients. The antihypertensive agents reserpine and guanethidine, which also have vasodilatory effects, have been used off-label in the past in thyroid storm.[199,236–241] Although they are not β-adrenergic receptor blockers, they both possess sympatholytic effects; however, they have troublesome side effects and the drugs are unlikely to be available.

In addition to propranolol, a number of other drugs have been shown to inhibit 5′-deiodination and thereby decrease peripheral T_3 production from T_4, including PTU (at doses ≥400 mg/day),

sodium ipodate, and dexamethasone. Other corticosteroids have been shown to share this effect, but dexamethasone has been the most extensively studied. Corticosteroids have also been recommended in the treatment of thyroid storm to cover for the possibility of concomitant adrenal insufficiency. Coexisting adrenal insufficiency has been observed in a small subset of patients with Graves disease.[242] The possibility of a more pervasive but subtle effect of thyroid storm on adrenal function was investigated by Tsatsoulis and associates.[243] Using overnight dexamethasone suppression and low-dose cosyntropin stimulation testing, they investigated the adrenocortical reserve before and after treatment in 10 patients with severe thyrotoxicosis and demonstrated an attenuated response to cortisol production in the thyrotoxic state compared with the subsequent euthyroid state. On the other hand, because cortisol-binding globulin (transcortin) levels are decreased in hyperthyroidism, plasma cortisol levels may be decreased sufficiently to interfere with the interpretation of total cortisol assays.[244] Thus low total cortisol levels in response to rapid cosyntropin stimulation testing may represent a false-positive indicator for adrenal insufficiency. Assaying free cortisol levels or transcortin level may avoid this interference, but these tests are not widely available. Of the 1324 patients with an ICD-10 diagnosis of thyroid storm in the Japanese retrospective study cited previously, mortality was 12.2% in the 62% of patients given steroids compared with 6.6% in those patients not given steroids ($P = 0.001$).[231] However, multiple regression analysis pointed to an underlying correlation between steroids and illness severity rather than outcome. Evidence-based treatment guidelines from the JTA and the Japan Endocrine Society recommend that patients with thyroid storm be given 300 mg of hydrocortisone or 8 mg of dexamethasone per day.[201] Hydrocortisone (or alternatively, dexamethasone) is also recommended for patients with thyroid storm by the 2016 ATA guidelines as prophylaxis against relative adrenal insufficiency.[36] For patients with individual circumstances that point to a specific disadvantage to the use of corticosteroids, consideration could be given to performing the rapid cosyntropin stimulation test to assess adrenal reserve.

Hyperthermia can occur in thyroid storm, sometimes with body temperatures exceeding 40°C. Temperature control measures may be necessary, including external cooling in some cases. Acetaminophen is the pharmacologic antipyretic of choice. Aspirin has the disadvantage of displacing thyroid hormones from plasma proteins, which conceivably could worsen the thyrotoxicosis.[59] Precipitation of thyroid storm ascribed to aspirin intoxication has been reported.[245] On the other hand, an individual benefit-risk analysis may favor using aspirin in the patient in whom acute coronary syndrome is either the precipitating factor or a secondary complication of thyroid storm. In all cases, there should be a diligent search for an underlying precipitating factor that may have provoked the thyrotoxic crisis. Usual supportive measures for critically ill ICU patients should be provided, including continuous electrocardiographic and pulse oximetry monitoring; general hemodynamic and respiratory support; appropriate correction of fluid, electrolyte and acid-base derangements; venous thromboembolism and stress ulcer prophylaxis; glycemic monitoring and control; nutritional support; and monitoring for signs of sepsis, delirium, and adverse drug effects.

In the case of serious overdose involving thyroid hormones, activated charcoal may be administered to patients who can protect their airway or have an endotracheal tube in place, if the ingestion occurred within the prior 1 hour.[246] Cholestyramine (or colestipol) can also be given to bind thyroid hormone in the gut. Because thyroid hormone suppresses hormone synthesis by the thyroid, thionamide therapy is not indicated in these cases. PTU could be used, however, to inhibit endogenous conversion of exogenous T_4 to T_3, but alternative pharmacotherapies are available (e.g., propranolol and corticosteroids). Charcoal hemoperfusion and plasmapheresis have been used to treat overdoses of thyroid hormone.[172,174] Conventional hemodialysis has little effect because only the unbound thyroid hormones are removed, which constitute less than 1% of the circulating hormone pool. Plasmapheresis, on the other hand, effectively removes the circulating plasma carrier proteins to which thyroid hormones are bound.

Plasma exchange and plasmapheresis have also been used outside the setting of overdose to treat thyroid storm owing to underlying hyperthyroidism, with numerous supporting case reports and case series.[173,174,236,247–249] It has been postulated that plasmapheresis exerts benefit not only by removing hormone, but also by removing autoantibodies, cytokines, and catecholamines.[247] The 2016 ATA guidelines acknowledge that plasmapheresis has been used to treat thyroid storm that responds poorly to conventional methods, but makes no recommendations regarding its use.[36] The 2016 JTA guidelines for treatment of thyroid storm recommend that therapeutic plasmapheresis should be considered if clinical improvement (e.g., fever, tachycardia, and sensorium) is not seen after 24 to 48 hours of initial treatment with appropriate pharmacotherapy; however, the recommendation is rated weak and the underlying evidence of low quality.[201]

Prognosis in Thyroid Storm

In the early 20th century, survival from thyroid storm was nil.[179,250] In three large series published in the 1930s, together reporting on a total of 176 patients with thyroid storm, the mortality rate was 100%.[251–253] In contemporary series the overall mortality ranges from 8% to 30%.[2,36,147,179,195,254] Mechanisms and causes of death in thyroid storm commonly involve single and multiple organ system failure, including CHF, cardiac dysrhythmias, circulatory shock, respiratory failure, and renal dysfunction.[2] Hyperthermia, pulmonary embolism, coagulopathy, and sepsis have also been reported.[2,255,256] For survivors, thyroidectomy is usually recommended. The use of therapeutic iodine during the acute phase precludes the use of radioactive iodine ablation unless thionamide treatment is continued until the thyroid recovers from the iodine exposure.[106]

Key Points

- A variety of drugs used commonly in the ICU setting, including glucocorticoids, amiodarone, dopamine, and heparin, can either affect thyroid function test results or affect actual thyroid function.
- Nonthyroidal illness syndrome, the finding of abnormal thyroid function test results in acutely ill patients who do not have thyroid disease, occurs frequently among ICU patients.

- The most common thyroid function test findings in NTI syndrome are low TT_3 and low FT_3 levels, with low FT_4 levels observed in the sickest patients.
- Critically ill patients with elevated TSH in conjunction with low FT_4 levels or FT_4I likely have primary hypothyroidism, particularly when the TSH level exceeds 20 mIU/L.
- Critically ill patients with elevated FT_4, FT_4I, TT_3, or FT_3 levels, in conjunction with an undetectable TSH level, likely have primary hyperthyroidism.
- Currently available evidence does not support thyroid hormone administration to patients with nonthyroidal illness syndrome.
- Patients with myxedema coma have an impaired ventilator response to both hypercapnia and hypoxemia and frequently develop acute respiratory failure.
- Thyroid storm is a medical emergency that requires specific multimodal pharmacotherapy, usually including a thionamide, some form of iodine, β-adrenergic blockade, and a glucocorticoid.

Review Questions

1. A 42-year-old woman with unknown past medical history was brought to the emergency department by ambulance after she was found crawling on a city sidewalk outside a grocery store. She was unable to give a meaningful history because of mental confusion. Physical examination findings included body temperature 38.7°C, heart rate 149 beats/min, respirations 34 breaths/min, blood pressure 180/54 mm Hg, disorientation, and agitation. Serum ethanol was undetectable and a urine drug screen result was negative. Other initial laboratory findings included serum sodium 145, potassium 4.5, chloride 104, total carbon dioxide content 27 mmol/L; serum glucose 128, urea nitrogen 24, creatinine 1.3 mg/dL; serum thyrotropin less than 0.006 (reference range 0.3–3.0) mIU/L, and free thyroxine level 4.9 (reference range 0.6–1.6) ng/dL. The intensivist concluded that she had thyroid storm. An immediate plan for pharmacotherapy was formulated to include administration of a β-adrenergic blocker, a thionamide, sodium iodide, and dexamethasone. Which of the following caveats is most important regarding the order of administering the initial dose of these therapeutic agents?

a. Administer the sodium iodide before the β-adrenergic blocker
b. Administer dexamethasone before sodium iodide
c. Administer the thionamide before sodium iodide
d. Administer the β-adrenergic blocker before the thionamide
e. Administer sodium iodide before the thionamide

Answer: c. All of the listed drugs have a potential role in the emergency treatment of the patient with thyroid storm. The purpose of a β-adrenergic antagonist drug is to blunt certain end-organ effects resulting from the thyrotoxic crisis. Dexamethasone inhibits peripheral conversion of circulating thyroxine to the more active triiodothyronine. Thionamide drugs, such as methimazole and propylthiouracil, inhibit synthesis of thyroid hormones by the thyroid. The purpose of sodium iodide (or other acceptable forms of iodine) in the treatment of thyroid storm is to prevent release of already synthesized thyroxine and triiodothyronine from the thyroid gland. However, by serving as added substrate, administration of iodine or iodide can stimulate additional thyroid hormone synthesis within the thyroid. To avoid worsening the thyrotoxic state, the initial dose of thionamide should be given 1 to 2 hours before administration of sodium iodide.

2. A 74-year-old woman was found at home on the floor by a neighbor. No other history was obtainable. In the emergency department her initial vital signs included a rectal temperature of 35.2°C, heart rate of 46 beats/min, respirations 10 breaths/min, and blood pressure of 145/83 mm Hg. Physical examination showed periorbital edema, a healed surgical scar on her anterior neck, clear lungs, benign abdomen, and nonpitting pretibial edema. She responded to strong tactile stimulation by localizing the stimuli and occasionally making some incomprehensible verbalizations. Arterial blood gas analysis performed while receiving supplemental oxygen by nasal cannula showed pH 7.10, partial pressure of arterial carbon dioxide 78 torr, and partial pressure of arterial oxygen 144 torr. After endotracheal intubation and initiation of mechanical ventilation, the serum thyrotropin assay result became available and was 122 mIU/L. Shortly thereafter the patient's free thyroxine assay result returned as undetectable. A plan was formulated for emergency treatment of myxedema coma. In addition to administering intravenous levothyroxine, which of the following pharmacologic agents should be urgently administered?

a. Hydrocortisone
b. Lugol iodine solution
c. Enteral levothyroxine
d. Iopanoic acid
e. Intravenous dextrose and insulin

Answer: a. Myxedema coma is an extreme form of hypothyroidism that is treated with thyroid hormone replacement, usually consisting of levothyroxine. Hypothyroidism can, in some cases, be associated with adrenal insufficiency. In those cases, the adrenal insufficiency may be compensated by the general decrease in basal metabolism caused by the underlying hypothyroidism. Administration of levothyroxine would be expected to restore the metabolic rate and could thereby increase corticosteroid requirements and lead to the development of acute adrenal insufficiency. Empiric administration of hydrocortisone is advocated as a means of preventing the potential complication of adrenal crisis.

3. Which of the following thyroid hormone patterns is most likely to be observed in a critically ill patient with nonthyroidal illness (sick euthyroid) syndrome?

a. Low total triiodothyronine, high total thyroxine, high free thyroxine, high thyrotropin
b. High total triiodothyronine, low total thyroxine, low free thyroxine, low thyrotropin
c. Normal total triiodothyronine low total thyroxine, low free thyroxine, normal thyrotropin
d. Normal free triiodothyronine, high total thyroxine, normal free thyroxine, high thyrotropin
e. Low free triiodothyronine, low total thyroxine, low free thyroxine, normal thyrotropin

Answer: e. Patients with no history of prior thyroidal illness and no physical findings or symptoms pointing to thyroid dysfunction but who develop a critical nonthyroidal illness frequently are found to have one or more abnormal thyroid function tests. The frequency of this condition, known as the euthyroid sick syndrome or the nonthyroidal illness syndrome, correlates with the severity of the acute illness. The most common thyroid function test abnormality is depression of total or free triiodothyronine (T_3). The most severely ill patients often progress to having low values for T_3, thyroxine (T_4), and thyrotropin (TSH). Free T_4 levels are less likely to be low compared with total T_4 levels in these patients. T_4 levels can sometimes transiently elevate slightly during the early phase of critical illness. TSH levels can similarly be slightly elevated during the early phase, and also transiently elevate during the recovery phase. Reverse T_3 levels are often elevated in critically ill patients with nonthyroidal illness. Other factors, such as concomitant use of certain drugs, can affect thyroid hormone levels in critically ill patients without thyroid disease.

Consciousness and Its Clinical Spectrum

Consciousness is defined as an individual's state of awareness of self and environment and his or her responses to internal and external stimulation.[1] The two basic components of consciousness—arousal and awareness—are regulated by different neuroanatomic domains within the central nervous system.

Arousal and ensuing wakefulness are tightly dependent on the network function of the ascending reticular activating system (ARAS), consisting of the midbrain reticular formation, mesencephalic nucleus and tegmentum, thalamic intralaminar (centromedian) nucleus, and dorsal hypothalamus. Self-awareness and the spectrum of cognitive interactions with the environment are the purview of the hemispheres. Simplistically, the hemispheres are composed of three functional systems: units that receive, process, and store sensory information; units that generate and regulate motor activity; and units that are responsible for programming, regulating, and verifying actions. These three functional systems operate as an intercortical network and relate to the experience of awareness and allow cognitive performance.

The partition of the arousal network and the intercortical (cognitive) network implies that the level of self-awareness and cognitive performance cannot be examined in a patient with lack of arousal. In other words, in a person with a quantitatively reduced state of consciousness, the qualitative assessment of the content of consciousness is not possible. The assessment of content (i.e., testing a patient's cognitive abilities and thinking) should be done after the best level of arousal has been achieved (i.e., during or shortly after stimulation). An individual with complete arousal can express completely normal or deficient awareness and cognitive performance. Conversely, failure of arousal renders it impossible to test awareness and cognition.

Alteration of consciousness secondary to brain insult is a frequent admission diagnosis to critical care services and should be regarded as a medical emergency. Immediate and often extensive diagnostic workup is required as both times to diagnosis and treatment initiation are decisive factors for further injury prevention and brain recovery. Accurate diagnosis and subsequent prognosis may be challenging, as disorders of consciousness exist on a continuum and subtle differences distinguish the degree of disordered consciousness (Table 58.1). Indeed, it is estimated that 30% to 40% of patients with disorders of consciousness are erroneously assigned a diagnosis of vegetative state.[2] Therefore defining each disordered state of consciousness in a succinct and operational manner will provide a deeper understanding of the depth of brain injury and avoid miscommunications and unrealistic prognostication.

Coma (from Greek κῶμα koma, or deep sleep) typically results from diffuse injury to the cerebral cortex, bilateral thalami, or the paramedian tegmentum of the midbrain and pons. Coma is best characterized as a continuous state of unresponsiveness identified by inability to arouse to vigorous (noxious) external stimuli and lack of spontaneous waking. In addition to a lack of speech or purposeful motor activity, clinical features of coma include persistently closed eyes accompanied by no diurnal electroencephalographic (EEG) activity. Coma most commonly lasts only a few weeks, in which time the patient's condition either deteriorates or transitions to another neurologic state, such as a vegetative state or even a minimally conscious state.

A stuporous patient (from Latin *stupure*, meaning insensible) requires repeated, stronger stimuli to show some arousal and these patients may or may not open their eyes. Full arousal and alertness is not achieved and with continuing external stimulation, restlessness and stereotypic motor responses are observed, but without appropriate cognitive interactions. A deep stuporous state closer to coma is differentiated by European clinicians and is referred to as sopor (from Latin *sopor*, meaning deep sleep).

The *vegetative state* is characterized by the complete absence of behavioral evidence for self or environmental awareness; however, brainstem and thalamic activity is present to a degree that clinical

TABLE 58.1 Characteristic Clinical Features of Disorders of Consciousness and Locked-In Syndrome

Disorder	Consciousness	Cognition	Receptive Language	Expressive Language	Visual Perception	Motor Function	Structure Injured
Coma	No sleep-wake cycles	None	None	None	None	Primitive reflexes only	RAS *OR* Diffuse brain damage
Vegetative state	Intermittent periods of wakefulness	None	None	None	Variable visual startle responses	Involuntary movements only	Cerebral cortex Thalamocortical pathway ± RAS
Minimally conscious state	Intermittent periods of wakefulness	Inconsistent but clear behavioral signs of self or environmental awareness	Inconsistently one-step command following	Aspontaneous and ranging from single words or short phrases	Visual pursuit Object recognition	Localize to noxious stimuli Object manipulation Automatic movement sequences	Normal to variable lesion in RAS
Akinetic mutism Abulia	Normal or depressed	Normal or depressed	Normal or depressed	Normal or depressed	Normal	Delayed, slow responses	Hypothalamic Basal forebrain
Acute confusional state	Extended period of wakefulness	Confusion and disorientation	Consistent one-step command following	Yes-no responses Perseverative Short sentences Confused	Object recognition	No functional deficit	Normal to variable lesions in RAS
Brain death	Absent	Absent	None	None	None	Preserved postural and motor reflex	Global brain damage
Locked-in syndrome	Normal sleep-wake cycles	Normal to near-normal	Normal	Aphonic	Normal	Quadriplegia	Bilateral ventral pons

RAS, Reticular activating system.

signs of spontaneous or stimulus-induced arousal and sleep-wake cycles are observed. Patients often show blink responses to light, intermittent eye movements (sometimes erroneously interpreted as following objects or looking at family members); stimulus-sensitive automatisms, such as swallowing, bruxism, and moaning; or primitive motor responses. If this state lasts longer than 30 days, it is referred to as *persistent vegetative state* and is used as a descriptive clinical syndrome rather than a disease-specific entity.

The *minimally conscious state* (MCS) is characterized by limited albeit inconsistent behavioral evidence of awareness of the environment. MCS has recently been further divided into a lower boundary (MCS–), which is defined by a patient's ability to visually track and an upper boundary (MCS+), which is reflected by recovery of command following.[3] The condition of MCS includes a particular subtype known as akinetic mutism, which is portrayed as a silent, alert-appearing immobility of a patient with injury to the hypothalamus or basal forebrain. It manifests as apparent depressed levels of consciousness in a patient with well-formed sleep-wake cycles and little or no evidence of awareness or spontaneous motor activity. However, high-intensity sensory or personally relevant stimuli may elicit appropriate behavioral responses in patients with akinetic mutism, indicating that it is a lack of motivation rather than a true perturbation of arousal.

The term *locked-in syndrome* was introduced by Plum and Posner to describe the quadriplegia and anarthria resulting from the disruption of corticospinal and corticobulbar pathways, respectively. The extent of the deficits in patients with locked-in syndromes can vary, but these patients are aware of the environment and can hear and understand what is discussed around them. They are able to retain some ability of oculomotoric (i.e., ability to open eyelids) or other residual cranial nerve (CN) or motor functions. These patients are also anarthric or severely dysarthric with varying degrees of motor deficits ranging from quadriparesis to complete quadriplegia. As consciousness is preserved, communication is possible using preserved vertical or lateral eye movements or blinking of the eyelid to signal yes/no responses. The majority of cases are caused by basilar artery occlusion leading to brainstem infarction in the ventral pons, yet numerous other etiologies have been described.

Drowsiness, sleepiness, and lethargy resemble reduced spontaneous physical and mental activities in a person who cannot sustain wakefulness without repeated external stimulation. These states are somewhat comparable to the experience of lighter sleep. However, drowsy patients almost always have reduced attention and concentration and some degree of associated mild confusion. Although sleep and pathologic states of consciousness share common features such

that sleeping individuals are unaware that their condition resembles unconsciousness, quick reversal to full consciousness is a classic feature of sleep.

Abulia (from the Greek word for lack of will) is an apathetic state in which the patient is awake, has normal sleep wake cycle, and is very slow to respond to stimuli. Mental function is usually normal when tested with sufficient stimulation. Abulia is secondary to bilateral frontal lobe disease and in severe instances may mimic or progress to akinetic mutism.

An *acute confusional state* is distinguished from MCS by the reestablished ability of the patient to engage in rudimentary communication or use common objects appropriately. The condition is referred to as a confusional state because patients commonly exhibit signs of confusion, including diminished focus and attention, anterograde amnesia, disinhibition, agitation, and sleep disturbances.[4,5]

Delirium involves a fluctuating level of consciousness and pervasive impairment in mental, behavioral, and emotional functioning. It is commonly acute in onset and short in duration and is frequently correlated to a specific etiology, such as medications, anesthesia, or sleep deprivation. The *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition criteria for delirium include a disturbance of consciousness with reduced ability to sustain or shift attention and focus. In our experience, attention and concentration deficits are always present in delirious patients and accompanied by a variable degree of cognitive dysfunction unattributed to preexisting dementia. The dysfunctions of this acute syndrome include memory deficits, disorientation, disturbance of language and situational perception, and disorganized behavior. Other delirium markers are its acute onset and tendency to fluctuate along a spectrum of hyperactivity (i.e., agitation, restlessness, emotional labiality), hypoactivity (withdrawal, flat affect, apathy, decreased responsiveness), or mixed presentations.

Neurobiology of Consciousness

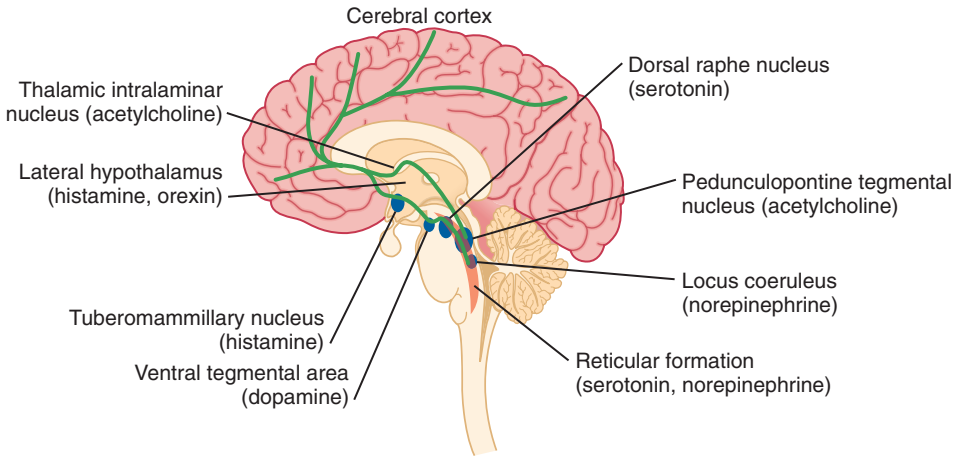
Neuroscientists have established a basic understanding of the neuroanatomic underpinnings of the two components of consciousness: arousal and awareness. The basic neuroanatomic relay stations underlying consciousness are depicted in Fig. 58.1.

The foundation of arousal is the ARAS, which consists of sets of brainstem nuclei extending from the medulla to the midbrain and including the midbrain reticular formation, mesencephalic nuclei (dorsal raphe nucleus, pedunculopontine tegmental nucleus, locus coeruleus), and ventral tegmental area. Various human actions are activated by processes that occur preconsciously (strategic arousal)—for example, gamma-band oscillations within the ARAS excite the rostral thalami, tuberomamillary nucleus, lateral hypothalamus, and basal forebrain.[6,7] In turn, the interlaminar and midline thalamic nuclei have a rich cortical interconnection allowing subsequent cognitive determination of the content of consciousness, or awareness.[8]

Different neurotransmitter systems are responsible for facilitating communication between the aforementioned brain areas, including excitatory effects from cholinergic, orexinergic, noradrenergic, and glutamatergic systems and inhibitor effects from gamma-aminobutyric acid (GABA)ergic pathways, all of which are illustrated in Fig. 58.1.[9] Neurons in the key brain regions associated with arousal and awareness may shift their firing patterns or cease transmission altogether. The hallmark of the awake state is the occurrence of high-frequency firing patterns across these brain regions, resulting in synchronous depolarization of larger cortical networks. Hyperpolarization of these neurons, on the other hand, is associated with progressive loss of consciousness, as seen with deepening stages of sleep.[10–17]

Pathophysiology of Impaired Consciousness

Indeed, just as a properly functioning ARAS gives rise to arousal and maintains wakefulness, injury to the ARAS results in reduced levels of alertness, if not complete failure to arouse. Lesions that result in impaired consciousness can therefore be thought of as supratentorial, such as damage to cortical projections in the cerebral hemispheres; infratentorial, such as brainstem injury; or both. Of note, currently used descriptors of disorders of consciousness (i.e., coma, stupor) are based on assessment of a patient's behavioral features, not on neuroanatomic or imaging data. To date, diagnostic categorizations based on root pathology do not exist. Nevertheless, a variety of pathophysiologic mechanisms causing impairment of consciousness can be described and loosely grouped into the



• **Fig. 58.1** The foundation of arousal is the ascending reticular activating system. It includes sets of brainstem nuclei extending from the medulla to the midbrain, as well as the midbrain reticular formation, mesencephalic nuclei (dorsal raphe nucleus, pedunculopontine tegmental nucleus, locus coeruleus), and ventral tegmental area.

TABLE 58.2 Etiologies and Clinical Features of Different Causes of Impaired Consciousness

	Etiology	Clinical Features for Differential Diagnosis
Supratentorial lesion	• Destructive—ischemic infarct, hemorrhage (SAH, SDH, ICH) • Compressive lesion—ischemic infarct, hemorrhage, aneurysm, vascular malformation, tumor, venous thrombosis, abscess • Head injury, concussion	• Initial focal cerebral dysfunction • Dysfunction progresses rostral to caudal • Signs reflect cortical dysfunction, often multifocal • Often asymmetric cortical involvement and presentation
Infratentorial lesion	• Destructive—ischemic infarct, hemorrhage (SAH, ICH) • Compressive lesion—ischemic infarct, hemorrhage, aneurysm, vascular malformation, tumor, venous thrombosis	• Symptoms of brainstem dysfunction or sudden onset coma (posturing) • Brainstem signs precede/accompany coma • Cranial nerve and oculovestibular dysfunction—ocular bobbing, vertical pendular oscillation (pons), monocular movement (midbrain) • Early onset of abnormal respiratory pattern
Diffuse brain lesion	• Traumatic brain injury • Anoxic injury • Toxic encephalopathy • Seizure, nonconvulsive, postictal • Primary neuronal disorder • Infectious encephalitis (prion disease, progressive leukoencephalopathy) • Inflammatory encephalitis (ADEM) • Vasculitis	• Often asymmetric in presentation • Focal signs depending on main brain lesion
Metabolic coma	• Hypoglycemia • Nutritional (thiamine, niacin, pyridoxine, cyanocobalamin, folic acid), Wernicke encephalopathy • Hepatic encephalopathy • Uremia and dialysis • CO_2 narcosis • Exocrine pancreatic encephalopathy • Endocrine—Addison disease, pheochromocytoma, diabetes • Paraneoplastic • Drug poisoning • Thermal injury • Electrolyte/acid-base imbalance	• Confusion/stupor precede motor signs • Motor signs usually symmetric • Pupil responses generally preserved • Myoclonus, asterixis, tremulousness and generalized seizures common • Acid-based imbalance common with compensatory ventilator changes • Periodic alternating gaze deviation • Systemic—altered mental state with normal brainstem function (especially normal pupils). Possible triphasic waves on EEG • Stimulant-induced coma (cocaine, amphetamine, phencyclidine, tricyclic antidepressant) • Fever, mydriasis (except miosis with phencyclidine), and seizure • Sedatives (alcohol, benzodiazepine, barbiturates, antiepileptics) • Ataxia, impaired eye movements but normal pupils • Opiate-induced miosis
Psychiatric	• Conversion disorder • Depression • Psychosis—catatonia	• Forced eye closure • Pupils reactive or dilated, nonreactive • Unpredictable oculocephalic reflex: nystagmus on caloric test • Normal or inconsistent motor tone • No pathologic reflexes • Awake-pattern EEG

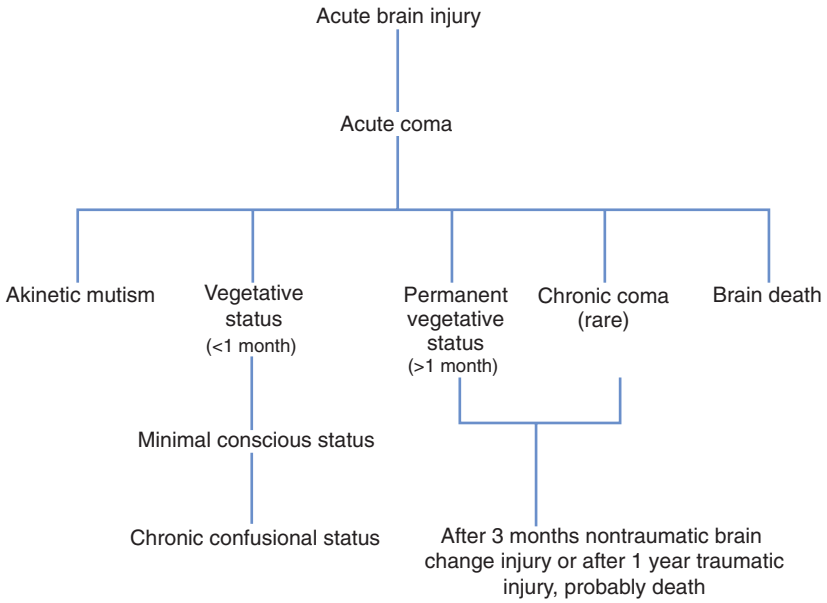
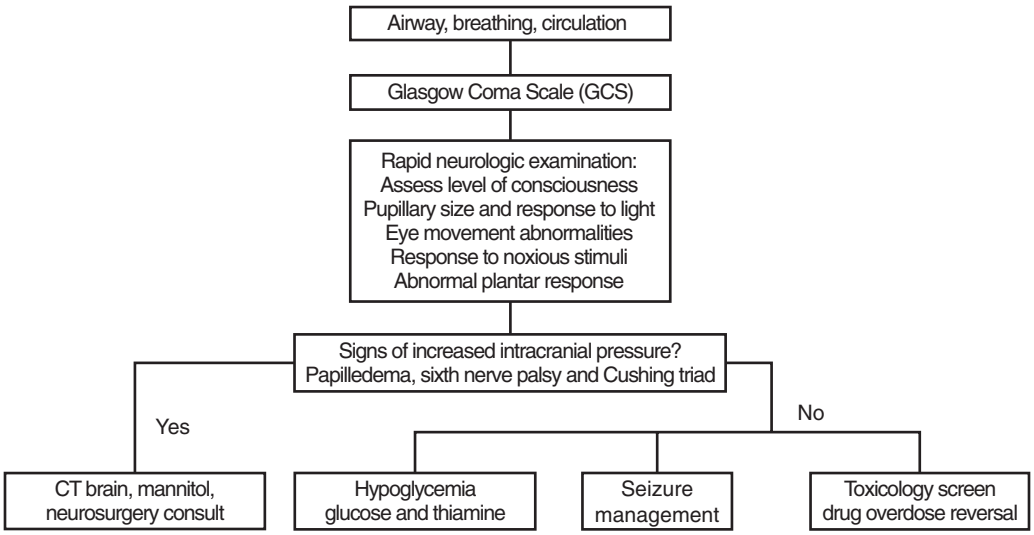
following categories: mass lesions, trauma, hypoxia/ischemia, encephalitis, and metabolic derangements. Each category is characterized by unique findings, as summarized in Table 58.2 and discussed further in later text. A neuronal-level mechanism has been proposed that outlines the transitions that occur from coma to less severe forms of disordered consciousness. This mesocircuit model illustrates the downregulation that occurs in the anterior forebrain secondary to widespread neuronal injury.[18,19]

Assessment and Acute Management of Coma

The initial approach to stupor and coma is based on the principle that all alterations in arousal are acute, life-threatening emergencies (Fig. 58.2). Interventions must be performed urgently in order to prevent or minimize permanent brain damage from reversible



• **Fig. 58.2** Natural course of acute coma.



• **Fig. 58.3** Management of acute coma.

causes. Patient evaluation and treatment must occur simultaneously (Fig. 58.3). Serial examinations with accurate documentation are necessary to determine a change in the patient's status. Accordingly, therapeutic management decisions must be made. The clinical approach to an unconscious patient entails the following steps:

1. Performing an initial assessment and providing appropriate emergency treatment
2. Obtaining a history from relatives, friends, and emergency medical personnel
3. Performing a thorough physical examination
4. Assigning a neurologic profile as this is the key to categorizing the nature of coma
5. Initiating specific therapeutic management relevant to the underlying cause of the patient's coma

Initial Assessment and Emergency Treatment

Initial assessment must focus on vital signs to determine appropriate resuscitation measures; in-depth diagnostic evaluation can occur later. Urgent and sometimes empiric therapy must be administered to avoid additional brain insult. While obtaining venous access, blood samples should be collected for anticipated tests (see Fig. 58.3).

Initial Assessment

A brief neurologic examination is mandatory. Signs of arousal include dilated and reactive pupils, copious tears, diaphoresis, tachycardia, and systemic hypertension. Although originally developed for assessment of patients with head trauma, the Glasgow Coma Scale (GCS) score can be derived by rapid bedside assessment and is useful for expedited assessment of level of consciousness (Fig. 58.4). Key points of a rapid neurologic examination are as follows:

- Assessment of level of arousal and level of consciousness (i.e., coma, stupor, lethargy)
- Checking pupillary size and response to light
- Assessing for abnormalities of eye movements (i.e., dysconjugate, unilateral paralysis, reflexive only, no movements)

Eye response (E)	Open spontaneously	4
	Open to verbal command	3
	Open in response to pain	2
	No response	1
Verbal response (V)	Talking and oriented	5
	Confused speech/disoriented	4
	Inappropriate words	3
	Incomprehensible sounds	2
	No response	1
Motor response (M)	Obeys commands	6
	Localizes to pain	5
	Flexion/withdrawal	4
	Abnormal flexion	3
	Extension	2
	No response	1
	TOTAL	3–15

Mild TBI	14–15
Moderate TBI	9–13
Severe TBI	3–8

• **Fig. 58.4** The Glasgow Coma Scale. *TBI,* Traumatic brain injury.

- Detecting grimacing and motor responses to noxious stimulation
- Observing an abnormal plantar response (Babinski sign)

Oxygenation and Intubation

Oxygenation must be ensured by establishing an airway for ventilation of the lungs. However, only after a brief neurologic examination has been performed should any sedative or paralytic for intubation be administered. The threshold for intubation should be low in a patient with altered mental status, even if respiratory function is sufficient for proper ventilation and oxygenation. The patient's level of consciousness may deteriorate or already be at a point at which airway reflexes are compromised. The patient's respiratory status may therefore decompensate suddenly and unexpectedly. A patent airway must be secured and protected from aspiration of gastric contents and blood. A nasogastric tube should be placed at the time of intubation to facilitate gastric lavage and decompression and to provide a route for administering oral medications. Indeed, a recent study found that early placement of a nasogastric tube does not increase risk of pneumonia, mortality, or poor functional outcomes in patients with stroke.[20]

If severe neck injury has not been excluded, intubation should be performed by the most skilled practitioner using in-line stabilization to avoid extension of the patient's neck, which may result in exacerbation of a cervical spine injury such as paralysis. Until the airway is secure with an endotracheal tube, bag-valve-mask ventilation should continue during the examination if necessary.

The preferred route of emergency intubation is orotracheal. Because laryngoscopy and placement of a tracheal tube is very stimulating, the patient may exhibit an intense, reflexive sympathetic nervous system response. In addition to hypertension and tachycardia, there is risk of a deleterious elevation of intracranial pressure (ICP). Therefore the patient should be adequately sedated. Etomidate (0.3 mg/kg intravenous [IV] push over 30–60 seconds) is the preferred sedative in patients with suspected ICP elevation as it reliably facilitates induction in less than 1 minute with a duration of action of 4 to 6 minutes. Propofol (1 mg/kg up to 2.5 mg/kg IV push every 10 seconds until induction onset) is another anesthetic agent that does not increase ICP. However, the use of propofol is often limited by its hypotensive effects, which can ultimately decrease cerebral perfusion pressure. Both medications result in a dose-dependent decrease of cerebral metabolic rate that reduces cerebral blood flow (CBF) and ICP. Ketamine (1.5–2 mg/kg slow IV) has a fast onset but may elevate ICP and cause paralysis, which should generally be avoided. Midazolam can alter the patient's mental status and may preclude a postintubation examination.

Respiration/PEEP

Generally, to rapidly decrease ICP, one should hyperventilate the patients (to reduce CBF), elevate the head of the bed (to facilitate cerebral venous return), and administer mannitol (0.25–1 g/kg as a 20%–25% solution bolus or in a pressure bag with filter over 30 minutes) or 23.4% sodium chloride (NaCl; 30 mL IV push over 2 minutes or IV piggyback over 10 minutes). However, in the setting of continuous cerebral spinal fluid (CSF) drainage, investigators have shown that transient hypercapnia and subsequent increases in CBF may be beneficial for patients with cerebral ischemia secondary to aneurysmal subarachnoid hemorrhage.[21]

The effect of positive end-expiratory pressure (PEEP) on ICP is only partly predictable for a number of reasons. Lung and pleural pressures are transmitted to the CSF column through intervertebral spaces and the vertebral venous plexus, and to the jugular venous

system through the superior vena cava. The effect of PEEP on ICP depends on both intracranial and pulmonary compliance and changes over time. ICP responses are not limited to PEEP but also relate to mean airway pressure, which can be elevated by many factors other than PEEP, including peak airway pressure and inspiratory time. Furthermore, the position of the patient's head and upper body can significantly affect ICP.

Circulation

Circulation must be maintained at a level that ensures adequate cerebral perfusion pressure (CPP). An arterial line may be placed in the radial artery for continuous blood pressure management and so that infusions administered for blood pressure control may be titrated to goal. An initial systemic mean arterial pressure (MAP) of approximately 100 mm Hg is adequate and safe for most patients (unless intracranial bleeding is suspected). Because CPP equals the difference between MAP and ICP, CPP-matching ICP therapy targets a CPP from 60 to 70 mm Hg in most instances. Invasive ICP monitoring is mandatory if ICP elevations are suspected. Hypotension may be treated by replacing blood and volume losses, and vasoactive agents may be used (if volume and cardiac status is adequate) to maintain target MAP and systolic blood pressures. In any patient with suspected brain injury, resuscitation fluids include isotonic solutions such as Normasol (Pfizer, Groton, Connecticut) or Plasma-Lyte (Baxter International, Deerfield, Illinois). Note that 0.9% sodium chloride solutions are slightly hypertonic (308 mOsm/L), and lactated Ringer solution is slightly hypotonic (273 mOsm/L). Norepinephrine infusions (1–40 μg/min IV infusion; titrate to effect) are often used as initial, first-line blood pressure–supporting agent. Hypertension should be aggressively managed with IV antihypertensive agents that do not elevate ICP by their vasodilatory effects. Thus labetalol and nicardipine are generally preferred and commonly used for managing uncontrolled hypertension. In most cases, including in patients with intracranial hemorrhage, systolic and diastolic blood pressures of less than 160 and 90 mm Hg, respectively, are tolerated and maintained. Urine output should be carefully observed as a surrogate of organ perfusion, with a goal of at least 0.5 mL/kg per hour. Accurate measurement of urine output requires bladder catheterization.

Glucose and Thiamine

Hypoglycemia is a frequent cause of altered consciousness and also leads to secondary brain injury if uncorrected. Glucose (25 g as a 50% dextrose solution) should be administered intravenously and immediately after blood is drawn for baseline values, as the benefits of empiric glucose in preventing possible hypoglycemic brain damage outweigh the risk of hyperglycemia. Thiamine (100 mg) may be given with the glucose infusion to prevent precipitation of Wernicke encephalopathy as seen in malnourished, thiamine-depleted patients receiving glucose infusions. In rare circumstances, an established thiamine deficiency can cause coma.

Seizures

Repeated generalized seizures invariably lead to secondary brain injury and should be treated aggressively with an IV benzodiazepine. Lorazepam (4-mg doses administered at 2 mg/min) has become the preferred agent owing to its longer duration of action; however, diazepam and midazolam are effective alternatives. Subsequent seizure control is maintained with an IV antiepileptic. Although there is no proven drug of choice, first-line agents generally include phenytoin (15–20 mg/kg IV bolus at a maximum rate of 50 mg/min), fosphenytoin (15–20 mg phenytoin sodium equivalents [PE]/kg IV bolus at a maximum rate of 150 mg/min), levetiracetam (1g IVP), or valproic acid (20–40 mg/kg IV bolus).[22] Fosphenytoin is often selected because of its faster rate of administration and lower risk of hypotension (as it is not formulated with propylene glycol). Phenobarbital (15–20 mg/kg IV bolus at a maximum rate of 100 mg/min) often requires intubation. Blood samples for drug levels of these agents should be drawn after the loading dose and maintenance dosing should be initiated. Corrected total target levels for phenytoin (and fosphenytoin) are 15 to 20 μg/mL; free levels can be drawn in patients who are critically ill or have low protein stores with a target of 1.5 2 μg/mL. Valproic acid target levels are 50 to 100 μg/mL, and phenobarbital target levels are 10 to 40 μg/mL. Seizure breakthrough requires immediate administration of benzodiazepines and loading of a second anticonvulsant. Continuous video EEG monitoring is frequently used to detect nonconvulsive seizures.

Sedation and Paralysis

Sedation is often required to facilitate comfort with respiratory support, to counteract agitation, or to treat elevated ICP. Short-acting medications administered as continuous infusions such as propofol or dexmedetomidine are preferred. However, deeper sedation, especially in patients with seizures, may require a midazolam infusion. Owing to accumulation of its active metabolite in patients with renal dysfunction, extended durations of midazolam should be avoided or interrupted if possible. Sedation should be titrated to a predefined goal using a validated sedation scale. The Richmond Agitation Sedation Scale is commonly used and a goal range of 0 (alert and calm) to −2 (light sedation, briefly awakens with eye contact to voice) is appropriate for most patients. Hourly interruption of sedation is needed to obtain serial neurologic examinations, except in paralyzed patients or those in whom awakening leads to deterioration of ICP. Additional analgesia (i.e., IV intermittent morphine [2–4 mg every 3–4 hours]) or a fentanyl infusion is often needed in postoperative patients or patients with traumatic injuries. Patients with critically high ICP should be paralyzed as part of the treatment regimen for increased intracranial hypertension; however, this should be done only after initiation of both a sedative and analgesic.

Reversal of Drug Overdose

Drug overdose is the largest single cause (30%) of coma in the emergency department.[23] Most drug overdoses are treated by supportive measures alone. Certain antagonists, however, specifically reverse the effects of coma-producing drugs. The μ-receptor antagonist naloxone (0.4–2 mg) is used as "test" antidote for opiate-induced coma and may be administered intravenously, intramuscularly, or subcutaneously. Caution is needed as the reversal of opioid effect may precipitate acute withdrawal in an opiate addict. In suspected opioid coma, the minimum naloxone dose (not complete reversal) should be given to establish the diagnosis by pupillary dilation and to reverse depressed breathing and consciousness. Because of its short half-life, patients who respond to naloxone reversal may require additional doses or a continuous infusion to avoid rebound sedation and respiratory depression.

IV flumazenil antagonizes benzodiazepine-induced coma and can be administered in 0.2-mg doses every minute for a maximum of 1 mg. In patients who initially respond to flumazenil reversal but experience recurrent sedation, flumazenil 1 mg may be redosed every 20 minutes with a maximum of 3 mg/h. Careful consideration should be given before administration of flumazenil as patients may experience benzodiazepine-withdrawal seizures. Thus, although

naloxone is commonly used with minimal serious adverse effects, the use of flumazenil should be restricted to select, low-risk cases.

The sedative effects of drugs with anticholinergic properties, particularly tricyclic antidepressants, can be reversed with 1 to 2 mg IV physostigmine (duration of action ~45–60 minutes). Pretreatment with 0.5 mg atropine will reduce the risk for symptomatic bradycardia. Of note, only full awakening is characteristic of an anticholinergic drug overdose because physostigmine has nonspecific arousal properties.

Body Temperature

Hyperthermia increases brain metabolic demands and may exacerbate brain injury.[24] Elevated temperature greater than 104°F (40°C) requires immediate, life-saving cooling measures, even before the underlying cause is determined and treated. In 2002, two research groups independently published that lowering the body temperature to 33°C for 12 or 24 hours in comatose survivors of cardiac arrest resulted in nearly doubling the number of patients who were discharged home or to rehabilitation. Modern technology provides a variety of noninvasive and invasive cooling equipments suitable to maintain any target core temperature desired. Core temperatures of less than 93°F (34°C) on admission should be slowly elevated to above 35°C to reduce the risks of unwanted side effects from uncontrolled, persistent hypothermia.

Patient History

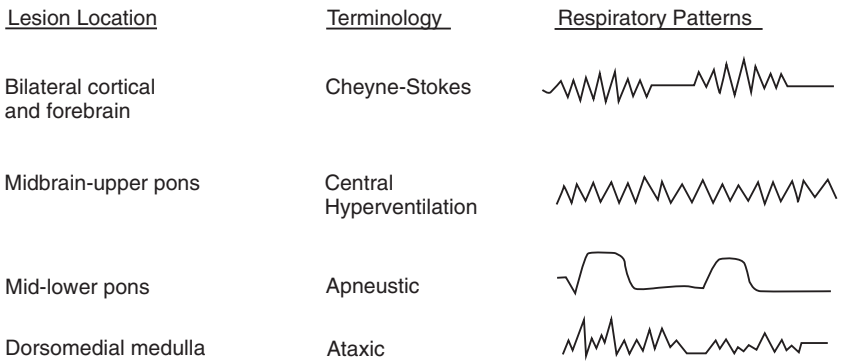
Once the patient's condition and vital signs have been stabilized, clues to the cause of coma should be sought by interviewing relatives, friends, bystanders, or medical personnel who may have observed the patient before or during the decline in consciousness. The history should address witnessed events, evolution of coma, recent medical and surgical histories, and medication/drug intake.

Thorough Physical Examination

A systematic, detailed examination is necessary when approaching a comatose patient. An in-depth physical and neurologic examination followed by serial neurologic evaluations (i.e., hourly) is the most important, indispensable, and most readily available method of assessing a comatose patient. However, in comatose patients the examination remains limited in detecting changes in brain function. Nevertheless, the astute clinician will carefully evaluate for changes in findings—that is, appearance of new asymmetry in examination or focal deficits, progressive loss of brainstem reflexes, or loss of reflex motor responses. Finding progression of impairment is of immense clinical value as it indicates a new or worsening "intracranial emergency" demanding immediate clarification and stabilization. Performing a skilled neurologic examination is challenging and provides a limited surveillance window of brain tissue at risk. Intracranial monitoring and, if needed, repeated head imaging have become the standard of care in neurocritical care units.

The differential diagnosis of a comatose patient is supported by the patient's risk factor profile, activity at symptom onset, and disease progression. For example, acute, devastating headaches with nausea and vomiting quickly followed by impaired consciousness in a hypertensive patient with a history of smoking should prompt a rapid workup for subarachnoid or intracerebral hemorrhage. Deterioration of consciousness hours after head injury necessitates immediate exclusion of newly emerging, delayed intracranial hematoma with ICP pressure crisis. In contrast, the slow progression of a focal neurologic deficit evolving to generalized depressed consciousness in an elderly individual directs diagnosis toward an intracranial metastasis with secondary seizures. Increased ICP is a common symptom seen in many acute and subacute central nervous system (CNS) injuries. Typical manifestations include headaches from the dural stretch of trigeminal (CN V) sensory fibers; intractable nausea and recurrent vomiting often associated with visual disturbances; some neurologic deficits on detailed examination; and in later stages, reduction in level of alertness.

When the neurologic examination is performed, vital signs should be considered as part of the autonomic nervous system evaluation. For example, the appearance of systolic hypertension, vagal bradycardia, and respiratory irregularity is known as the Cushing triad and indicates increased ICP. In addition, changes in the pattern of respiration in a spontaneously breathing patient can help localize the level of injury (Fig. 58.5). Abnormalities of respiration can range from apnea to hyperpnea with undulating crescendo-decrescendo patterns as well as complete irregularity of breathing with erratic pauses, which finally terminate in complete apnea. This "autonomic survey" is followed by the assessment of a patient's level of arousal. The reduction in response to external stimulations provides the basis for commonly used classification schemes such as the GCS (see Fig. 58.4). If the patient's level of alertness permits, then orientation, attention, concentration span, and intactness of cognitive functions are examined next. This is followed by a detailed assessment of CN, motor, and peripheral reflex status. Optic nerve (CN II) head edema (papilledema) is an important and, if present, reliable manifestation of raised ICP. Additional findings of increased ICP on fundoscopy include venous engorgement, loss of venous pulsation, optic disc hemorrhage with increased disc diameter, and blurring of disc margins. Compression of the oculomotor nerve (CN III) may result from a variety of intracranial processes, including uncal herniation and aneurysms



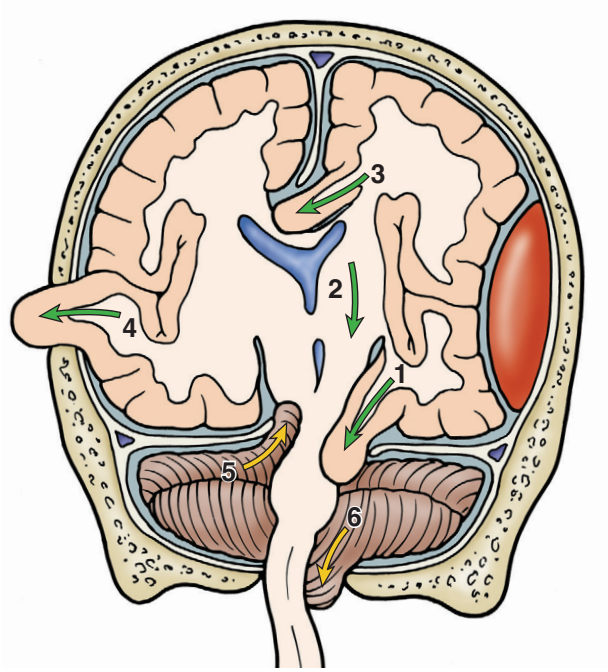
• **Fig. 58.5** Locations of lesions and patterns of respiration.

of the posterior communicating artery. It is identified by pupillary dilatation, ptosis, and various degrees of ophthalmoparesis except for abduction and intorsion-depression. A sixth nerve (abducens nerve) palsy, typically a nonlocalizing sign, is identified by abduction deficit and is seen in patients with elevated ICP or hydrocephalus and stretching of the nerve, but it is also present in patients with intrinsic brainstem injury (i.e., strokes).

Patients with acute intracranial mass lesions and increased ICP commonly develop herniation syndromes—that is, shifting of brain tissue from areas with higher regional ICP toward areas with normal ICP. If the mass lesion is predominantly located within one hemisphere, the main force vector will shift the brain primarily laterally across the midline and toward the opposite hemisphere as it impresses on the upper brainstem and thalamic structures during lateral displacement. More centrally located mass lesions—that is, acute, obstructive hydrocephalus, or global brain swelling as seen in fulminant encephalitis or hepatic encephalopathy—will instead lead primarily to downward herniation with the main force vector impressing on the brainstem. Different herniation syndromes have different clinical presentations and therapeutic approaches (Fig. 58.6). Readers are referred to Table 58.3 for further details. When intracranial hypertension remains uncontrolled and escalates, uniformly central, downward herniation occurs, increasing involving more brainstem structures in a rostrocaudal fashion. The terminal event is complete brainstem destruction resulting invariably in brain death. During this course, progressive loss of brainstem reflexes can be determined on examination and at this stage, the patient is deeply comatose. Injury to the trigeminal nerve nucleus within the pons results in loss of the corneal reflex. A vestibulocochlear (CN VIII) nerve nucleus compromise results in loss of the oculocephalic reflex and manifests as "doll's eyes" or the inability to maintain eye position as the head moves. Medullary injury with damage to the ninth and tenth nerves results in loss of lower CN reflexes, including absence of gag and cough reflexes.

Ipsilateral hemiparesis indicates the possibility of uncal herniation causing compression of the contralateral cerebral peduncle as temporal lobe tissue herniates into the space between the tentorium and brainstem. For example, a left-sided subdural hematoma causing temporal herniation pushes the opposite cerebral peduncle and its motor fibers against the right tentorial edge (right-sided Kernohan notch) leading to a hemiparesis on the same side as the hemispheric lesion (see Fig. 58.6).

Posturing is involuntary flexion or extension of the arms or legs spontaneously or elicited by stimulation, and it is included in the GCS as a measure of the severity of brain injury. Three types of posturing can be observed depending on the level of brain injury: decorticate (flexor), decerebrate (extensor), and opisthotonos (body arching along the craniospinal axis) posturing. Injury involving the brainstem above or below the red nucleus in the midbrain leads to decorticate and decerebrate posturing, respectively. Of note, flexion or extension can be witnessed either unilaterally or bilaterally, sometimes seen only intermittently and can involve one or all extremities. Decorticate posturing commonly indicates damage of the cerebral hemispheres, the internal capsule, and the thalamus, possibly also involving the uppermost brainstem. Decerebrate posturing is involuntary extension of both upper (elbow) and lower extremities indicating brainstem damage below the midbrain. Progression from decorticate to decerebrate posturing is indicative of progressive transtentorial herniation. Opisthotonic posturing is an infrequently encountered sign seen with severe brainstem injury or extrapyramidal lesions involving the axial muscles. Importantly, increasing downward pressure leads to dysfunction first at the level of the diencephalon (i.e., thalami), next affecting the upper and middle sections of the brainstem (midbrain and pons), and ultimately impeding medullary function, leading to deep coma without any reflexes or motor responses (flaccidity). Once complete rostrocaudal herniation has occurred the patient is brain dead.



• **Fig. 58.6** Herniation syndromes.

Assigning a Neurologic Profile

Correctly characterizing disorders of consciousness continues to pose interesting clinical questions and diagnostic challenges with important ethical consequences. Not only may an individual patient acutely fluctuate in his or her examination findings, but recovery may also take place over prolonged time periods necessitating frequent reassessments. To address this uncertainty, standardized neurobehavioral assessments have become the best tool in categorizing coma and its transitional stages. Predicting long-term outcome has significantly improved when standardized assessments are used. Generally speaking, clinical and electrophysiologic markers of coma and its transitional states remain unsatisfactory. Readers are reminded that larger observational studies identified a high rate of misdiagnoses (>40%), especially in patients in vegetative state, when assessment is made on clinical grounds only.[25]

Standardized Neurobehavioral Assessment

The behavioral diagnosis of the level of consciousness in severely brain-damaged patients remains challenging. To improve differential diagnostic evaluations, evidence-based recommendations endorse neurobehavioral characteristics using standardized tools.[25] The Coma

TABLE 58.3 Types of Brain Herniation Syndromes

Syndrome	Mechanism	Imaging Findings	Clinical Presentation
Uncal	• Downward displacement of medial temporal lobe into the posterior fossa through the incisural opening • Seen in patients with unilateral hemispheric mass lesions	• Contralateral temporal horn widening • Ipsilateral ambient and prepontine cistern widening • Uncus extending into the suprasellar cistern	• Ipsilateral pupil dilation and ophthalmoplegia • Contralateral or ipsilateral hemiparesis • Decerebrate posturing
Central (transtentorial)	• Downward displacement of cerebral hemispheres and basal nuclei compressing and displacing diencephalon and midbrain rostrocaudally through the tentorial notch	• Effacement of the sulci • Obliteration of the suprasellar cistern • Compression and posterior displacement of the quadrigeminal cistern	• Medium-sized, fixed pupils • Early coma • Decorticate posturing • Cheyne-Stokes respiration • Diabetes insipidus
Cingulate (subfalcine)	• Lateral displacement of the cingulate gyrus under the anterior falx	• Attenuation of ipsilateral aspect of frontal horn • Asymmetric anterior falx • Obliteration of ipsilateral atrium of lateral ventricle • Septum pellucidum shift	• Small reactive pupils • Headache • Contralateral leg paralysis
Ascending	• Infratentorial mass effect protruding through the tentorial opening compressing the midbrain and cerebellar structures at the tentorial edges	• Spinning top appearance of midbrain • Narrowing of bilateral ambient and quadrigeminal cisterns	• Progressive stupor • Nausea and vomiting
Tonsillar	• Cerebellar tonsils protruding into the foramen magnum compressing adjacent medulla and upper cervical cord	• Cerebellar tonsils at the level of the dens on axial view and 5 mm below foramen magnum on sagittal view (7 mm in children)	• Cushing triad • Coma • Bilateral arm dysesthesia

Recovery Scale-Revised (CRS-R) has excellent content validity and is a solid tool addressing all established differential diagnostic criteria. To differentiate vegetative MCS from emerging MCS, several other tools have demonstrated good validity, including the Sensory Modality Assessment and Rehabilitation Technique (SMART), Sensory Stimulation Assessment Measure (SSAM), Wessex Head Injury Matrix (WHIM), and Western Neuro Sensory Stimulation Profile (WNSSP). The Full Outline of UnResponsiveness (FOUR) and CRS-R tools showed substantial evidence of good interpreter reliability. Our recommendations are to use the CRS-R as a valid and reliable tool in most situations for differential diagnostic assessments. With reservations, the SMART, WNSSP, SSAM, WHIM, and Disorders of Consciousness Scale can be used.[26] The lack of evidence with respect to content validity, standardization, and reliability make the FOUR, Innsbruck Coma Scale, GCS, Swedish Reaction Level Scale-1985, Loewenstein Communication Scale, and Comprehensive Level of Consciousness Scale undesirable.[26]

Neuroimaging

Improvements in neuroimaging have rendered these studies more useful in determining an accurate diagnosis and prognosis for patients in a coma. Indeed, combining structural and functional imaging with a thorough standardized coma assessment seems to provide the best estimates for long-term outcome. Advanced neuroimaging studies have provided considerable evidence for the existence of major functional differences between the vegetative state and the minimally conscious state (Table 58.4). For example, positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies delineated more extended cerebral processing in response to various external stimuli in patients with MCS. Resting-state fMRI studies identified that MCS patients have preservations of functional connectivity to higher-order associative cortices, such as default networks.[27–29] Complementary to these results, brain tissue integrity, as assessed by diffusion-weighted imaging and gray matter volumetry, is more preserved in MCS compared with a vegetative state.[29,30] These findings correlate to the relative improved long-term prognosis in MCS.[31]

MRI remains the procedure of choice for structural and functional imaging of the brain. Further experience with MR tractography, estimating the extent of brain connectivity, and MR spectroscopy, evaluating regional neuronal chemistry, will continue to enhance outcome predictions in patients with severe brain injury. In addition, passive, active-response, and resting-state functional MRI paradigms are currently being validated to help in differentiating impaired states of consciousness.

Conventional MRI

Commonly available morphologic MRI acquisitions include non–contrast-enhanced sagittal T1, axial diffusion, axial fluid-attenuated inversion recovery (FLAIR), axial T2 spin echo (SE), and coronal T2* (or gradient echo) sequences as well as three-dimensional (3D) T1-weighted volume acquisitions. FLAIR and T2-SE sequences are commonly used to delineate, measure, and monitor the extent and impact of acute brain injury. Common

TABLE 58.4 Neuroimaging and Electrophysiologic Techniques and Findings in Disorders of Consciousness

Technique	Measurement	Strengths	Limitations	Vegetative State	Minimally Conscious State	Comatose
FDG-PET	Metabolic	Relatively direct measure of neuronal energy use (glucose uptake)	Ionizing (limited repeated measures)	Voxel-based: Hypometabolism in lateral and medial frontoparietal cortices	Metabolic dysfunction in left hemisphere	
Functional MRI	CBF	High-resolution structural imaging of grey-white matter (DTI) and functional imaging (spectroscopy, resting, passive, and active CBF paradigms)	Sensitive to movement artifacts requiring sedation/anesthesia Incompatible with ferromagnetic material (deprivation, pumps, electrodes)	Activation fMRI: Low-level cortical activation DMN—partially preserved	Activation fMRI: Near-normal high-level cortical activation	
EEG/ERPs	Electrical	Repeatable, portable, and inexpensive	Muscle, eye, and dysautonomia artifacts Challenging source reconstruction		EEG: slow-wave activity through night and periods of REM sleep	ERP-poor outcome with absence of a cortical response to electrical stimulation of median nerves
EEG-TMS	Electrical	Stereotaxic stimulation connectivity studies	Stimulation areas are limited by muscle artifacts	TMS triggers a simple, local EEG response similar to deep sleep/anesthesia	Complex activations in distant cortical areas	

CBF, Cerebral blood flow; *DMN,* default model network; *DTI,* diffuse tensor imaging; *EEG,* electroencephalogram; *ERPs,* event-related potentials; *FDG,* ^{18}F-fluorodeoxyglucose; *fMRI,* functional magnetic resonance imaging; *REM,* rapid eye movement; *TMS,* transcranial magnetic stimulation.

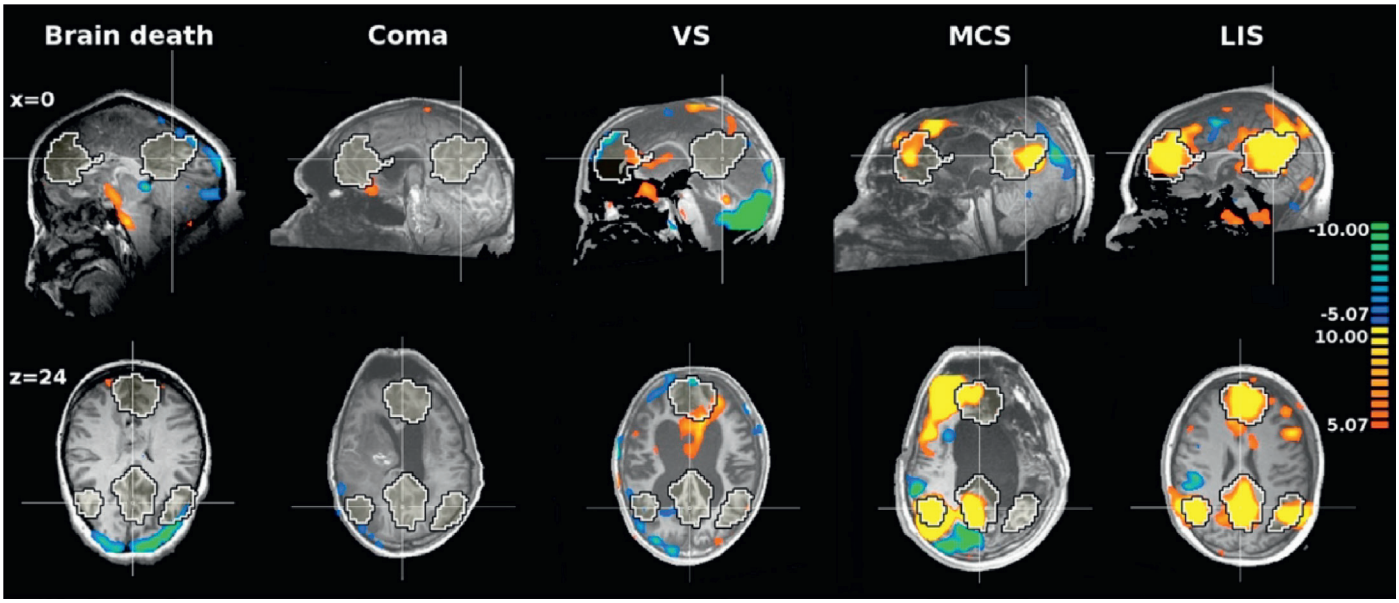
pathologies detected include brain edema, contusions, intracerebral, dural or subarachnoid blood, herniation syndromes, and hydrocephalus. T2* and susceptibility-weighted imaging are useful in detecting blood and hemorrhagic diffuse axonal injuries (DAI). Diffusion tensor imaging (DTI) can be viewed as an extension of diffusion-weighted imaging where diffusion-restricted water molecule movement (i.e., water trapped in ischemic cells or, in DTI, confined to axonal spaces) is preferentially visualized. As with most conventional MRI techniques, obtaining results with DTI is independent of the coma or sedation status of a patient.[33] Serial changes in white matter DTI metrics can be used as surrogate markers to evaluate treatment responses even when clinical scores cannot be obtained.[30] Whole brain white matter and regional DTI measures have become sensitive markers of traumatic body injury (TBI) impact correlating with acute and discharge injury severity, especially when adjusted for age, gender, and admission GCS score.[32,33] Three-dimensional rendering allows evaluating and quantifying brain atrophy after injury.[34]

Proton Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) reveals metabolic information of targeted brain regions, which correlates with the functional neuronal state of the examined sample region. To assess brain function, comprehensive MRS protocols using axial chemical shift imaging at the level of the cortical white matter,[35,36] splenium,[37] basal ganglia,[38] insular cortex, and pons[39] have been used. This approach enables detection of posttraumatic neurochemical damage and neuronal dysfunction in brain areas where conventional MR imaging techniques show no abnormalities.[40] In a TBI case-control study, the *N*-acetyl-aspartate (NAA)/creatinine (Cr) ratio correlated as a good neuronal marker with the overall recovery (and therefore lack as reliable index of unfavorable outcome after TBI), whereas less consistency was found using the choline (Cho)/Cr[41] or NAA/Cho ratios.[42] Moreover, early posttraumatic spectroscopic assessment of axonal damage is clinically relevant for prognostication and significant increases in brain lactate levels seem to be a dependable index of injury severity and outcome in TBI.[43]

Positron Emission Tomography

PET is a nuclear medicine, functional imaging technique that produces a 3D image of functional processes in the body. Using a radiopharmaceutical agent such as 18-fluorodeoxyglucose (FDG), glucose utilization may be evaluated, providing insights in neuronal metabolism that correlate with regional functional performance. For example, in acute vegetative state, overall glucose utilization was significantly reduced to 50% to 70% compared with age-matched healthy controls.[44] As expected, patients with locked-in syndrome (i.e., pontine lesions) showed normal cortical metabolism. Patients with TBI who had diffuse axonal injury had neuronal hyperglycolysis and metabolic depression.[45] Carbon 1 (^{1}C)-flumazenil-PET measures the density of benzodiazepine receptors, providing an estimate of neuronal integrity. Oxygen-15 H_2O (^{15}O-H_2O) PET imaging delineates activation-induced changes in regional CBF in response to passive external (auditory,



• **Fig. 58.7** Functional magnetic resonance imaging studies on the default/internal network of patients with brain death, coma, vegetative state *(VS)*, minimally conscious state *(MCS)*, and locked-in syndrome *(LIS)*. The black-and-white contour represents a template of the internal network extracted from 11 awake, healthy subjects. *Yellow* and *orange* areas represent activities that positively correlate with the time course of the internal network. There is decreased corticocortical connectivity in patients with disorder of consciousness and an absence of connectivity in brain death. Precuneus connectivity was significantly stronger in patients with MCS compared with patients in a VS. Patients with LIS were not significantly different from healthy control subjects. (From Noirhomme Q, Soddu A, Lehembre R, et al. Brain connectivity in pathological and pharmacological coma. *Front Syst Neurosci.* 2010;4:160.)

somatosensory or visual) stimulation. The combination of preserved activation of primary cortices (i.e., visual) but lack of coactivation of secondary processing areas provides evidence that "higher-order" associative cortical networks are disconnected from the primary sensory cortex.[46–51] Thalamocortical disconnections have also been reported using this technique.[52]

Functional MRI

fMRI imaging provides activity measures of brain regions at rest and after both passive (internal, thought-induced) and active (external, command-induced) stimulation (Fig. 58.7).[52] Such acquisitions can obtain estimates of average metabolic activity in relatively short time periods (i.e., 10 minutes) compared with PET (~30 minutes).[53] fMRI has been shown to be a good predictor of outcome in patients with impaired consciousness.[54–59] Evidence from PET studies of preserved but isolated (disconnected) cortical activation areas in patients in a vegetative state (discussed earlier) was corroborated by fMRI.[60–65]

Electrophysiology

Although a single EEG study can be a helpful diagnostic tool (i.e., to identify seizures), diagnostic certainty improves with continuous or serial EEG monitoring. Reactivity—the increase in brain wave frequencies with patient stimulation—has been used to assess thalamocortical function. For example, a patient with renal or hepatic dysfunction may have slowed background rhythms with triphasic waves and rather preserved or absent reactivity. Cerebral hypoxia, drug intoxications, sedative medications, and other CNS depressants produce abnormal EEG patterns, including burst suppression, alpha coma, and spindle coma. Focal EEG slowing with or without evidence of abnormal excitability (i.e., focal spikes) can be found in comatose patients with structural lesions, either focal cortical, focal deep-seated diencephalic or mesencephalic reticular formation, or diffuse bihemispheric. Furthermore, EEG is the primary diagnostic tool to identify patients with impaired consciousness caused by nonconvulsive seizures or status epilepticus.

Interpreting EEG can be challenging for anyone not trained in neurophysiology. However, despite the numerous etiologies leading to coma, EEG in coma patients is dominated by a few stereotypic patterns generally providing good indicators of the depth of the coma. Separating three common themes of interpretations will aid the nonexpert in using EEG for diagnosis and prognosis in patients with disorders of consciousness. EEG findings can be categorized into responsiveness (reactivity to acoustic, painful and photic stimuli), brain wave frequency abnormalities (focal or global), and specific EEG patterns (i.e., seizure discharges). The common EEG findings are discussed next.

In patients with alpha coma, the underlying brain wave activity is predominantly in the (normal) alpha range, from 8 to 12 Hz. In contrast to the normal EEG in a healthy, awake person, the EEG pattern found in comatose patients lacks alpha reactivity, implying a significant disturbance of thalamocortical pathways. Three major brain injury categories have been observed in alpha coma: status postcardiorespiratory arrest (anoxic encephalopathy), toxic encephalopathies, and de-efferentiated (locked-in) state (i.e., pontine hemorrhage).[66,67]

Patients with theta coma and alpha-theta coma show slower brain wave activities in the theta 4- to 7-Hz range (theta coma), which in some is superseded by a predominance of alpha activity (alpha-theta coma).[66] In many comatose patients, the alpha and

theta activities change after about 5 days to a more permanent pattern, at which time the EEG may be uniformly slow and depressed. EEG reactivity may emerge in subsequent studies as a relatively favorable sign; however, resolution into a burst-suppression pattern without reactivity signifies unfavorable outcome after anoxic encephalopathy.[68]

Beta coma consists of fast activities in the 12- to 16-Hz range, usually with frontal predominance. Interspersed alpha, theta, delta, and spindle (sleep)-like activities can be found. The most frequent cause for beta coma is sedative-hypnotic overdose, such as benzodiazepines and barbiturates.[69]

Intermittent rhythmic delta activity consists of low-amplitude, slow 2- to 3-Hz sinusoidal waves. These waves can appear intermittently during early stages of impairment of consciousness and soon after loss of alpha rhythm.[66] This nonspecific pattern can be seen in many metabolic and toxic encephalopathies, hemispheric lesions, acute brain injuries, and other conditions affecting cortical and subcortical structures diffusely. The prognosis of intermittent rhythmic delta activity depends on the underlying etiology.

Continuous high-voltage delta activity consists of arrhythmic, high-amplitude, polymorphic 1- to 2-Hz delta activity. This pattern is seen in later stages of coma and may evolve out of theta coma. This contrasts with the slow, nonreactive theta and delta coma EEG of low amplitude (<20 μV) and without reactivity.

Spindle coma consists of an EEG pattern predominated by 11- to 14-Hz spindle discharges, which are generally symmetric and synchronous, that appear as sleep-like oscillations on a background rhythm dominated by theta and delta activities. It resembles the EEG of a sleeping person and additional findings include anterior, low-voltage rhythmic bursts, K-complexes, vertex waves, and delta slowing. However, in these patients, wakefulness is not regained after stimulation and depth of consciousness does not fluctuate in spindle coma. These patterns indicate dysfunction at the brainstem level. TBI, anoxic encephalopathy, infectious encephalitis, drug-induced and metabolic encephalopathy, as well as postictal states can lead to this EEG finding.[70–72]

Periodic lateralized epileptiform discharges (PLEDs) occur asymmetrically (lateralized) and are episodic in nature. Morphologically, variations include sharp waves, spikes, slow waves, or a combination of these followed by a slow wave with a periodicity ranging from 0.3 to several seconds.[73] PLEDs are nonspecific and can be seen in a wide variety of brain injuries such as after cortical ischemia and with brain tumors. They are also associated with recent seizures, herpes simplex virus encephalitis, alcohol withdrawal and toxic-metabolic encephalopathy.[74] In contrast, generalized periodic epileptiform discharges are seen bilaterally and typically occur at a frequency below 1 Hz. Subclassifications define the interval between discharges and include periodic short-interval diffuse discharges, periodic long-interval diffuse discharges, and suppression-burst patterns.[75] GPEDs are seen after global brain injury—for example, after hypoxic or hepatic encephalopathy, drug intoxication, but also with various degenerative disorders.[75]

Bilateral independent periodic lateralized epileptiform discharges are slow (<1 Hz), bilateral independent epileptiform activity[76] seen in coma as the result of bihemispheric lesions. For example, after anoxic encephalopathy and infections, they are associated with a poorer prognosis[77] about two times higher overall mortality than patients with PLEDS.[76,78]

The burst-suppression pattern identifies an EEG demonstrating generalized, synchronous bursting of slow but mixed-frequency waves of high-voltage alternating periodically interspersing within longer periods of isoelectric (flat) EEG. It identifies abnormal cortical excitability,[77] and with deepening coma, the isoelectric periods become longer. The main etiologies include anoxic encephalopathy, severe intoxication, or sedative/anesthesia-induced coma states. The overall prognosis is determined by the underlying etiology.[79]

Triphasic waves are distinct, blunt delta waves (~2–3 Hz) consisting of a high-voltage positive wave preceded and followed by lower-amplitude negative waves. This nonspecific EEG can be seen in various brain injuries, among them serotoninergic syndrome, Creutzfeldt-Jakob disease, lithium and baclofen toxicity, hepatic and renal insufficiency, and neuroleptic malignant syndrome.[80]

Event-Related Potentials

Event-related potentials (ERPs) are EEG potentials identifiable after signal-averaging EEG-derived potentials evoked by a specific sensory, cognitive, or motor stimulus. Under normal circumstances, the brain generates event-related, neuronal (electrical) responses to stimulation. This neuronal activation can be detected by surface EEG; however, it requires specific mathematical processing of the EEG signal to identify brain oscillations that are time- and phase-locked to particular events (stimuli). Detection of such ERPs in patients with impaired consciousness has been interpreted as the brain's ability to process stimulus information and for cortical movement preparation. Advantages of this approach include detected signals that have an excellent time-stimulus correlation (within the millisecond range) helpful to relate a particular stimulus to certain cortical processing. The method is low-cost, noninvasive, and it can be used to monitor the brain function. Recently fast processors have allowed the development of brain-computer interfaces based on event-related signal responses that assist communication with brain-injured patients. Several ERP paradigms have been developed, allowing identification of specific response signals. The N1-P2 complex has been identified in visual ERPs and its presence interpreted as negative correlation to repressiveness.[81] The P300 (or P3) is an average, positive potential with a latency of about 300 msec. It is generated when a patient mentally reacts to a defined cognitive stimulus and is related to positive outcomes in coma.[82] Cognitive responses to command have been verified in patients with complete locked-in syndrome after basilar artery thrombosis.[83]

Brainstem auditory evoked responses (BAERs) are a series of seven potentials recorded at specific time intervals at the skull after defined auditory stimulation using headphones. Based on the redundancy and interconnections of the auditory pathways, BAERs are very robust and can be obtained in many patients with depressed level of consciousness, including patients under anesthesia or deep sedation. This implies that the absence of BAERs, or the lemniscal complexes III-IV reflecting the integrity of the upper brainstem, uniformly infers a poorer prognosis in coma (i.e., 3 to 6 days after head injury.[84] In addition, BAERs have been used as a "brainstem monitoring" tool to identify progressive downward brain herniation. Frequently, in clinical settings, BAER monitoring is combined with somatosensory evoked potential (SEP) and EEG monitoring. Somatosensory evoked potentials (SSEPs) are a series of peaks recorded over the neck and scalp in response to electrical stimulation of a peripheral nerve, usually the median nerve. The N13 wave is a negative peak at 13 msec, reflecting activity at the cervical cord, whereas the N20 wave is a negative peak at 20 msec, reflecting the earliest cortical activity. Longer latency responses are also seen at 25, 35, 45, 70, and 95 msec, reflecting higher cortical processing. Multimodality evoked potentials combine simultaneous brainstem auditory, somatosensory, and visual evoked potential monitoring[85]

to enhance the predictive value of evoked potential monitoring—for example, in TBI patients[86] or during induced barbiturate coma when examinations cannot be obtained.[87]

Cerebral Blood Flow Monitoring

Transcranial Doppler (TCD) records the velocity and pulsatility of CBF, allowing hemodynamic analysis, despite the use of sedatives or moderate hypothermia. TCD has been used for serial examinations in comatose patients after initial recovery from cardiac arrest to detect and treat early cerebral hemodynamic changes. If a patient has an appropriate temporal ultrasound window, TCD can determine cerebral perfusion arrest, and hence can be used as an ancillary study to determine brain death.[88] Further, velocity and pulsatility indices correlate as a noninvasive measure with ICP elevations and also identify delayed presence of a hyperemic flow pattern—that is, high velocities with low pulsatility as seen in patients with intracranial hypertension from hyperemia.[89]

Xenon computed tomography (CT) uses the diffusion of xenon into the CNS to determine CBF—for example, to assess perfusion deficits after a TBI.[90] Using hyperventilation, xenon CT can be used to estimate cerebral vasoreactivity, a marker correlating with outcome in comatose patients with TBI.[90]

Near-infrared spectroscopy is used to derive the levels of oxygen saturation by estimating deoxygenated and oxygenated hemoglobin in the brain. In TBI, near-infrared spectroscopy can be used to monitor the trend of deviation from the baseline cerebral oxygen saturation levels.[91]

Initiating Target Treatments Based on Etiology of Coma

General Treatment Approach

As discussed earlier, the immediate goals in a comatose patient are stabilization of vital signs, rapid diagnosis, immediate treatment to reverse the primary injury (i.e., recanalization of CBF) and minimization of further nervous system damage from secondary injury (i.e., brain swelling). These general goals are greatly facilitated by a team approach of medical and nursing staff with expertise in acute brain injuries. To improve outcome, subsequent management of a patient in a coma should be guided by the underlying etiology of the patient's brain injury, which is not always readily known.

It is important to keep in mind that *coma* is a descriptive term based on examination findings and it may result from a range of heterogeneous etiologies. Therefore first dividing coma into traumatic and nontraumatic etiologies can be useful, as each group is predominated by different demographics and disease prognoses.

Traumatic Etiologies of Coma

TBI, which is defined as physical injury to the head resulting in disruption of normal brain functioning, can manifest in severity from "mild" (i.e., transient alteration of mental status) to "severe" (i.e., coma). The leading causes of TBI include falls, being struck by or against an object, motor vehicle accidents, and assault.[92]

Therapeutic interventions after severe TBI should focus on blocking the primary injury process and preventing or reducing secondary brain injury. Primary injury in severe TBI includes hematoma formation, diffuse axonal injury after high-velocity injury (i.e., vehicle collisions, falls from a great height), and ischemic brain injury owing to traumatic vascular lesions (i.e., arterial dissection in the neck). Immediate arrest of the ongoing primary injury (i.e., by acute recanalization of a dissected arterial occlusion, reversing anticoagulation during ongoing intracerebral bleeding or hypoxia/hypotension) should be attempted whenever possible. Unfortunately, little can be done to treat or reverse the primary injury in TBI.

Secondary brain injuries after TBI are common and include brain edema with subsequent brain tissue shifts and reduction in cerebral perfusion pressure, formation of new hematoma, prolonged seizures, hypoxia, neurogenic/hypovolemic hypotension, uncontrolled hyperventilation, hypoglycemia, thromboembolism from venous thrombosis, and so on Therefore early TBI management strategies should focus on prevention and early recognition of such complications. A combination of intracranial (i.e., ICP, brain temperature, brain oxygen tension, and perfusion) and systemic monitoring as well as repeated neuroimaging is indicated in these patients.

Noncontrast CT is the most common imaging evaluation tool in patients with TBI. A cervical spine CT with reconstructed views and head and neck CT angiogram are often added during initial evaluation, if injury to the neck and arteries, respectively, is suspected. An experienced neuroradiologist should review bone and brain windows separately. Imaging has a good sensitivity for the presence of pathologic air, skull fractures, hemorrhagic lesions, abnormalities of the brain parenchyma (i.e., shift), and obstruction of CSF spaces (hydrocephalus). Injury to the neuroanatomic structures of consciousness or the presence of additional etiologies for coma (i.e., alcohol) should be considered when disparities between CT findings and examination exist.

Compared with CT, MRI has a higher sensitivity to detect DAI; however, this advantage has not translated into improved clinical outcomes as there is currently no treatment for this condition. However, both the detection of DAI and delineating injury of major motor (i.e., corticospinal) tracts on DTI can be used together with the clinical course to prognosticate TBI.[93] MRS provides additional "chemical" information, especially of the white matter injury process.[94]

The presence and severity of secondary brain injury should constantly be assessed and managed throughout the acute phase of TBI. Although the time course of secondary injury can be variable, it is somewhat predictable. For example, the development of a new hematoma may occur in the first several hours, whereas brain edema is usually seen within 1 to 3 days. Vasospasm, which may cause delayed brain ischemia, typically occurs even a week after injury secondary to irritation from subarachnoid blood.

There is only limited evidence to support the use of ICP monitoring. ICP monitoring has evolved as an essential tool and also as one of the earliest monitoring tools in clinical practice; thus many believe clinical trials cannot ethically be justified. The ongoing debate of ICP monitoring stemmed from the Benchmark Evidence from South American Trials: Treatment of Intracranial Pressure (BEST TRIP) trial, a randomized clinical trial that demonstrated that care focused on maintaining ICP at 20 mm Hg or less was not superior to a treatment protocol guided by CT imaging and examination without ICP monitoring.[95] Several criticisms include the primary impact of the study is that the trial is research based and should not alter clinical study, accumulating evidence demonstrates there are several mechanisms of secondary brain injury (SBI) that cannot be detected using an ICP monitor, and a need for multimodal monitoring should be adapted to improve outcome. Therefore current Brain Trauma Foundation management

guidelines recommend its use in severe TBI. Of note, head imaging cannot predict ICP. Furthermore, treating for elevated ICP (other than empirically in the emergency setting) and not monitoring ICP can be deleterious and results in a poor outcome.[96] In addition to ICP, other brain monitoring techniques used in modern TBI management include jugular venous and transcranial oxygen saturations (near-infrared spectroscopy); brain tissue oxygen tension; brain tissue metabolism (microdialysis) and temperature; direct brain perfusion; and TCD, sonography, and electrophysiologic studies such as EEG and evoked potentials. A discussion of these techniques is beyond the scope of this chapter, and readers are referred to recent reviews.

The management of severe TBI includes emergent decompressive craniectomy in controlling intractable ICP, especially if deterioration is associated and there is some evidence that there will be positive outcomes in surviving patients.[97–102] Although the timing of decompressive craniectomy remains controversial, early referral seems most intuitive. IV mannitol and hypertonic saline solutions are main building blocks in the management of increased ICP.[103–108] The superiority of one agent over the other is uncertain, and both approaches are routinely used in the management of severe TBI.[109]

Therapeutic hypothermia is postulated to exert neuroprotective effects by several mechanisms, including reducing cerebral metabolic rate/requirement, modulating apoptosis or programmed cell death, reducing intracellular calcium/toxic excitatory neurotransmitters/inflammation, and preserving protein synthesis.[110–115] However, the reported impact on neurologic outcome in severe TBI remains inconsistent and a meta-analysis of randomized controlled trials suggests its lack of benefit in severe TBI.[115] Therapeutic hypothermia is used as last-resort therapy and commonly, together with pentobarbital therapy and ICP-matching, CPP elevation to protect the brain from otherwise intractable ICP elevations. Studies have shown a specific group of patients, such as those with focal hematomas that can be surgically removed or patients treated in Asian centers, may benefit from moderate (32°C–35°C) hypothermia, if such treatment is implemented early and maintained for at least 48 hours.[116] Until well-designed, randomized controlled trials are available, temperature control should be determined with the intent to avoid hyperthermia while limiting hypothermia unless ICP is exceedingly difficult to control.

The initial GCS seems to be a reasonable marker to predict mortality from severe TBI. To further improve prediction, models include a combination of clinical data, imaging results, GCS score, and patient demographics.[117] In a large, traumatic coma databank study,[118] patients with severe injury (GCS scores 3–8) had approximately 36% mortality. In one study of 170 patients, the GCS score 5 hours after injury was compared with the Glasgow Outcome Scale (GOS) score at 1 month, and positive recovery was seen in 99% of patients with mild TBI (GCS scores 13–15), 71% of patients with moderate TBI (GCS scores 9–12), and in only 35% of patients with severe TBI. In contrast, only 2% to 3% of patients with mild TBI (GCS scores 13–15) died. Generally speaking, clinical outcome after TBI is more variable than in nontraumatic coma (i.e., after hypoxia).[119] Furthermore, outcome predictions for patients with intermediate GCS scores identify that midline shift of less than 4.1 mm on initial CT scanning had a significantly higher favorable outcome rate compared with patients with a larger shift.[120]

Biomarkers after TBI, such as cellular glial fibrillary acidic protein (GFAP) and S100B released with astrocyte injury, may offer diagnostic and prognostic tools in addition to clinical indices. In 79 patients with TBI (GSC score ≤12), identified intracranial mass lesion, pupillary reactivity, GFAP, and S100B were the strongest predictors of death and unfavorable outcome with S100B as the strongest single predictor of unfavorable outcome with 100% discrimination.[121] SEPs in 58 patients with TBI who were unconscious for more than 30 days were compared with outcome at 12 months,[122] showing excellent prediction for outcome (persistent coma or MCS, 92% and 86%, respectively) at 12 months when combined with age, sex, and GCS score.[123] Furthermore, among electrophysiologic tests SEPs and brainstem auditory evoked potentials are more sensitive indicators than EEG (i.e., 45%–60% sensitive vs. 35%); and if EEG and SEPs show opposing results, generally speaking, prognosis is linked to the better test result.[124] The results of multimodality evoked potentials can be used as a reliable prognostic indicator (91% accuracy) in patients with TBI.[85]

The International Mission for Prognosis and Analysis of Clinical Trials in TBI (IMPACT) is a prognostic model predicting 6-month functional outcome (GOS) and mortality in 587 patients with severe TBI (mean age 38 ± 17 years). At the sixth month, the median GOS was 3 (interquartile range 3) and 6-month mortality was 41%; age, motor score, pupillary reactivity, head CT findings, secondary insults, and laboratory values displayed good prediction ability for unfavorable outcome and mortality.[123]

Nontraumatic Etiologies of Coma

Determining the cause of nontraumatic coma can be challenging given the lack of clear external signs of injury. Brain imaging by CT scan may aid diagnoses by allowing the practitioner to distinguish between structural (i.e., cerebral infarction, intracranial hemorrhage, intracranial malignancy, or infection) and nonstructural (i.e., toxins, epilepsy, sepsis, metabolic disturbances, or anoxic injury caused by circulatory shock, respiratory failure, or cardiac arrest) causes of nontraumatic coma. Indeed the most common causes of nontraumatic coma are post–cardiac arrest anoxic brain injury, stroke, toxins, and metabolic disturbances.[124]

Coma After Cardiac Arrest (Anoxic Brain Injury)

Cardiac arrest remains one of the leading causes of mortality, affecting more than 300,000 people each year in the Unites States alone. In those who are successfully resuscitated, survival rates are low, ranging from 10% to 30%,[125] with morbidity and mortality attributable to the anoxic-ischemic encephalopathy that occurs after arrest.

The American Academy of Neurology recently published guidelines to address three major points in the management of patients who are comatose after successful cardiopulmonary resuscitation: (1) the utility of therapeutic hypothermia (TH) or targeted temperature management (TTM), (2) the role of neuroprotective drugs, and (3) additional medical interventions that may improve outcomes.

For patients who are comatose in whom the initial cardiac rhythm is ventricular tachycardia (VT) or ventricular fibrillation (VF), TH (32°C–34°C for 24 hours) is highly likely to be effective in improving neurologic outcome and survival compared with patients without TH. For patients who are comatose in whom the initial cardiac rhythm is either VT/VF or asystole/pulseless electrical activity after out-of-hospital cardiac arrest, targeted temperature management—which includes 36°C for 24 hours, followed by 8 hours of rewarming to 37°C, and temperature maintenance below 37.5°C until 72 hours—is likely as effective as TH. Lastly, for patients who are comatose with an initial rhythm of pulseless electrical activity/asystole, TH possibly improves survival and functional neurologic outcome at discharge compared with standard of care. In regard to neuroprotective drugs, none has been shown

to be effective in improving survival or neurologic outcome in patients who are comatose after cardiac arrest to date.[126]

Certainly, TH has improved outcomes for patients in a coma after out-of-hospital ventricular fibrillation arrest. Hypothermia has multiple actions not only within the CNS but also systemically. Among them are depression of neuronal activity, amelioration of intracellular postischemic reactions mitigating secondary cell injury, cardiac arrhythmias, hypocoagulability, decrease in immune defense, and reduction in drug metabolism and clearance. Notably, the latter can lead to misinterpretation of the prolonged effects of sedatives and paralytics. Therefore interpretation of the neurologic examination and prognostication in patients undergoing hypothermia or rewarming is complex and challenging. Generally speaking and without the use of hypothermia, the absence of brainstem reflexes implies that the cortex is severely affected as the brainstem neurons are more resistant to hypoxia-ischemia than cortical neurons. Absence of pupillary reflexes at 72 hours predicts poor outcome with high specificity; however, the opposite—reflexive pupils—predicts good outcome in about only 21% of cases. Studies performed after the introduction of hypothermia delineate predictive findings for absent papillary responses but indicate that the corneal reflex seems to be more vulnerable to prolonged sedative and hypothermic effects.[127–130] With respect to motor responses, studies performed before hypothermia identify a high predictive value for poor outcome for the absence of motor responses at 72 hours, a clinical finding that outperformed even SSEP prediction.[131] On the contrary, recent studies suggest that the lack of motor responses does not invariably predict poor outcome in patients treated with hypothermia (i.e., positive predictive values of 92% and negative predictive values of 85%) and exceptions have been reported.[127,129,130,132]

EEG is used in post–cardiac arrest patients not only to determine outcome but also to differentiate myoclonus from shivering and detect seizures. Generalized EEG suppression, burst suppression with or without epileptiform activity, and a flat background with intermittent generalized periodic complexes are indicators of poorer prognosis. The opposite is true for finding reactivity and variability of the EEG pattern in both patients treated with or without cooling. Larger prospective studies are currently lacking; however, some recent reports identify some hypothermia-treated patients with postanoxic status epilepticus who can achieve good outcome,[133] especially when the status evolves from a continuous EEG pattern and not from burst suppression.[134] As seizures and status epilepticus are seen in up to 65% of patients with less severe cortical damage, continuous EEG is indicated to guide management and prognostication in many postarrest patients.

Another frequently seen pattern after cardiac arrest is myoclonic status epilepticus. These are generalized, multifocal, repetitive muscle jerks involving some or all parts of the body. They are seen within 24 hours after arrest and EEG often shows burst suppression or bursts of generalized spikes. Whether myoclonic discharges actually represent seizures remains controversial and as patients may have severe cortical damage and clinical myoclonic at the same time, it is postulated that myoclonus status epilepticus is subcortical in origin.[133] In contrast, postanoxic status epilepticus is cortical in origin (but some overlap to myoclonic status may exist), whereas the posthypoxic myoclonus (Lance-Adams syndrome) is generally seen after primary respiratory failure. It is triggered by startle, often subsides over time, and the patient may be aware and distressed by it. Myoclonic status epilepticus has been associated with poor prognosis and remains poor even in the setting of hypothermia.[127,130,133]

According to current practice parameter from 2006, the absence of the N20 (primary cortical somatosensory) wave on SSEPs in the first 3 days after cardiac arrest identifies a high likelihood for poor outcome. In contrast, only about 41% of patients with a present N20 wave will recover. Prognosticating based on SSEP findings in patients treated with hypothermia has only been reported in a few smaller studies with uncertain overall results[135,136]; however, SSEP likely remains useful as evoked potentials are relatively resistant to metabolic and temperature derangements. Also, neuron-specific enolase (NSE) is a frequently administered and validated biochemical marker used for prognostication. Levels above 33 μg/L at 72 hours or earlier were found to have a zero false predictive rate in patients not treated with hypothermia. However, hypothermia decreases NSE levels. Some recent studies have shown that a similar cutoff also holds true for the populations of hypothermia-treated patients,[137–140] whereas other authors found unacceptable false-positive rates for the cutoff value 33 μg/L.[141,142]

Certain MRI findings such as severe cortical abnormalities on diffusion-weighted imaging have been shown to correlate to poor outcome, but imaging studies often report on smaller patient numbers and are performed unblended, thereby reducing their value for prediction.[143] Some recent studies identify that most patients who regained consciousness had normal cortical structures, some of them having involvement of the deep gray nuclei.[144,145] Further prospective studies are needed; however, clinicians should be cognizant of the following points to maximize the benefits of neuroimaging for prognostication[146]:

1. Neuroimaging should not be used in isolation to determine prognosis.
2. It may be reasonable to repeat imaging if the initial imaging is not consistent with the patient's clinical status.
3. It is reasonable to procure a CT immediately after arrest to evaluate for possible intracerebral hemorrhage or if the cardiac cause is unclear. However, using CT for prognostication purposes may be misleading and premature.
4. The optimal timing for prognostication may be 2 to 3 weeks after arrest, especially in a cooled patient.
5. It is reasonable to obtain an MRI if CT results are unrevealing. The optimal timing to visualize ischemic changes may be 3 to 5 days after arrest, or longer if the patient undergoes targeted temperature management.
6. Neuroimaging does not exclude poor prognosis.

In the past, recommendations suggested that assessment of the postarrest patient treated with hypothermia take place 72 hours after arrest. However, it is now known that delayed awakening (up to 96 hours after arrest) may be associated with good neurologic outcome after TH in patients recovering from cardiac arrest.[147–150]

Still, examination should take place at least 12 hours after termination of all sedatives and later if concomitant renal and liver damage are confounding factors. Prognostic variables associated with but not invariably predictive of poor outcomes are as follows:

1. Absence of brainstem reflexes
2. Absence of motor responses or extensor posturing
3. EEG abnormalities, including generalized suppressions or periodic complexes on suppressed background, and burst-suppression pattern with generalized epileptiform activity
4. Myoclonic status epilepticus
5. MRI with widespread cortical injury on diffusion-weighted imaging or CT with loss of gray-white matter differentiation and sulcal effacement
6. High nonspecific enolase levels
7. Absence of N20 on SSEPs

Ethical Considerations

Advanced Care Planning Documentation

Patients with brain injuries severe enough to necessitate a stay in the neuroscience intensive care unit often lack the capacity to make treatment decisions for themselves. Advance care planning documentation based on previous conversations with other health care providers may exist. However, many times limitations and variability inherent in these advance care planning documents render them outdated. The only exception is physician orders for life-sustaining treatment (POLST), which provides legal protection to patients who explicitly expressed their wishes before hospitalization.

Surrogate Decision Makers

For patients with no living will who lack capacity, a surrogate decision maker is often appointed with the sole purpose of directing care in accordance with the patient's previously declared or presumed wishes. A surrogate designated by the patient has precedence over other potential decision makers and is delineated by an advanced directive, also known as health care proxy, health care agent, or durable power of attorney for health care. If there is not a readily obvious person to serve as surrogate, a court-appointed surrogate or a legal guardian may be necessary. Most states have an outlined hierarchy of those who may serve as a surrogate, with highest priority typically given to the spouse, followed by adult children or extended family members, although the order of surrogacy and the power granted to surrogates chosen by default vary from state to state.[151]

Prognostications

Decisions to withdraw care are profoundly influenced by physicians' prognosis of a patient's potentials for improvement of consciousness. Identifying medical futility in a patient with markedly impaired consciousness allows the surrogate and physician to withdraw life-supporting therapy. It is important for physicians to reiterate to the family that coma progression into vegetative state is not considered an improvement. Sleep-wake cycles, roving eye movements, startle, and other witnessed phenomena are merely reflexive and do not indicate consciousness or awareness. Greater prognostic uncertainties exist for patients in an MCS as they have consistent evidence of consciousness, awareness, and, in some, the ability to communicate.

Physicians have long considered the prediction of disease and injury outcome as one of their most important duties. But just as they rightfully regard prognostication as a professional responsibility, physicians should be aware of their limited ability to accurately predict the probability of recovery from impaired consciousness and of the limited persuasiveness of their prognostication on some patients and families. Furthermore, recovery is a dynamic and fluctuating process with individual differences. Therefore patient and family values are as important as physician prognostication in decision making.

Underrepresented Patients

Underrepresented patients lack the capacity to make medical decisions for themselves and have no legal or surrogate decision maker to do so. Current laws, institutional policies, and organizational recommendations regarding limitation or continuation of life-sustaining therapy vary among states and depend on the patient's background, if known. Regardless of the statutory requirements, in most cases there exists a presumption that physicians should pursue urgent or emergent life-sustaining treatment or life-saving interventions.[152] Institutional protocols on limitation of life-sustaining treatment typically entail constructing an overview of the patient's life, thus providing a framework to guide how the patient might weigh the various risks and benefits of treatment.

Physicians have fiduciary obligations toward the underrepresented that cannot be deferred to or discharged by third parties. However, physicians should also not act without input from third parties such as ethics committees.[153] It is crucial that all efforts are exhausted to track down individuals who may actually be reasonable surrogates and to ensure due diligence in learning about the patient as a person. Third-party involvement can help ensure that decision making is transparent and that appropriate efforts have been made to define the underrepresented patient's best interests, personal values, and preferences. Physicians should be the default decision makers regarding limitation or continuation of life-sustaining treatment, with organizations such as ethics committees playing an advisory role for the underrepresented.

Key Points

- Coma is a state of pathologic unresponsiveness from which the patient cannot be aroused. The eyes are closed, and only reflex responses or no responses at all can be elicited from the patient when applying vigorous stimulation.
- The cause of coma is diverse and follows neuronal injury, reversible or irreversible, to both cerebral hemispheres or to the reticular activating system in the diencephalon and brainstem.
- A supratentorial mass legion located within one hemisphere can induce a lateral herniation syndrome with lateral torsion of the midbrain plus uncal herniation. In contrast, a mass lesion located within the brain midline (i.e., acute hydrocephalus) primarily leads to downward herniation with rostrocaudal compression of the brainstem.
- An acute mass lesion below the tentorium (i.e., a cerebellar hemorrhage) compresses the brainstem early on, leading to cranial nerve deficits, obstructed CSF outflow resulting in hydrocephalus, and, if large enough, herniation of brain tissue upward through the tentorium and downward through the foramen magnum. On examination these patients may present with a complete lack of all cranial nerve and motor function, yet hemispheric function may be preserved.
- Initial attention must focus on the restoration of respiratory, hemodynamic, and metabolic homeostasis in parallel with a search to identify the cause and acuity of the coma state. Generally, a comatose patient's recovery depends on appropriate treatment of the underlying disorder but also very much on monitoring and stabilizing brain function (ICP, perfusion, and so on).
- Status epilepticus is characterized by either clinically detectable (convulsive) or EEG-identified (nonconvulsive) seizure activity. Both require immediate and aggressive treatment to avoid permanent brain damage.

- Alteration in cognitive function (especially attention and concentration deficit) is the earliest manifestation of metabolic encephalopathy. Some disease processes may provide specific diagnostic clues.
- The neurologic examination consists of an assessment of the level of arousal determined by eye opening, verbal responses, and reflex or purposeful movements in response to noxious stimulation of the face, arms, and legs. Neuro-ophthalmologic function is evaluated by spontaneous eye movements, pupillary size and response to light, oculocephalic responses (doll's eyes), and oculovestibular (ice water caloric) responses. Autonomic function is assessed by the respiratory pattern and observing the monitored vital sign changes before and during examination.

Review Questions

1. A 72-year-old woman is brought to the emergency department (ED) by her daughter because of a change in mental status. The patient was noted to have acute onset of confusion, agitation, and gait disturbance. Her medical history includes hypertension, insomnia, and depression (since the death of her husband 3 months ago). The patient is taking hydrochlorothiazide, amitriptyline, and baby aspirin and has recently started to take fluoxetine. Her vital signs are as follows: temperature 100°F; pulse 120 beats/min; blood pressure (BP) 130/85 mm Hg; respirations 16 breaths/min. Physical examination is positive for confusion, ataxia, dilated pupils, dry mucous membranes, and tachycardia. Laboratory results are pending. Electrocardiogram (ECG) reveals tachycardia with QT-interval prolongation. Urine dipstick results are within normal limits. What is the *most* likely cause of acute mental status change?

a. Salicylate overdose
b. Tricyclic antidepressant (TCA) toxicity
c. Sepsis from urinary tract infection (UTI)
d. Acute intoxication with ethanol

Answer: b. Fluoxetine inhibits cytochrome 2D6, which will cause an increase in the levels of TCAs. The signs and symptoms of TCA overdose include anticholinergic effects, agitation, restlessness, ataxia, tachycardia, prolonged QT interval, hyperthermia, and convulsions. Sepsis from UTI is possible but unlikely with a urine dipstick result within normal limits. An acute cerebellar stroke or acute ethanol intoxication would explain some but not all of the clinical findings.

2. You are consulted to see a 36-year-old patient in the ED with history of epilepsy. She has been stuporous for more than 6 hours and has a right hemiparesis, including the face, arm, and leg. The computed tomography (CT) scan of the brain is normal. The paramedics have already administered glucose, thiamine, and naloxone without any improvement. Which one of the following agents would be contraindicated in this case?

a. Lorazepam
b. Phosphenytoin
c. Flumazenil
d. Valproic acid

Answer: c. A patient with history of epilepsy, focal motor signs, normal CT scan, and stuporous state in the ED is in nonconclusive status epilepticus (NCSE) until proved otherwise. Although stroke is a possibility, a normal CT scan in a patient with focal neurologic signs should exclude intracranial hemorrhage or cerebral infarction. All antiepileptics mentioned could be used in sequential order with the aim to stop NCSE. Flumazenil, on the other hand, a gamma-aminobutyric acid (GABA) receptor antagonist, would be contraindicated in this case, as it would aggravate ongoing ictal activity.

3. A 45-year-old man is brought to the ED after a motor vehicle collision in which he suffered a closed head injury. His initial Glasgow Coma Scale (GCS) score was 6. He was intubated and admitted to the intensive care unit (ICU). Eight hours later the patient remains comatose. Which of the following is considered a reliable predictor of poor outcome at 6 months?

a. Number and location of skull fractures
b. Initially increased intracranial pressure (ICP) requiring a ventriculostomy to normalize ICP
c. Initial poor prognostic electroencephalogram (EEG) pattern with normal somatosensory evoked potential (SEP)
d. Absence of pupil reaction and eye movements at 24 hours

Answer: d. The most reliable predictors of outcome at 6 months after head injury include age, GCS score, pupil reaction, motor response at 1 week, and uncontrolled increased ICP. Lack of pupil reaction at 24 hours predicts death or vegetative state in 90% of patients. The mechanism of head injury, presence or absence of skull fractures, and the extent of other extracranial injuries have little impact on outcome. Initial poor-prognosis EEG findings with normal SEPs still allow the chance of neurologic recovery and the patient should be aggressively supported. When compared the using initial degree of neurologic deficit, patients with traumatic causes for coma have more complete recoveries than do patients with medical coma. Although uncontrolled increased ICP is a reliable indicator of poor neurologic outcome, an initially increased ICP (promptly controlled with a ventriculostomy procedure) is not.

4. A 58-year-old woman is admitted for altered mental status. On examination her GCS score is 8, she has a dense flaccid left hemiparesis, and her eyes show a conjugated gaze deviated to the right with right blown pupil 6-mm fixed and nonreactive. What pathophysiologic mechanism is most likely associated with this clinical picture?

a. Subfalcine herniation left to right
b. Right downward transtentorial herniation
c. Intraventricular hemorrhage with hydrocephalus
d. Unruptured right posterior communicating artery aneurysm

Answer: b. This patient is eliciting classic signs of a massive right cerebral infarct with cerebral edema and downward transtentorial herniation. The comatose state is explained by the stretching of the reticular activating system caused by a right-to-left shift of midline structures (diencephalon). The left hemiparesis is explained by corticospinal tract dysfunction or injury, and the gaze deviation is explained by unopposed activation of the left frontal eye fields displacing the eyes to the right (patient looks to the lesion). The right pupil is dilated because of cranial nerve III stretching and subsequent palsy. The intraventricular hemorrhage alone with hydrocephalus would not explain the focal findings seen in this case. Similarly, an unruptured posterior communicating aneurysm will manifest only with cranial nerve III palsy or injury but not with mental status changes, forced gaze deviation, or hemiparesis. This would be, however, a medical emergency demanding further workup such as CT angiography or magnetic resonance angiography and aneurysm repair.

Neurologic Criteria for Death in Adults

FRED RINCON

CHAPTER OUTLINE

Historical Perspective and Definitions

Determination of Brain Death
- Clinical Evaluation of Coma and Prerequisites
- Absence of Brainstem Reflexes
- Apnea
- Pitfalls and Mimics

Confirmatory Testing
- Origins of Confirmatory Testing in Brain Death
- Accuracy of Confirmatory Tests
- Recommendations for Confirmatory Testing

Special Circumstances
- Determination of Brain Death After Cardiac Arrest in the Era of Therapeutic Hypothermia
- Extracorporeal Membrane Oxygenation

Conclusions

The clinical examination in brain death is the most unequivocal in neurology. Most of the time, establishing the diagnosis of brain death on clinical grounds is not a difficult task, as long as providers follow established protocols and guidelines for the interpretation of findings during clinical examination.[1,2] However, there may be confusion based on the variability of the interpretation of current guidelines,[3–5] hurdles to clinical examination in specific patient populations such as trauma victims, laws from specific jurisdictions, and the changing face of outcomes after severe brain injury in an era of advancements in critical care and resuscitative medicine. In this chapter we review current procedures and recommendations for the evaluation of comatose patients presumed to be brain dead, the concept of brain death substantiated by anatomic and physiologic bases, important concepts for the determination of brain death in the setting of novel interventions such as hypothermia and extracorporeal circulation, and how to avoid pitfalls during the evaluation of patients presumed to be brain dead.

Historical Perspective and Definitions

The concept of brain death is modern to medicine, but the definition of death has historically been associated with physiologic cessation of cardiopulmonary function. With advancements in mechanical ventilation, life support, and resuscitation medicine, a new state in which a patient's cardiopulmonary functions could be sustained in the absence of neurologic function emerged. In 1959, Mollaret and Goulon described 23 patients with irreversible coma, whose clinical syndrome was characterized by the absence of brainstem function, spontaneous respiratory function, and cardiovascular collapse that ensued without the use of vasopressors, in what became the birth of the concept of brain death.[6] In 1963, Harvard neurologists proposed that a patient be certified as dead in the setting of coma, absence of brainstem reflexes, apnea for 30 minutes, and an isoelectric electroencephalogram (EEG) tracing in all leads for more than 30 minutes,[7] despite the presence of cardiac function. The first guideline (the Harvard criteria) for deciding brain death was established in 1968.[8] This concept has been accepted worldwide, although its fundamental meaning is not exactly globally uniform yet. Some countries, such as the United States, accept the concept of brain death as "whole brain death," which is defined as irreversible loss of all cortical and brainstem function. The Medical Royal Colleges of the United Kingdom established the definition of brain death on a "lower brain" concept of brainstem death.[9] In the opinion of the Royal Medical College, permanent unconsciousness secondary to neuronal death of brainstem structures such as the reticular-activating system (RAS) is irreversible.[9]

In 1981, a Presidential Commission in the United States was formed to address the issue of death by neurologic criteria.[10] The President's Commission established the foundations of the criteria currently used in the United States for the diagnosis of brain death: the cause of brain death should be known and irreversible and no improvement in neurologic condition should occur during a period of observation; the period of observation was left at the discretion of the physician, but periods of 6 to 12 hours were recommended depending on the availability of confirmatory testing such as EEG or cerebral perfusion scans.[10] Although the President's Commission suggested periods of observation of 24 hours for cases of ischemia-anoxia,[10] more recent clinical experience in the era of therapeutic hypothermia and published guidelines suggest a period of observation of up to 72 hours in patients with hypoxic-ischemic coma.[11] The President's Commission guidelines for the determination of brain death culminated in a proposal for a legal definition that led to the Uniform Determination of Death Act (UDDA) in 1981. Under the law, the determination of death must be made with accepted medical standards and can be established only if an individual "has sustained either: 1) irreversible cessation of circulatory and respiratory functions, or 2) irreversible cessation of all functions of the entire brain, including the brain stem." The UDDA establishes the legal definition of death on the basis of neurologic criteria but does not provide guidelines or recommendations regarding how to arrive to such conclusion. To this end, the medical community is free to formulate acceptable parameters or guidelines

on the basis of clinical examination, and availability of diagnostic tests and biomarkers.

In 1995, the American Academy of Neurology (AAN) published the practice parameter to delineate the medical standards for the determination of brain death.[1] The guideline emphasized the three clinical findings necessary to confirm irreversible cessation of all brain functions, including the brainstem: (1) known cause and presence of coma, (2) absence of brainstem reflexes, and (3) apnea.[1] Despite this publication, there is considerable practice variation in the adherence to the AAN guidelines for the determination of brain death, particularly in areas related to definitions of acceptable core temperature, number of required examinations, ancillary testing to be used, and deficiencies in documentation.[3,5] In response to this phenomenon, the AAN published an evidence-based update of the 1995 Practice Parameter[2] to answer the main questions related to practice variability in the determination of brain death.[3,12]

Recovery of neurologic function has not been reported since the clinical diagnosis of brain death was established with the criteria set forth by the 1995 AAN guideline. This guideline and the further revision highlight the prerequisites for brain death determination to avoid potential misdiagnosis and pitfalls.[2]

The brain death concept is universally accepted worldwide and there are no concerns about the validity within physicians. However, diagnostic brain death criteria vary throughout the world. In Europe, for example, there is considerable variation in the use of ancillary testing such as EEG or cerebral blood flow studies. Most countries of the European Union do not require ancillary testing in support of brain death diagnosis.[13] In other countries, different practices reflect the interest of local committees and groups of experts to introduce safeguards. Major differences in these countries are related to the time of observation, the need for apnea and ancillary testing, and the number of health care providers authorized to diagnose brain death.[14]

In the United States, most state laws have adopted the UDDA, and some have added their own amendments. All states and the District of Columbia have statutes for determining brain death based on the UDDA, but certain statutes differ in minor points such as the requirement that determination of brain death should be done by two different physicians, the use of confirmatory testing, and the notification of next of kin before the declaration of brain death. To this end, it is important for the practitioner to understand local hospital policies for the declaration of brain death that should abide by the laws of their respective jurisdictions.

Determination of Brain Death

The most common causes of brain death in the adult population are traumatic brain injury, aneurysmal subarachnoid hemorrhage, hypoxic-ischemic injury, and fulminant hepatic failure.[15] It is estimated that the diagnosis of brain death is made at least 25 to 30 times a year in large referral centers, but this number may be lower in nonacademic centers.[15] The determination of brain death is based on the UDDA and supported by the AAN Practice Parameter.[1,2] The diagnosis is based on the establishment of three main criteria: (1) known cause and presence of coma, (2) absence of brainstem reflexes, and (3) apnea. Therefore the clinical diagnosis, when considering accepted guidelines, is the most unequivocal in neurology.

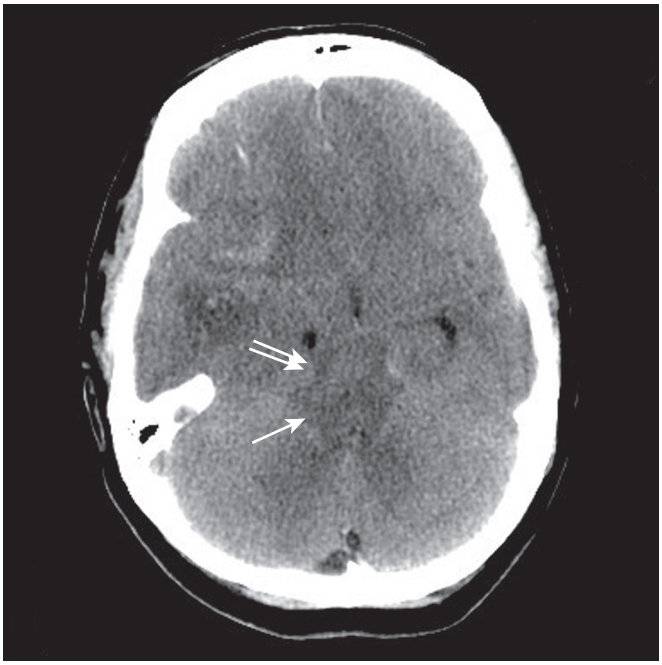
In general, most jurisdictions require that the determination of brain death be made by a licensed physician, which in most of the cases should be an attending physician who has experience in the assessment of comatose patients and the legal requirements applicable to the jurisdiction of practice. Some centers require the testing to be performed by two different physicians, and some centers require one of these physicians to be a neurologist, neurosurgeon, or critical care specialist. In the United States, 42% of top neuroscience centers required the brain death examination to be documented by a neurologist or neurosurgeon, and only 35% required that an attending neurologist or neurosurgeon be involved; of the 42% of centers, residents could document the examination in up to 65% of the centers.[3] In those circumstances in which the patient is a potential organ donor, the clinical team may not be directly involved with the discussions of organ procurement, as a conflict of interest may be apparent.

To provide standardization in the process of diagnosing brain death, the Neurocritical Care Society in the United States has developed a toolkit to educate anyone who may be involved in the determination of brain death. The toolkit includes access to multiple instructional videos, webinars and web-based courses, and sample brain death policy and checklists (https://www.pathlms.com/ncs-ondemand/courses/1223).

Clinical Evaluation of Coma and Prerequisites

Practitioners should first determine the cause of coma by history, physical examination, neuroimaging, and laboratory testing. Exclusion of central nervous system depressants should be attempted by careful history taking, drug screen testing, and calculation of drug clearance using the rule of five times the drug's half-life (assuming a normal hepatic and renal function) or drug plasma levels below therapeutic ranges.[2] In the setting of abnormal hepatic or renal function, or after use of therapeutic hypothermia, caution should be taken before entertaining the diagnosis of brain death based on changes in drug metabolism inherent to these clinical settings to avoid catastrophic and embarrassing misdiagnoses.[16] In these circumstances, more than recommended times for observation are suggested or the use of confirmatory testing may be sought. The legal limit for ethanol is a blood alcohol content of 0.08%, which is a practical threshold below which an examination to determine brain death could reasonably proceed.[2] In patients exposed to pentobarbital for the management of intracranial hypertension, an accepted level in which a clinical examination can proceed without chance of confounding is 10 μg/mL.[2] There should be no temporal administration of neuromuscular blockers, and this can be assessed definitely by the presence of train-of-four twitches with maximal ulnar stimulation. Acid-base status and electrolyte levels must not be severely deviated from the norm, but the presence of signs and symptoms of *diabetes insipidus* does not preclude the diagnosis of brain death; however, treatment with fluids and vasopressors such as vasopressin will target both sodium and blood pressure requirements to allow for adequate neurologic assessment. With more cardiac arrest survivors being exposed to therapeutic hypothermia, practitioners should now achieve a normal core temperature, defined as near-normal temperature or core temperature higher than 36°C, before attempting to determine brain death. Patients should have normal blood pressure, defined as systolic blood pressure equal to or higher than 100 mm Hg, as the neurologic examination is usually reliable at this level of blood pressure.

A temporal cause of severe brain injury must be established. Irreversibility from neurologic injury is recognized by the extent of the injury, the devastation in neurologic findings, and the lack of improvement. Neuroimaging is useful in establishing an acute neurologic catastrophe that is compatible with the clinical diagnosis.



• **Fig. 59.1** Computed tomography scan of a young patient with traumatic brain injury showing right frontal contusion, mild subarachnoid hemorrhage, and severe cerebral edema. The patient had a bilateral transtentorial uncal herniation (*double arrow*, for right-sided uncus); note that the horn of the right lateral ventricle has been pushed toward the midline. The perimesencephalic cisterns are effaced *(single arrow)*. There is slight hypodensity in the midbrain suggesting edema or ischemia.

In most cases, a computed tomography (CT) scan reveals specific findings such as diffuse cerebral edema, mass lesions with severe shift of midline structures, and herniation (Fig. 59.1; also see Fig. 59.4).

Coma is established by the lack of all evidence of responsiveness. That is, eye opening or eye movement to noxious stimuli must be absent. The motor responses to noxious stimuli should not be flexor or extensor but spinally mediated. The clinical differentiation of motor responses may require experience and specific training in neurology or neurosurgery. When flexor posturing of the upper extremities and extension of the lower extremities (decorticate) or extensor posturing of both the upper and lower extremities (decerebrate) are observed, the diagnosis of brain death cannot be entertained and an additional period of observation is recommended. (For an interactive brain death assessment, visit Brain Death Examination at https://www.pathlms.com/ncs-ondemand/courses/1223/video_presentations/11133 or Brain Death Testing Demo at https://www.youtube.com/watch?v=OEuP2C5UEp8.)

The basis of these responses is related to the patency of the rubrospinal and vestibulospinal tracts and lower segments of the medulla that connect with the spinal cord.[17] Brain dead patients typically exhibit spinal cord–mediated motor responses characterized by "en bloc" flexor responses of the lower extremities with flexion of the hip, flexion of the knee, and dorsiflexion of the ankle and toes (the so-called triple flexion response or Babinski en bloc spinal cord sign). More complex movements that have been referred to as brain death–associated reflexes (Lazarus sign, spinal man, spinal reflexes, or spinal automatisms) have been described in patients who otherwise meet all other brain death criteria.[18] The key point to differentiate spinal versus centrally mediated responses is to determine if the responses are also elicited from stimulation above the foramen magnum. This is easily achieved by introducing noxious stimulation through pathways mediated by cranial nerves. When in doubt, the neurologic examination of a comatose patient becomes equivocal, and in these circumstances, additional observation or a confirmatory test may be warranted.

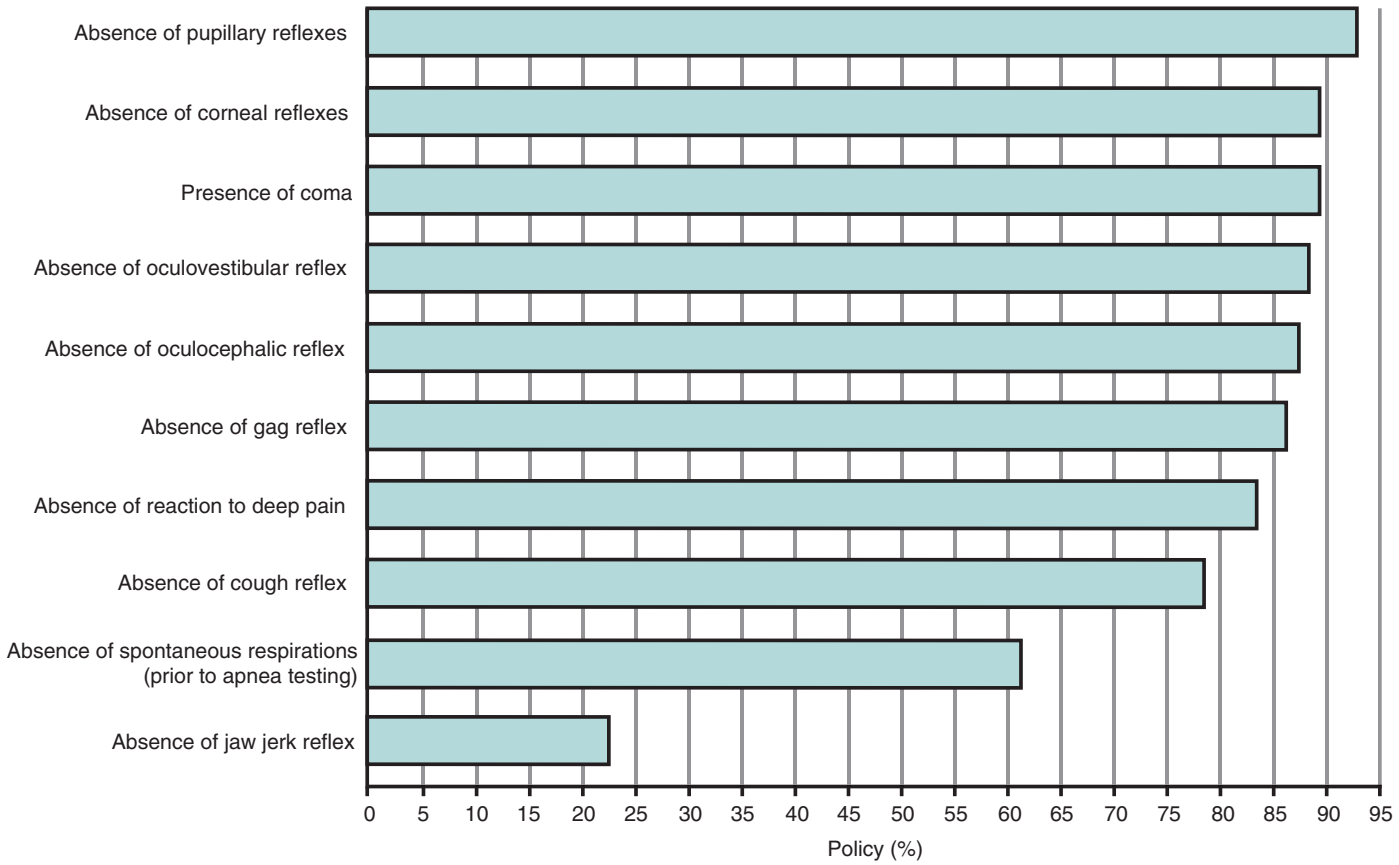
Absence of Brainstem Reflexes

All segments of the brainstem should be tested in the clinical examination. The highest segments are examined by documentation of the pupillary response to bright light in both eyes (cranial nerves II and III). The usual presentation is dilated fixed pupils, which may be asymmetrical. Constricted pupils may mean drug intoxication or lesions at the level of the pons causing de-efferentation from sympathetic fibers and unopposed activation of parasympathetic centers located in the rostral area of the midbrain (Edinger-Westphal nucleus). Absence of ocular movements using oculocephalic and oculovestibular reflex testing can be achieved after ensuring integrity of the cervical spine (cranial nerves III, IV, VI, and VIII [vestibular part]). The oculocephalic reflex is tested by briskly rotating the head side to side and vertically. Vertical oculocephalic movements are important for the determination of brain death as injuries in the lateral portions of the pons may manifest with bilateral palsies of horizontal eye movements but would spare the vertical eye movements. The oculovestibular or cold-caloric reflex is tested by irrigating each ear with 50 mL of iced water and observing the response for up to 1 minute. The absence of corneal reflexes (cranial nerves VII, V, and others) is demonstrated by touching the cornea with a cotton swab or gauze. Painful noxious stimulation in the cranium, trunk, or limbs should not produce any facial movement or grimacing (cranial nerve VII). Absence of pharyngeal (cranial nerve IX) or gag reflex (cranial nerve IX) is demonstrated by stimulating the back of the mouth or oropharynx with a suction device or tongue blade. The tracheal reflex (cranial nerve X) is tested by examining the cough response to tracheal stimulation provided by suctioning. Additional cranial nerve reflexes such as the "jaw jerk" (cranial nerve V) may be assessed for completeness and to follow established guidelines.[1] Any unanticipated movement of any segment of the face, trunk, or limbs during brainstem examination implies intact brainstem efferent connections and precludes the diagnosis of brain death. In trauma victims with facial trauma in whom adequate examination of brainstem patency cannot be substantiated, the use of confirmatory testing may be warranted.

Deviations from accepted guidelines during clinical examination of comatose patients presumed to be brain dead may be associated with false-positive results, so a thorough examination of all segments of the brainstem is required. Areas of particular deviation from the AAN Practice Parameter for the determination of brain death include failure of testing for pain above the foramen magnum, the oculocephalic reflex, the jaw-jerk reflex, and establishing the absence of spontaneous respirations[3] (Fig. 59.2).

Apnea

Complete absence of breathing drive must exist to confirm the diagnosis of brain death. The absence of respiratory drive is tested with a carbon dioxide (CO_2) challenge, which requires all of the following: (1) normotension, (2) normothermia, (3) euvolemia, (4) eucapnia (partial pressure of carbon dioxide in arterial blood [$PaCO_2$] 35–45 mm Hg), (5) absence of hypoxia, and (6) no prior evidence of CO_2 retention (chronic obstructive pulmonary disease,



• **Fig. 59.2** Variability during clinical examination of brain dead patients in top neuroscience centers of the United States. severe obesity, or sleep apnea syndrome).[2] The test is started by preoxygenating the patient with a fraction of inspired oxygen (FIO_2) of 1.0 for 10 minutes to achieve an alveolar oxygen partial pressure (PaO_2) of more than 200 mm Hg using a respiratory rate of 10 per minute to achieve eucapnia. If the patient remains hemodynamically stable and with oxygen saturation more than 95%, the patient is disconnected from the ventilator and oxygenation is preserved by placing a catheter through the endotracheal tube and close to the level of the carina delivering O_2 at 1.0 FIO_2 with a flow of 6 L/min. During the following 8 to 10 minutes, the practitioner should look carefully for respiratory movements (abdominal or chest excursions and may include a brief gasp).[2] The test should be aborted if oxygen saturation drifts lower than 85% for more than 30 seconds. If this is the case, the test can be repeated later using a T-piece, continuous positive airway pressure with 10 cm H_2O, and O_2 with 1.0 FIO_2 with a flow of 12 L/min.[2,19] The test result is considered positive if respiratory movements are absent and the $PaCO_2$ is higher than 60 mm Hg or 20 mm Hg change from baseline supporting the diagnosis of brain death.[2] (See Apnea Testing in Brain Death at https://www.pathlms.com/ncs-ondemand/courses/1223/video_presentations/11134.)

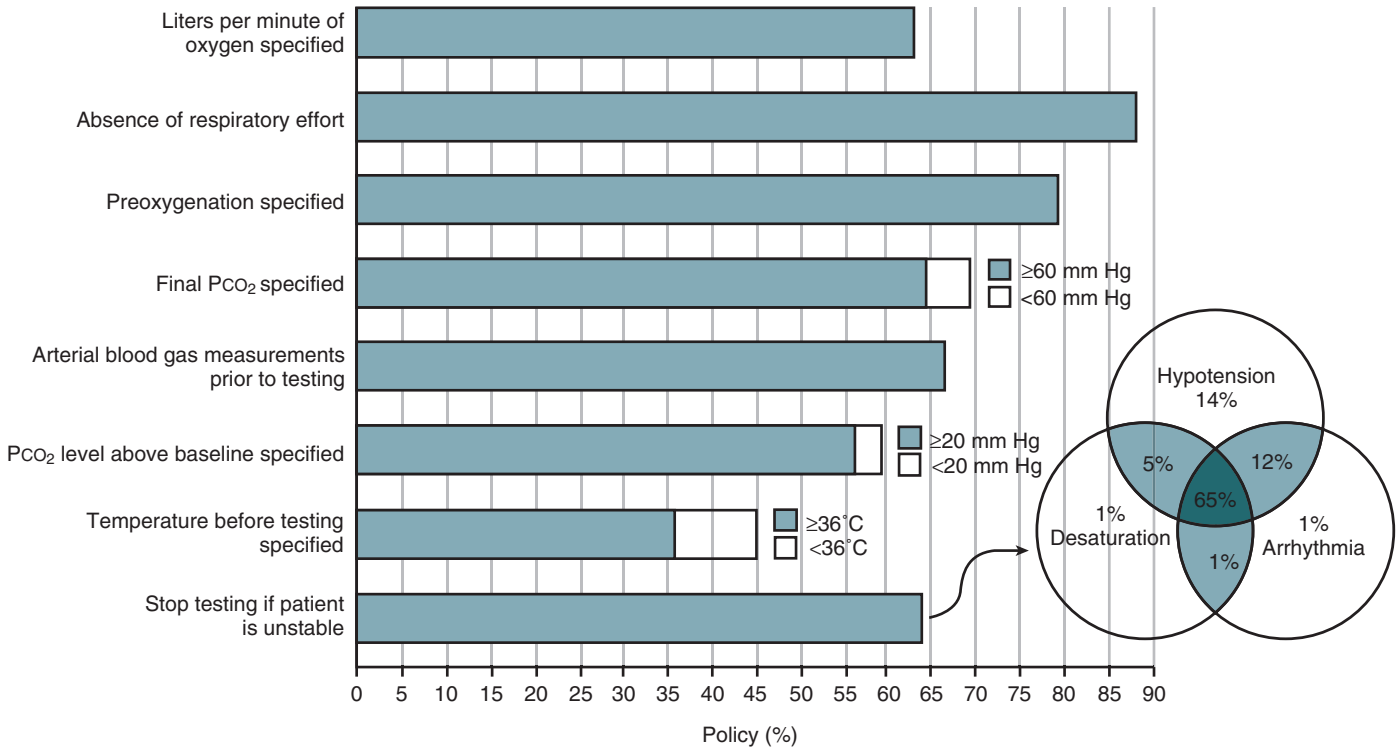
Although the apnea test is not a new procedure, it still lacks consensus standardization regarding the actual test, consent processes, monitored parameters, and evidence-based safety measures that may be used to prevent complications. Practitioners should keep in mind that the apnea test is not without complications. Potential complications during apnea test include hemodynamic decompensation, hypoxia and hypercarbia, and tension pneumothorax.[20]

Pitfalls and Mimics

In clinical practice, certain circumstances can mimic brain injury; these include high cervical spinal cord injury, fulminant acute inflammatory demyelinating neuropathy, organophosphate intoxication, baclofen intoxication, lidocaine toxicity, and delayed muscular blocker clearance (i.e., vecuronium). Pitfalls in the diagnosis of brain death may be related to circumstances involving interference with the appropriate clinical diagnosis of brain death such as patients with (1) facial trauma (inability to appropriately examine cranial nerve responses or to elicit sensory/motor responses from stimulation above the level of the foramen magnum), (2) preexisting pupillary abnormalities, (3) toxic levels of anesthetics, sedatives, tricyclic antidepressants, anticholinergics, antiepileptics, or neuromuscular blocking agents, and (4) severe chronic respiratory acidosis (chronic obstructive pulmonary disease, severe obesity, or sleep apnea syndrome). In these circumstances, a confirmatory test may be warranted.

There is still significant variability in brain death policy application the United States, particularly in definition of appropriate targets for temperature, blood pressure, and $PACO_2$ level at the time of the assessment (Fig. 59.3). This variability highlights the



• **Fig. 59.3** Variability of prerequisites for apnea test procedure for the determination of brain death in the United States. Poor compliance occurred mainly in goal core temperature and baseline and goal end partial pressure of carbon dioxide ($Paco_2$). (From Greer DM, Wang HH, Robinson JD, et al. Variability of brain death policies in the United States. *JAMA Neurol.* 2016;73:213–218.)

need to further standardize the brain death assessment as one of most crucial bedside clinical assessments in critical care.

Confirmatory Testing

The role of confirmatory testing in brain death differs among jurisdictions.[14] In the United States and the United Kingdom, they are discretionary.[1,2,21] According to the AAN guidelines, confirmatory tests are required only when specific components of the clinical examination cannot be reliably assessed.[1,2] In some European countries such as Italy, France, and the Netherlands, among others, these tests are mandatory[14,20]; however, there is still significant variability in the approach to determining brain death in the world.[14]

A specialist in the neurosciences and any other skilled physician should be able to determine brain death using clinical criteria alone, so the main purpose of confirmatory testing besides being a diagnostic safeguard is to support the diagnosis of brain death in the setting of failure to complete a thorough neurologic examination or an apnea test. The important point about confirmatory testing is that these tests should never replace the clinical examination and should never be ordered before attempts to complete a thorough neurologic examination.[22]

Origins of Confirmatory Testing in Brain Death

In the earlier years of refining the clinical picture of brain death, there was a desire to demonstrate absence of brain function with information different from clinical data. In the 1950s Michel Jouvet[23] in France and Charles Miller Fisher[24] in the United States began to use electrocerebral science to study a group of patients who would have poor neurologic outcomes. Although these studies provided the basis for defining brain death by the Ad Hoc Committee of the Harvard Medical School[8] a year later, Beecher, who served as the chairman of the committee, mentioned in an editorial that EEG was "not essential to a diagnosis of reversible coma, but provides valuable supporting data,"[25] and this statement was later endorsed by the American Neurological Association.[26] Additional confirmatory tests, which can be divided into those that test for electrical function and those that test for blood flow, have been introduced and are aimed at confirming cerebral death (Table 59.1). Electrophysiologic tests include EEG, brainstem auditory evoked potentials, and somatosensory evoked potentials (SSEPs); blood flow tests include four-vessel cerebral angiography, transcranial Doppler, CT angiogram, magnetic resonance angiogram, and nuclear brain scan (Fig. 59.4). SSEPs and brainstem auditory evoked potentials are currently not recommended to be used in aiding or confirming the diagnosis of brain death.[1,2] More recent ancillary tests used for the determination of brain death include the bispectral index scale monitor[27] (BIS, mathematical algorithm of EEG), jugular bulb venous oxygen saturation ($Sjvo_2$),[28] and brain tissue oxygenation ($Pbto_2$)[29] but are not yet standardized in aiding in the diagnosis of brain death.

Accuracy of Confirmatory Tests

Practitioners must be careful at the time of interpreting the results of confirmatory tests and be knowledgeable of the technology being used, as there are disparities in the accuracy of confirmatory tests that could lead to potential pitfalls in the determination of

brain death (Box 59.1). Based on the absence of gold standards from a physiologic and pathologic perspective,[30] the results of confirmatory testing may confound the practitioner in two ways: tests results can be labeled as false positives or false negatives when they are compared against each other. False-positive results occur when the test suggests brain death and the patient does not meet clinical criteria. False-negative results are more common (Table 59.2); they occur when the patient is clinically brain dead but the test shows otherwise,[22] which may be more common with EEG.[31]

Recommendations for Confirmatory Testing

Current evidence-based guidelines from the AAN recommend the use of only one confirmatory test for the determination of brain death in those cases in which an additional period of observation, an apnea test, or clinical examination is not feasible to fully establish the clinical criteria of brain death.[2] In a large study of brain death determination at the Mayo Clinic, the apnea test was aborted in 3% of patients and in 7% of patients the apnea test was not performed as it was not deemed to be safe, a situation that occurred more frequently in patients with polytrauma or with chest trauma.[32] In practice, practitioners should anticipate that 1 in 10 patients with devastating neurologic injury will be unable to have an apnea test, and declaration of brain death may not be possible on clinical grounds. Families should be informed about the unlikely event of meaningful recovery and in these circumstances, if the patient is a candidate for organ donation, donation after circulatory

determination of death may be considered; most hospitals have protocols for donation under donation after circulatory determination of death,[22] and this approach could potentially increase the supply of deceased donor organs.[33]

Special Circumstances

Determination of Brain Death After Cardiac Arrest in the Era of Therapeutic Hypothermia

About 450,000 Americans have cardiac arrest annually.[34] The face of prognostication after cardiac arrest has changed in recent years based on clinical trials suggesting a robust effect of therapeutic hypothermia on clinical outcomes.[35] In 2006, the AAN published an algorithm to facilitate prognostic determination in patients who are resuscitated within 24 hours after cardiac arrest.[11] The AAN algorithm requires modification as more information accrues on the effects of hypothermia and with validation of other tests for poor and favorable outcomes.[36] Several studies have challenged the validity of single-endpoint assessments proposed by the 2006 AAN guideline, and most experts suggest a "multimodal" prognostication algorithm that would include several variables including the physical examination.[37,38] In this model, the patient enters the evaluation after 72 hours of observation after cardiac arrest. At this stage, the presence of coma, absence of pupillary or corneal reflexes, and the absence of bilateral N20 responses on SSEP indicate high likelihood of poor outcome. If neither of these features is present, the provider should wait at least another 24 hours before a second reassessment. In this second stage, two or more of the following indicate high likelihood of poor prognosis: myoclonic status epilepticus on EEG for less than 48 hours, a high neuron-specific enolase level, an EEG with burst-suppression pattern and lack of reactivity, nonconvulsive status epilepticus on EEG, and/or diffuse anoxic injury either on brain CT scan or magnetic resonance imaging. If none of the above criteria are met, then consider further time for observation[37] (Fig. 59.5). A recent study showed that prognostication after cardiac arrest occurs on the basis of insufficient clinical data, which may lead to early withdrawals on the basis of self-fulfilling prophecies of doom.[39]

•BOX 59.1 Potential Pitfalls With Confirmatory Tests Used in Determination of Brain Death

Cerebral angiogram
- Image variability with injection of arch or selective arteries
- Image variability with injection and/or push technique
- No guideline for interpretation, operator-dependent

TCD
- Technically difficult and skill-dependent
- Normal findings in anoxic-ischemic injury

EEG
- Artifacts in intensive care settings
- Information from mostly cortex

SSEP
- Absent in comatose patients without brain death

CT angiogram
- Interpretation difficulties
- Retained blood flow reported in 205 cases
- Possibility to miss flow states because of rapid acquisition of images
- Delayed flow in low-flow states (e.g., shock, heart failure)

Nuclear brain scan
- Areas of perfusion in thalamus in patients with anoxic injury or skull defect

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is increasingly used as a means of extracirculatory support to patients in severe, reversible cardiac or respiratory failure. Patients presumed to have brain death may have earlier withdrawal of ECMO support,[40] which would limit the possibility of organ donation in patients who would otherwise be declared brain dead. In these circumstances, confirmatory testing may be warranted. A protocol of apnea testing involving the addition of CO_2 to the oxygenator to a target of 60 mm Hg or more than 20 mm Hg from the baseline normal

CO_2 value may be used in lieu of the conventional protocol for apnea testing, but this protocol requires future validation.[41] Recent case reports have indicated that to assess brain death in patients supported by ECMO, apnea testing can be performed without compromising oxygenation by decreasing without stopping the sweep gas flow and increasing oxygen delivery through the membrane.[42,43]

Conclusions

In the United States, current legislation allows physicians to determine death on the basis of neurologic criteria. The diagnosis of brain death on clinical grounds is not a difficult task, provided providers follow established protocols and guidelines for the interpretation of findings during the clinical examination. The establishment of a known cause and presence of coma, the absence of brainstem reflexes, and apnea support the diagnosis of brain death. Most jurisdictions require that the determination of brain death be made by a licensed physician, which in most cases should be an attending physician who has experience in the assessment of comatose patients and the legal requirements applicable to the jurisdiction of practice. When in doubt, an additional period of observation or a confirmatory test should be done to support the determination of brain death.

Key Points

- The clinical examination of brain dead patients is the most unequivocal in neurology.
- The determination of brain death in a comatose patient with catastrophic neurologic injury requires several consecutive steps supported by well-established guidelines.
- When the clinical diagnosis is in doubt or interferences to obtain a thorough clinical examination are present, a confirmatory test may be used to determine brain death in adults.

- Confirmatory testing should not be used in lieu of clinical examination, and when indicated, only one confirmatory test should be performed.
- A period of observation of up to 24 hours after cardiac arrest in patients exposed to therapeutic hypothermia may be required before fully entertaining the determination of brain death.

Review Questions

1. A 67-year-old man has a respiratory arrest in the hospital. He was found unresponsive by the nursing staff, without a pulse or blood pressure, with an unknown down time. The patient was intubated and Advanced Cardiac Life Support (ACLS) resuscitation measures were initiated by the code team. In the intensive care unit (ICU), the patient develops tonic jerking motions of the upper extremities with any stimulation. These movements do not stop with benzodiazepine or propofol infusion. On examination, cranial nerves are intact but he does not respond to visual or auditory stimuli. Sleep/wake cycles are preserved. Examination findings and his condition persist for 1 month during which the patient is chronically ventilated but hemodynamically stable. Which one of the following *best* describes this patient's condition?

a. The patient is brain dead.
b. This patient is in a persistent vegetative state (PVS).
c. The diagnosis of this condition can be made 1 week after initial insult.
d. These patients commonly have no evidence of bladder or bowel incontinence.

Answer: b. The patient in this question is in a PVS. He is comatose but retains brainstem function; therefore he cannot be brain dead. PVS commonly occurs after anoxic or traumatic brain injury. It differs from brain death in many ways. First, brainstem function remains intact in PVS. These patients are also not considered medically or legally dead. A multidisciplinary task force defines PVS as "a condition of complete unawareness of self and environment." As stated, brainstem or autonomic function remains intact. These patients show no voluntary, reproducible, or purposeful responses to stimuli. They have no language comprehension or expression. They also are incontinent. Spinal reflexes are variably preserved.

2. Apnea represents one of the diagnostic criteria for brain death. Which one of the following is *most* correct regarding the apnea test and brain death?

a. The arterial partial pressure of carbon dioxide ($PaCO_2$) goal is above 60 mm Hg.
b. In patients with chronic obstructive pulmonary disease (COPD) with presumed hypoxic respiratory stimulation, PaO_2 levels should be allowed to decrease to less than 50 mm Hg before testing.
c. One should always begin the test with a normal pH and alveolar oxygen partial pressure ($PaCO_2$).
d. Testing should last for 10 minutes and continue with mild desaturation (80%–90%) or mild hypotension (80–90 mm Hg systolic).

Answer: c. All published criteria for brain death include irreversibility of brain damage, absence of neurologic function, the use of additional confirmatory testing, and the presence of apnea. Because most patients are ventilated, the failure of normal respiratory stimulation by a predetermined level of $PaCO_2$ must exist in the presence of apnea. This may be difficult, or in some patients, impossible (i.e., COPD, lung disease). Therefore, although a $PaCO_2$ level above 60 mm Hg is acceptable in patients with normal lungs, this level may not be adequate in all situations. Although some patients may require a level of hypoxemia to stimulate breathing (e.g., PaO_2 level <50 mm Hg), this should not be allowed during testing. Furthermore, no instances of hypotension should be allowed during testing. Should this occur, testing should be halted and the hypotension corrected. Should patients not be candidates for apnea testing, other confirmatory tests should be used.

3. A 27-year-old Hispanic woman arrives at a county hospital with multiple closed head injuries after a car collision. In addition, the patient has multiple internal abdominal injuries that caused frank hemorrhage and prolonged hypotension before resuscitation at the crash scene. Initial computed tomography (CT) of the head shows multiple small contusions. The patient was diagnosed as having moderate to severe anoxic brain injury. She remained in the ICU supported by mechanical ventilation and vasopressor support after initial resuscitation and surgery to stop internal bleeding. On neurologic examination, brainstem reflexes were absent. Which one of the following pertains to further confirmation testing for brain death?

a. The most sensitive test remains cerebral angiography documenting absence of intracerebral filling at the carotid bifurcation or the circle of Willis.
b. The finding of an isoelectric electroencephalogram (EEG) on one test is a highly specific and sensitive test for the diagnosis of brain death.
c. Transcranial Doppler (TCD) findings in brain death include absent or reversal of flow in systole and a sharp diastolic upstroke.
d. Somatosensory evoked potentials (SEPs), which test the integrity of sensory pathways, are highly sensitive and specific tests for brain death.
e. Technetium 99m hexamethylpropylene amine oxime (^{99m}TC HM-PAO) brain scan shows rapid uptake of isotope in nonfunctioning areas of brain consistent with brain death.

Answer: a. Although not necessarily required for diagnosis, additional confirmatory tests may be useful to diagnose brain death. The most sensitive test is cerebral angiography. Findings consistent with brain death include a lack of intracerebral filling at the level of the carotid bifurcation or the circle of Willis. The presence of electrocerebral silence on EEG during a 30-minute study remains the EEG diagnostic criteria for brain death. However, diagnosis should not be based on a single EEG test result. SEPs are controversial. Patients in a PVS may have findings similar to those with brain death. TCDs are noninvasive and can be done at the bedside. The test requires an experienced ultrasonographer and can be affected by changes in $PaCO_2$, hematocrit, and cardiac output. Findings on TCD consistent with brain death include absent or reversal of flow in diastole (not systole) and a sharp systolic (not diastolic) upstroke, or small spike waveforms above or both above and below the baseline at the beginning of systole. ^{99m}Tc HM-PAO scanning shows no uptake of isotope in brain parenchyma after brain death. The reported good sensitivity (94%) and specificity (100%) of this test and good correlation with angiography make this test a possible standard in the future.

4. Which one of the following conditions would not preclude a conclusive brain death diagnosis?
a. Serum sodium level of 120 mg/dL.
b. Temperature of 35°C.
c. A blood pressure of 180/90 mm Hg.
d. Use of cisatracurium for neuromuscular blockade.
e. Serum alcohol level of 209 mg/dL.
Answer: c. To diagnose brain death, certain factors must be absent so that the results of brain death testing are not jeopardized. These factors include the *absence* of (1) hypothermia, (2) intoxication, (3) sedative medications, (4) neuromuscular blockade, (5) electrolyte abnormalities, (6) acid-base abnormalities, and (7) endocrine crises.

5. A 28-year-old man with multisystem trauma involving his head was admitted to the ICU. He has remained comatose for 3 days, developed severe hypoxia and acute respiratory distress syndrome (ARDS), required continued levophed infusion to maintain a cerebral perfusion pressure of greater than 60 mm Hg, and developed intracranial hypertension with intracranial pressures (ICPs) in the mid-30s, sustained despite appropriate advanced thermoregulation (hypothermia to 33°C), pentobarbital infusion, and pharmacologic interventions with hyperosmolar and hypertonic solutions. He has extensive facial trauma, and a tracheostomy was inserted emergently as part of the initial management. Currently he has no response to deep pain, has no brainstem reflexes but pupils could not be examined because of palpebral edema, and has no motor responses as evidenced by the primary neurosurgeon and a consultant neurologist. Which of the following is the best course of action at this time?
a. Continue current management and perform gastrostomy for long-term care.
b. Perform an apnea test.
c. Rewarm to normothermia and request an EEG.
d. He is brain dead, and therefore the team can "pronounce" him and send him for organ donation.
e. Rewarm to normothermia and request a cerebral angiography or cerebral perfusion scan.
Answer: e. This patient has sustained catastrophic brain injury. His examination suggests that he may well be brain dead. Continuing medical care may be ineffective and physicians seem to have exhausted all therapies available. However, we cannot entertain this diagnosis as he is currently under therapeutic hypothermia and received pentobarbital. An apnea test, once he is rewarmed and not receiving pentobarbital, may be ideal, but he likely will not tolerate it (hypoxia and hypotension). A confirmatory test such as a cerebral angiography or perfusion scan could be performed in this case on the basis of extended facial trauma and inability to examine components of the brainstem reflexes (pupils) and other confounders such as pentobarbital exposure. An EEG in the setting may produce a false-positive test result.

Summary

Historical Background

Stroke has a major impact in the United States, with a current yearly incidence of 795,000 new and recurrent strokes.[1] Stroke constitutes the fifth leading cause of death and is a major cause of disability.[2] Historically, stroke was not emphasized in the critical care setting because of the limited scope of interventions in the past. In the early 1990s, neurologic diseases, including but not limited to stroke, accounted for a mere 6% to 7% of admissions to critical care units.[3] Now there is acute treatment for stroke—namely, the use of tissue plasminogen activator (tPA) for ischemic stroke within 3 hours[4] or even 4.5 hours[5] of symptom onset, as well as intraarterial thrombolysis[6] and endovascular clot extraction[7] during the 6 hours after stroke onset. Frequent monitoring in a critical care unit is required after these interventions.

Overview

This chapter reviews the general diagnosis and treatment of ischemic stroke. Stroke includes ischemic infarction as the result of vessel thrombosis (87% of cases), intracerebral hemorrhage (ICH; 10% of cases), and subarachnoid hemorrhage (3% of cases).[2]

Stroke is defined as a focal neurologic deficit of presumed vascular onset, lasting 24 hours or longer, as opposed to a transient ischemic attack (TIA), which is an episode shorter than 24 hours in duration.[8] Many TIAs actually last for less than 60 minutes.[9]

Stroke symptoms, including retinal TIA *(amaurosis fugax),* arise either from the territory fed by the internal carotid artery or from the vertebrobasilar system. The carotid, through its major branches, the anterior cerebral arteries and middle cerebral arteries (MCAs), provides blood to the major portion of the cerebral hemispheres. The vertebrobasilar system, in contrast, perfuses the brainstem and cerebellum, as well as the inferior and medial aspects of the occipital and temporal lobes, and the thalamus.

Carotid symptoms, as listed in Box 60.1, primarily consist of hemisensory loss, hemiparesis, and retinal ischemia (monocular blindness). Left hemispheric ischemia, generally in the perisylvian area, may result in varying degrees of aphasia.[10] Involvement of the sensory association areas within the right parietal lobe can produce the phenomenon of neglect.[11] In neglect, a stimulus is felt when it is alone but not in the presence of a competing stimulus. For example, a touch on the left hand or an object in the left visual field may be perceived when alone, but not when another stimulus is simultaneously presented, generally on the right side (double simultaneous stimulation). In that instance the right-sided stimulus alone is perceived.

Box 60.1 lists symptoms resulting from ischemia in the vertebrobasilar territory, which includes the cerebellum, brainstem, and the medial aspect of the occipital lobe, as well as the thalamus and the inferomedial portions of the temporal lobe. As a result, vertebrobasilar ischemia can produce cranial nerve dysfunction, nystagmus, cerebellar dysmetria, ataxia, and long tract signs such as sensory loss or motor impairment. These may involve one or both sides of the body. Memory disorders and visual field deficits also occur. In extreme circumstances, when the basilar artery becomes occluded, coma or quadriparesis may develop, although the presentation may vary, as described by Kubik and Adams[12] in 1946. As a result of coma or quadriparesis, mechanical ventilation may be required, and the prognosis in such patients is grim. In one study,[13] 22 of 25 patients died, and the other 3 lingered in the "locked-in syndrome" owing to pontine infarction.[14] Such patients can communicate only through eye blinking. Diifferentiating between carotid and vertebrobasilar symptoms is important to avoid unwarranted intervention on stenotic vessels.

Box 60.2 lists those entities that most frequently mimic stroke. Hypoglycemia may produce focal neurologic deficits. Occasionally a mass lesion such as tumor or subdural hematoma may present with fluctuating deficits or be revealed by seizure activity that may be confused with stroke. Mass lesions and hemorrhage are frequently marked by confusion, decreased level of consciousness, or headache, but if the lesion is small, these symptoms may not appear. Consequently, blood sugar measurements and computed

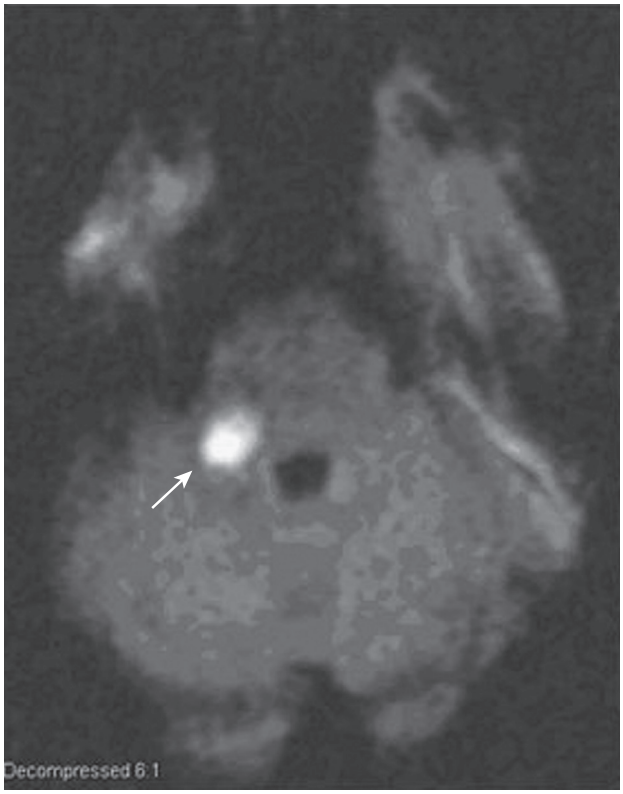
tomography (CT) scans (without contrast) are obligatory in suspected stroke. Within the first 6 hours of the event, CT results may well be negative. Its main role is excluding the presence of small hemorrhages.

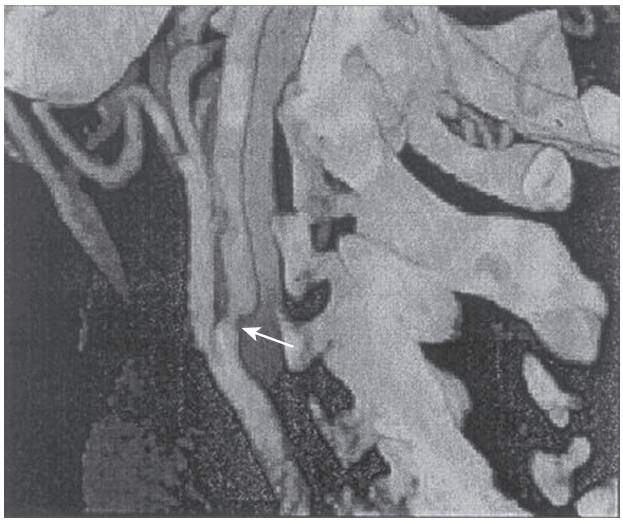
Advances in Radiology

With the advent of diffusion-weighted imaging (DWI), magnetic resonance imaging (MRI) scans (Fig. 60.1) can now be used to detect acute cerebral ischemia within the initial 6-hour period after symptom onset.[15] This allows determination of the presence of stroke in doubtful cases. In the instance of a seizure in a patient with prior stroke, DWI discriminates between seizure alone and new stroke. If an old neurologic deficit worsens, DWI clarifies whether there is new stroke or just intercurrent illness. DWI can also reveal silent areas of cerebral ischemia. The coincident development of ischemia in different vascular territories may point to vasculitis, hypercoagulable state, or cardiac emboli. MRI has been proved to be just as effective as CT in detecting ICH.[16] Unfortunately, MRI is less immediately available, requires more time and cooperation from the patient, and may not be feasible if the patient has claustrophobia or retained ferromagnetic particles. Also, in about 8% of cases, especially milder strokes as the result of small vessel disease or in the posterior circulation, DWI results may prove negative initially.[17]

MR and CT can delineate the cerebral vasculature in detail, starting from the aortic arch and extending to the circle of Willis. Computed tomographic angiography (CTA) is accurate for both the intracranial vasculature[18] and the extracranial segment of the carotid artery[19] (Fig. 60.2). Magnetic resonance angiography is notably less sensitive than CTA in studying intracranial vessels[20] (Figs. 60.3 and 60.4). Consequently, CTA is increasingly the test



• Fig. 60.1 Cerebral infarction as shown by diffusion-weighted imaging *(arrow)* on magnetic resonance imaging. Hyperdensity in the right middle cerebellar peduncle is demonstrated.

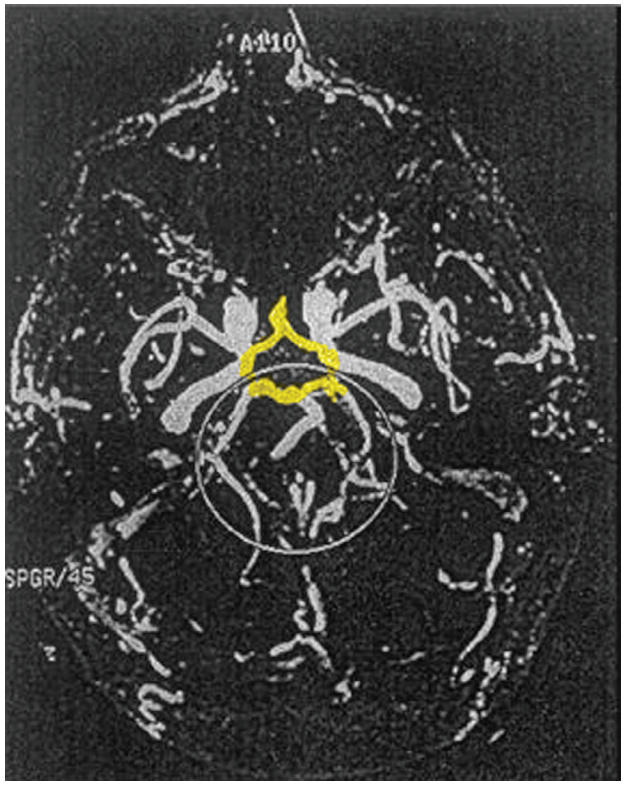


• Fig. 60.2 Computed tomography angiogram of the extracranial carotid artery. An area of stenosis *(arrow)* is shown in the internal carotid artery.

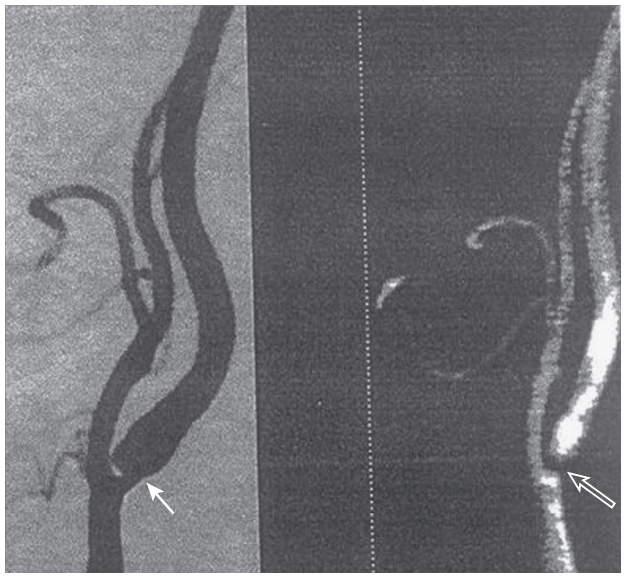
of choice and conventional cerebral angiography is limited to specific indications, as outlined in Box 60.3.

Thrombolysis in Stroke

The era of thrombolysis in acute stroke began with the publication of the National Institute of Neurological Disorders and Stroke (NINDS) tPA trial in 1995,[4] which demonstrated the benefit of



• **Fig. 60.3** Magnetic resonance angiogram demonstrating circle of Willis *(highlighted)* and its vertebrobasilar component *(circle)*.



• **Fig. 60.4** Shown are magnetic resonance angiography *(left)* and computed tomographic angiography *(right)* of the extracranial carotid artery in a patient with internal carotid artery stenosis *(arrows)* located above the common carotid bifurcation.

tPA when given to patients presenting within 3 hours of event onset. Using the National Institutes of Health Stroke Scale (NIHSS) (Table 60.1) score, a reliable measure[21] to measure disability, the improvement was from 20% with minimal or no disability with placebo to 31% with tPA. This was counterbalanced by an increase in the rate of ICH, from 0.6% in the placebo group to 6.4% in the tPA cohort. Half the subjects in the placebo group who sustained ICH died, whereas the mortality rate from ICH in the tPA cohort was 2.9% (less than half). Hemorrhage after tPA use occupies the same area of the brain affected by the initial thrombosis in most, but not all, cases.[22]

• BOX 60.3 Indications for Conventional Cerebral Angiography

- To ascertain the precise degree of arterial stenosis, most often of the extracranial carotid artery, in doubtful cases
- To detect and map intracranial aneurysms and arteriovenous malformations
- To determine patterns of collateral flow in the brain
- To diagnose vasculitis
- To detect intraluminal thrombus
- To enable intraarterial thrombolysis or mechanical clot extraction
- To perform carotid angiography and stenting

Inclusion (Box 60.4) and exclusion (Box 60.5) criteria are applied to attempt to minimize the risk of ICH. Some exclusion criteria are absolute and some are relative (Box 60.6).[23] The time of onset of symptoms is the last time that the patient was seen to be normal. The blood glucose and head CT scan must be checked before initiating tPA. The CT scan must be scrutinized for mass/hemorrhage, and also for early ischemic changes (sulcal effacement, hypolucency, or loss of definition of structures within the brain) and for a hyperdense MCA, suggestive of thrombosis.[24] Whether ischemic changes on CT predict a heightened risk of hemorrhagic transformation is controversial.[22,25] However, CT findings appear more commonly among subjects with scans performed relatively late in the course of their stroke.[25] Their appearance should prompt reevaluation of the time of onset of the stroke. A systematic assessment of hypolucency in the MCA territory, the Alberta Stroke Program Early CT Score (ASPECTS)[26] has been devised, and extensive hypolucencies do correlate with poor outcome. However, it is not clear that thrombolysis should be withheld on that basis alone.[27] Prior ICH, recent stroke, and hypertension at presentation are believed to increase the risk of sustaining ICH. Systemic bleeding may cause hypotension and worsening of the neurologic deficit and must be avoided. Extremes of blood glucose values or the presence of a coincident seizure may make the neurologic deficit seem worse than it is.

A sample for a platelet count must also be drawn before starting thrombolysis, but treatment need not await results unless there is reason to suspect a low platelet count. If the platelet count is less than 100,000 μL, the tPA infusion must be stopped. For a patient receiving anticoagulant therapy, the appropriate clotting parameter must be available before proceeding with treatment. If a patient starts thrombolysis and the coagulation profile proves abnormal, the infusion must be stopped. If a patient is receiving full-intensity low-molecular-weight heparin, tPA must be withheld. Testing for the activity of factor Xa antagonists is not yet standardized, although a normal thrombin time, among other tests, may suggest that thrombolysis is safe.[28]

If the blood pressure is elevated (>180 mm Hg systolic or 110 mm Hg diastolic), labetalol, 5 to 10 mg IV (intravenous), may be given and repeated to a maximum dosage of 40 mg. A nicardipine drip may be used as well. If the blood pressure rebounds, tPA should not be given. If the pressure should rise above 180 mm

	Partial neglect	1
	Complete neglect	2

Hg systolic or 105 mm Hg diastolic after starting the tPA infusion, IV agents must be given to reduce it (Table 60.2).[29] It is worth emphasizing that blood pressure should be treated acutely only when there exists a specific indication for doing so, as defined in the table.

• BOX 60.4 Thrombolysis Inclusion Criteria at 0–3 h

Acute ischemic stroke with clearly defined time of onset
Neurologic deficit measurable using the NIH Stroke Scale
CT scan of the brain without evidence of intracerebral hemorrhage
Age 18 years or older

CT, *Computed tomography;* NIH, *National Institutes of Health.*

• BOX 60.5 Absolute Thrombolysis Exclusion Criteria

Major head or spine injury within the past 3 months
Systolic blood pressure >185 mm Hg or diastolic blood pressure >110 mm Hg
Symptoms suggestive of subarachnoid hemorrhage
Gastrointestinal or genitourinary hemorrhage within the previous 21 days
Evidence of significant bleeding or significant fracture on examination
Heparin use within 48 h before treatment and elevated PTT
Therapeutic dosing of low-molecular-weight heparin
Prothrombin time >15 s or INR >1.7
Platelet count <100,000/μL
Current use of direct thrombin or factor Xa inhibitors (within the past 48 hours), with elevated laboratory tests (PTT, INR, platelet count, ecarin clotting time, thrombin time, or factor Xa activity assay)
Presence of intraparenchymal brain tumor
CT scan of the brain with hypodensity involving more than one-third of the cerebral hemisphere
Arterial puncture at a noncompressible site within the previous 7 days

CT, *Computed tomography;* INR, *international normalized ratio;* PTT, *partial thromboplastin time.*

• BOX 60.6 Relative Thrombolysis Exclusion Criteria

Minor deficit or rapid neurologic improvement leaving a minor deficit
Major surgery within the previous 14 days
Prior history of intracerebral hemorrhage
Presence of meningioma
Seizure with postictal residual neurologic deficits
Blood glucose <50 mg/dL or >400 mg/dL
Large myocardial infarction in the past 3 months
Stroke in the last 3 months
Hemorrhagic diabetic retinopathy
Lumbar puncture in the last week

tPA is often not given for a deficit mild enough that reasonable recovery may be expected within 3 months. However, there is not a clear cutoff based on the NIHSS. A partial hemisensory loss, facial palsy, or mild dysarthria would not normally warrant treatment with tPA, but isolated motor or speech deficits would. Difficult choices exist in the setting of mild deficits. Patients with such deficits may recover well, but 30% of patients presenting with mild stroke are left with significant impairment in one series, even after tPA treatment.[30] Moreover, a percentage of subjects will experience worsening of their condition while in the hospital and then no longer be candidates for rescue using thrombolysis. This is particularly likely in the setting of rapid recovery of the initial deficit and if there is an underlying large vessel stenosis.[31] The benefit of tPA in these circumstances has not been studied.

TABLE 60.2 Approach to Elevated Blood Pressure in Acute Ischemic Stroke

Blood Pressure Level (mm Hg)	Treatment
A. Not Eligible for Thrombolytic Therapy	
Systolic <220 mm Hg OR diastolic <120 mm Hg	Observe unless other end-organ involvement (e.g., aortic dissection, acute myocardial infarction, pulmonary edema, hypertensive encephalopathy) Treat other symptoms of stroke (e.g., headache, pain, agitation, nausea, vomiting) Treat other acute complications of stroke including hypoxia, increased intracranial pressure, seizures, and hypoglycemia
Systolic >220 mm Hg OR diastolic 121–140 mm Hg	Labetalol 10–20 mg IV over 1–2 min May repeat or double every 10 min (maximum dose 300 mg) OR Nicardipine 5 mg/h IV infusion as initial dose; titrate to desired effect by increasing 2.5 mg/h every 5 min to maximum of 15 mg/h Aim for a 10%–15% reduction in blood pressure
Diastolic >140 mm Hg	Nitroprusside 0.5 μg/kg per minute IV infusion as initial dose with continuous blood pressure monitoring Aim for a 10%–15% reduction in blood pressure
B. Eligible for Thrombolytic Therapy	
Pretreatment	
Systolic >185 mm Hg OR diastolic >110 mm Hg	Labetalol 10–20 mg IV over 1 to 2 min, may repeat ×1 OR Nitropaste 1–2 inches OR Nicardipine infusion, 5 mg/h, titrate up by 2.5 mg/h at 5- to 15-min intervals, maximum dose 15 mg/h; when desired blood pressure attained, reduce to 3 mg/h If blood pressure does not decline and remains >185/110 mm Hg, do not administer rtPA
During/After Treatment	
1. Monitor blood pressure	Check blood pressure every 15 min for 2 hr, then every 30 min for 6 hr, and finally every hour for 16 hr
2. Diastolic >140 mm Hg	Sodium nitroprusside 0.5 mg/kg per minute IV infusion as initial dose and titrate to desired blood pressure
3. Systolic >230 mm Hg OR diastolic 121–140 mm Hg	Labetalol 10 μg IV over 1–2 min May repeat or double labetalol every 10 min to maximum dose of 300 mg; or give initial labetalol dose, then start labetalol drip at 2–8 mg/min OR Nicardipine 5 mg/h IV infusion as initial dose and titrate to desired effect by increasing 2.5 mg/h every 5 min to maximum of 15 mg/h; if blood pressure is not controlled by labetalol, consider sodium nitroprusside
4. Systolic 180–230 mm Hg OR diastolic 105–120 mm Hg	Labetalol 10 mg IV over 1–2 min May repeat or double labetalol every 10–20 min to maximum dose of 300 mg; or give initial labetalol dose, then start labetalol drip at 2–8 mg/min

IV, Intravenous; *rtPA,* recombinant tissue plasminogen activator.

Guidelines for the early management of adults with ischemic stroke: a guideline from the American Heart Association/American Stroke Association Stroke Council, Clinical Cardiology Council, Cardiovascular Radiology and Intervention Council, and the Atherosclerotic Peripheral Vascular Disease and Quality of Care Outcomes in Research Interdisciplinary Working Groups: the American Academy of Neurology affirms the value of this guideline as an educational tool for neurologists. *Stroke.* 2007;38:1655–1711.

Subjects who have been taking antiplatelet agents such as aspirin before their event may receive tPA, but no anticoagulants or antiplatelet agents should be given for the 24 hours after the start of tPA therapy. Arterial punctures, nasogastric tubes, and catheterization should be avoided unless they are essential to care to minimize the risk of bleeding.

Hypotension may develop, raising the concern of systemic hemorrhage. The most feared event after tPA use is the development of ICH. The presenting signs and symptoms appear in Box 60.7. Hypertension is a compensatory response to increased intracranial pressure (ICP), to maintain cerebral perfusion, and bradycardia occurs secondary to it.

Box 60.8 shows the steps to be taken with suspected ICH.[32] It is relatively uncommon for neurosurgeons to intervene on hemorrhages in the setting of tPA because of the risk of further bleeding into the surgical bed. Systemic hemorrhage is handled in a similar fashion, and red blood cell transfusion may be necessary.

• BOX 60.7 Signs and Symptoms of Intracerebral Hemorrhage

New neurologic deficits
Worsening of existing neurologic deficits
Headache
Nausea, vomiting
Decreased level of consciousness, coma
Marked hypertension
Bradycardia

The benefit of tPA is greatest in small vascular occlusions[33] and least in carotid[34] occlusions. Older subjects with particularly severe strokes are most likely to have a poor outcome, but even in this group tPA remains beneficial overall.[35] The sooner tPA is administered, the higher the likelihood of successful recovery.[36] A residual

• BOX 60.9 Additional Thrombolysis Exclusion Criteria at 3.0–4.5 h

These are all relative criteria:
Age over 80
NIHSS of 25 or greater
Combination of prior stroke and diabetes
Oral anticoagulant therapy

CT, *Computed tomography;* NIHSS, *National Institutes of Health Stroke Scale.*

benefit of tPA exists as far out as 6 hours from the ictus. Two studies[37,38] that specifically examined treatment beyond 3 hours failed to show a benefit of administration of tPA within a 5- or 6-hour time frame. More recently, however, the ECASS-III (European Cooperative Acute Stroke Study III) trial[5] established the utility of tPA administration in the 3.0- to 4.5-hour period after stroke onset. The inclusion and exclusion criteria are more restrictive than those for treatment within 3.0 hours (Box 60.9). Initially, there was some concern about the administration of tPA within the 3.0- to 4.5-hour window to subjects with a history of both prior stroke and diabetes. A statistical analysis[39] based on datasets from large registries suggests that neither factor predisposes to poor outcome in reality. No doubt there exists a subgroup of subjects who present after 4.5 hours who remain amenable to treatment, but this group cannot yet be identified.

Various authors have identified different predictors of ICH after treatment with tPA. Levy and colleagues[40] identified the dosage of tPA given, the age of the subjects, and diastolic hypertension as pertinent factors. Larrue and colleagues[22] also found age to heighten the risk of development of ICH, but not the degree of hypertension or the time to treatment. It has become clear that tPA can be given safely in the community[41] and that complication rates of tPA use can be lowered to a satisfactory level by careful adherence to the exclusion criteria.[42]

Radiologic imaging has been proposed as a tool to determine when individual subjects may be suitable for intraarterial intervention, regardless of time from stroke onset. Specific patients may, by virtue of good collateral flow, possess a significant area of ischemic but viable brain that may be salvaged by endovascular treatment, even if intervention begins beyond standard time windows. This algorithm may apply particularly to "wake-up" strokes. Computed perfusion tomography (CT perfusion) can be used to estimate the size of the ischemic area but not infarcted area at presentation,[43] and diffusion-weighted/perfusion-weighted MRI may identify those patients who will benefit from intervention.[44] However, these tools need validation and standardization in large studies to attain clinical efficacy.

• BOX 60.10 Thrombolysis in Cerebral Infarction Scale

Grade 0: no perfusion
Grade 1: penetration with minimal perfusion
Grade 2: partial perfusion
  Grade 2A: only partial filling (less than two-thirds) of the entire vascular territory is visualized
  Grade 2B: complete filling of all of the expected vascular territory is visualized but the filling is slower than normal
Grade 3: complete perfusion

Endovascular Mechanical Thrombectomy

As mentioned earlier, IV thrombolysis with tPA changed the landscape for acute stroke management and improved patients' outcomes.[4] However, this effect was less pronounced in patients with large vessel occlusion, defined as terminal ICA (intracranial segment of the internal carotid artery before its bifurcation), proximal MCA (M1 segment of the MCA), and basilar artery.[34]

Endovascular mechanical thrombectomy is a procedure in which a series of telescoping catheters are introduced through the femoral artery and guided by fluoroscopy into the anterior cerebral circulation via the internal carotid artery, or into the posterior circulation via the vertebral and basilar arteries. Contrast dye is injected and the site of occlusion appears as a sharp interruption of flow.

The techniques used to reestablish flow through an occluded segment have evolved from simple injection of intraarterial recombinant tPA to dissolve an occlusive thrombus locally, to the introduction of suction catheters where negative pressure is applied proximally to the thrombus to aspirate it. Other novel techniques include the introduction of a simple ball tip wire to macerate the thrombus, or complex tipped wires deployed distal to the thrombus and pulled back to "uncork" the blocked artery. Although some of these techniques are still in use sporadically, the current standard intervention for thrombectomy is "stent retrieval"[45] in which a wire with a soft expandable stent at its tip is deployed past and through the occluded segment. As the stent expands, it macerates the thrombus and traps it within its mesh; the stent is then carefully pulled back under negative suction. The procedure may be repeated s few times until successful. A semiquantitative scoring system, the Thrombolysis In Cerebral Infarction (TICI) score,[46,47] is used to assess the efficacy of revascularization. A grade of 2B or 3 (Box 60.10) is considered adequate revascularization.

Mechanical thrombectomy is used following IV tPA if a vessel occlusion persists, or alone in patients who cannot receive tPA.

Although the results of earlier studies[48–50] were equivocal, several recent multicenter randomized prospective trials[51–55] showed efficacy of mechanical thrombectomy (sometimes after IV tPA) compared to standard medical treatment. A meta-analysis of all 8 studies[7] showed that patients who underwent endovascular treatment had significant benefit across the spectrum of disability (odds ratio [OR] 1.56; 95% confidence interval [CI] 1.14–2.13; $P = 0.005$). Functional independence at 90 days occurred among 557 of 1293 patients (44.6%; 95% CI 36.6%–52.8%) in the endovascular therapy group versus 351 of 1094 patients (31.8%; 95% CI 24.6%–40.0%) in the standard medical care group (risk difference, 12%; 95% CI 3.8%–20.3%; OR 1.71; 95% CI 1.18–2.49; $P = 0.005$). Compared with standard medical care, endovascular thrombectomy was associated with significantly higher rates of angiographic revascularization at 24 hours (75.8% vs. 34.1%; OR 6.49; 95% CI 4.79–8.79; $P < 0.001$) but no significant difference in rates of symptomatic intracranial hemorrhage within 90 days (70 events [5.7%] vs. 53 events [5.1%]; OR 1.12; 95% CI 0.77–1.63; $P = 0.56$) or all-cause mortality at 90 days (218 deaths [15.8%] vs. 201 deaths [17.8%]; OR 0.87; 95% CI 0.68–1.12; $P = .27$).

The striking benefit of endovascular therapy in addition to access to specialized neurocritical and neurosurgical care has prompted a structural change in regional care delivery. Patients with acute stroke who are candidates for neurointervention or at risk of hemorrhagic complications should be transferred to comprehensive stroke centers for optimal management.

Symptomatic Carotid Disease/Stenting

Carotid endarterectomy (CEA) dramatically reduces stroke risk in patients with cerebral or retinal ischemia with significant carotid stenosis ipsilateral to the affected hemisphere.[56,57] In the North American Symptomatic Carotid Endarterectomy Trial (NASCET),[57] the risk of stroke fell from 26% over 2 years in the nonsurgical group to 9% over 2 years in the surgical group, with a surgical morbidity and mortality rate of 5.6%. The patients had stenosis of 70% or greater. A more modest benefit was seen in men with stenoses between 50% and 69%—namely, a reduction in stroke risk from 22.2% over 5 years without surgery to 14.9% over 5 years with surgery. This is an absolute reduction of the stroke rate of 7.3% over 5 years, as opposed to an absolute reduction of 17% over 2 years in the group with stenosis greater than 70%. Superior surgical skill is necessary to ensure that the procedure remains beneficial in this cohort.

There must also be a reasonable expectation of survival without major disability over a 5-year period. Thus subjects with moderately advanced dementia, hepatic failure, or renal failure are generally not considered suitable candidates for CEA.

Other considerations indicate which patients carry an increased risk of poor outcome acutely from endarterectomy. Such factors include[58] poor or unstable neurologic status, cerebral ischemia within 24 hours of surgery, congestive heart failure, recent cardiac ischemia, marked hypertension, emphysema, age older than 70 years, and severe obesity. The presence of a contralateral carotid occlusion places subjects at extremely high risk of stroke if left untreated but also carries a high morbidity and mortality risk acutely.[59]

The likelihood of stroke in patients with carotid stenosis rises steadily with increasing severity of stenosis greater than 70%[57] and then decreases again as the stenosis reaches 94% to 99%. However, surgery remains beneficial in this range.[60] In addition, hemispheric symptoms predict roughly twice the danger of stroke as do isolated retinal symptoms.[61] Men benefit more from carotid surgery than women. In contrast to prior findings,[58] there is greater benefit of the procedure in persons older than 75 years. Most importantly, the benefit of endarterectomy is maximal within 2 weeks of the sentinel event and diminishes rapidly if surgery is delayed.[62] When severe disability exists, endarterectomy may be reasonably delayed to await recovery.

• BOX 60.11 High-Risk Criteria for Entry Into the SAPPHIRE Trial

Clinically significant heart disease: congestive heart failure, abnormal stress test, or need for open heart surgery
Severe pulmonary disease
Contralateral carotid artery occlusion
Contralateral laryngeal nerve palsy
Previous radical neck surgery
Previous radiation therapy to the neck
Carotid restenosis after endarterectomy
Age older than 80 years

SAPPHIRE, *Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy.*

Protected carotid angioplasty and stenting (CAS) has been compared with CEA in a controlled, randomized trial.[63] Study participants were 18 years of age or older and had either a greater than 50% symptomatic stenosis or a greater than 80% asymptomatic stenosis. They were at high risk, as defined by at least one of the factors listed in Box 60.11.

The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial showed a trend favoring CAS for the incidence of death and major ipsilateral stroke, both in the year following intervention. These gains fell short of statistical significance, perhaps because the study was terminated prematurely. There was a significant decline in the rate of myocardial infarction (MI) at 1 month after intervention in the CAS group when compared with endarterectomy, caused primarily by a fall in the incidence of non–Q-wave MI. Some of this benefit may reflect the added use of clopidogrel in addition to aspirin for 2 to 4 weeks after treatment in the CAS group. CREST The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST)[64] was a randomized comparison of CAS and CEA, including both symptomatic and asymptomatic subjects. It revealed increased risk of stroke acutely with stenting, whereas endarterectomy acutely was associated with an increased risk of heart attack, without, however, increased mortality. Over 2.5 years of follow-up, there was no significant difference in outcome. Endarterectomy appears to be superior, again, in patients older than 70 years. Recovery from nonfatal MI is less problematic than recovery from stroke, and the increased stroke risk in the CAS group occurs early. These results do not support adoption of CAS as an alternative to CEA.

Symptomatic intracranial stenosis appears not to benefit from warfarin when compared[65] to high-dose aspirin, in part because of increased risk of gastrointestinal bleeding. Subsequently,[66] intracranial angioplasty and stenting was compared to intensive medical therapy, including the use of aspirin in conjunction with clopidogrel for 90 days. The study was stopped prematurely because of a high risk of periprocedural stroke and a low risk of stroke in the medically treated arm. One cannot support the routine performance of intracranial angioplasty and stenting on symptomatic vessels.

• BOX 60.13 Indications for Anticoagulation in Stroke

Atrial fibrillation, with or without rheumatic heart disease
Prosthetic heart valve
Deep venous thrombosis, with or without the potential for paradoxical embolus
Hypercoagulable state
Venous sinus thrombosis
Arterial dissection (less definite)

Anticoagulation in Stroke

Anticoagulants occupy an important but limited place in stroke therapy. The acute use of heparin in unselected stroke patients was studied some years ago but not justified.[67] When warfarin is given to unselected stroke patients in a population including a slight majority of subjects with lacunar stroke, it confers no advantage relative to aspirin.[68] Warfarin does not reduce the incidence of stroke among subjects with a decreased ejection fraction (<35%) when compared to aspirin.[69]

Warfarin clearly prevents stroke among subjects with nonrheumatic atrial fibrillation, even if they have never had a stroke or TIA.[70] The risk of stroke falls by 64%. The CHADS2[71] score and now its successor, the CHA2DS2-VASc score[72] (Box 60.12) are used commonly to assess the risk of stroke. A score of 0 on the latter indicates low risk, 1 intermediate risk, and 2 and above high risk.

Individuals with atrial fibrillation who sustain a minor stroke or TIA have a high stroke risk (12% per year), which falls to 4% per year upon treatment with warfarin. A 2.8% yearly risk of all bleeding complications with warfarin exists, as opposed to 0.7% with placebo.[73] It remains uncertain when in the course of stroke to initiate anticoagulant therapy. However, it is clear from a meta-analysis[74] that treatment within 48 hours with heparin or low-molecular-weight heparin does not improve outcome but increases the risk of ICH. Beyond that, acute anticoagulation with oral agents following a stroke should be delayed if there is a sizable infarct as measured by the NIHSS (perhaps a score of ≥12) or on CT (>⅓ of MCA territory), which could progress to herniation and death as a result of ICH. The 185/110 mm Hg cutoff measurement used in the NINDS tPA trial may indicate the blood pressure range of hypertension that would cause one to delay anticoagulation. In contrast, one should move quickly to anticoagulation following TIA or minor stroke occurring in conjunction with atrial fibrillation or any other indication for such therapy.

Other indications for anticoagulation appear in Box 60.13. Some, such as the presence of rheumatic heart disease with atrial fibrillation, prosthetic heart valve, or deep venous thrombosis (DVT), are long established. Anticoagulation carries more urgency when a DVT coexists with a communication across the atrial septum, such as patent foramen ovale (PFO), because there is risk of both recurrent stroke and pulmonary embolism.

The utility of warfarin is limited by the need for regular blood work and difficulty in regulating its dosage. Factor II and factor Xa inhibitors have recently been studied for stroke prevention in the setting of atrial fibrillation. Dabigatran (Pradaxa), rivaroxaban (Xarelto), and apixaban (Eliquis) are marketed in the United States. Apixaban reduces the risk of stroke[75]—when compared with aspirin—in patients deemed unsuitable for warfarin use, without an increase in major or intracranial hemorrhage. When compared to warfarin, apixaban reduces the risk not only of stroke but also of both intracranial hemorrhage and serious hemorrhage.[76] Rivaroxaban[77] appears equivalent to warfarin in stroke prevention and is less likely to produce intracranial hemorrhage but carries a higher risk of major gastrointestinal hemorrhage. Dabigatran, at the dosage of 150 mg twice daily[78] is associated with a smaller stroke risk and, like rivaroxaban, a lesser risk of intracranial hemorrhage but a higher risk of major gastrointestinal hemorrhage exists compared with warfarin.

The main concern with these agents is the lack of means to reverse their effect in the setting of hemorrhage. One patient taking dabigatran has died[79] from relatively minor head trauma leading to progressive intracranial hemorrhage. It may be possible to reverse the effects of rivaroxaban, but not dabigatran, through the use of prothrombin complex concentrate,[80] although dabigatran may be cleared through dialysis.[81] Fortunately, these agents have short half-lives and are cleared rapidly.[82] Nevertheless, care is enjoined in their use, both in the setting of renal insufficiency and in conjunction with aspirin.[83] Idarucizumab fully reverses the anticoagulant effects of dabigatran[84] and is now marketed as Praxbind. However, hemorrhage in patients using factor II and factor Xa antagonists will remain troublesome until means to reverse the anticoagulation produced by all these agents are developed, together with the capability to monitor the process in real time.

Venous sinus thrombosis is an uncommon condition that manifests with headache and papilledema, as well as focal symptoms, and often leads to ICH.[85] Diagnosis is by T2-weighted MRI and magnetic resonance venography, or by head CT and CT venography.[86] Treatment is with heparin acutely, even in the presence of ICH.[87] More recent reports have established the safety of low-molecular-weight heparin followed by 3 months of warfarin therapy for this condition, although only a trend toward favorable outcome emerged.[88] Retrograde thrombolysis through the venous system with tPA in conjunction with IV heparin is effective in more serious cases.[89]

Spontaneous dissection of the carotid and vertebral arteries is the subject of a review by Schievink.[90] This is a significant cause of stroke in younger individuals. Carotid dissection often presents with neck pain, radiating to the head, and with components of Horner syndrome (ptosis, miosis, and anhidrosis). Vertebral dissection

• BOX 60.14 Causes of Hypercoagulable States

Coexistent symptomatic peripheral arterial disease

presents with pain in the neck or back of the head initially. Either may proceed to cerebral infarction or to retinal infarction in the case of carotid dissection. Magnetic resonance angiography diagnoses carotid dissection quite accurately and vertebral dissection less so.[91] Anticoagulation is commonly used but has not been subjected to a rigorous trial. The presence of dissection does not appear to contraindicate the performance of thrombolysis by whatever route.[92]

Box 60.14 lists the hypercoagulable states.[93] Most of these lead mainly to the development of venous thrombosis, although antiphospholipid antibodies and the lupus anticoagulant may produce both venous and arterial thrombosis. The duration of anticoagulation rests on the judgment of the treating physician. Three to 6 months of therapy is commonly undertaken if the episode of thrombosis is isolated.

Antiplatelet Agents in Stroke

Secondary stroke prevention continues to depend on aspirin, as it has for many years. A meta-analysis conducted in 1994[94] showed that antiplatelet therapy, primarily with aspirin, reduces the risk of stroke, MI, and vascular death by 25%. A similar analysis[95] focusing on stroke found a lesser benefit of aspirin, on the order of 13%. The optimal dosage of aspirin remains unknown, but low dosages such as 81 mg are commonly used to reduce the risk of systemic bleeding, which is dose-related.[96,97]

The limited effect of aspirin on stroke recurrence led to a search for other antiplatelet agents. Clopidogrel, a thienopyridine, has exhibited minimal benefit compared with aspirin in preventing stroke.[98] It has subsequently proved useful together with aspirin in the treatment of unstable angina[99] and acute MI[100,101] and after stent placement in the coronary vessels.[102]

However, two separate studies[103,104] have not only failed to show improved outcomes in stroke with such combination therapy when compared with either agent alone, but have also shown increased risk of systemic bleeding. Combination therapy may be useful in the setting of acute cerebral ischemia. Aspirin alone is beneficial in acute stroke when instituted within 48 hours of onset,[105] and one study conducted in China has shown benefit of clopidogrel when given in addition to aspirin within 24 hours of stroke onset.[106] A study is ongoing[107] to confirm these findings in an American population. Comparison of a newer thienopyridine, ticagrelor, against aspirin in the treatment of minor stroke and TIA has shown no difference in outcome.[108] Clopidogrel remains the drug of choice under certain restricted circumstances (Box 60.15). Clinicians often change therapy from one antiplatelet agent to another following the development of a cerebral ischemic event, but there is a significant failure rate with any of them. Aspirin will remain the agent of choice for most patients, in part because of its low price.

Patent Foramen Ovale

PFO is a recently recognized cause of cardiac embolization to the brain. PFO is detected by two-dimensional echocardiography with injection of agitated saline solution or by transesophageal study. In one report it appeared in 18% of young control subjects and in 40% of subjects with cryptogenic stroke. PFO was more common as well in younger as opposed to older patients with cryptogenic stroke (stroke of unknown origin following standard evaluation).[109] The combination of PFO with atrial septal aneurysm in stroke patients younger than the age of 55 years has been associated with a high (15.2% over 4 years) risk of recurrent stroke.[110] Others[111] have found a large diameter (>4 mm) of the PFO to predict increased risk of stroke recurrence. PFO can be treated with warfarin, aspirin, surgical closure, and now endovascular closure. No data suggest conclusively that one treatment surpasses the others.[112] Although there may be a modest benefit of closure, the procedure carries a potential risk of atrial fibrillation, and there is clear risk of procedural complication. At this time, closure of a PFO may be indicated in the absence of another explanation for multifocal infarction or after failure of medical therapy to prevent recurrent stroke.

Prolonged Cardiac Monitoring

Recent investigations have shown that prolonged cardiac monitoring reveals a significant incidence of atrial fibrillation lasting at least 30 seconds in subjects with stroke of unknown etiology (cryptogenic stroke). Thirty-day monitoring has shown a 16% incidence,[113] whereas implantable loop recorders have shown a 12% incidence at 1 year, rising to 30% after 3 years of monitoring.[114] In both studies, patients often began anticoagulation when atrial fibrillation was found, especially if it lasted for periods of 5 minutes or more. However, there is no consensus as to which type of monitoring is preferable, nor is it proven that the monitoring in fact reduces stroke incidence.[115]

Massive Hemispheric Cerebral Infarct

Infarction of the entire MCA territory leads to the development of the "malignant MCA" syndrome.[116] This major injury leads to death in 78% of cases in the first week after the ictus, as the result of cerebral edema leading to transtentorial herniation, and the survivors are quite disabled. Brain swelling peaks at 3 to 5 days after stroke onset.

The presence of early CT changes—namely, hypodensity of more than 50% of the MCA territory—indicates a poor prognosis.[117] In the absence of appropriate intervention, midline displacement of the pineal gland greater than 4 mm predicts death reliably. Large volume of infarction (Fig. 60.5) and displacement of the

• **Fig. 60.5** Massive middle cerebral artery (MCA) infarct. Hypolucency of the entire right MCA territory *(open arrows)* and compression of the right lateral ventricle *(white arrows)* are demonstrated.

septum pellucidum also indicate a poor outcome.[118] At initial presentation, aphasia or neglect may be present, depending on the hemisphere affected. Characteristically, the patients display hemiplegia and a dense hemisensory loss, although the leg may be relatively spared. Quite often, there is a forced eye deviation and hemianopia may coexist. The mortality rate is higher in older individuals with this syndrome,[119] but transtentorial herniation is a more significant cause of death among younger subjects with ischemic stroke.[120] Presumably younger individuals have less cerebral atrophy and less room within the cranial vault to accommodate brain swelling.

Treatment of this syndrome has so far proved disappointing, as reviewed by different authors.[121–123] The review by Wijdicks[123] is particularly comprehensive. Standard therapies include hyperventilation and the administration of IV mannitol. Mannitol is a dehydrating agent, an osmotic diuretic, that aims at reducing cerebral volume and thus ICP. It is given initially at a dosage of 1 g/kg, followed by recurrent dosing 4 times daily with 0.25 to 0.5 g/kg. The goal of therapy is a serum osmolality of 315 to 320 mOsm/L. Mechanical ventilation with hyperventilation produces hypocarbia, which leads to cerebral vasoconstriction, reduced cerebral blood volume, and decreased ICP. The target range for partial pressure of carbon dioxide in arterial blood ($PaCO_2$) is not well defined. Steiner and colleagues[122] state that lowering the partial pressure of carbon dioxide (PCO_2) from "35 to 29 mm Hg lowers ICP by 25% to 30% in most subjects." The benefit of these interventions in clinical practice appears to be short-lived. Because hyperventilation is associated with decreased blood flow, it should be viewed as a temporizing measure only.

• BOX 60.16 Indications for Critical Care Consultation

Intubation and mechanical ventilation
Administration of continuous infusions of antihypertensive agents
Administration of pressor agents
Monitoring not feasible in other settings
Intraventricular drainage

More promising therapies include hypothermia and decompressive hemicraniectomy. Hypothermia in one pilot trial[124] lowered ICP temporarily when instituted within 14 hours of onset of major MCA stroke. Hypothermia has also been used[125] shortly after thrombolysis. The use of a device placed in the inferior vena cava lowers body temperature much more quickly than surface cooling,[126] although there is a concern regarding the development of DVT. Hypothermia to 33°C for 24 hours, after tPA administration within 6 hours of stroke onset, is safe, apart from an increased risk of pneumonia.[127] A larger randomized trial of hypothermia after thrombolysis was stopped prematurely but showed trends toward increased mortality and increased pneumonia among the hypothermia patients.[128]

Decompressive hemicraniectomy with durotomy in early studies appeared beneficial when compared with medical treatment,[129] particularly when intervention occurred before the appearance of signs of incipient herniation.[130] However, the surgically treated patients in these two reports differed significantly from the control patients. The surgical patients were younger, and subjects with large left hemispheric infarcts producing global aphasia were not considered for surgery. Some, if not all, of the benefit in the surgically treated group may be explained by this imbalance between the control and treated groups. More recently, three randomized trials have been cojducted[131–133] and a preplanned pooled analysis[134] of their results published. Two of these studies were terminated prematurely.[131,132] All the studies revealed reductions in mortality rate, but benefits in functional outcome were lesser and not consistently significant. The pooled analysis, looking at the benefit of hemicraniectomy in patients younger than 60 years of age treated within 48 hours, showed significant benefits both in mortality rate and in functional outcome, such that hemicraniectomy has been adopted into general practice. A subsequent study, DESTINY II (DEcompressive Surgery for the Treatment of malignant INfarction of the middle cerebral arterY II),[135] has shown benefit of hemicraniectomy in subjects older than 60 years. Mortality fell, but the subjects remained significantly disabled, with Rankin Scale scores of 3 or greater. The decision to proceed must take note of patient and family opinions as to acceptable quality of life.

Surgical intervention also exists for cerebellar infarction, which, when large, may expand and place pressure on the brainstem.[136] Both ventriculostomy to relieve hydrocephalus acutely and decompressive craniotomy are used. The main determinant of survival and recovery is the absence of coma on presentation. Surgery is the accepted treatment, but the exact timing of intervention remains uncertain.[137]

Critical Care Consultation

Critical care consultation for stroke patients is indicated for a number of reasons (Box 60.16).

Summary

In conclusion, stroke therapy is advancing significantly. Thrombolysis and endovascular therapy have developed over the past 20 years. Advances in radiology have improved imaging of strokes and of blood vessels and will facilitate patient selection for acute intervention. Endarterectomy has become established in the treatment of carotid disease and angioplasty and stenting for the treatment of high-risk cases. New anticoagulants have appeared, although they are not free of risk. No longer is aspirin the only antiplatelet agent available. Decompressive surgery can save lives that would otherwise be lost. Much of this activity has taken place in the critical care unit. As our means for intervention increase, so will the role of critical care in reducing death and disability from stroke.

Key Points

- Determine time of onset of all new strokes.
- Consider IV thrombolysis with tPA if within 4.5 hours of onset.
- Consider endovascular intervention for basilar thrombosis or if within 6 hours of stroke onset.
- Consider rescue therapy with mechanical clot extraction if IV tPA is not efficacious and there is an arterial clot.
- Observe published guidelines for blood pressure control.
- Use MRI and magnetic resonance angiography or CT and CTA to visualize the brain and its vasculature.
- Proceed promptly to carotid endarterectomy or carotid angioplasty and stenting.
- Administer anticoagulants when indicated.
- Use antiplatelet agents according to specific indications.
- Treat malignant MCA infarction with craniectomy.
- Consider surgical intervention for large cerebellar infarcts.
- Consider prolonged cardiac monitoring after cryptogenic stroke.

Review Questions

1. A 58-year-old patient with history of hypertension and paroxysmal atrial fibrillation (AF) is admitted to the emergency department (ED) for new-onset global aphasia, right face, arm, and leg within 3 hours. The National Institutes of Health Stroke Scale (NIHSS) score is 18. The only treatment option associated with improved functional outcomes at 3 months is which of the following?

a. Intravenous (IV) heparin drip
b. Recombinant tissue plasminogen activator (tPA)
c. Intraarterial tPA
d. Therapeutic induced hypothermia

Answer: b. IV thrombolysis with recombinant tPA is the only intervention associated with improved functional outcome at 3 months. The 1995 National Institutes of Neurological Disorders (NINDS) trial demonstrated an effect on functional outcome but not mortality rate at 3 months. Subsequent studies and reanalysis have demonstrated this robust effect. Heparin may not be indicated in paroxysmal AF–related stroke, at least in the first days, because of the higher risk of hemorrhagic convertion. Intraarterial thrombolysis with tPA has been studied in this setting. There are some modest results indicating that rates of recanalization are better without meaningful translation into outcomes. Hypothermia has not been associated with improved outcomes in ischemic stroke but ongoing trials are testing this hypothesis.

2. Which of the following is *not* a contraindication for IV tPA within the 3- to 4.5-hour window?

a. Prior stroke
d. History of diabetes mellitus
c. Unruptured aneurysm
d. Age older than 80 years

Answer: c. A history of unruptured or treated cerebral aneurysms is not a contraindication for the administration of IV tPA. However, one must be careful to determine if the reason for the admission or neurologic symptoms is related to a ruptured cerebral aneurysm (i.e., worst headache of life, subarachnoid blood in the computed tomography [CT]). Age older than 80 years, history of prior ischemic stroke, diabetes mellitus, and anticoagulation (even if the international normalized ratio [INR] is <1.7) are all contraindications for the administration of IV tPA within the 3- to 4.5-hour window.

3. Which of the following does *not* increase the chance of hemorrhagic conversion after ischemic stoke?

a. Diabetes mellitus
b. Uncontrolled hypertension
c. Lower score in the NIHSS
d. Thrombocytopenia

Answer: c. The score in the NIHSS is inversely related to the risk of hemorrhagic conversion. This means that larger strokes will be associated with a higher risk of hemorrhagic conversion. Hyperglycemia, uncontrolled hypertension, and thrombocytopenia are all independent predictors of hemorrhagic transformation after cerebral infarction. The risk increases with the administration of IV tPA.

4. Which of the following is the best treatment option for cerebral edema associated with lower mortality rate and improved functional outcome in a 48-year-old woman with a large left middle cerebral artery infarction secondary to a left internal carotid artery dissection?

a. Targeted temperature management for induction of hypothermia
b. Decompressive hemicraniectomy (DHC)
c. Hypertonic saline
d. Hyperosmolar therapy

Answer: b. The only intervention, based on three major randomized clinical trials, associated with improved mortality rate and functional outcome for large hemispheric infarction (also known as malignant middle cerebral artery stroke) is DHC. All other interventions are associated with improved measures in cerebral edema, intracranial pressure, and cerebral complications, but not with mortality rate or functional outcome benefit.

- Prognosis

Myasthenia Gravis
- Clinical Presentation
- Pathophysiology and Prognosis
- Diagnosis
- Treatment
- Medications to Avoid
- Mortality

Complications
- Respiratory Failure
- Pain and Sensory Disturbance
- Other Complications

Historically, the most common neuromuscular condition that required prolonged mechanical ventilation (MV) was poliomyelitis.[1,2] The epidemics of the 1940s and 1950s resulted in large polio wards with negative-pressure ventilators.[2] With the advent of the Salk vaccine, however, this is no longer the case. Currently, Guillain-Barré syndrome (GBS) and myasthenia gravis (MG) account for the majority of patients with neuromuscular illness requiring intensive care.[3]

Guillain-Barré Syndrome

Incidence

GBS is an acute inflammatory polyneuropathy with a reported incidence of 1.1 to 1.7 per 100,000 persons per year in 1980.[4,5] A recent meta-analysis of 13 studies of GBS performed between 1935 and 2002 reported crude incidence in North America and Europe from 0.81 to 1.89 (median, 1.11) cases per 100,000 person-years. The rate of GBS increases exponentially with age, with a regression analysis showing a 20% increase in the average GBS rate for every 10-year increase in age with an incidence of 2.22 per 100,000 after 70 years of age. The risk of GBS is higher for males than females.[6]

Pathophysiology

GBS, also known as acute inflammatory demyelinating polyradiculoneuropathy (AIDP), is an immune-mediated injury affecting the motor and sensory peripheral nerves. Although initially described as a demyelinating process with loss and dysfunction of the myelin sheath, an axonal variant with damage or degeneration of the nerve cell axon is also described.[7] With the former, classically, nerve conduction velocity studies confirm a demyelinating process with slowing of the conduction velocity and an increase in the distal latency of the neurons. In the axonal variant, there is a decrease in the amplitude of the compound motor action potential. This axonal variant, also known as an acute motor axonal neuropathy (AMAN), had been considered to have a slower recovery pattern and worsened prognosis; however, more recently it is recognized that these patients can show two patterns of clinical recovery. In contrast to the uniform recovery of patients with AIDP, some patients with AMAN have a rapid recovery, whereas others have a more prolonged course; however, even the most severely disabled patients are usually able to walk independently within a few years.[8,9] Rapid recovery is explained by a subset of patients who have early resolution of physiologic conduction failure at the nodes of Ranvier in the motor fibers or by collateral sprouting of surviving axons.[10]

GBS is an autoimmune disease that is triggered by a preceding bacterial or viral infection. *Campylobacter jejuni,*[11] *Haemophilus influenza,*[12] *Mycoplasma pneumonia*, cytomegalovirus,[13] Epstein-Barr virus, and Lyme virus have been associated with GBS. More recently, mosquito-borne viruses such as the alphavirus, Chikungunya,[14] and the flavivirus Zika have been associated with GBS. It is estimated that GBS develops in 1 in 4000 (0.24/1000) affected with a Zika viral infection. This is lower than the estimate following a *C. jejuni* infection (0.3–1.17/1000).[15,16] The delayed interval between a Zika or Chikungunya viral infection and onset of neurologic symptoms of 3 to 12 days is consistent with a postinfectious autoimmune mechanism as opposed to the direct neurotropic effects of other flaviviruses such as the West Nile Virus and Japanese encephalitis virus.[14]

In the AMAN form of GBS, the infectious organisms share homologous epitopes to a component of the peripheral nerve. The molecular mimics are glycans expressed on lipooligosaccharides from a microbial stimulus such as *C. jejuni* that induces a humoral response with primarily complement-fixing immunoglobulin (Ig) G1 and IgG3 antibodies that cross-react with axonal components mainly against gangliosides G_{M1} and G_{D1a}, but also against GM_2, GD_{1b}, and GT_{1b}.[17–19] Antibodies fix complement, recruit macrophages, and deposit membrane complex in the axolemmal membrane. If the immune injury to the neuronal membrane disrupts the anatomic integrity of the nerve, the patient will exhibit slow recovery. When the immunologic injury is targeted to the membranes in the nerve terminals or nodes of Ranvier causing a nerve conduction blockade, a more rapid recovery is expected.[10,20] In AIDP, the immune reaction is targeted to epitopes of the Schwann cell or myelin. Interestingly, the more common form of GBS in Europe and North America is AIDP, whereas AMAN is more frequently reported in East Asian countries such as China and Japan. This is likely due to geographic genetic variants of the viruses.[21]

Clinical Presentation

GBS often presents as a symmetric ascending flaccid paralysis typically starting in the legs followed by arm weakness. Because GBS is a demyelinating or axonal degenerating process of the lower motor neuron, patients are areflexic, although early in the course, deep tendon reflexes may be present. Symptoms may also include paresthesias if the sensory nerves are involved. The autonomic system can be involved. These patients exhibit cardiac arrhythmias, including severe, life-threatening bradycardia, orthostatic hypotension, sweating abnormalities, urinary retention, and gastrointestinal dysfunction, or unreactive, dilated pupils.[22,23] The degree of weakness is often graded using the British Medical Research Council (MRC) scale for muscle strength. On this scale, 5 indicates normal power; 4 opposes resistance; 3 opposes gravity; 2 moves the joint with active movement with gravity eliminated; 1 is a flicker or trace contraction; and 0 reflects absent contraction. Severe weakness is defined as MRC grade or 2 or lower.[24]

A clinical variant of GCS includes a classic triad of ataxia, areflexia, and ophthalmoplegia causing diplopia. This is known as the Miller Fisher syndrome (MFS). An overlap syndrome of GBS and MFS can result in evolution of further cranial nerve involvement with facial and bulbar weakness and varying degrees of limb weakness and respiratory failure. MFS is often associated with serum antibodies to GQ_{1b}.[25–27] The GQ_{1b} epitope has been found in the lipopolysaccharide of *C. jejuni* isolated from patients with MFS.[26] An anti-GQ_{1b} mouse monoclonal antibody immunostains the paranodal regions of the extramedullary portion of the human oculomotor, trochlear, and abducens nerves and weakly stains the deep cerebellar nuclei.[25] In addition, biochemical analysis shows that the human oculomotor nerve contains more GQ_{1b} than does the ventral and dorsal horn of the spinal cord.[17] Therefore it is thought that the anti-GQ_{1b} antibodies account for the ophthalmoplegia found in MFS. Some have suggested that patients with MFS may be less responsive to immunomodulatory therapy than those with classic GBS.[28]

Other closely related autoimmune entities along the continuum of GBS and MFS include an isolated acute ophthalmoplegia with elevated anti-GQ_{1b} IgG titers[29] and Bickerstaff brainstem encephalitis (BBE) with elevated anti-GQ_{1b} IgG antibody titers in up to 66%.[30] Again, both have an antecedent history of infectious symptoms within 4 weeks of the onset of neurologic symptoms. BBE is characterized by a progressive, relatively symmetric ophthalmoplegia and ataxia with mental status changes including coma or stupor or pyramidal signs such as hyperreflexia or pathologic reflexes. Pupillary abnormality and bulbar palsy are also seen. Like MFS, neither the isolated acute ophthalmoplegia entity nor BBE have significant limb weakness with strength 5 or 4 on the MRC scale unless there is an overlap syndrome with classic symptoms of GBS.

Differential Diagnosis

The clinical history and pattern of rapidly progressive limb weakness can help pinpoint the diagnosis. The differential diagnosis may include botulism, organophosphate poisoning, MG, or a spinal cord lesion (Table 61.1). However, GBS presents with a history

TABLE 61.1 Clinical Patterns of Acute Neuromuscular Weakness

Cause	Cranial Nerve Involvement	Limb Weakness	Reflexes	Sensory	Autonomic Changes
Guillain-Barré syndrome	Common, facial diplegia	Distal (ascending)	Absent	Common	Possible (20%)
Miller Fisher syndrome	Hallmark: ophthalmoplegia	Variable Hallmark: ataxia	Absent	Rare	Rare
Myasthenia gravis	Common, ptosis, facial, oculomotor	Proximal (shoulders and thighs)	Normal	Present	Present
Botulism	Symmetric diplopia, ptosis, dysarthria, dysphagia	Descending	Absent or decreased	No	Yes (e.g., ileus, mydriasis, reduced salivation, urinary retention)
Organophosphate poisoning	Bulbar dysfunction, dysarthia, dysphagia	Diffuse	Decreased	Late	Yes (e.g., bradycardia, sialorrhea, bronchorrhea, lacrimation, diarrhea, miosis causing blurry vision)
Brainstem	Common, ocular movement	Crossed findings (face/limbs)	Increased	Common	Rare
Spinal cord	No	Quadriparesis or paraparesis	Decreased then increased	Loss below level	If above thoracic level

of a viral or diarrheal prodrome followed in 1 to 2 weeks by a rapidly progressive, monophasic disease course typically lasting 1 month. The pattern of weakness typically includes a symmetric ascending paralysis with bilateral facial weakness.

A patient with botulism may also have a symmetric pattern, but initial symptoms are descending with initial facial and bulbar weakness. The symptoms associated with botulism typically include diplopia, ptosis, dysarthria, and difficulty swallowing followed by a descending pattern of appendicular weakness. Arreflexia is seen with both GBS and botulism; however, botulism does not have sensory findings. Autonomic findings can be found in both conditions, but botulism is more likely to include mydriasis and urinary retention.

Patients with organophosphate poisoning should have an exposure history. Because organophosphates are acetylcholinesterase inhibitors, symptoms are those of excessive cholinergic stimulation with fasciculations followed by diffuse weakness, blurry vision, miosis, and bulbar dysfunction, and autonomic dysfunction such as bradycardia, sialorrhea, bronchorrhea, lacrimation, emesis, and diarrhea. Decreased reflexes and late sensory findings can also occur.

Patients with MG, which is detailed later in this chapter, present with proximal weakness of the shoulder and hip girdle with difficulty holding their arms over their head (e.g., to brush their hair) or difficulty climbing stairs. Commonly, MG presents with ocular findings including ptosis, diplopia owing to oculomotor dysfunction, and facial weakness. Reflexes are typically normal. Sensory and autonomic dysfunction have not been well recognized but can be seen with MG.

Other forms of rapidly progressive weakness that arise from the central nervous system include brainstem pathology, such as tumor, hemorrhage, or ischemic stroke; however, motor findings are typically asymmetric and crossed—for example, ipsilateral face with contralateral arm and leg weakness. Deep tendon reflexes are brisk owing to involvement of the upper motor neurons. Depending on the level of injury, eye movement and sensation are also affected. Spinal cord pathology will have typically caused a sensory and motor level that is referable to the level of spinal cord injury. In patients with injury above the thoracic level, autonomic changes, such as bradycardia and hypotension, can be seen owing to dysfunction of the sympathetic system that has thoracic innervation.

Diagnostic Testing

Electrophysiology testing of the nerves demonstrates slowing of the nerve conduction, an increase in latency, or an axonal loss with decreased amplitude of the compound motor action potential. In addition, cerebrospinal fluid (CSF) testing can be helpful. Although a small percentage (<15%) may have a mild pleocytosis (5–50 cells/μL),[31] the hallmark of GBS is an elevated CSF protein level with lack of cells that is known as CSF albuminocytologic dissociation. In one study, nearly 50% of patients had elevated CSF protein concentration in the first few days and 83% had elevated concentration by 8 to 14 days.[31]

The serum level of anti-$G1_b$ IgG antibody may be a more sensitive marker for detecting MFS, because CSF albuminocytologic dissociation was found in 59% of 123 MFS patients during the first 3 weeks of illness, whereas the serum anti-GQ_{1b} IgG antibody result was positive in 85% with the peak within the first week of illness.[32]

Neurodiagnostic imaging studies are not useful in diseases of the peripheral nervous system such as GBS; however, in the spectrum of the autoimmune, BBE has been associated with abnormal high-intensity areas on magnetic resonance imaging (MRI) T2-weighted images in about one-third of patients.[33] Areas involved include the brainstem, thalamus, cerebellum, and cerebrum, and symptoms may wax and wane depending on the clinical course.[34]

Clinical Course

Patients reach their nadir by 4 to 6 weeks. The progressively worsening phase typically lasts less than 1 week in half of patients, less than 2 weeks in 80%, and less than 4 weeks in 97%.[31] Typically there is a plateau of 7 days to several months, although the recovery phase ensues thereafter. Nine percent to 10% of patients exhibit treatment-related fluctuation that by definition occurs within 8 weeks of start of treatment.[31,35] In one cohort, about 5% of patients exhibited a clinical deterioration after 8 weeks of weakness onset. When more than two recurrent deteriorations occur, the clinician should consider the diagnosis of chronic inflammatory demyelinating polyneuropathy (CIDP). The clinical course of CIDP is stepwise and fluctuating. It typically has a less severe course and is less likely to be associated with respiratory failure and cranial nerve dysfunction.[20] CIDP is treated with corticosteroids, whereas AIDP is not.[35]

Treatment

Plasma Exchange

Given the autoimmune etiology of GBS, treatment targets inactivation of complement, removal of idiotypic antibodies, cytokine inhibition, and saturation of Fc receptors on macrophages. To remove the antibodies, plasma exchange (PE) was first introduced as a potential treatment in 1978.[36] Subsequently, multiple trials comparing PE with supportive care alone have shown significant improvement in outcome at 4 weeks.[37–39] Studies typically use disability scales such as the Hughes Functional Grading Scale to grade outcome: grade 0 is a normal functional state; grade 1 is the ability to run with minor signs and symptoms; grade 2 is the ability to walk 5 m independently; grade 3 is the ability to walk 5 m with assistance; grade 4 is bedbound or chairbound status; grade 5 indicates the requirement for assisted ventilation; and grade 6 is death.[40]

The French Cooperative Group on Plasma Exchange in Guillain-Barré Syndrome trial showed that four courses of PE treatments were better than two courses in bedbound patients who were not ventilated mechanically. Specifically, of 155 patients treated with 4 PE courses, 64% recovered full muscle strength after 1 year compared with 48% of 149 treated with 2 courses.[41] In a parallel trial, 161 ventilator-dependent patients were randomly assigned to receive four or six courses of PE and showed no significant differences in recovery. Overall, PE decreases the likelihood of worsening when treatment is started when the patient is still ambulatory and decreases the time on MV and time to independent ambulation by 50%. For this reason, although the optimal number and volumes exchanged is not yet established,[42] based on previous trials,[45,47] the recommendation is to perform 5 exchanges totaling 200 to 250 mL/kg every other day or over about 10 days. Additional information from the French Cooperative Group showed that fresh frozen plasma was associated with more adverse incidents than albumin when used as a replacement fluid during PE.[43]

Intravenous Immunoglobulin

Intravenous Ig (IVIg) can modulate complement activation products, neutralize idiotypic antibodies, saturate Fc receptors on macrophages to prevent activation, and suppress various inflammatory mediators such as cytokines, chemokines, and matrix metalloproteinases.[44] The

first trial of IVIg was in 1988.[45] Multiple randomized controlled trials of immunotherapy have shown that both PE and intravenous administration of pooled γ-globulin (IVIg) are equally effective for the treatment of GBS.[46–51] The standard dose is 0.4 g/kg daily for 5 days.

The choice of using IVIg over PE may include the availability of the different modalities locally; however, for patients with issues such as severe hemostasis, unstable hemodynamics, or uncontrolled sepsis, IVIg is likely to be better tolerated. In this subset of patients who received IVIg for 6 days compared with 3 days of treatment, a randomized, double-blind, multicenter phase II trial showed that mechanically ventilated patients benefited significantly, with a drop from a mean of 152 days (range 54–332 days) to 86 days (range 13–151 days) when given the 6-day course of treatment.[52]

Current recommendations for nonambulatory or mechanically ventilated patients with GBS includes treatment with PE or IVIg as early as possible and at least within 4 weeks of symptom onset.[42,53] For milder cases of GBS in which ambulation is preserved, recommendations are to consider treatment within 2 weeks of symptom onset.

In severe GBS, combined therapy of PE followed by IVIg in 128 patients compared to PE in 121 patients showed no significant advantage in 4-week disability outcome, time to independent walking, duration of ventilation, or death, or in 12-month outcome of death or disability.[49] In a nonrandomized trial comparing PE followed by IVIg in 24 patients to PE alone in 13 patients also showed no difference in outcome.[54] Therefore combination therapy of PE and IVIg for GBS is not recommended as it increases cost but has not been shown to improve outcome.

Although either plasmapheresis or immunoglobulin therapy has been shown to be equally effective in altering the course of GBS, multiple studies of enteral and parental corticosteroids have not.[46,55] A multicenter randomized trial of prednisolone in patients with BGS showed greater improvement in the control group than the prednisolone group with a higher rate of relapses in those treated with prednisolone.[40] For this reason, corticosteroid treatment is not used for GBS.

Prognosis

The prognosis for the Miller Fisher variant is good; recovery typically begins within 2 to 4 weeks of symptom onset and full recovery occurs within 6 months. BBE, despite altered mental status changes, also has a good outcome; 50% of patients show complete remission with no residual outcomes by 6 months.[30]

Most patients with GBS begin recovery within the first weeks. However, after discharge, 72% may have sensory disturbances and 89% have residual weakness. At 1 year, about one-third of patients feel completely cured,[56] although up to 14% may have persistent disability.[57] Approximately one-third are unable to return to their previous work.[56] Some patients have reported recovery in up to 2.5 to 6.5 years after onset.[58] However, of those who survive, most do well with more than 80% able to walk independently at 6 months.[57] Even 79% of those who require MV eventually regain independent ambulation.[59]

As noted previously, compared with patients with AIDP, those with AMAN typically have either a slow recovery (inability to walk independently at 6 months) or rapid recovery (improvement by 2 Hughes grades or more within the first 4 weeks). Patients with AIDP have a more uniform recovery time for improvement of one grade.[8,9]

GBS has a mortality that varies between 1% and 18%, with the higher rate of 10.4% to 38.3% found in those who require MV.[59–61] The most common causes are pneumonia, sepsis, acute respiratory distress syndrome, pulmonary embolism, or autonomic dysfunction with dysrhythmias.[57] Predictors of mortality include older age, MV, cardiac complications, and sepsis.[5,62]

Myasthenia Gravis

MG affects approximately 15 to 20 per 100,000 people in the United States.[63] A systematic literature review of 31 studies published between 1980 and 2007 estimated a worldwide incidence of 30.0 per 1,000,000/year with a noted increase over time that is attributed to greater awareness and improved methods of diagnosis rather than a true increase in incidence.[64] In a U.S. national inpatient database, MG has a bimodal distribution such that it could be considered a disease of young women and old men. Women have a two to three higher admission rate during the first 5 decades, whereas men have a higher rate of admission during the sixth, seventh, and eight decades. In this database, older age and respiratory failure were the predictors of death.[65]

Clinical Presentation

The clinical characteristics of MG include a fatigable muscle weakness of the limb, ocular, facial, oropharyngeal, and respiratory muscles. In those with limb weakness, the initial presentation often is weakness of the proximal—that is, limb girdle muscles with difficulty climbing stairs or raising arms over one's head in tasks such as brushing one's hair. More than 50% of patients present with diplopia and ptosis; others have difficulty with mastication, whereas bulbar findings such as dysarthria and dysphagia are the presenting symptoms in about 15%.[66–68] If MG is associated with a thymoma, also known as paraneoplastic MG, it often presents with ocular, bulbar, neck, and respiratory symptoms rather than appendicular weakness.[69] Those presenting with ocular and bulbar symptoms may be differentiated from another acute neurologic diagnosis—botulism toxin poisoning—by clinical history as it lacks an exposure event, even though both can present with similar clinical findings. Of those with a primarily ocular presentation, the generalized disease develops in approximately half within 2 years.[66,70] The Osserman classification is utilized by the Myasthenia Gravis Foundation of America and allows the standardization of clinical symptoms (Table 61.2).[71]

Pathophysiology and Prognosis

Although both MS and GBS are autoimmune diseases, unlike GBS, in which antibodies target the peripheral nerve, MG affects the neuromuscular junction (NMJ). Autoantibodies are directed against the muscle acetylcholine receptor (AChR) in approximately 85% of patients[72] or to the muscle-specific tyrosine kinase (MuSK) in approximately 50% to 70% of patients who do not have autoantibodies against the AChR.[73–75] Both sites are on the postsynaptic membrane of the NMJ. Autoantibody binding to proteins at these sites leads to impaired neuromuscular transmission and muscle weakness. MuSK is an enzyme critical for the formation and maintenance of the NMJ by agrin-induced AChR clustering.[73,76] Anti-AChR and anti-MuSK antibodies account for more than 90% of cases of MG.[77]

The anti-AChR antibodies in MG are of the IgG subclass 1 or 3 and affect the NMJ by three mechanisms: (1) causing complement activation with destruction and focal lysis of the postsynaptic folds at the NMJ and the destruction of the AChR and AchR-related

TABLE 61.2 Osserman Classification Used by the Myasthenia Gravis Foundation of American to Standardize Clinical Symptoms[71]

Class I	Any ocular muscle weakness
Class II	Ocular muscle weakness of any severity, MILD limb weakness
Class IIa	Predominantly limb and/or axial muscle weakness
Class IIb	Predominantly bulbar and/or respiratory muscle weakness
Class III	Ocular muscle weakness of any severity, MODERATE weakness of other muscles
Class IIIa	Predominantly limb and/or axial muscle weakness
Class IIIb	Predominantly bulbar and/or respiratory muscle weakness
Class IV	Ocular muscle weakness of any severity, SEVERE weakness of other muscles
Class IVa	Predominantly limb and/or axial muscle weakness
Class IVb	Predominantly bulbar and/or respiratory muscle weakness
Class V	Intubation with or without mechanical ventilation

proteins at the end plate; (2) cross-linking the adjacent AChRs, which causes early internalization and degradation of the receptors; and (3) blocking the acetylcholine-binding site. Anti-AChR antibody levels generally correlate with but do not precisely predict disease severity and response to treatment.[74]

The anti-MuSK antibodies in human MG are predominantly of the IgG 4 subclass and do not activate complement.[78] Their action may be that they bind to the N-terminal portion of the extracellular domain of MuSK, which has been shown in vitro to inhibit agrin-induced AChR clustering, which causes AChR dispersion and end plate disruption.[73,79] Interestingly, it appears that anti-MuSK IgG interferes with the anchoring of MuSK to the collagen tail (ColQ) of the end plate acetylcholinesterase (AChE), which is responsible for the hydrolysis of acetylcholine (ACh). At the NMJ, three tetramers of AChE are linked by ColQ; however, disruption of this complex by anti-MusK antibody makes the AChE complex less effective.[80] Similarly, human congenital defects of ColQ cause an end plate AchE deficiency and result in a myasthenic syndrome.[81,82] This may provide an explanation for the finding that MuSK antibody–positive patients are less responsive to AChE inhibitors.

Antibodies to other muscle antigens are also found in patients with MG. Up to 95% of patients with thymoma and 50% of patients with late-onset MG without thymoma have autoantibodies to striated muscle antigens such as titin and ryanodine receptors (RyR). Titin is a large protein that develops the passive force in stretched sarcomere.[83] Ryanodine is the calcium channel of the sarcoplasmic reticulum that releases calcium into the sarcoplasm and results in muscle contraction. In vitro RyR antibodies can inhibit calcium release. MG patients with RyR antibodies have been described as having a characteristic presentation of bulbar, respiratory, and particularly neck weakness.[84] Also, titin and RyR antibodies also may target cardiac muscle antigens, and myositis and myopathy with atrophy are seen in some thymomatous MG patients.[85] With the high likelihood of finding titin or RyR antibodies in the presence of thymoma, their presence can facilitate the diagnosis of thymomatous MG as they typically indicate a thymic pathology.[86]

More recently, antibodies against low-density lipoprotein receptor-related protein 4 (LRP4) were found to be present in 1% to 3% of all patients with MG[87] and in 9.2% of patients with double-seronegative MG.[88] LRP4 is a newly identified receptor for agrin that increases agrin interaction with MuSK to activate the kinase and initiate downstream signaling cascades for AChR clustering essential for NMJ formation.[89] These antibodies inhibit binding of LRP4 to its ligand and belong to the IgG1 subclass that activates complement. These patients typically have mild to moderate symptoms; however, more information is needed to elucidate differences in their response to therapy. The remaining patients were considered to have idiopathic or "seronegative" MG; however, they too have autoantibodies, and like those with antibodies against AChR and MuSK, will benefit from treatment targeting immunosuppression or immunoabsorption.[90]

The thymus is the site of maturation for T cells. Thymic hyperplasia and thymoma are risk factors for MG with anti-AChR antibodies.[91–93] MG develops in 50% of patients with thymoma,[94,95] whereas 15% of MG patients have thymomas.[96] A thymoma associated with MG is typically a neoplasm derived specifically from thymic cortical epithelial cells. Cortical thymomas have properties that propagate the maturation of immature naïve CD4 T cells and export mature naïve T cells into the periphery and create this paraneoplastic syndrome. In contrast, thymomas histologically similar to medullary thymic tissue lack developing T cells and are not usually associated with MG.[97,98]

Thymomas occur equally in males and females and are uncommon in children and young adults. The incidence rises in middle age and peaks in the seventh decade of life.[99] The overall incidence in the United States is 0.13 per 100,000 person-years.

Thymomatous MG has a pattern similar to late-onset MG. Both are associated with a later age of onset, lower AChR antibody titer, the presence of titin or RyR antibodies, a more severe course, the frequent need for immunosuppressant medications, and a higher mortality rate. In contrast, patients with early-onset nonthymomatous MG typically have an elevated AChR antibody concentration, almost no titin or RyR antibodies, a lower requirement for immunosuppressive medications, a less severe course, low MG-associated mortality rates, and a favorable thymectomy outcome.[100]

Classification of MG into different subtypes such as those found in Table 61.3 may be helpful to identify and predict prognosis and the clinical response to various treatment modalities.[101–103] New work identifying subgroups based on early onset, late onset, thymomatous, MuSK, LRP4, seronegative, and ocular MG is attempting to adapt existing therapy to the characteristics of the individual patient.[104]

Diagnosis

The diagnosis of MG is based in part on the clinical history of fatigable weakness in the patterns discussed earlier. Edrophonium, a short-acting parenteral AChE inhibitor, was previously available to administer at the bedside to determine whether the patient had improved strength compared to a placebo of saline solution.[105] It is no longer widely available. Neostigmine, an AChE inhibitor that is longer-acting and easily available because it is used for reversal of neuromuscular blocking agents in the postoperative arena, can also be used.[106,107] Close care is needed during administration of a parenteral AChE inhibitor, especially the longer-acting neostigmine, to monitor for parasympathetic effects such as bradycardia,

TABLE 61.3 Serologic and Clinical Presentation of Myasthenia Gravis Subgroups[84,100–104,136]

	AChR Antibody	MuSK Antibody	Striated Muscle Antigens Titin Antibody Ryr Antibody	Age at Onset Sex	Clinical Findings	Response to Therapy	Response to Thymectomy	Prognosis
Ocular MG	50%–75%	None	None	Older Males	Ocular	Good	Good	Good (but 50% can develop generalized MG in 2 yr)
Early-onset generalized MG	80%–85% (high titer)	None	None-rare	<50 yr	General	Rarely needs immunosuppression	Good	Less severe Low mortality
Late-onset generalized MG	None–rare	None	50% 54% titin 33% RyR	≥50 yr	General	Often requires immunosuppression	Poor	Severe
Thymomatous-associated MG	Positive, nearly 100% (low titer)	None	95% 50% titin 47% RyR	Ranges: Older but <40 yr if RyR	General If RyR: ocular, bulbar, respiratory weakness	Often requires immunosuppression	Fair	RyR: invasive, malignant thymoma Severe Higher mortality
Generalized MG MuSK positive	None	100%	None	Younger Female	Facial, bulbar, neck, respiratory weakness paraspinal, esophageal muscles	Poor response to AChE inhibitors	Poor (no thymic changes)	Severe, progressive course
MG with thymic hyperplasia	89%	None	None	Younger Female	General	Good	Good	Good
ACh antibody negative	Negative	Negative	Present	Younger Female	General	Poor		Fair

ACh, Acetylcholine; *AChE*, acetylcholinesterase; *MG*, myasthenia gravis; *RyR*, ryanodine receptor.

sialorrhea, and bronchoconstriction. Atropine should be readily available for administration during the testing. An ice-pack test can be used in ocular MG patients who present solely with mild ptosis. An ice pack is placed over lightly closed eyes for 2 minutes with resultant improvement in ptosis.[108]

Confirmation can be made by electrodiagnostic studies with a characteristic decremental response to a 2- to 3-Hz repetitive nerve stimulation on electromyographic examination. This classic finding is seen in two-thirds of MG patients.[109] Single-fiber electromyography is more sensitive but less specific and technically more difficult. Increased jitter, or variability of the time interval between the action potential of two single muscle fibers in the same motor unit with a normal fiber density is suggestive of MG.[110,111]

Serologic examination for autoantibodies against AChR, MuSK, LRP4, and striated muscle (i.e., titin and RyR) should be performed to confirm the diagnosis and help direct therapy. Anti-AChR antibodies are detected in approximately 85% of patients with generalized MG and 50% to 75% of patients with ocular MG. As noted earlier, AChR and MuSK antibodies account for 90% of patients with MG. The detection of antibodies to titin and RyR strongly suggests the presence of a thymoma; however, in any case, if a diagnosis of MG is made, a computed tomography scan of the chest examining the anterior mediastinum for the presence of a thymoma should be performed.

Treatment

Acetylcholinesterase Inhibitors

If a patient with known MG has a worsening weakness, this is a myasthenic crisis and the patient may need close observation in a monitored or intensive care unit (ICU) for impending ventilatory failure. The initial pharmacologic treatment of MG includes AChE inhibitors. AChE terminates the impulse transmission at the cholinergic synapses by rapid hydrolysis of ACh. Inhibition results in a greater concentration of circulating ACh in the synaptic cleft. Long-acting oral AChE inhibitors such as pyridostigmine are used. For the reasons already discussed, patients with MG associated with anti-MuSK antibodies may not always benefit from treatment with cholinesterase inhibitors.[112,113]

When treating MG patients with increasing weakness, the differential diagnosis may include a cholinergic crisis from overtreatment with AChE inhibitors because overstimulation of the NMJ may cause fasciculation, paralysis, or weakness. However, unless other signs of cholinergic stimulation are present (such as bradycardia, sialorrhea, urinary urgency, lacrimation, diarrhea,

bronchorrhea, bronchospasm, or miosis), it is more likely that the patient will benefit from increased doses of AChE inhibitors. If the patient requires MV, once intubation is complete, it often may be beneficial to either stop administration or decrease the AChE inhibitor dosage in an attempt to restore sensitivity to the receptors; or when extubating the patient, to decrease the oral secretions that result from the cholinergic stimulation of the AChE inhibitor.

Immunosuppression

The next choice of treatment in MG includes immunosuppressive medications such as corticosteroids, typically prednisone or methylprednisolone. It is important to recognize that when initiating corticosteroid treatment, clinical symptoms, and specifically bulbar and respiratory weakness, may first worsen. Dysphagia with the inability to handle oral secretions accompanied by a decreased respiratory reserve and cough may result in the need for MV.

In severely weak patients who do not yet have the diagnosis of MG but in whom the diagnosis is suspected, the first-line agent is AChE inhibitors. Again, if corticosteroids are also initiated, the patient should be closely monitored for worsening weakness and respiratory failure. Slow incremental dosing of steroids is safest, especially in the setting where the patient is not in a closely monitored setting. If the patient is in not in the ICU, a ramp-up dosing of prednisone might include alternate-day dosing of oral prednisone starting with 10 mg, increased in 10-mg steps up to 100 mg on alternate days or to 1.5 mg/kg of body weight, whichever is lower. When patients are stable or after surgery, tapering typically is slow—for example, by 10 mg every 2 weeks until 40 mg is reached with further tapering by 5 mg every month until either discontinued or the desired baseline dosage is achieved.

If long-term treatment with steroids is needed, then steroid-sparing immunosuppressants are used. These include cyclosporine, tacrolimus, azathioprine, cyclophosphamide, methotrexate, mycophenolate mofetil, and rituximab.[114] Approximately 80% of patients with MG and 95% of thymoma patients with MG require immunosuppressive treatment for longer than 1 year.[115]

It is interesting to note that the immunosuppressant tacrolimus has been found to enhance RyR-induced sarcoplasmic calcium release, which is blocked by autoantibodies to RyR. Thus tacrolimus may be particularly beneficial in patients with thymoma as they frequently have RyR autoantibodies.[69,116]

Immunoabsorption

IVIg is a well-accepted treatment for moderate to severe MG. Based on one class I study of 24 patients with worsening MG treated with IVIg 2 g/kg compared with 27 patients who received placebo, the outcome was improved with active treatment in patients with moderate or severe MG.[117] Based on this, the American Academy of Neurology (AAN) guidelines notes level B evidence that IVIg is "probably" effective in the treatment of MG.[53] An older study of 173 MG patients with exacerbation of symptoms showed improvement but no superiority of IVIg 1g/kg given on 2 consecutive days compared with a single dose of 1 g/kg.[118] The current recommended dose is a targeted total dose of 1 to 2 g/kg, typically given at doses of 0.5 g/day for 2 days or 0.4 g/day for 5 days. The duration of efficacy lasts approximately 3 to 4 weeks.[119]

Despite the frequent use of PE in patients with MG, the 2011 AAN PE guidelines regarding the efficacy for myasthenic crisis or thymectomy cited the lack of randomized, blinded controlled studies for the inability to support or refute the efficacy of PE in MG.[42,120] Similarly, a Cochrane meta-analysis first published in 2002 and updated in 2011 after a new search for studies and content had no change in its conclusion that PE offered no improvement at 2 or 4 weeks over prednisone or IVIg. They concluded that the existing studies had a high risk for bias and weak statistical power, although case series and one RCT with severe exacerbation did show a difference between PE and IVIg.[121]

Since then, a small randomized trial of 84 patients with moderate to severe MG compared IVIg 1 g/kg per day for 2 consecutive days to PE of 1.0 plasma volume exchange for 5 days in moderate to severe MG. Fourteen days after treatment, the proportion of patients showing an improvement as determined by a quantitative myasthenia score was similar with 69% with IVIg and 65% with PE. Both treatments were well tolerated. The presence of AChR antibodies and greater baseline disease severity predicted a better response to therapy.[122] From this information, one might extrapolate that either treatment could be used as effectively.

The combination therapy of both IVIg with PE was explored in one small retrospective study of 72 patients.[123] Those who received the combination had a statistically improved outcome and shorter length of stay (LOS) of 20.0 days compared with 30.7 days with PE alone. The LOS in those treated with IVIg alone did not differ from those who received the combination. However, these data should be interpreted with caution because side effects such as allergic reactions, hypocoagulability, and bronchorespiratory infections were significantly more frequent in the PE group than in the other two groups (36.9% PE; 4.2% IVIg; 3.6% combination). These complications with PE have not been seen in other trials and would suggest bias among treatment groups.

Given the current limitations in the quality of the evidence, recent meta-analyses and current treatment recommendations support no evidence for superiority in the efficacy or safety of IVIg or PE in the treatment of acute exacerbations of MG.[124] The AAN guidelines acknowledge that despite lack of strong evidence for efficacy of PE in myasthenic crisis and prethymectomy MG, PE is used in many medical centers for these indications.[42] Clinically, the practitioner has the option to use either and the choice is typically made on the availability and access to each treatment. From the cost perspective, patients in MG crisis treated with IVIg in some studies had a shorter ICU LOS by up to 3 days and hospital LOS by 5 to 8 days, with decreased inpatient costs compared to PE.[125,126]

Complications Associated With Immunoabsorption

In a large cohort of 1606 hospitalized patients with MG, those in crisis treated with PE had more complications than those treated with IVIg (30.06% vs. 14.79%, $P < 0.001$).[126] Previously, complications associated with PE included infection[127]; however, currently more common complications include hypotension in as many as 8% of treatments, arrhythmias, anxiety, cold sensation, paresthesias, or transient hyperthermia. Laboratory abnormalities may include anemia, thrombocytopenia, hypokalemia, hyponatremia, and hypocalcemia.[128]

IVIg has been associated with headaches, fever, mild hypertension, chills, nausea, urticaria, and aseptic meningitis. The clinician should be attentive to those with cardiac, coronary, or cerebrovascular disease, as IVIg is hyperviscous and may precipitate deep venous thrombosis, ischemic stroke,[129] myocardial infarction,[130] or renal failure.[131] Rarely, anaphylaxis can develop in patients who are IgA deficient—for example, those with anti-IgA antibodies who are treated with IVIg.[132] Although attributed to IgG or IgE anti-IgA antibodies, the etiology is not fully elucidated.[133]

Thymectomy

If a thymoma is found, the treatment is thymectomy with a consideration for prethymectomy immunoabsorption with PE or

IVIg to minimize the risk for postthymectomy MG exacerbation. However, even when the computed tomography scan shows no thymic abnormality (i.e., nonthymomatous MG), recommendations still include thymectomy. The first case series of 6 patients reported in 1941 showed a 50% response rate.[134] Subsequent retrospective studies showed overall but variable benefit in clinical response and remission rate. However, a more recent trial randomly assigned 126 nonthymomatous MG patients to thymectomy with prednisone or prednisone alone.[135] After thymectomy, MG patients had improved clinical outcomes, required less immunosuppressive therapy (i.e.. prednisone and azathioprine therapy), and had fewer clinical symptoms and need for hospitalization to manage disease exacerbations over a period of 3 years. Recent findings that the presence of anti-AChR antibodies correlates with thymic germinal centers and the degree of thymic follicular hyperplasia explain the benefit of thymectomy even in early-onset nonthymomatous MG patients.[93] For patients with ocular myasthenia, 70% can be cured or have symptom improvement after thymectomy.[136]

Medications to Avoid

Some medications can worsen MG by actions in the presynaptic terminal, including a decrease in ACH release by inhibition of calcium influx into the presynaptic terminal, changes in the postsynaptic ion permeability preventing action potential transmission past the post synaptic terminal, and blockade of the postsynaptic AChR preventing binding of ACH.[137] Medications that should be avoided are found in Table 61.4. Not all are absolutely contraindicated, but the practitioner should weigh the risk and benefits of the administration of such medications and should be knowledgeable about the potential to increase weakness and worsen myasthenic symptoms.

Mortality

Mortality during a myasthenic crisis is highest in those with acute respiratory failure, major cardiac complications such as congestive heart failure, and acute renal failure. As one might expect, age and respiratory failure are associated with a higher complication rate.[126] Previously, the mortality rate was as high as 42% in the 1960s[138]; however, likely owing to advances in MV and critical care, mortality in those requiring MV now varies between 4% and 14.8%.[139,140]

Complications

Respiratory Failure

Depending on the cohort, respiratory failure requiring MV develops in 9% to 30% of patients with GBS.[5,141,142] Approximately 60% to 90% of MG patients in myasthenic crisis admitted to an ICU will require intubation and MV.[139,140] Unlike pulmonary disease, where MV typically is a failure in oxygenation, in neuromuscular disease such as GBS and MG, the major causes for intubation are (1) lack of neuromuscular strength needed for an effective cough, deep breathing, and adequate tidal volume and (2) dysphagia that prevents the ability to protect the airway from aspiration of oral secretions. These patients are at high risk for atelectasis and pneumonia, which prolongs MV, LOS, and as noted earlier, increases mortality.

In both diseases, the vital capacity, residual lung volume, and negative inspiratory force fall owing to respiratory muscle weakness and a reduction in chest wall compliance caused by atelectasis and restriction of chest wall movement. Diaphragmatic weakness alone can reduce vital capacity (VC) by 25% during sitting and lying.[143] Additional respiratory compromise occurs as the result of weakness of the thoracic and abdominal musculature. Passive inspiration requires contraction of the diaphragm. Active inspiration requires the sternocleidomastoid muscle, which elevates the sternum with innervation from the eleventh cranial nerve (spinal accessory nerve); however, when parasternal muscles and external intercostal muscles contract, they raise the ribs to increase thoracic volume laterally. Scalene muscles contract to elevate the ribs in an anteroposterior direction and splints the chest wall. This allows the intercostal muscles to be more effective in expanding the thorax while the diaphragm descends.

Quiet expiration results from passive recoil from the thorax and lungs. Active expiration requires contraction of the internal intercostal muscles, with the exception of the interchondral section, to depress the ribs. Finally, contraction of the abdominal muscles depresses the lower ribs and compresses the abdominal contents against the diaphragm to further decrease the volume of the thorax. This maneuver increases the intrapulmonary pressure above atmospheric pressure to facilitate exhalation. Of note, because the thoracic and abdominal musculature is necessary for active breathing, although diaphragmatic innervation occurs at cervical levels 3 through 5, patients with a cervical cord lesion below this level can exhibit respiratory failure.

Monitoring for impending neuromuscular respiratory failure includes periodic measurements of handheld bedside spirometry for forced vital capacity and negative inspiratory force. A normal vital capacity (VC) is approximately 65 mL/kg. A poor cough occurs at around 30 mL/kg and requires additional chest physiotherapy to clear secretions and minimize atelectasis. Typically a VC of less than 20 mL/kg ideal body weight or a rapidly declining VC on serial measures are indications for elective endotracheal intubation.[144–146]

In GBS, the best clinical predictors of MV have been identified as a rapid onset of symptoms to hospital admission of fewer than 7 days, facial or bulbar weakness, an inability to cough, and the MRC motor score with specifically the inability to stand, inability to lift the elbows, and inability to lift the head.[57,146,147]

Predictors of successful extubation have shown that a higher vital capacity of at least 20 mL/kg correlates best. A lower negative inspiratory force of −50 cm H_2O compared with −28 cm H_2O can also be predictive.[148] Also, pulmonary comorbidities and autonomic dysfunction may be predictors of extubation failure.

Prolonged MV, defined as 14 days or longer, is helpful to determine patients who will benefit from tracheostomy. One prospective study of 552 patients with GBS showed that 27% of patients required MV, and of these, 71% required prolonged MV. The strongest predictors were muscle weakness, defined as those who were unable to lift their arms from the bed at 1 week after intubation, and electrophysiology studies showing axonal degeneration or unexcitable nerves at 1 week.[142]

The use of noninvasive ventilation has been reported in a few patients with GBS.[149,150] However, because these patients often have a progressive course of worsening and may have bulbar dysfunction, noninvasive ventilation is thus unlikely to be successful. Patients with GBS are best treated with endotracheal intubation.[151]

Noninvasive ventilation has been used more successfully in MG patients with a myasthenic crisis.[152,153] Subsequent failure requiring eventual endotracheal intubation was best predicted by the initial

TABLE 61.4 Medications to Avoid in Myasthenia Gravis[137]

Medications to Avoid	Examples	Recommendation for Avoidance	Mechanism of Weakness
Antibiotics			
Aminoglycosides	Gentamycin Streptomycin	Contraindicated	Blocks ACh receptor, prevents release of ACh
	Tobramycin Amikacin	Less likely problematic	
Antimalarials	Quinine Chloroquine	Contraindicated	Presynaptic blockage of voltage-dependent sodium channels and postsynaptic potentiation of depolarization
Macrolides	Erythromycin, Tetracycline Azithromycin	Relative	Affects presynaptic transmission
Fluoroquinolones	Moxifloxacin Ciprofloxacin Levofloxacin Ofloxacin	FDA black box warning	Unknown
Ketolide	Telithromycin	FDA black box warning	Unknown
	Polymyxins	Contraindicated	Presynaptic and postsynaptic effects
Cardiovascular			
Antiarrhythmics	Procainamide Propafenone	Contraindicated	Decreases the release of ACh Sodium influx blocker
β-Blockers	Propranolol Atenolol Ophthalmic timolol	Relative	Unclear—may be at the neuromuscular junction or muscle membrane
Calcium channel blocker	Verapamil Amlodipine	Relative	Presynaptic and postsynaptic blockade of L-type calcium channels
Anticonvulsants			
	Phenytoin	Relative	Depressed postsynaptic response to ACh; inhibition of calcium channel; increase in muscle membrane threshold
	Carbamazepine	Relative	Triggers immune response
	Gabapentin	Relative	Binds voltage-gated calcium channel
Chemotherapeutic Agents			
	Doxorubicin Etoposide Cisplatin	Relative	Unknown
Others			
	Interferon	Relative	Autoantibody production
Neuromuscular blocking agents	Atracurium Cisatracurium Vecuronium	Relative	Blocks ACh receptors
Statins		Relative	Unknown
Corticosteroids		Relative	Direct blocking of ACh receptor through ionic channels
Botulinum toxin		Contraindicated	Impairs synaptic transmission
Magnesium		Relative	Impairs synaptic transmission
Penicillamine		Contraindicated	Binds the ACh receptor; induces antibodies to receptor

ACh, Acetylcholine; *FDA*, U.S. Food and Drug Administration.

presence of hypercapnia, defined as a partial pressure of carbon dioxide greater than or equal to 45 mm Hg[154] or 50 mm Hg.[155]

Pain and Sensory Disturbance

Neuropathic pain can be as high as 89% in patients with GBS.[156] In one study, 36% of patients reported pain that preceded weakness, whereas 66% reported pain in the acute phase of the first 3 weeks of their illness. Up to 38% still had pain at 1 year.[157] Treatment can include opioids and anticonvulsants such as carbamazepine, gabapentin, and pregabalin.

Although MG is typically considered a muscle disorder characterized by fatigue and muscle weakness, the altered cholinergic neural transmission also affects the sensory system.[158] Abnormal sensory input can cause restlessness in lower limbs in up to 43.8% of patients with MG.[159] Pain scores of moderate or high severity are as high as 50%.[160] Numbness and paresthesias are found in at least 10%. Approximately 67% of patients with MG have higher tactile

perceptual thresholds compared with healthy controls.[161,162] They also have visual complaints that are not explained by oculomotor disturbance but from optic nerve abnormalities because visual evoked responses are impaired.[163] Autonomic disturbances can also be seen in MG that may vary from decrease to hyperactivity in sympathetic and parasympathetic tone.[164] It may be difficult to differentiate these symptoms as causative from the primary disease rather than from the medication effects of AChE inhibition, but orthostatic dizziness, abnormal thermoregulation, impaired gastrointestinal motility, and pupillary changes have been reported.[165,166] The incidence of sensory dysfunction with MG is not well known as previous large studies have focused on motor findings alone.[167] Others are working to establish a sensory rating scale in MG that includes changes in tactile perception and olfactory, vision, taste, audition, corneal, autonomic, and sleep function.[158]

Other Complications

As expected in any patient who is nonambulatory or bedbound, patients with GBS and MG are at risk for pneumonia, thromboembolic disease, and decubiti. More than half of patients who were mechanically ventilated had a LOS longer than 3 weeks.[168] Critical care should be focused on appropriate chemoprophylactic therapy and the classic elements of the ABCDEF care bundle that focus on: 1) assessing, preventing, and managing pain; 2) both spontaneous awakening trials and spontaneous breathing trials to facilitate liberation from the ventilator; 3) choosing appropriate analgesic and sedative medications and doses; 4) assessing, preventing and managing delirium; 5) providing early mobility and exercise; with 6) Family and patient engagement to empower them and facilitate recovery for the best outcome.[169]

Key Points

- GBS is typically a demyelinating disease of the peripheral nervous system, although axonal variants occur.
- The pattern of weakness with GBS is an ascending areflexic paralysis, but it can also manifest with a Miller Fisher syndrome of ophthalmoplegia, ataxia, and areflexia.
- MG may be divided into subgroups depending on the clinical presentation and the autoantibody type found in a myasthenic patient. Most patients have antibodies to AChR or MuSK. These subtypes may assist in determining the therapeutic response to prognosis.
- Increasing or initiating steroids in a myasthenic patient may worsen symptoms and precipitate ventilator failure requiring intubation. The clinician should also be aware of other medications that may precipitate weakness in a patient with MG.
- Respiratory failure in patients with neuromuscular weakness typically occurs because of dysphagia and the inability to protect the airway as well as the ability to take deep breaths and maintain an adequate tidal volume. Ventilatory reserve in these patients and impending respiratory failure can be monitored by bedside spirometry with vital capacity above 20 mL/kg.

Review Questions

1. A 45-year-old man had a diarrheal illness with a low-grade fever that lasted for 4 days. One week later, he noted tingling and numbness in his feet followed by leg weakness. The following day he was unable to walk and went to the emergency department. He is admitted to the intensive care unit (ICU) for impending respiratory failure. His examination shows flaccidity of his arms and legs. A lumbar puncture shows a white blood cell count of 3 cells/mL, protein of 95 mg/dL, glucose level of 80 mg/dL and is culture negative. The nerve conduction study shows slowing with increased latency. The electromyogram is normal. The treatment of choice includes which of the following?

a. Azathioprine
b. Intravenous immunoglobulin (IVIg) followed by plasmapheresis.
c. Plasmapheresis.
d. Prednisone
e. Pyridostigmine

Answer: c. This is a case of Guillain-Barré syndrome (GBS), an autoimmune disease that induces homologous epitopes to the peripheral nerve. It is characterized by a demyelinating process that results in slowing of the nerve conduction velocity and is associated with an albuminocytologic dissociation with elevation of cerebrospinal fluid protein without pleocytosis. GBS follows an antecedent upper respiratory tract infection in about 38% of patients, although it can be diarrheal in about 24% of cases. GBS is not responsive to corticosteroids and long-term immunosuppression with medications such as azathioprine. It is responsive to both IVIg or plasmapheresis, although the combination has not been shown to improve outcome but will increase the cost of care. Pyridostigmine, an acetylcholinesterase inhibitor, is indicated in myasthenia gravis but has no role in the treatment of GBS.

2. Which of the following is least likely to precipitate ventilatory failure in a patient with myasthenia gravis?

a. Azithromycin
b. Cefepime
c. Gentamicin
d. Prednisone
e. Verapamil

Answer: b. There is a long list of medications that can exacerbate weakness in patients with myasthenia gravis. Chief among these calcium channel blockers, β-blockers, antiarrhythmic agents, and antibiotics such as aminoglycosides, macrolides, and fluoroquinolones. Others include antimalarials, corticosteroids, and anticonvulsants such as carbamazepine, gabapentin, and phenytoin. Cephalosporins, however, are well tolerated.

3. A 70-kg 65-year-old man who is 5 foot 9 inches tall is diagnosed with myasthenia gravis and has been receiving increasing doses of pyridostigmine. He is admitted to the ICU with ptosis, difficulty swallowing, and is mildly short of breath. Vital signs include a temperature of 38.5°C, heart rate of 85 beats/min, blood pressure of 150/80 mm Hg, respiratory rate of 16 breaths/min, and oxygen saturation of 96%. His breath sounds are clear and the chest radiograph shows no infiltrates. He is able to move all extremities but has mild fatigability to repetitive testing of his deltoids. Handheld spirometry shows a negative inspiratory force of −50 cm H_2O and vital capacity of 1.8 L. Which of the following is the best immediate therapy?

a. Corticosteroids
b. Endotracheal intubation
c. IVIg
d. Plasmapheresis
e. Pyridostigmine

Answer: e. This patient is exhibiting signs of a myasthenic crisis and the most immediate treatment for improvement would be to administer an acetylcholinesterase inhibitor. He does not have signs of overtreatment with a cholinergic crisis, which would include bradycardia, diarrhea, and bronchorrhea, and there are few risks to administering more pyridostigmine. With a myasthenic crisis, steroids may be indicated but can worsen symptoms. Plasmapheresis or IVIg may be indicated but will not have an immediate effect to improve his symptoms. Endotracheal intubation should always be considered in a patient in myasthenic crisis; however, if the patient is not in respiratory distress, handheld spirometry can help determine the need for intubation. A negative inspiratory force of less than 20 cm/H_2O or vital capacity of less than 20 mL/kg would be indicators for immediate intubation. This is not the case with this patient. Therapy with pyridostigmine may help avert the need for intubation; however, the patient will need to be continuously monitored for signs of worsening.

  Controversial Management Issues
Prognosis

Seizures complicate the course of up to 10% of adult patients admitted to intensive care units (ICUs) for nonneurologic conditions[1,2] and occur more frequently in specialized neuroscience ICUs.[3] There are several reasons for which intensivists of all fields should be comfortable with the recognition and management of seizures. First, seizures are often the first indication of a central nervous system (CNS) complication in their patients, and a rapid etiologic diagnosis is likely to improve their outcomes. Furthermore, because epilepsy is a common disorder (affecting about 2% of the general population), patients with preexisting seizure disorders occasionally require ICU admission for intercurrent conditions, during which time their risk of breakthrough seizures will invariably be heightened. And most importantly, several interventions required for treatment of refractory seizures, such as mechanical ventilation and vasopressor usage, require the expertise of an intensivist in addition to a neurologist.

History

Although seizures have been recognized at least since Hippocratic times, their relatively high rate of occurrence in critically ill patients has only recently been recognized. Seizures as a side effect of critical care treatments (e.g., as a complication of lidocaine infusion for ventricular arrhythmias) are also a recent phenomenon.

The first recorded description of status epilepticus (SE) is by Gavasetti in 1586.[4,5] Sir Thomas Willis described the complications of untreated SE in 1667:

> *…as to what further belongs to the prognostication of the Disease, if it end not about the time of ripe age, neither can be driven away by the use of medicines, there happens yet a diverse event in several sick Patients, for it either ends immediately in Death, or is changed into some other Disease, to wit, the Palsie, stupidite, or melancholly, for the most part incurable. As to the former, whenas the fits are often repeated, and every time grow more cruell, the animal functions are quickly debilitated; and from thence, by the taint, by degrees brought on by the Spirits, and the Nerves serving the Praecordia, the vital function is by little and little enervated, till at length, the whole body languishing, and the pulse is loosned, and at length ceasing, at last the vital flame is extinguished.*[6]

Attempts at treating SE in the nineteenth century included bromide,[7] morphine,[8] and ice applications. Barbiturates were introduced in 1912, followed by the identification and use of phenytoin (PHT) in 1937; these were the first rational treatments for SE.[9] Paraldehyde gained brief prominence in the next decades.[10] The most recent major improvement is the use of benzodiazepines, pioneered by the French in the 1960s.[11]

Epidemiology

More data are becoming available concerning the epidemiology of seizures in ICU patients. In a 2-year prospective study of a medical ICU, we found an incidence of approximately 35 patients with seizures per 1000 admissions.[1] Most recently, retrospective studies including patients with primary nonneurologic diagnoses found an incidence of electrographic seizures of up to 22% of medical ICU patients[12] and 16% in surgical ICU patients.[13] The incidence of seizures is probably higher in pediatric ICUs than in medical ICUs.[14–16]

The epidemiology of SE is somewhat better understood. Estimates of the incidence of generalized convulsive SE in the United States range from 50,000 cases/year[17] to 250,000 cases/year.[18] Between 6% and 12% of epilepsy patients present with SE,[19] and about 20% of seizure patients will experience an episode of SE within 5 years of their first seizure.[20] Towne and colleagues demonstrated that 8% of an unselected series of comatose medical ICU patients had unsuspected nonconvulsive status epilepticus (NCSE).[21]

TABLE 62.1 Etiology of Status Epilepticus in Adults in the Richmond, Virginia, Study

Etiologic Factor/Disorder[a]	Distribution (%)
Low antiseizure drug levels	34
Remote (prior history of CNS insults)	
Chronic cerebral infarction	19
Chronic intracerebral hemorrhage	3
Previously diagnosed CNS tumor	2
Acute cerebrovascular disease (vascular occlusion, embolism, or hemorrhagic infarction)	22
Hypoxia/anoxia	18
Metabolic disturbance	15
Alcohol related (withdrawal or intoxication)	13
Primary or metastatic CNS tumor	7
Drug overdose	3
CNS infection	3
Head trauma	3
Idiopathic/cryptogenic	3
Acute primary intracerebral hemorrhage or subarachnoid hemorrhage	1

[a]Some patients had more than one etiology.
CNS, Central nervous system.

Certain ICU patients appear to be at increased risk for seizures, but the degree of that increased risk has not been quantified. An independent predictor in medical ICU patients is the presence of sepsis. Oddo and colleagues showed that about 30% of patients with sepsis have periodic epileptiform activity or NCSE when recorded for 24 hours or longer on an electroencephalogram (EEG).[12] Thus intensivists should have a low threshold for EEG monitoring when septic encephalopathy is not improving with antimicrobial treatment or is out of proportion to illness severity. Other risk factors include chronic or acute renal failure, administration of medications that may lower seizure threshold (such as penicillins, carbapenems, cefepime,[22] meperidine, cyclosporine, and neuroleptics) and any rapid osmolar shifts such as those induced during treatment of sodium abnormalities or hemodialysis. Hyperglycemic crises, either nonketotic or ketotic, have a high likelihood of focal seizures,[23,24] and treatment of these should focus on correcting the electrolyte abnormality.

In the Richmond, Virginia, SE study, the most common cause of SE in adults was stroke (acute or remote, ischemic or hemorrhagic), followed by withdrawal from antiseizure drugs, and SE related to ethanol withdrawal, anoxia/hypoxia, and metabolic disorders (Table 62.1).[25] Systemic infection was the most commonly diagnosed cause of SE in children; this was followed by congenital abnormalities, anoxia, metabolic disorders, antiseizure drug withdrawal, CNS infections, and trauma.

Nosology and Semiology

Numerous systems have evolved for the classification of seizures; the most frequently used today is that of the International League Against Epilepsy[26] (Box 62.1). This schema allows classification based primarily on clinical criteria, without inferences about cause.

• BOX 62.1 International Classification of Epileptic Seizures

I. Focal (aware, impaired awareness, or unknown awareness; ± to bilateral tonic-clonic)
  A. Motor
    1. Tonic
    2. Atonic
    3. Myoclonic
    4. Clonic
    5. Epileptic spasms
    6. Hypermotor
  B. Nonmotor
    1. Sensory
    2. Cognitive
    3. Emotional
    4. Autonomic
II. Generalized
  A. Motor
    1. Tonic-clonic
    2. Tonic
    3. Atonic
    4. Myoclonic
    5. Myoclonic-atonic
    6. Clonic
    7. Clonic-tonic-clonic
    8. Epileptic spasms
  B. Absence
    1. Typical
    2. Atypical
    3. Myoclonic
    4. Eyelid myoclonia
III. Unknown onset (aware, impaired awareness, or unknown awareness)
  A. Motor
    1. Tonic-clonic
    2. Tonic
    3. Atonic
    4. Epileptic spasms
  B. Nonmotor
IV. Unclassified
